In a series of survivors of childhood Hodgkin's disease from Stanford, the actuarial risk of cardiac disease requiring pericardiectomy was 4% at 17 years. [131] Patients with severe pericardial complications received little or no cardiac blocking, and most were irradiated before the introduction of subcarinal blocking. The recognition of radiation-induced pericardial disease described in this and other series has resulted in the modification of irradiation techniques to reduce the dose of radiation to the heart.[132] The rates of acute pericarditis and effusion have declined in later cohorts in which patients received partial cardiac shielding and subcarinal blocking, [133] confirming that risks for radiation-related significant pericardial disease are attributed to the total cardiac dose and volume.

Premature coronary artery disease and acute myocardial infarction have also been reported in pediatric Hodgkin's disease survivors. [131,134] Young age at diagnosis increases the risk. In the Stanford series, there is a 45-fold excess mortality risk from acute myocardial infarction in patients who received mediastinal irradiation in doses exceeding 30 Gy before age 20 years.[131] With lower volumes of radiation and protective cardiac shielding, the risk of radiation-related cardiac injury is greatly diminished. The Stanford cohort of 192 children treated with combined-modality treatment using lower doses and volumes of radiation reveal no death from myocardial infarction. Other cardiovascular sequelae, including arterial vascular injury, underdevelopment of the great vessels, coronary artery disease with coronary fibrosis, and accelerated atherogenesis, have been observed in long-term survivors of Hodgkin's disease treated with high-dose mantle irradiation. [89] The true incidence after modern treatment may be difficult to determine, as appropriate radiation treatment plans now prescribe low doses and volumes of mediastinal radiation and protective cardiac shielding.

The most common chemotherapeutic agents implicated in the development of cardiovascular complications in patients with Hodgkin's disease include the vinca alkaloids, alkylating agents, and anthracyclines. Raynaud's disease is an uncommon toxicity observed in some patients. This phenomenon appears to be caused by irreversible microvascular injury in patients treated with combination of vinblastine and bleomycin. Rarely, myocardial infarction in Hodgkin's patients has been attributed to vinca alkaloid therapy. Proposed mechanisms for this complication include ischemia resulting from coronary artery spasm or hypercoagulability. Although high cumulative doses of cyclophosphamide have resulted in adverse effects on the myocardium, these have largely been in the setting of HSCT in adults. Conventional doses of cyclophosphamide may exacerbate either anthracycline- or radiation-induced cardiac injury.

The cardiac dysfunction most commonly occurring after chemotherapy is related to anthracycline therapy, particularly with doxorubicin. Acute toxicities observed are relatively common and include sinus and supraventricular tachycardias and premature ventricular complexes. More serious arrhythmias, such as complete heart block, ventricular tachycardias, and sudden death, are uncommon. These abnormalities bear no relationship to chronic cardiomyopathy. Congestive heart failure with pericardial effusion and diffuse myocardial injury may occur acutely or as a chronic event with progressive failure associated with early mortality. The incidence of congestive heart failure increases with the cumulative doxorubicin doses greater than 550 mg per $m^2$ in adults. Young children may be more sensitive to anthracycline injury because of its adverse effect on cardiac myocyte growth.[135] In addition, children have a high frequency of anomalies of afterload and contractility. [135] Mediastinal radiation and other chemotherapies are thought to lower the threshold cumulative doses to the range of 350 to 400 mg per $m^2$. The risk of cardiotoxicity may also be impacted by the schedule of administration of doxorubicin. Schedules using smaller weekly doses or continuous infusion are associated with a lower incidence of congestive heart failure than are large doses given every 3 weeks. Factors associated with late cardiac decompensation include childbirth, viral infections, isometric exercises, alcohol and drug ingestion, and growth hormone–induced growth spurts. With current protocols using three to four cycles of ABVD and total cumulative doxorubicin doses of 150 to 200 mg per $m^2$and low-dose radiation, the incidence of clinically symptomatic cardiac disease is low. [90,91] Nevertheless, all patients treated with doxorubicin-containing chemotherapy and cardiac radiotherapy should be followed systematically for potential cardiac injury.

### *Endocrine Sequelae*

Using an elevated thyroid-stimulating hormone (TSH) level to define hypothyroidism, the incidence of thyroid dysfunction in irradiated patients has ranged from 4% to 79%. The sensitivity of the preadolescent thyroid may be higher than that of the adult gland. The iodine load of a pre-radiotherapy lymphangiogram has also been implicated as a factor in thyroid damage. The dose of radiation is important; only 17% of children who received neck irradiation of less than 26 Gy developed thyroid abnormalities compared with 78% in children who receive 26 Gy or more. In this series, investigators noted improvement in 36% of biochemically compensated hypothyroid children with time.[136] Thyroid nodules, hyperthyroidism, and thyroid cancer have been observed in patients treated for Hodgkin's disease. TSH and free thyroxine levels should be checked annually in patients who have received radiotherapy to the neck, and children who have elevated TSH levels should receive thyroid replacement therapy to reduce stimulation from prolonged TSH elevation.

Sterility, alterations in fertility, and potential gonadal injury after staging and treatment are important issues that should be addressed at the time of diagnosis and before therapy is instituted.[137] Pelvic radiation carries a high likelihood of ablation of ovarian function. The technique of oophoropexy, with transfer of the ovaries to a midline location, has allowed the preservation of ovarian function in young women with Hodgkin's disease. [80]

The younger the woman at the time of therapy, the higher the probability of maintenance of regular menses after therapy. When chemotherapy and radiation are used, the potential exists for increased risk of ovarian failure, although in the Stanford series, 87% of girls with Hodgkin's disease had normal menstrual function at long-term follow-up.[138] Normal pregnancies can occur after oophoropexy and pelvic radiation with no increased risk of fetal wastage or spontaneous abortion. [138,139] Of the pregnancies carried to term, no increase in birth defects was observed when compared with the offspring of sibling controls.

Treatment for Hodgkin's disease may carry a considerable risk of premature menopause related to the specific treatment modality and age at the time of therapy. Byrne and colleagues[140] reported a significantly increased relative risk of menopause during the early 20s in young women treated with either radiation alone or alkylating agents alone. The group at highest risk comprised women treated with alkylating agent chemotherapy and subdiaphragmatic radiotherapy (27-fold); 42% of these women had reached menopause by age 31 years compared to 5% for controls. The Stanford group has not observed an excessive risk of premature

menopause among young women with early-stage disease treated with radiation alone in doses of 40 to 44 Gy to radiation fields that omit the pelvis, however. [141]

The sterility issue in males is of much greater severity. Primary gonadal dysfunction may exist at the time of diagnosis of Hodgkin's disease in 30% to 40% of patients,[142] but despite this, pretreatment storage of sperm should be considered in older patients. High-dose radiation to the pelvis or a standard inverted-Y field may be associated with a transient oligospermia or azoospermia; however, recovery of function is common. [88] Six to eight cycles of MOPP and ChlVPP chemotherapy are associated with azoospermia in 80% to 90% of adult or pediatric males. [143,144] and [145] A high and dose-related incidence of testicular dysfunction has also been reported in pediatric patients treated with OPPA or OPPA/COPP, which is the result of the gonadotoxic agent procarbazine. [146] Anthracycline-based regimens, such as ABVD, are associated with a lower incidence of testicular damage: approximately 30% of males. [16,140,143] This azoospermia is transient with full recovery of spermatogenesis. Recovery of spermatogenesis has also been reported 10 to 15 years after documented azoospermia in boys after six cycles of MOPP in childhood [138] and in 50% of adult males after two to three cycles of MOPP.[85] The etoposide-based regimen of OEPA [vincristine (Oncovin), etoposide, prednisone, and doxorubicin] also has been used in boys with pediatric Hodgkin's disease.[147] Testicular function was normal in 27 boys receiving two cycles. However, when two to four cycles of COPP were added, the basal follicle-stimulating hormone levels rose to abnormal levels. The hormone-producing cells of the testes are more resistant to the effects of treatment than are the spermatogonia, so boys continue to grow and develop normally. Current treatment approaches are risk adapted in an effect to spare those patients with favorable and early-stage disease from the gonadotoxic sequelae, which result from the chemotherapy treatment programs needed to cure more advanced and unfavorable stage disease.

***Second Malignant Tumors***

The development of a second malignant neoplasm is the most serious late treatment complication among Hodgkin's disease survivors. The most common risk factors, particularly in those treated during childhood, are potential genetic influences and the type of treatment received. Newly acquired knowledge of genetic predisposition and secondary carcinogenesis related to tumor suppressor genes such as *RB1* and *p53* has greatly augmented our understanding of cancers. Among survivors of Hodgkin's disease, the association between malignancy and treatment for Hodgkin's disease has been given more attention than the genetic influences, predisposing survivors to a second malignancy. Possible genetic influences are of particular importance in light of the current knowledge of *BRCA1* and *BRCA2* genes with specific solid tumors. In addition, Hodgkin's disease is accompanied by defective cellular immunity, which may predispose to the development of a new malignancy. As well, it is important to consider causes of mortality among the population of interest. In the Stanford experience of 694 children and teenagers followed for up to 31 years after treatment of Hodgkin's disease, recurrent Hodgkin's disease accounted for greater than one-half of all deaths, accidents and other causes for one-fourth, and secondary cancers for one-fifth.[149]

Secondary acute nonlymphocytic leukemia (s-ANLL) and its precursor—a pancytopenic myelodysplastic syndrome—represents the most common second cancer seen in these patients. A standardized incidence ratio (SIR) (calculated as the ratio of observed to expected cases, or relative risk) for any leukemia of 78.8 [95% confidence interval (CI), 56.6 to 123.2) and an SIR of 321.3 (95% CI, 207.5 to 467.1) for acute myeloid leukemia/myelodysplastic syndrome have been reported from the Late Effects Study Group (LESG) for children younger than 16 years treated with chemotherapy.[150] This SIR for ANLL was reduced to 122 (95% CI, 36 to 254) with lower cumulative doses of alkylating agents and the omission of mechlorethamine as reported by German/Austrian investigators. [84]

The use of ABVD in lieu of MOPP and its derivatives greatly reduces the leukemia risk. [151] However, the epipodophyllotoxins and nitrosoureas are associated with s-ANLL.[152] The leukemia risk after radiation alone is extremely low (zero probability in LESG experience).

The peak frequency for secondary leukemia is within the first 5 to 10 years after treatment. [153] Some investigators have described a higher frequency of s-ANLL in splenectomized adults with Hodgkin's disease and have suggested that the spleen has a protective role, [152,154] whereas other investigators have found no such effect in adults,[155,156] or in children younger than 16 years when treated. [157]

The risk for NHL is also increased with an SIR of 20.9 (95% CI, 7.7 to 42.0) in the LESG experience. [150] An SIR of 15 (95% CI, 4.9 to 35.0) is reported for children younger than 20 years from five Nordic countries. [158] The risk of NHL may be related to overall immunosuppression associated with the disease as well as its treatment.

A variety of secondary solid tumors have been observed in patients treated for Hodgkin's disease. The risk of a secondary solid tumor escalates with the passage of time after diagnosis of Hodgkin's disease, with a latency of 20 years or more. The SIR of a solid tumor after treatment for Hodgkin's disease in the LESG data is 11.8 (95% CI, 8.7 to 15.4).[150] The most common solid tumors in that report were breast (SIR 75.3; CI, 45 to 118), thyroid (SIR, 32.7; CI, 15 to 55), bone (SIR, 24.6; CI, 6.4 to 54.5), brain (SIR 10.5; CI, 3 to 23), colorectal (SIR, 38.9; CI, 7.3 to 95.0), and stomach (SIR, 121.3; CI, 11.4 to 145.0). Similarly the Stanford experience in individuals younger than 21 years of age revealed increased risks for sarcoma, melanoma, breast, lung, thyroid, salivary gland, and stomach. [149] Nonmelanotic skin cancers, including basal cell cancers, are also common. Other institutions have reported similar data. [148,152,159,160] and [161] Several investigators have shown that age at treatment has a major effect on risk of second malignant tumors after treatment for Hodgkin's disease, and the increased risk of solid tumors in adolescent and young adults decreases as these individuals grow older. [152] The risks of secondary solid tumors vary by treatment and are largely related to radiation and radiation plus chemotherapy.[152] The risks greatly increase after relapse of Hodgkin's disease, thus requiring aggressive retreatment. [152,162]

Much attention has been given to the significant risk of secondary breast cancers in young women. [149,160,163,164] and [165] This risk increases with follow-up. The risk is highest for girls who received radiation at age younger than 15 years and declines with increasing age. There is no increased risk in women older than 30 years at the time of radiotherapy.[166] A high dose of radiation is a risk factor, with most breast cancers arising after 40 to 46 Gy of mantle irradiation, which includes treatment to the axilla.[166]

The quantitative estimate of risk of secondary cancers after pediatric Hodgkin's disease varies, depending on the length and completeness of follow-up. The updated Stanford experience of secondary cancers is especially valuable, as it contains a large number of patients with consistent and thorough long-term follow-up, with a median of 14.4 years (range, 1 to 37) as shown in Table 23-12.[167] This experience reviews 694 pediatric patients with 82 malignancies occurring in 78 patients. The data are compared with the 1994 Surveillance, Epidemiology, and End Results program cancer statistics. The estimated number of excess breast cancers per 10,000 person-year (absolute risk) is 63.1. These data highlight the importance of long-term monitoring of these patients, as the highest reported risks appear in series with the longest follow-up.

| Variable | Observed/ expected | Relative risk | Person-years |
|---|---|---|---|
| All cancers, female | 51/3.16 | 16.1 | 4,211 |
| All cancers, male | 27/3.18 | 8.49 | 5,197 |
| Leukemia | 8/0.25 | 32.3 | 9,657 |
| Non-Hodgkin's lymphoma | 3/0.49 | 6.09 | 9,657 |
| Breast cancer, female | 28/0.85 | 32.8 | 4,301 |
| Sarcoma | 15/0.11 | 135.0 | 9,637 |
| Other solid tumors | 27/6.52 | 4.1 | 9,530 |

**TABLE 23-12. RELATIVE RISK OF SECOND CANCER AFTER PEDIATRIC HODGKIN'S TREATMENT AT STANFORD**

Importantly, the risk of second malignant tumors comes from treatment given many years ago and does not reflect contemporary therapy. Thus, with the current recommended treatment of risk-adapted multi-agent chemotherapy and low-dose, involved-field radiotherapy, the risk of second cancers is expected to be substantially lower than that reported in the past.

Many groups have shown that the highest risk of complications of treatment is relapse of the Hodgkin's disease itself. [149,168] Thus, the goal for pediatric Hodgkin's

disease must continue to be curative treatment with initial therapy, resulting in the overall treatment that carries with it minimal morbidity and the highest quality of life.

# MALIGNANT NON-HODGKIN'S LYMPHOMAS IN CHILDREN

IAN T. MAGRATH

## NATURE OF MALIGNANT LYMPHOMAS

Most cancers are neoplastic proliferations of an organ or tissue and therefore originate in a circumscribed anatomic location and spread from the point of origin by local invasion or by the process of metastasis. Malignant lymphomas differ radically from this pattern. They are neoplasms of the constituent cells of the immune system, cells that normally circulate throughout the body to subserve their functions. Therefore, with some exceptions, lymphomas are generalized diseases from the outset and have patterns of spread that mimic the migration patterns of normal lymphoid cells.[1] Malignant transformation can occur in any of the functionally different subpopulations of lymphoid cells, or, more likely, the precursors of these subtypes. Consequently, all except neoplasms of natural killer (NK) cell origin will manifest clonal rearrangements of immunoglobulin or T-cell receptor genes (clonal, because of the need for multiple molecular abnormalities to occur in the same cell, or its progeny, for full neoplastic transformation to occur) and will also express many of the immunophenotypic characteristics of a specific lymphoid subset, for a block to differentiation appears to be a general feature of lymphoid neoplasms. Sometimes, aberrant differentiation may occur (e.g., the expression of myeloid antigens or rearrangement of both immunoglobulin genes and T-cell receptor genes in immature lymphoid neoplasms). There are several possible explanations for this phenomenon. There may have been a failure to inhibit differentiation along a specific pathway, or, in the case of biphenotypic characteristics, aberrant expression of a small number of genes because of molecular genetic aberrations. Alternatively, transformation may have occurred in cells that are continuously generated in normal individuals only to be eliminated by apoptosis (but inhibited from undergoing apoptosis by pathologic molecular events).

It should not be assumed that all of the molecular abnormalities present in the cell occurred at the same point in its differentiation. Indeed, cells at different levels of differentiation may be more or less susceptible to specific molecular abnormalities. For example, translocations involving immunoglobulin or T-cell receptor genes are likely to occur during or close to the point in normal lymphoid cell differentiation when these genes undergo rearrangement to generate functional T- or B-(immunoglobulin) cell receptors. The molecular genetic events that lead to lymphoid neoplasia are, thus, best understood in the context of the normal events occurring during lymphocyte development (ontogeny), whereas the clinical features of each lymphoid neoplasm will, to a greater or lesser degree, reflect the behavior of its normal counterpart cell or cells.[1,2] Our understanding of lymphoid neoplasia will continue to increase *pari passu* with our knowledge of normal lymphocyte ontogeny, lymphocyte function, and the derangements of molecular pathways brought about by pathologic genetic changes.

Histopathologic evaluation, including immunophenotyping, remains the primary and most widely used means of classifying the lymphoid neoplasms, but the most precise diagnosis is likely to be made when the identification of the associated nonrandom molecular abnormalities is added to these standard diagnostic modalities. It is these molecular abnormalities, in the setting of the intracellular milieu on which they are superimposed, that ultimately determine the characteristics of the tumor cells. It is because the molecular genetic abnormalities are “context specific” that they are not exclusively associated with a specific neoplasm, although this frequently is the case. Thus, the mere presence of a single genetic lesion is not always sufficient to establish a diagnosis. For example, follicular and large B-cell lymphomas (LBCLs) may both contain 14;18 translocations. The former, however, a rare tumor in children, can also evolve into the latter, suggesting at least a close relationship between neoplasms with the same molecular lesions, even if they are histologically and clinically quite different. Conversely, the same functional end result can be achieved by quite different genetic lesions. For example, the same gene may be deregulated by a process of chromosomal translocation—in some cases by several different chromosomal translocations—by other forms of chromosomal rearrangement, such as amplification or deletion, or by point mutation. Alternatively, the altered expression of genes that lie on the same molecular pathway or interact with the same molecular pathway, or even the expression of viral genes in a cell, can create similar or identical functional end results.

Just as the consequences of genetic lesions are dependent on the cell in which they occur, so, too, the genetic lesions themselves (particularly chromosomal aberrations) tend to be cell-type, or at least lineage specific. This presumably reflects the likelihood of a given genetic abnormality arising (which is influenced by both chromatin and gene expression patterns) or its ability to create neoplastically relevant functional changes within a given cell type. Some genetic lesions, however, can arise in a broad variety of cells (e.g., p53 mutations). Such lesions may contribute to a variety of cancers because of a pivotal role in the life cycle of the cell—they are frequently involved, as in the case of p53, in cell proliferation or apoptosis (programmed cell death). Apoptosis is a critical element of both lymphocyte ontogeny (only functionally competent cells are permitted to survive) and of the immune response (with respect to both the regulation of the expansion of lymphoid and other cell populations and the killing of cells targeted by the immune response). Indeed, malfunction of genes involved in apoptotic pathways is robably an essential element of all carcinogenic events and is likely to be essential to the survival of cells containing genetic lesions that would otherwise cause them to be diverted to an apoptotic pathway. The inhibition of apoptosis may itself contribute to the stepwise accumulation of genetic lesions in the process of lymphomagenesis. The need for inhibition of apoptotic pathways in the course of carcinogenesis is emphasized further by the fact that genes involved in cell proliferation, such as c- *myc*,[3] are invariably coupled to apoptotic pathways, doubtless as part of the regulatory mechanisms that govern normal cellular proliferation.

Lymphomas, then, are neoplasms of lymphocytes or their precursors, which arise as a consequence of genetic aberrations that influence their proliferation, differentiation, and ability to undergo apoptosis. To a varying extent, however, neoplastic cells remain sensitive to the signals received by normal cells, which govern these processes, as well as their migration. Tumor cell viability, for example, may be tissue dependent, accounting for the growth of tumor in some parts of the body or, at a microscopic level, in specific areas of lymphoid tissue. To a degree, tissue-dependent survival is lymphoma subtype specific, such that each lymphoma is associated with a different, although overlapping pattern of tissue and organ distribution.

Broadly, lymphomas can be divided into B- and T-cell types according to the lineage they have arisen from and reflected in the predominant rearrangement of antigen receptor genes (T- or B-cell receptors). The uncommon NK cell–lineage lymphomas, encountered almost exclusively in pediatric lymphomas in anaplastic large cell lymphomas (ALCLs), is an exception to this, because, although more closely resembling T cells, they do not have rearranged antigen receptor genes. Lymphomas can also be classified according to whether their immunophenotype is of immature lymphoid or mature lymphoid origin. Because mature B- and T-cell lymphomas subserve different functions (respectively, the production of antibodies and the regulation, directly or indirectly, of other cell types, including the killing of cells expressing foreign antigens), B- and T-cell lymphomas have broadly different presentations, although there is considerable overlap. T-cell lymphomas, in general, are much more likely to involve the skin and even lung and muscle than are B-cell lymphomas, although both may frequently involve the nasopharynx, bone marrow, or central nervous system (CNS). In the case of precursor cell neoplasms, involvement of the thymus, the site of T-cell differentiation, is frequently present in immature T-cell neoplasms [e.g., lymphoblastic lymphoma (LL)]. This must be qualified, however, by the recognition that there are mature B-cell populations present in the thymus, such that some mature B-cell lymphomas may also present with thymic (mediastinal) enlargement.

The major childhood lymphomas that are discussed in this chapter include Burkitt's (BL), Burkitt's-like (BLL), and LBCLs, which fall on a continuous spectrum of histologic appearances but which all have a mature B-cell immunophenotype; LL, which is predominantly but not always of precursor T-cell origin; and ALCL and other peripheral T-cell lymphomas, all of which have a mature T-cell or null cell immunophenotype. The existence of a B-cell form of ALCL is controversial. These lymphomas can be grouped according to their histology and immunophenotype and, to a large degree, cytogenetic abnormalities. These subtypes differ with respect to their patterns of presentation, although there is overlap ( Table 24-1).

| Histologic category | Immunophenotype | Most common cytogenetic abnormalities[a] | Most common sites of presentation |
|---|---|---|---|
| Burkitt lymphoma, Burkitt's-like lymphoma, large B-cell lymphoma | B cell | t(8;14) and variants | Abdomen |
| Lymphoblastic lymphoma | Pre-T | Many | Thorax |
| | Pre-B cell | Many | Lymph nodes, bone |
| Anaplastic large cell lymphoma | T cell or null (natural killer?) | t(2;5) and variants | Lymph nodes, skin, soft tissue, bone |
| Other peripheral T-cell lymphomas | T cell | Unknown | Variable |

[a]Not all tumors in each category contain one of the translocations shown.

**TABLE 24-1. SUMMARY OF HISTOLOGIC CATEGORIES (WORLD HEALTH ORGANIZATION CLASSIFICATION), IMMUNOPHENOTYPE, AND MAJOR CLINICAL FEATURES OF CHILDHOOD NON-HODGKIN'S LYMPHOMAS**

One final area that needs to be addressed in these introductory remarks is the relationship between leukemia and lymphoma. All lymphoid neoplasms may present with diffuse involvement of the bone marrow, which may be accompanied by lymphomatous masses in other parts of the body. An arbitrary criterion of greater than 25% neoplastic cells in the bone marrow has been required for a diagnosis of leukemia among pediatric oncologists, but there is no biologic significance to this criterion, nor has prognostic significance been established. It is important to recognize that within each lymphoma category, bone marrow involvement is a sign of extensive disease rather than an indication of a different disease. Use of the term *acute B-cell leukemia* is unhelpful in this regard because this designation includes several lymphoma categories and is not, therefore, a precise diagnosis. The majority of such cases in children is BL with diffuse marrow involvement and should be treated as such. A smaller proportion is diffuse LBCLs, which can be treated with the same type of regimen used for BL. The designation of *acute B-cell leukemia* should not be interpreted as indicating that such patients should be treated with regimens used for acute lymphoblastic leukemia (ALL).

## HISTORICAL PERSPECTIVE

Before our modern conception of lymphomas, based on a knowledge of the normal immune system and of the molecular changes associated with lymphoma cells, there was a great deal of confusion regarding the nature and origins of what we recognize today as lymphoid neoplasms. With no unifying principles, it is not surprising that a plethora of terms, originating from many different perspectives (e.g., Ki-1 lymphoma, LL, centroblastic lymphoma, large cell lymphoma, BL), and a number of different classification schemes, some of which used the same term for different tumors (e.g., LL), were developed. Recently, improved classification systems for lymphoid neoplasms have been published—the REAL classification [4] and its derivative, the World Health Organization (WHO) classification [5]—and it is to be hoped that these will be sufficiently widely used to lead to a uniform usage of terms, although for long the excellent Kiel classification system [6] has held sway in Europe and may continue to do so. Just as the lack of knowledge concerning the origins of lymphomas led to competing classification systems, so too, the evolution of therapy has been largely empirical and at times arbitrary, and present approaches to treatment have resulted from empirical observations made over the course of many years. Perhaps in part because lymphoid neoplasms are highly responsive to chemotherapy, however, the most widely used regimens in use today are very effective, with anticipated cure rates of 80% to 90%, such that radical alteration of treatment approaches may be considered unethical unless justified by potential for significant benefit, such as a reduction in toxicity, and examined in a research context. It is, perhaps, worthy of note that this state of affairs has developed within a period of approximately 50 years, before which children with lymphoma had an abysmally poor prognosis. Indeed, as late as the middle of the twentieth century, lymphoid neoplasms were poorly understood, reflecting the lack of knowledge of lymphocytes and the immune system in general.

The modern era can be considered as beginning in the 1950s in Kampala, Uganda, where Denis Burkitt, an Irish surgeon, was working. Burkitt [7] recognized the clinical characteristics of the lymphoma still referred to by his name (after an intermediate period when, in the United States at least, the term *small noncleaved cell lymphoma* was preferred), although he initially believed it to be a sarcoma. At the same time, O'Conor [8] reported that approximately one-half of all childhood tumors seen in Kampala were lymphomas. Subsequently, O'Conor and colleagues,[9] Dorfman,[10] Wright,[11] and others realized that a proportion of childhood lymphomas in Europe and the United States were histologically indistinguishable from BL as originally described in Africa, although at the time considerable debate occurred as to whether the characteristic jaw tumors as well as the absence of bone marrow involvement should be required for this diagnosis to be made. Burkitt and, notably, Clifford also made major contributions to the treatment of childhood lymphomas by identifying a rather large list of chemotherapy agents to which BL would respond, occasionally with long-term cures.

### Evolution of Classification Schemes

When BL was incorporated into the earlier Rappaport classification, [12] the major classification scheme then in use in the United States, it was classified as a subtype of undifferentiated lymphoma—that is, a lymphoma that, at a time when immunophenotyping was not yet possible, showed no evidence of differentiation toward either a lymphocyte or a histiocyte, the two major categories of the Rappaport scheme. Subsequently, it was recognized that almost all lymphomas composed of large cells, which Rappaport considered to be of histiocytic origin, were actually of lymphoid origin. In the Rappaport scheme, undifferentiated lymphomas were classified into either Burkitt's or non-Burkitt's types, according to the degree of cellular pleomorphism. [12] Lukes and Collins,[13] recognizing that some cells in normal germinal centers of lymphoid tissue were similar to those of BL (or “undifferentiated lymphoma”), proposed replacing the term *undifferentiated lymphoma* by the descriptive term *malignant lymphoma of small noncleaved follicular center cells*, also to be subdivided into BL and non-BL. By then the division of the immune system into humoral (B) and cellular (T) components was established, and investigators recognized that lymphomas could also be classified on this basis. Because Lukes and Collins considered the small noncleaved cell lymphomas to be derived from germinal center cells, similar to most of the NHLs available to them for study, they considered them to be of B-cell lineage, a conclusion consistent with the earlier demonstration of the expression of surface immunoglobulin on the surface of BL-derived cell lines,[14],[15] and [16] and subsequently, on BL cells derived from patients in a leukemic phase. [17] Lennert and colleagues,[18] the main proponents of the Kiel classification scheme and also, from the early 1970s, advocates of classifying lymphomas on the basis of their presumed normal cell counterparts in the immune system (hence, into lymphomas of B- and T-cell origin), initially classified BL as a lymphoblastic B sarcoma (the term *sarcoma* being then used in European lymphoma classification

schemes to signify a highly aggressive tumor). Subsequently, they referred to it as a *malignant lymphoma of lymphoblastic type*, this category being subdivided primarily into BL and, following Lukes and Collins, lymphomas of convoluted cell types. Thus, LL, in the earlier German classification scheme, included the two major subtypes of NHL that we recognize today in children.

Lukes and Collins[13] described their malignant lymphoma of convoluted lymphocytes more than 16 years after the original description of BL. They suggested that this new entity was likely to be of T-cell origin and commented on the frequent involvement of the thymus and the higher frequency of the tumor in children and adolescents. Shortly afterward, Nathwani and colleagues[19] distinguished LL from the Rappaport category of diffuse, poorly differentiated lymphoma and identified it with the Lukes and Collins convoluted T-cell lymphoma, although Nathwani et al. also realized that many otherwise morphologically identical tumors lacked nuclear convolutions. Other neoplasms included in the category of diffuse, poorly differentiated lymphomas proved to be predominantly of B-cell origin, occurred almost exclusively in adults, and had different clinical courses from that of LL. It soon became apparent that LLs, similar to undifferentiated lymphomas, had a predilection at the time of relapse for the bone marrow and CNS and that most patients developed recurrent disease at these sites—at least in North America. [20,21] LL has subsequently been shown to be indistinguishable morphologically from ALL but to be almost the mirror image immunophenotypically, being of precursor T-cell origin in approximately 85% and of precursor B-cell origin in the remainder of cases (over 85% of ALL is of precursor B-cell origin).

Childhood lymphomas of the large cell type have been recognized for many years, being referred to by Rappaport as histiocytic lymphomas, as mentioned above, because of their large size and abundant cytoplasm.[12,20,22,23] Subsequently, Lukes and Collins[13] divided them into immunoblastic lymphomas and lymphomas of large follicle center cells, most of which were believed to be of B-cell origin. In the Kiel classification, these lymphomas were referred to respectively as immunoblastic and centroblastic lymphomas, the latter being the term used in Europe for the large cells in lymphoid germinal follicles. [14] Clearly there was considerable agreement between the Kiel and the Lukes and Collins classification schemes, both of which, as pointed out already, were presciently based on the probable normal counterpart cells in the immune system. In North America, however, the Rappaport classification remained in use, leading to considerable (if only continuing) confusion regarding the classification of NHLs. The National Cancer Institute of the United States (NCI), therefore, sponsored the development, in the early 1980s of what was called a *Working Formulation for Clinical Usage* and, presumably to avoid offending authors of rival schemes, presented it as a means of “translating” from one system to another.[24] The major drawback of what was, in effect, simply a new classification scheme, was that it was based purely on histology, and although it included terms used by Lukes and Collins, such as *malignant lymphoma of small noncleaved cells*, it most closely resembled the Rappaport scheme. European pathologists consequently continued to use the Kiel classification for the most part, and although the Working Formulation was used until quite recently, its failure to go beyond histology, with the result that each of its categories included multiple NHL subtypes, led to increasing difficulties for both pathologists and clinicians as new entities were described using a combination of histology, immunophenotyping and, increasingly, cytogenetic or molecular characterization. One of these new entities was a large, anaplastic lymphoma (ALCL) that expressed high concentrations of the Ki-1 antigen, originally recognized on cultured Reed-Sternberg cells. [25] It is now known that approximately one-half of childhood large cell lymphomas belong to the category of ALCL. Additional new entities included mantle cell lymphoma and lymphomas of mucosal-associated lymphoid tissue (MALT), and eventually a number of pathologists recognized that the time had come to develop a new classification scheme that incorporated the latest available information regarding the immunology and molecular abnormalities of lymphoid neoplasia.

Accordingly, in April of 1993, 19 hematopathologists from Europe and the United States recategorized lymphomas, using all of the criteria possible, including histology, immunophenotype, genetic features (cytogenetic or molecular), and their major clinical presentations and course. This resulted in the REAL (revised European American lymphoma) classification,[4] which has subsequently been updated in conjunction with a committee of expert clinicians, as the WHO classification. [5] In these classifications, all NHLs were divided into B- or T-cell lymphomas, each of which was further subdivided into precursor (i.e., lymphoblastic) or peripheral subtypes. Although of great significance to the understanding and classification of lymphomas in general, this has not resulted in major differences to the classification of the pediatric NHLs.

**Evolution of Therapy**

The results of treatment of pediatric lymphomas before the 1970s were extremely poor, with 5-year survival ranging from 5% to 33% (overall, closer to 5%) in various series.[2] The only therapy that could lead to cure in approximately 20% of patients with localized disease (stage I) was irradiation. [2,26,27] The use of single cytotoxic agents only slightly enhanced the results with radiation therapy alone, and because it was still not widely recognized that a high proportion of childhood NHLs were histologically identical to the African tumor discovered by Burkitt, treatment approaches evolved separately in Africa [28] and the United States and Europe.[2]

In African BL, some remarkable cures were observed by Burkitt and others with a small number of doses (even one) of cyclophosphamide or other chemotherapeutic agents, although most patients cured by such limited therapy also had limited disease. [28,29 and 30] Some North American patients with limited BL also achieved long-term survival after treatment with cyclophosphamide as a single agent.[31] The success of the MOPP [mechlorethamine, vincristine (Oncovin), procarbazine, prednisone] combination drug regimen in Hodgkin's disease[32] heralded the modern era of combination chemotherapy, and application of a combination of cyclophosphamide, methotrexate (MTX), and vincristine, initially in African BL [28] and subsequently in U.S. patients[33] demonstrated the advantages of combinations of drugs over single-agent chemotherapy.

Meanwhile, the clinical and morphologic similarity of LL to ALL and the high frequency of bone marrow relapses in lymphoblastic and non-LLs was instrumental in the development of the concept that malignant NHLs in children represented variants of acute leukemia. This concept led pediatric oncologists to apply regimens designed for ALL to the treatment of children with NHL, even in the absence of bone marrow involvement. The most successful of the leukemia regimens was the $LSA_2L_2$ regimen used at the Memorial Sloan-Kettering Cancer Center in New York.[34] The success of this regimen, coupled with the demonstration at the NCI that regimens based on repeated doses of cyclophosphamide, MTX, vincristine, and prednisone were quite successful in the treatment of BL, [33] led to the need to determine which of the two main approaches—lymphoma therapy, derived from the combination used in BL, or leukemia therapy, based on the successful $LSA_2L_2$ regimen—was more appropriate for the treatment of childhood lymphomas and whether prognosis with each of these regimens depended on histology. The results of this now classic study by the Children's Cancer Study Group (CCSG) indicated that the four-drug COMP regimen [cyclophosphamide, vincristine (Oncovin), MTX, prednisone], using the same drugs as in the NCI regimens, although with somewhat different dosage and schedule, was superior to the ten-drug $LSA_2L_2$ regimen for what were then referred to as *small noncleaved cell lymphoma*, but inferior to the $LSA_2L_2$ regimen for LLs.[35] Large cell lymphomas, comprising, in retrospect, both ALCLs and diffuse B-cell lymphomas, had a similar prognosis with both regimens. It was concluded from this study that lymphoblastic leukemia is best treated with an ALL-type regimen (in this case $LSA_2L_2$) while BL is best treated with repeated cycles of a cyclophosphamide and MTX-containing regimen. This principle has persisted until the present day, although the original 18-month therapy duration for BL has been drastically shortened and intensified for high-risk patients, and treatment results also appear to have improved in LL, although the optimal therapy duration for LL remains uncertain.

The treatment regimens in Africa did not include radiation therapy, because it was unavailable in Uganda. However, Swedish investigators working in Nairobi had reported very poor local control of BL with irradiation. [36] Despite this, the cure of a small number of patients with localized NHL using irradiation in the United States and Europe[37] led to the continued use of radiation directed to as many sites of disease as possible, as was practiced in the CCSG study referred to above. This tradition was slow to disappear but has at last been abandoned because of evidence from a randomized trial, and subsequent treatment of many more patients without radiation, showing that the latter modality increases toxicity without providing therapeutic advantage in patients with limited disease (treated, of course, with effective drug combinations).[38,39] In patients with advanced disease, excellent disease-free survival rates have also been obtained using chemotherapy alone (better, in fact, than those achieved when local radiation was used with less intensive chemotherapy), [26] and in many such patients, it would not be feasible anyway to irradiate all sites of disease.

Complete surgical resection of abdominal tumor was originally shown in African BL[40] to be associated with excellent survival rates if followed immediately by chemotherapy, although relapse remained relatively frequent. In North America and Europe, however, excellent results using chemotherapy alone, even in patients with advanced disease, have been achieved. This, coupled to evidence that the main determinant of outcome is tumor bulk rather than the surgery itself (at least in the United States and Europe), has led to surgical debulking no longer being recommended. [41,42] Nevertheless, a fraction of patients will continue to have complete surgical resection at the time of diagnosis—those, for example, who present with an acute abdomen, who generally have very limited tumor volumes that cause major symptoms because of intussusception or intestinal obstruction. Resection of all tumor is frequently necessary to deal with the acute problem. Such patients do very well,[39] but almost certainly, given their small tumor volume, would have done just as well had it been possible to treat them with combination chemotherapy alone, so that this observation cannot be said to support surgical resection as an elective procedure. It must be said, however, that in countries with limited resources, in which only minimal chemotherapy (e.g., cyclophosphamide as a single agent) can be given, surgical resection of tumor, as long as essentially all tumor can be resected without mutilation, may remain advantageous.

Since the classical studies of the mid-1970s, steady progress in the achievement of improved cure rates in all pediatric NHLs has been achieved. In B-cell

lymphomas, including BL and diffuse LBCL, and probably also in ALCL, this has resulted largely from the addition of high dose S phase agents along with additional drugs such as ifosfamide and etoposide to the therapy regimens of patients with more extensive disease. In LL, this has been associated with the gradual improvement of the regimens used for the treatment of ALL, particularly more intensive induction and consolidation (reinduction) regimens as well, perhaps, as the inclusion of relatively high dose asparaginase in these early treatment cycles.

## EPIDEMIOLOGY AND PATHOGENESIS

Lymphomas (Hodgkin's and NHLs) constitute 10% to 15% of all childhood cancers in the more developed countries; they are third in relative frequency after acute leukemias and brain tumors. In the United States, according to the NCI's Surveillance, Epidemiology and End Results program, 1.7% of all new cases of NHL occurring between 1992 and 1996 were in patients younger than 20 years old, and the average annual incidence rate for this age group was 1.0 per 100,000. [43] In 1996, 15.4% of all newly diagnosed cancers in persons younger than 20 years were lymphomas, and 6.4% were NHLs. Unlike Hodgkin's disease, which has a bimodal incidence curve, the incidence of NHL increases steadily with age throughout life, although the age-specific incidence of various subcategories varies markedly. The incidence of NHL in male children is approximately twice as high as that in female children. During the period 1973 to 1996, there was a 35% increase in the incidence of NHL in patients younger than 20 years but an increase of only 4.8% in those younger than 14 years. Although these figures are not greatly different from those in most European countries, the incidence and relative frequency of NHL varies considerably in different world regions ( Table 24-2): the incidence of BL varies from less than 1 to 36 per million children aged 0 to 14 years, whereas that of other NHLs ranges from 2.5 to 15.4 per million. [44]

| | Burkitt's lymphoma | | | Non-Hodgkin's lymphoma | | |
|---|---|---|---|---|---|---|
| | Male | Female | Total | Male | Female | Total |
| Uganda (Kampala) | 48.5 | 25.2 | 36.1 | 11.0 | 10.4 | 10.7 |
| Nigeria (Ibadan) | 24.1 | 11.9 | 18 | 2.1 | 1.5 | 2.0 |

**TABLE 24-2. AGE-STANDARDIZED (0 TO 14 YEARS) INCIDENCE RATES PER MILLION OF BURKITT'S LYMPHOMA AND OTHER NON-HODGKIN'S LYMPHOMAS IN SELECTED REGISTRIES REPORTING TO THE INTERNATIONAL AGENCY FOR RESEARCH IN CANCER, LYON, FRANCE**

The incidence of NHL is much lower in children compared with adults, and it seems likely that age-related differences in the frequency of various histologic categories in children versus adults reflects, at least in part, the cellular composition of the immune system at different ages. Children and adults, however, also differ greatly in the type and duration of exposure to various environmental agents, and cell populations at risk as well as environmental exposures are likely to account for the differences in the patterns of NHLs at different ages.

### Geographic Differences in the Incidence of Lymphoid Neoplasms in Children

Just as the incidence of NHL varies markedly from country to country, [44] so does the relative frequency. In equatorial Africa, for example, approximately 50% of childhood cancers are lymphomas, [28] with this markedly increased frequency resulting from the very high incidence of BL in this region coupled to the low incidence of ALL. LL and large cell lymphomas also occur in equatorial Africa, probably with a similar incidence to that in the more developed countries, although accurate figures are unavailable and little is known of their biology. In Europe and the United States approximately one-third of childhood lymphomas are LL, one-half are BL or BLL, approximately 15% are large cell lymphomas (50% LBCL and 50% ALCL), and the remainder are unclassified.

### Burkitt's Lymphoma

There are a number of differences between equatorial African BL, often referred to as *endemic* because of the relatively high incidence of BL in this region, and BL in other parts of the world, frequently referred to as *sporadic* (Table 24-3). The term *sporadic* originally referred to BL in the United States and Europe and may not be appropriately used in other regions, in which the incidence, sometimes the pattern of presentation, and the proportion of tumors associated with Epstein-Barr virus (EBV) (see below) are between that of equatorial Africa and the United States and Europe. The reason(s) for these differences in incidence is unknown, although variability in the environment is the most likely explanation, perhaps resulting in differences in the cell type that undergoes transformation or in the set of genetic abnormalities present in the tumor cells. African BL was originally recognized because of the high incidence of jaw tumors, but this is not a site of predilection in patients outside Africa, although abdominal involvement is frequent in both endemic and sporadic varieties. One of Burkitt's [45] major contributions was to demonstrate the remarkable geographic distribution of the endemic tumor in equatorial Africa and to show that the apparent limits of its distribution were climatically determined. This observation led to the hypothesis that a vectored virus could be of pathogenetic importance and prompted a search for associated viruses that resulted in the discovery of EBV. [46] Although 95% of all equatorial African tumors carry EBV genomes in their cells, this is true for only approximately 15% to 20% of North American tumors. [28,47] Moreover, this difference does not simply reflect exposure to EBV, because even patients with EBV-negative tumors generally have antibodies to EBV [28,44] and the ubiquity of EBV infection clearly indicates that EBV itself is not responsible for the characteristic geographic distribution of BL in Africa. One striking difference in the epidemiology of EBV in Africa versus the regions in which “sporadic” BL occurs, however, is the difference in the age at which EBV infection occurs. Almost the entire population has been infected by the age of 3 years in Africa, whereas in affluent nations, primary infection frequently occurs in late adolescence or early adulthood. [48] BL in developing countries other than Africa also tend to be more often EBV associated (40% to 80%), supporting the notion that perinatal infection with EBV and low socioeconomic status increases the likelihood of developing BL. [49,50] and [51]

| | Endemic form | Sporadic form |
|---|---|---|
| Average annual incidence (children <16 yr) | 10 per 100,000 | 0.2 per 100,000 |
| Occurrence | Climatically determined | Not climatically determined |
| Association with Epstein-Barr virus[a,b] | 95% | 15% |
| Chromosome 8 breakpoints[c] | 75% upstream of c-*myc* | More often within c-*myc*[d] |
| Common sites of tumor | Jaw, abdomen, orbit, paraspinal, CNS | Abdomen, bone marrow, serous membranes |

CNS, central nervous system.
[a]Depending on world region.
[b]Presence of Epstein-Barr viral DNA in tumor cells.
[c]Applies to t(8;14) chromosomal translocations; in variant translocations breakpoints are invariably downstream of c-*myc*.

**TABLE 24-3. DIFFERENCES BETWEEN ENDEMIC AND SPORADIC BURKITT'S LYMPHOMA**

If we accept a role for EBV in the pathogenesis of BL—the International Agency for Research on Cancer considers that there is sufficient supportive evidence to draw this conclusion [52]—it remains still to be determined whether EBV infection simply predisposes to the development of African BL (and presumably those sporadic tumors that contain EBV sequences) or whether EBV is an essential component of pathogenesis. EBV's ability to infect and cause proliferation of B cells *in vitro* certainly accounts for its infectivity and persistence in humans. *In vivo*, this ability of EBV to “transform” B cells could result in an increase, whether transient or permanent, in the size of certain B- or pre-B–cell populations, with a consequent increased risk of the development of genetic abnormalities relevant to the genesis of BL in such cells, and this possibility, for long, was the leading hypothesis to account for EBV's association with BL. As more is learned of the functions of EBV genes,

however, the possibility that the expression of one or more of them in the tumor cells, or in precursor tumor cells, is relevant to pathogenesis, must be considered. Even during acute malaria, which is known to decrease T-cell mediated immunity directed toward EBV-infected cells and, consequently, to increase the fraction of circulating EBV-containing B lymphocytes and presumably the body burden of EBV-containing cells, [53,54 and 55] only a small fraction of the B cells present in the body are infected by EBV. Thus, the increased risk of developing BL based solely on an EBV-induced increase in the pool of B cells in which appropriate genetic changes can occur would seem to be small. Moreover, given the very small percentage of B cells infected by EBV, unless EBV has some kind of direct role, EBV association would be a very uncommon event.

Of course, if EBV does or can have a direct role in pathogenesis, the effect, in equatorial Africa at least, of the immunosuppressive effect of malaria (which is holoendemic in the regions of high incidence of BL in equatorial Africa), could be critical to EBV's potential pathogenetic role—increasing the risk of its development by a factor equivalent to the increased number of EBV-containing B cells, or at least, to the increased number of EBV-infected B cells capable of sustaining a relevant genetic lesion (it is highly unlikely, for example, that resting B cells would be susceptible to chromosomal translocation). Malaria-induced B-cell hyperplasia may even predispose to chromosomal translocation. Indeed, the close relationship between the distribution of malaria and that of BL in equatorial Africa is likely to account for the geographic distribution of this tumor within the African continent. More definitive conclusions are likely only to be reached by the identification of the specific molecular pathways through which EBV genes may act. Increasing information relating to the roles of the genes expressed by EBV in the latent phase of infection—that is, in the absence of virus production (which itself is incompatible with neoplasia because it results in cell lysis)—has at least identified several ways in which viral genes could contribute to pathogenesis. Of particular relevance to such considerations is the finding that one EBV protein, EBNA-1, is expressed in the vast majority of BL cells, so that if EBV does play a direct role in pathogenesis or, at least, in maintenance of the transformed phenotype, it could be via EBNA-1. This possibility is supported by the demonstration that EBNA-1 transgenic mice develop B-cell lymphomas. [56] Recently, the description of polymorphic variants of EBNA-1 and the demonstration that the most prevalent subtype is rarely associated with BL has provided further evidence that EBNA-1 may contribute to pathogenesis, although this story is still unfolding. [57] The negative effect of other EBV latent genes (EBNA-2 and LMP-1), both involved in the transformation of B lymphocytes, suggests that the EBNA-1–only pattern of gene expression in BL is a powerful clue to its role in BL. [58] Finally, the occurrence of familial BL in Tanzania provides evidence that inherited genetic abnormalities play a role, at least in some cases, in the pathogenesis of BL. [59]

### Other Non-Hodgkin's Lymphomas

Little epidemiologic information is available with regard to the other varieties of childhood NHL, but there is no doubt that the relative frequency of BL and LL varies markedly in different world regions. [60,61 and 62] LL appears to be very uncommon, along with ALL, in children in equatorial Africa. [63] No virus association has been observed with LL, nor is there a single specific chromosomal abnormality associated with LL, which appears to be similar to T-cell ALL with respect to its genetic lesions (see Chapter 17). Even though LLs are predominantly of T-cell origin, a small fraction have pre–B-cell characteristics. It seems likely that LL encompasses several etiologically distinct diseases. In Southeast Asia, virus-associated hemophagocytic syndrome (usually EBV) is associated with an increased risk of T-cell lymphoma development, and peripheral T-cell lymphomas represent a higher fraction of NHL in this world region. [64,65 and 66]

### Prelymphomatous States

Because lymphomas arise from the cells of the immune system, it is not surprising that disorders associated with abnormal regulation of lymphocyte proliferation and function are associated with an increased incidence of NHL. EBV also appears to be important in the pathogenesis of lymphomas in immunodeficiency states because the cells of a majority of these lymphomas and lymphoproliferative syndromes contain multiple EBV genomes. One possible explanation is that defective T-cell regulation permits an increase in the development and expansion of EBV-infected clones of B cells that would normally be tightly controlled but that, due to the influence of viral genes, have a selective advantage over uninfected cells. Such cell clones would then be at increased risk for developing genetic changes capable of causing neoplasia. The topic of lymphomas in immunosuppressed individuals is discussed in Chapter 25. Recently, a new syndrome known as *autoimmune lymphoproliferative syndrome* associated with mutations in the Fas (CD95) receptor was described, in which splenomegaly, lymphadenopathy, and autoimmune phenomena presumably occur as a consequence of defective regulation of T-cell activation because of impaired apoptosis. [67] Such patients have also been shown to be prone to the development of NHL of a variety of subtypes. [68]

### Drugs and Radiation as Predisposing Factors

There is little evidence that radiation is an important predisposing factor for lymphomas. In atomic bomb survivors, there appeared to be slightly increased prevalence rates of lymphoma in individuals who received more than 200 rads in Nagasaki and those exposed to more than 100 rads in Hiroshima, but there was no significant trend for increased incidence with increased dose during the period 1950 to 1978. [69] The relative risk during this same period for individuals exposed to greater than 200 rads was 1.6. The majority of the lymphomas in the exposed groups was NHLs of large cell type.

Although a four- to fivefold increased risk of lymphoma development has been observed in U.S. radiologists and uranium workers exposed during the 1950s and a twofold increase in the risk of lymphoma development observed for patients irradiated for ankylosing spondylitis for at least 6 years, there is little evidence for a lymphomagenic effect of the once-practiced thymus gland irradiation in children.

Patients with Hodgkin's disease treated with combined modality therapy are at increased risk to develop NHL—perhaps 4% to 5% of all patients so treated will develop NHL lymphoma within 10 years. [70,71] The precise risk for children with Hodgkin's disease treated with either chemotherapy alone or combined-modality therapy has not been determined because of small numbers of treated patients compared to adults. Apart from immunosuppressive drugs used in transplant recipients, information regarding the capacity of other drugs to induce lymphoma is limited. Hydantoin derivatives are known to cause pseudolymphomas that regress with cessation of therapy, and there are reports of the development of lymphomas in long-term recipients of these drugs. [72,73] However, no accurate figures are available regarding the size of this risk, but in view of the widespread use of these compounds, it is probably very low. [74] Various organic solvents, including dioxins, benzene, the herbicide 2,4D, and hair dyes have been incriminated in the etiology of NHLs, but there is no evidence that they represent significant factors in the occurrence of childhood lymphomas. [75,76 and 77]

## HISTOPATHOLOGY AND IMMUNOPHENOTYPE OF CHILDHOOD NON-HODGKIN'S LYMPHOMA

### Burkitt's and Burkitt's-Like Lymphomas

BL cells (Fig. 24-1) have a high nuclear to cytoplasmic ratio. The nucleus is round or oval and has an “open” nuclear chromatin pattern (i.e., giving the appearance of being able to see through the network of chromatin), a feature that contrasts with the appearance of the chromatin in LL. There are multiple (usually two to five), readily discernible nucleoli. Occasional cells may have only a single central nucleolus, but if such cells are frequent, many pathologists would diagnose BLL ( Fig. 24-2). The rim of cytoplasm is very basophilic (staining intensely with methyl green pyronine) because of the high RNA content and usually contains lipid vacuoles (which stain with lipid stains such as oil red O). Macrophages (so-called tingible body macrophages) are frequently interspersed among the tumor cells. These contain nuclear debris, probably ingested from tumor cells that have undergone apoptosis, and give rise to the oft-quoted “starry sky” appearance. This pattern is not pathognomonic of BL or BLL and may be seen in any rapidly proliferating tumor. BL and BLL differ with respect to the uniformity of the tumor cells. BL cells are, at least in histologic preparations, rather regular in size and shape, whereas BLL cells are more pleomorphic, with some cells being indistinguishable from BL cells, some indistingushable from large cell lymphoma cells, and some intermediate in appearance. As might be anticipated, the dividing line between these tumors cannot be made reproducibly. Indeed, in the new WHO classification, it is recognized that the histologic entity of BLL includes tumors that could well be classified as LBCLs, and with respect to biologic characteristics, may be closer to this entity than to BL, particularly in adults. Because such tumors, however, behave clinically as BL—that is, are rapidly progressive tumors and respond well to therapy designed for BL—it would be a mistake to eliminate this entity. On the other hand, some BLLs, particularly in children, contain the nonrandom chromosomal translocations that are observed in BL; it is likely that BLL also includes at least some classic BLs. These observations suggest that BLL may not be a biologic entity at all but is composed of a mixture of BL and a rapidly proliferative variant of LBCL, the relative proportions of each entity varying in children and adults (presumably because LBCL has a much higher incidence in adults). Until more definitive guidelines can be established, according to the new WHO classification, a diagnosis of BLL will only be made when a tumor with an appropriate histologic appearance also has a high proliferative potential, as evidenced by very high Ki-67 or MIB-1 positivity (99%). [5]

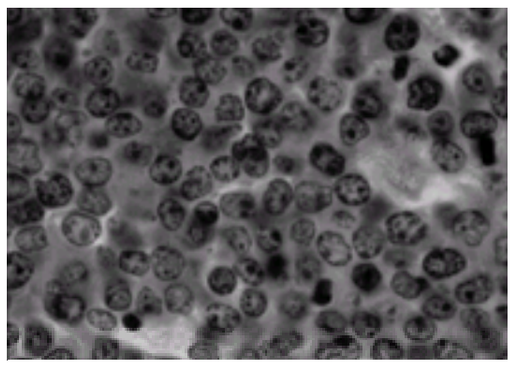

**FIGURE 24-1.** Histologic appearance of Burkitt's lymphoma. (From E.S. Jaffe. Histopathology and immunopathology. In Magrath I, ed. The non-Hodgkin's lymphomas, 2nd ed. London: Arnold, 1997:79–108, with permission.)

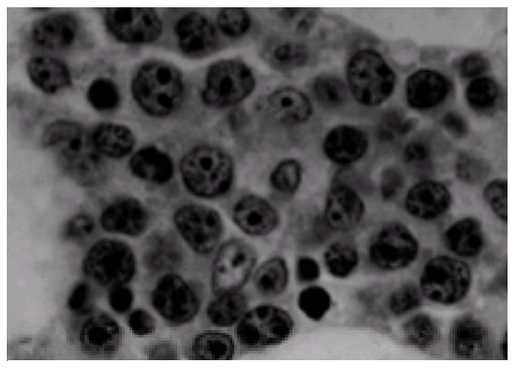

**FIGURE 24-2.** Histologic appearance of Burkitt's-like lymphoma. (From E.S. Jaffe. Histopathology and immunopathology. In Magrath I, ed. The non-Hodgkin's lymphomas, 2nd ed. London: Arnold, 1997:79–108, with permission.)

BL has the phenotype of a germinal center cell, expressing surface immunoglobulin (SIg), which, in more than 90% of cases, is IgM, associated with either kappa or lambda light chains. At a molecular level, the immunoglobulin (but not T-cell receptor) genes are always rearranged [4,5] and contain hypervariable mutations,[78,79] a finding that, in normal cells at least, is believed to indicate that the cell has entered the germinal center, the anatomical location at which hypervariable mutation and most class switching takes place. Other B-cell–associated antigens are expressed in BL, including CD19, CD20, CD22, CD79a, and CD77. [4,5] CD10, which is present on both lymphocyte precursor cells and germinal center cells, is also positive, as is CD38, another antigen expressed on germinal center cells, although terminal deoxynucleotidyl transferase (TdT) is negative. The immunophenotype of BLL is more variable, and in view of the diagnostic variability, less well characterized than BL, although similar. Occasional tumors may lack SIg, more often in adults. In at least some cases this may result from the presence of two translocations involving the immunoglobulin heavy-chain locus 14q32—both t(8;14) and t(14;18). [80,81] Rare tumors with the immunophenotype of immature B cells, including the expression of TdT, but containing 8;14 translocations have also been described.

**Large B-Cell Lymphoma**

LBLC comprises a heterogeneous mixture of tumors, at least with regard to their molecular genetic characterization. The degree of heterogeneity is likely to be greater in adults than in children, although little information on the genetics of LBCL in children has been published. There is some variation in the histology of LBCL, but attempts to subdivide LBCL reproducibly on the basis of histology have largely been unsuccessful. In adults, the separation of LBCL into centroblastic and immunoblastic subcategories may have prognostic implications. [82] In children, there is no evidence that this is the case. There is little doubt, however, that there are subcategories of LBCL. Those that present with a mediastinal mass, for example, appear to be the malignant counterpart of the B-cell population that is present in the thymus. It is also probable that at least some large cell lymphomas in children will prove to be similar or identical to LBCL in adults at a genetic level, but whether there is a subcategory of LBCL that occurs predominantly in children is unknown. In adults, LBCL accounts for the vast majority of rapidly proliferative B-cell lymphomas, and a number of distinct genetic lesions have been identified. The most frequent are chromosomal translocations involving the *bcl*-6 or *bcl*-2 genes. Approximately 5% to 10% have 8;14 or variant translocations, [83] suggesting that lymphomas that are biologically very closely related to BL can sometimes fall morphologically into the category of LBCL. In children, it seems likely that a higher percentage of LBCLs will prove to be of this type, because BL is the predominant childhood B-cell lymphoma and the morphological borders between BL and LBCL are not sharp. B-cell lymphomas (primarily LBCL, but sometimes BL) that arise in patients with underlying immunodeficiency may also differ biologically from their counterparts in nonimmunosuppressed children. LBCL, for example, is frequently associated with EBV in this setting.

LBCLs are composed of cells with nuclei generally larger than those of macrophages, which can usually be found among the tumor cells, and perhaps twice the size of a small lymphocyte nucleus (Fig. 24-3). The cytoplasm is basophilic, and nucleus vesicular with prominent nucleoli. The range of appearances of the tumor cells is variable, and most tumors comprise a mixture of cells that more or less closely resemble the centroblasts of germinal centers, immunoblasts, and less often multilobulated cells or even cells indistinguishable from those of T-cell ALCL, which are described below. Sometimes one or another of these populations predominates, hence the attempt by pathologists to subdivide these tumors. LBCLs have rearrangements of immunoglobulin genes, both heavy and light chain, but do not have rearrangements of T-cell receptor genes. They express B-cell associated antigens, including CD19, CD20, CD22, CD38, and CD79a. CD10 is occasionally expressed, but TdT is negative. SIg may be absent in up to one-third of these tumors [4,5] and is generally absent from LBCL of the mediastinum. It seems probable that most LBCLs originate in germinal centers or at least have a phenotype consistent with germinal center cells. The not infrequent lack of SIg is then consistent with the observation that a proportion of large, rapidly proliferating cells in normal germinal centers cells fails to express SIg. [84,85] It has been proposed that the temporary absence of SIg occurs during the process of somatic mutation of immunoglobulin gene variable regions. Immunoglobulins containing hypervariable region mutations are subsequently expressed on the cell surface, and cells bearing immunoglobulins with the highest affinity for antigen are selected by virtue of the greater likelihood that they will bind and be activated by antigen. [84,85 and 86] This process, which can involve multiple transitions between resting centrocytes and dividing centroblasts in normal germinal centers, each cycle associated with the production of additional mutations, is entirely consistent with the observation that LBCLs, similarly, carry multiple mutations (more than in BL) in the hypervariable regions of their immunoglobulin genes. [87] Indeed, the expression of CD38 and CD10 is also consistent with a germinal center cell phenotype of these neoplasms. Some tumors do appear to have a more mature phenotype in which plasma cell antigens, such as PCA-1, are expressed, and such cells may fail to express other B cell antigens such as CD19, CD20, CD21, CD24, and SIg.

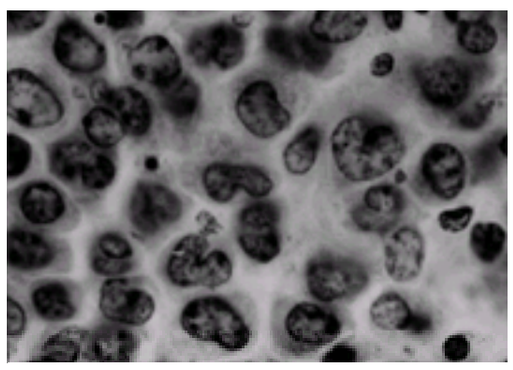

**FIGURE 24-3.** Histologic appearance of large B-cell lymphoma. (From E.S. Jaffe. Histopathology and immunopathology. In Magrath I, ed. The non-Hodgkin's

lymphomas, 2nd ed. London: Arnold, 1997:79–108, with permission.)

Whether there is an entity that should be referred to as anaplastic LBCL is still disputed, but a small number of LBCLs do appear to inappropriately express the p80 kinase. p80 is overexpressed in T-cell ALCL as a result of the formation of a fusion protein (NPM-ALK) by the 2;5 translocation. [88] In a small fraction of B-cell NHLs, p80 is overexpressed in the absence of this translocation. Such B-cell lymphomas may also express the CD30 antigen. Thus, there may be a B-cell equivalent to anaplastic T-cell lymphoma, although such tumors appear to be rare. Relatively low levels of expression of CD30 may also occur in the absence of other distinguishing features of ALCL—for example, on LBCL of the mediastinum.

LBCLs also contain various admixtures of normal cells, particularly macrophages and lymphocytes. On occasion, these populations can be sufficiently prominent (doubtless as a consequence of the production of relevant cytokines) to lead to nomenclature such as *T-cell rich B-cell lymphoma*. This entity is rare in children [89] and appears to be closely related to, and maybe coexistent with, a subtype of Hodgkin's disease known as *nodular lymphocyte predominant Hodgkin's disease*.

LBCL of primary mediastinal (thymic) origin is similar in appearance to other LBCLs, although the cytoplasm is more often pale than basophilic, and Reed-Sternberg–like cells may be present. There is often fine sclerosis within the tumor that can give the appearance of creating compartments.

**Anaplastic Large Cell Lymphoma**

ALCL is a relatively recently recognized entity [25] that was clearly misdiagnosed in the past as histiocytosis, carcinoma, sarcoma, or melanoma. The tumor has been given various and not necessarily synonymous labels, including Ki-1 lymphoma, because of its discovery through the use of this anti-CD30 antibody. [90] The term ALCL is based on the histologic characteristics of this entity. A number of subtypes have been defined on the basis of characteristic histologic features (e.g., lymphohistiocytic). [91] There remain rather imprecise borders between ALCL and Hodgkin's disease and ALCL and other peripheral T-cell lymphomas. [4,5,91] There can also be difficulties in differentiating between ALCL and the skin disease known as *lymphomatoid papulosis*. [91] That these two are related is clearly demonstrated by the transformation of some cases of lymphomatoid papulosis into ALCL. [92] In adults, ALCL can be secondary to a preexisting disease such as Hodgkin's disease or indolent peripheral T-cell lymphomas, particularly cutaneous T-cell lymphomas, but such secondary forms of ALCL are essentially unknown in children.

The hallmark of ALCL is the presence of anaplastic cells—that is, large pleomorphic cells containing horseshoe-shaped or multiple nuclei, with prominent, usually multiple, nucleoli (Fig. 24-4). Some of the cells may resemble Reed-Sternberg cells. The cells tend to be cohesive and to preferentially involve the sinuses of lymph nodes. Admixtures of normal cells, particularly granulocytes and macrophages, are present. In addition to CD30, ALCLs generally express the epithelial membrane antigen, EMA, which may lead to an erroneous diagnosis of carcinoma. They may or may not express CD45, CD15, or other T-cell–associated antigens. [4,5] A high fraction of ALCLs have a clonal rearrangement of T-cell receptor genes, usually Tb associated with biallelic deletion of Td, indicating Ta rearrangement, but some of these tumors appear to be of NK-cell origin and do not have rearranged T-cell receptor genes. [93,94] and [95] ALCL is uncommonly associated with EBV, particularly in children, [96] although some authors have reported significant rates of association. [97] ALCL is, however, nearly always EBV-associated in patients with underlying human immunodeficiency virus (HIV) infection.

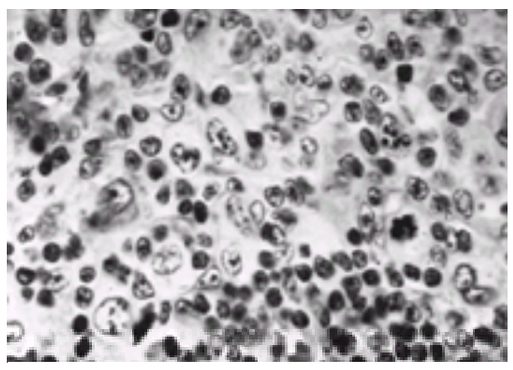

**FIGURE 24-4.** Histologic appearance of anaplastic large cell lymphoma. (Courtesy of Jeffrey Cossman.)

Sometimes the predominant malignant cells are not anaplastic but are small and relatively homogeneous. This subtype is known as the *small cell variant of ALCL*. In the lymphohistiocytic variant, the cells also tend to be smaller than the classic variety of ALCL, and there are copious admixtures of macrophages. A variant of ALCL exclusively involving the skin, which lacks the 2;5 translocation and EMA but expresses the cutaneous lymphocyte antigen CLA, has been described in adults, and although tumors that only involve the skin are occasionally seen in children, it is unclear whether this is the same entity as in adults. [98] Although most ALCLs contain a 2;5 translocation, it is not essential to the diagnosis. Recently, it was shown that inappropriate expression of ALK, the tyrosine kinase deregulated by the 2;5 translocation through the formation of the NMP-ALK fusion gene, can also be caused by other genetic abnormalities, including other translocations, [99,100] and [101] and it would seem probable that it is the ALK deregulation, rather than the mechanism of achieving this, that is the characteristic feature of systemic ALCL.

**Lymphoblastic Lymphoma**

LLs are indistinguishable histologically and cytologically from the lymphoblasts of ALL ( Fig. 24-5). The cells are usually quite uniform in appearance, with a high nuclear to cytoplasmic ratio—frequently even higher than that of BL, although there is variation in the quantity of cytoplasm from one tumor to another (similar to the L1 and L2 designations of ALL). A variable percentage of the cells may contain irregularly shaped or linear-patterned (“crow's foot”) nuclei. This appearance led to the term *convoluted T-cell lymphoma*. [13] The nuclear chromatin is finely stippled. Although multiple nucleoli are present, they are difficult to discern.

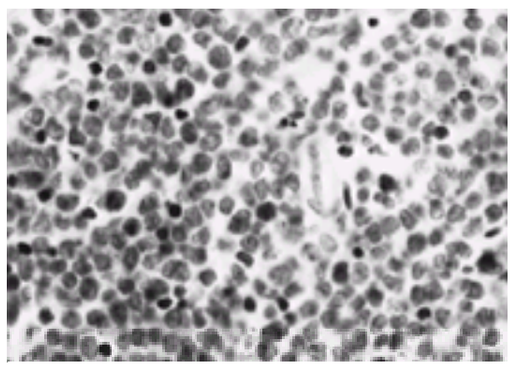

**FIGURE 24-5.** Histologic appearance of lymphoblastic lymphoma. (Courtesy of Jeffrey Cossman.)

LL, in addition to its distinctive histology, differs from all other lymphomas by virtue of the almost invariable presence of the enzyme TdT. [4,5,102] This can be demonstrated immunohistochemically, [103] and is a valuable means of confirming the diagnosis of a neoplasm derived from precursor lymphocytes. TdT participates in the generation of diversity in antigen receptor genes of both T and B cells by catalyzing the insertion of random nucleotides during the process of antigen receptor

gene rearrangements.[104,105] Its presence, therefore, indicates that the cell type is immature. Only a small percentage (some 5%) of LLs of the most mature stage of thymic differentiation fail to express TdT.[106,107] Many translocations probably occur around the time of B- and T-cell ontogeny, when precursor lymphocytes are rearranging their antigen receptor genes. It seems likely that such translocations involve the same enzymes that mediate antigen receptor gene rearrangement, because re-ligation of DNA ends produced by the immunoglobulin gene recombinases (RAGs), acting at specific recombination signal sequences, is mediated by nonhomologous end-joining enzymes such as Ku70 and Ku80 (which activate the large DNA–protein kinase subunit), XRCC4, and DNA ligase IV, all of which are involved in the repair of double-stranded DNA breaks in general.[108,109]

The presence of TdT is not diagnostic of a lymphoid neoplasm of precursor origin. Some nonlymphomatous tumors of childhood may express TdT, especially medulloblastoma.[110] Additional immunophenotypic characteristics are also essential in diagnosis. Mantle cell lymphoma, for example, has a blastic variant that closely resembles LL morphologically. Study of the expression of TdT, SIg and cyclin D1 (CD99), which is deregulated in mantle cell lymphoma, are valuable means of distinguishing these tumors, which respond very differently to therapy.[111]

The majority of LLs arises from T-cell precursors undergoing differentiation in the thymus.[112] They express T-cell markers corresponding to the stages of T-cell intrathymic differentiation, usually designated as early, intermediate, and late ( Fig. 24-6).[113,114] CD7 is a particularly valuable marker of the early T-cell lineage and is present on essentially all immature T-cell malignancies—that is, LLs and ALLs of T-cell type.[115,116] Additional antigens expressed at the surface of T-cell LLs predominantly reflect an intermediate (CD7, CD5, CD2, CD1, CD3±, CD4, and CD8) or late thymocyte phenotype (CD7, CD2, CD3, and either CD4 or CD8), although atypical patterns are quite frequently observed.[117,118,119 and 120] CD2 is usually present on LL cells, although it may not be expressed by the earliest cells of the T lineage. Such normal cells do, however, frequently express CALLA (CD10) and HLA-DR antigens, although these antigens are not commonly detected on LLs. CD3, a heterodimer that is expressed in concert with the antigen receptor itself to form the antigen receptor complex[120] may be present in the cytoplasm of immature T cells even though it is not expressed at the surface.[121] CD1 is only expressed on intermediate thymocytes, whereas CD4 and CD8 are expressed on the same cell in intermediate thymocytes but separately on more mature cells of helper and suppressor (or cytotoxic) phenotypes, respectively. All of the antigen receptor molecules are present in the cytoplasm before expression at the cell surface in concert with the CD3 protein.[122,123]

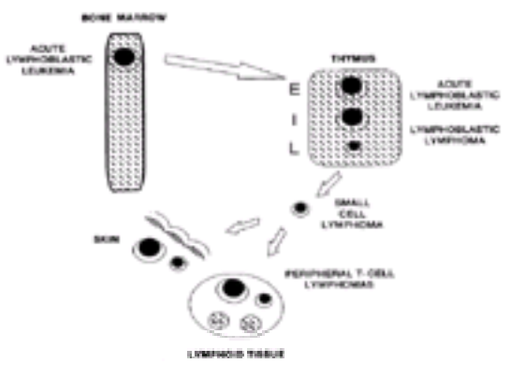

**FIGURE 24-6.** Cellular origins of T-cell lymphomas. T cells originate in the bone marrow and migrate to the thymus where they undergo differentiation. Intrathymic differentiation is arbitrarily divided into three main stages: early (E), intermediate (I), and late (L). Lymphoblastic lymphomas (LLs) predominantly arise from the intermediate and late stages, hence their frequent presentation as a thymic (mediastinal) mass. Bone marrow involvement may occur, however, whether the phenotype is early, intermediate, or late such that there is no clear distinction between T-cell acute lymphoblastic leukemia and LL apart from the arbitrarily chosen degree of bone marrow involvement (25%). T-cell lymphomas with a mature phenotype (peripheral T-cell lymphomas) may occur at any of the sites at which T cells are found—that is, in almost all organs and tissue of the body, but particularly in lymph nodes, and at surfaces prone to invasion by microorganisms or foreign bodies.

It is not at all clear that acute lymphocytic leukemia and LL differ in their clinical characteristics because they are neoplasms of different thymocyte stages. Leukemias tend to have a more immature thymocyte phenotype, but in a series of T cell ALLS from Egypt, the phenotype was predominantly that of intermediate (58.1%) or late thymocytes (16.1%).[124,125] Bone marrow and blood involvement is, therefore, an unreliable discriminator between early and late-stage T-cell lymphoblastic neoplasms. Furthermore, although the likelihood of a mediastinal mass is greatest in the intermediate group, and least in the most mature and immature groups,[107,118,126] mediastinal masses are frequently present in both T-cell LL and leukemia. In this circumstance, there appear to be no differences in the immunophenotype whether the disease is classified as lymphoblastic leukemia or LL.

T-cell LLs have clonal rearrangements of their T-cell receptor genes, which correlates with their degree of differentiation. The most immature neoplasms usually have a clonal rearrangement of a Td gene without rearrangement of other T-cell receptor genes.[120,122,127] Such tumors sometimes express Td transcripts. Rarely, in pre-T neoplasms, all of the T-cell receptor genes are in the germline configuration. T-cell neoplasms of intermediate maturity (cytoplasmic CD3) have rearrangements of Td, Tg, and Tb, and some may have biallelic deletion of Td, which indicates a rearrangement because the d locus lies within the a locus. The more mature lymphoblastic neoplasms (expressing surface CD3 with either CD4 or CD8) have Tg and Tb rearrangements with biallelic deletion of Td.[122,127,128] This pattern is similar to that of the peripheral T-cell lymphomas and is sometimes accompanied by expression of Ta/b transcripts.[120] Ten percent of T-cell lymphoblastic neoplasms have rearrangements of immunoglobulin receptor genes.[129,130 and 131]

Approximately 10% to 15% of LLs express the phenotype of pre-B cells as seen in ALL—CD19 and HLA-DR, usually with CD10 but without SIg.[132,133] Such tumors have a rearrangement of at least a heavy-chain gene, and may, similar to ALL, have a rearrangement of a light-chain gene. Of considerable interest is the pattern of rearrangement of T-cell receptor genes in such cases. Seventy percent to 100% have rearrangements or deletions of the Td gene, and only a slightly lower proportion, of Tg. Some 10% have rearrangements of Tb,[129] and some even have biallelic deletion of Td, indicating Ta rearrangement.[120,122,127,130] This could be due to an origin of these neoplasms from an uncommitted precursor cell. However, the lack of T-cell immunologic markers in such tumors argues against this. The alternative hypothesis is that rearrangement of antigen receptor genes occurs in these tumors because the cell type is one in which the recombinases that catalyze such events remain active for at least some time after malignant transformation.[122,130]

Recently, LL with a phenotype consistent with that of NK cells (including CD56 expression) was described.[134,135 and 136] The few cases so far reported appear to have a poor prognosis.

### Rare Childhood Non-Hodgkin's Lymphomas

Although the vast majority of childhood lymphomas can be categorized as BL, BLL, LBCL, ALCL, or their variants, tumors that occur commonly in adults are occasionally seen. These include marginal zone B-cell lymphomas,[137] although these are significantly more common in children with HIV infection,[137a] follicular lymphoma,[138,139,140,141 and 142] and peripheral T-cell lymphomas that do not fall into the category of ALCL.[139,143,144,145 and 146] Histology and immunopathology are similar to equivalent adult tumors, but it is likely that there are biologic differences. In childhood follicular lymphoma, for example, the disease tends to be localized, testicular involvement has been reported more frequently than would be expected, and the chromosomal translocation (14;18) present in adult follicular lymphomas is absent, at least in the testicular cases.[142,147] In patients described to date, the prognosis is good even with conservative management.[140,141] Peripheral T-cell lymphomas may be more common in some world regions, for example, Southeast Asia, where at least some arise in the context of a virus-associated hemophagocytic syndrome frequently caused by EBV.[64,65 and 66] Another rare disease, hepatosplenic g/d lymphoma, occurs predominantly in young adult males but rarely in children younger than 15 years.[148,149,150 and 151] To date, such patients have had a poor prognosis regardless of treatment.

## CYTOGENETICS AND MOLECULAR PATHOLOGY

In the NHLs of childhood, a number of nonrandom cytogenetic abnormalities, predominantly reciprocal chromosomal translocations, have been identified. Many such translocations involve an antigen receptor gene—either an immunoglobulin or a T-cell receptor gene, depending on the cell lineage—at one of the locations of the chromosomal breakpoints. There are good reasons to believe that the enzymatic apparatus needed for antigen receptor gene rearrangement may also mediate

chromosomal translocation.[152,153] Although the signal sequences required for the recombinases (RAG-1 and RAG-2) are generally absent from the sites of chromosomal recombination or, at best, show poor homology, these could well have been removed during the process of translocation. Furthermore, RAG genes are responsible only for cleaving the DNA at specific cleavage sites, whereas re-ligation is accomplished by nonhomologous recombinases. [154] Such enzymes seem very likely to be involved in mediating chromosomal translocations. An alternative possibility is that differences in chromatin structure that occur in the process of gene rearrangement[155] may provide a "fragile site" prone to breakage. In either event, it seems probable that immature lymphoid cells capable of antigen receptor gene rearrangement are particularly prone to translocations involving these genes and, further, that nuclear topography may be a factor in determining the most likely partner chromosomes in differentiating or proliferating cells. [156] Because a single genetic event is insufficient to induce neoplasia, it should not be assumed that cell differentiation is blocked at the time of the first genetic event. Cells may well undergo further differentiation during the accumulation of additional lesions—indeed, such differentiation may even be necessary to this process. This is consistent with the possibility that translocations occur at or close to the point in lymphoid differentiation at which immunoglobulin or T-cell receptor gene rearrangement is occurring, although the final phenotype is that of a more mature cell.

The translocations that occur in lymphoid neoplasia frequently involve genes whose products function as transcription factors, that is, proteins that regulate the expression of genes, or as proteins that modulate the activity of transcription factors, usually via direct binding to the transcription factors. Two major patterns can be identified: those in which one of the involved chromosomal regions is an antigen receptor locus (BCR or TCR) and another in which a fusion gene and fusion protein results from the translocation (Fig. 24-7). It is probable that the frequency with which genetic abnormalities result in the modulation or alteration of transcription factor function arises from the fact that such genes may have critical roles in the control of or interactions between entire molecular pathways relevant to cell proliferation or differentiation. In the first of the two major types of translocations involving transcription factors, abnormal expression of a transcription factor occurs because its regulation is usurped by the regulatory regions of the antigen receptor gene, which is expressed continuously in cells of the lymphoid lineage beyond the precursor stage. In the second type of translocation, a chimeric or fusion gene consisting of parts of two transcription factors is created. It appears that the chimeric protein is expressed as if it were the gene comprising the upstream element of the fusion gene, which contains the promoter and at least some of the regulatory elements of the gene. The functional properties of the chimeric protein (i.e., the specificity of DNA binding and genes regulated by the transcription factor) may be precisely those of the downstream fusion partner, or possibly different from either of the partners because of new properties conferred on the fusion protein.

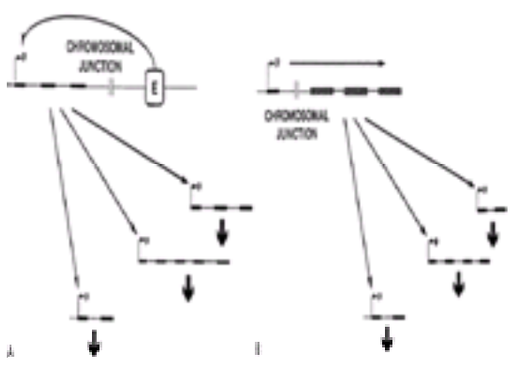

**FIGURE 24-7.** The major types of chromosomal translocation that have been described in leukemias and lymphomas. **A:** Deregulation by juxtaposition of a gene on one chromosome to an enhancer region (a regulatory element that can increase transcription from upstream or downstream promoters)—frequently one associated with an antigen receptor (T- or B-cell) locus—on a second chromosome. **B:** Fusion of two genes, each located on a different chromosome but in the same orientation. This fusion (chromosomal junction) leads to various effects—for example, the expression of one (i.e., the downstream component) as if it were the other (i.e., the upstream component, which includes a promoter), or enhanced or altered function due to alteration in protein binding properties, changes in phosphorylation, or other functions. A similar effect—that is, generation of a fusion protein—can be created by deletion of sequences between two genes. In this diagram, the genes are shown as transcription factors that influence the expression of other genes, but genes involved in other vital cellular functions, such as kinases (e.g., ALK, described in the text), or anti-apoptotic, genes may be involved in either type of translocation, with resultant important functional consequences. E is an enhancer, frequently derived from an antigen receptor locus, and P indicates promoters. The transcription factors and the genes they control are shown as lines (signifying intervening sequences, or introns) and boxes (signifying exons, which are present in the mature messenger RNA). Long arrows indicate positive transcriptional influences, either *cis* or *trans*. Broad arrows indicate expression of the genes controlled by the transcription factors.

Among other important functional consequences of translocations is the altered (usually overexpression) of a kinase—that is, a protein involved in the activation or deactivation of other proteins. Such kinases have a greater or lesser degree of specificity and can, in some ways, be considered to subserve a regulatory function at the protein level, which is the equivalent of that mediated by transcription factors at the level of messenger RNA (mRNA) expression. Finally, whether mediated by a translocation or by another type of genetic abnormality, altered proliferation or differentiation by itself is not enough. Because of the critical regulatory role that apoptotic pathways serve in the regulation of both of these essential components of the lives of cells, relevant apoptotic pathways must, in some way, be inactivated or at least prevented from causing the death of the potential or actual tumor cell because of the modifications brought about in its proliferation or differentiation. Indeed, because the latter are fundamental cellular activities, which are essential to the very existence of the organism, they are invariably connected to apoptotic pathways.[157,158,159 and 160] The processes of cell proliferation, differentiation, and survival are thus closely integrated, as is well illustrated by the example of c- *myc,* a gene that appears to be a central element in a broad range of cellular functions (not excluding metabolism) relevant to these processes. [3,162]

New microarray techniques that permit the examination of the expression of tens of thousands of genes simultaneously may lead to a new understanding of the consequences of the genetic abnormalities of neoplastic cells, because the consequences of all genetic lesions must ultimately be a modification of the pattern of gene expression.[162] Examination of protein expression patterns proteomics may provide even more information than does the presently more widely used mRNA expression microarray analyses. In addition to an understanding of pathogenesis, such techniques are likely to lead to more precise diagnosis as well as improved prediction of response to treatment. In some cases, it may be useful to define remission at a level beyond that of clinical and radiological examination. For this, polymerase chain reaction (PCR) is likely to be more useful than microarray analyses, because it is capable of identifying individual tumor cells among hundreds of thousands of malignant cells. Molecularly defined remission using PCR is already possible because several of the nonrandom chromosomal translocations or other genetic lesions associated with lymphoid neoplasia can be detected by this technique, providing a highly sensitive method for the detection of residual cells from the malignant clone (also detectable via identification of the clone at the level of BCR or TCR). Detection of the 14;18 translocation, in particular, has undergone and continues to undergo extensive evaluation with respect to the definition of molecular remission and its clinical utility. [163,164 and 165] This translocation is uncommonly associated with childhood NHL, although it may occur in some LBCLs or BLLs. Because of the possibility of identifying specific molecular changes through PCR, this technique may also prove to be a useful adjunct in diagnosis and risk assignment, while the genetic lesions themselves provide potential targets for new, highly specific therapeutic approaches.[166,167 and 168]

### Burkitt's Lymphoma

BL is associated with characteristic nonrandom, reciprocal chromosomal translocations that are predominantly between chromosomes 8 and 14 (some 80% of tumors),[169] and less often, between chromosomes 8 and 2 or 8 and 22.[170] The breakpoint on chromosome 8 coincides with the location of a proto-oncogene (c- *myc*, on band q24),[171,172 and 173] while the breakpoint on the other partner chromosome is in an immunoglobulin chain locus—either that of the heavy chains (chromosome 14, band q32) or that of one of the light chains (chromosome 22, band q11 or chromosome 2, band p11/p12, the loci of lambda and kappa genes, respectively). [173] In 8;14 translocations, the c- *myc* gene is translocated from chromosome 8 to the heavy chain locus on chromosome 14, whereas in the so-called variant translocations involving immunoglobulin light chains a part of the constant immunoglobulin locus is translocated to chromosome 8, distal to the c- *myc* gene. The common feature of all three translocations is the juxtaposition of the c- *myc* gene to immunoglobulin constant region sequences, whether of heavy- or light-chain origin ( Fig. 24-8). The expression of the c-*myc* gene, whose own regulatory regions are damaged or even deleted during the process of chromosomal translocation, becomes subordinate to the influence of the immunoglobulin gene regulatory sequences that now lie adjacent to it on the same chromosome. Because immunoglobulin genes are constantly expressed in B cells, the c-*myc* gene remains switched on, even when it should not be expressed. The Myc protein is known to be necessary for cellular proliferation,[174,175] and it is, therefore, highly likely that it is the inappropriate expression of Myc, occasioned by the translocation, that maintains the cell in a proliferative state. It is unlikely, however, that deregulation of c- *myc* alone is sufficient to cause BL, in spite of its broad range of functions relevant to cell growth and differentiation,[161,176] because its inappropriate expression (i.e., expression in the absence of appropriate signals induced by growth factors) will cause apoptosis. [3] Myc overexpression would, therefore, be expected to lead to cell death in the absence of additional genetic lesions within the Myc-regulated apoptotic pathways, such as

the Fas (CD95) pathway.[3,177] The myc-immunoglobulin translocation and its consequences are depicted in Figure 24-9. It has been postulated that the chromosomal translocation occurs in a proliferating immature B cell either during or shortly after the process of immunoglobulin gene rearrangement. [178] The possibility that the chromosomal translocation may occur in a germinal center cell cannot be ruled out, because some breakpoints are in switch regions, and it has recently been shown that immunoglobulin recombinases are expressed in germinal center B cells. [179,180] However, such cells clearly have an immature phenotype, and because the switch region is susceptible to chromosome breakage even in pro-B cells [181] and heavy-chain class switching has been described in pre-B cells, [182] these observations do not refute the likelihood that translocations occur in immature B cells. The hypothetical scenario in which the chromosomal translocation occurs in immature B cells is depicted in Figure 24-10.

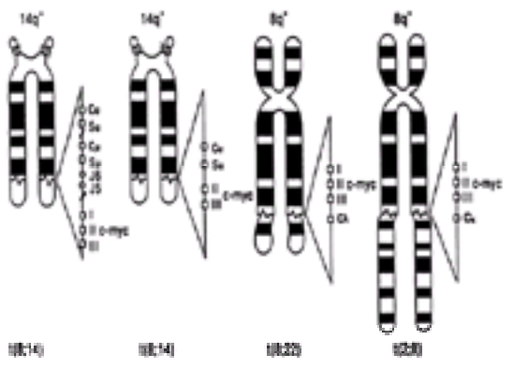

**FIGURE 24-8.** Chromosomal translocations occurring in Burkitt's lymphoma at cytogenetic and molecular levels. In each case, the c- *myc* gene is juxtaposed to an immunoglobulin heavy- or light-chain constant region. Two different types of t(8;14) are shown in which various gene segments of c- *myc* (I, II, III) and Ig heavy [Cμ, Sμ, J(no.), etc.] are shown in different relationships. See Figure 24-9 for further information. Cμ, μ constant region; J(no.), one of several J segments; Sμ, μ switch region; I, first exon of c-*myc*; II, second exon of c-myc; III, third exon of c-*myc*.

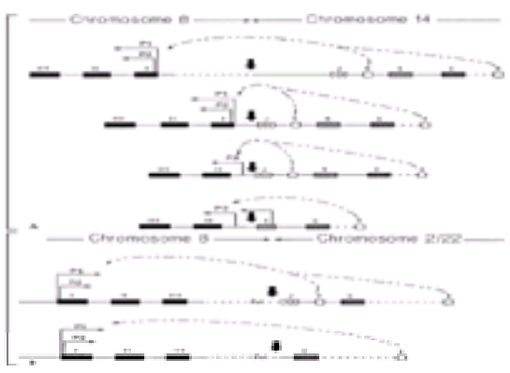

**FIGURE 24-9.** Molecular rearrangements that occur as a consequence of the 8:14 translocation. **A:** Juxtaposition of c-*myc* to the heavy-chain locus on chromosome 14. From the top down, it is seen that the breakpoint can vary in different tumors: upstream of c- *myc*, in the immediate 5' region, or in the first exon or intron. In all of these diagrams, the breakpoint on chromosome 14 is depicted in the J region. In the lowest diagram of **(A)**, the breakpoint is shown in the switch μ region of the immunoglobulin gene; it may also occur, although less commonly, in other switch regions of the heavy-chain locus. **B:** Juxtaposition of c-*myc* with a light-chain locus, as occurs in the variant translocations. The Pvt region was first described in mouse plasmocytoma as a cluster region for variant translocation breakpoints. Its significance remains uncertain. Exons are shown as boxes, either solid, hatched, or open.

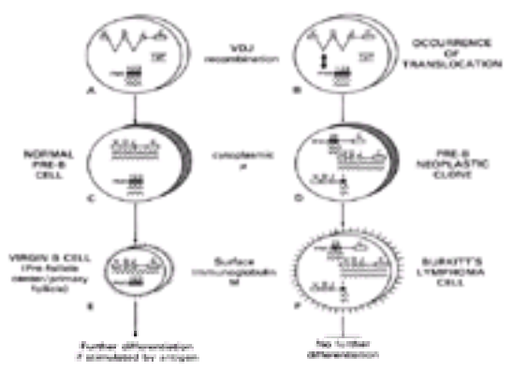

**FIGURE 24-10.** Hypothetical schema depicting the pathogenesis of Burkitt's lymphoma. On the left, the normal series of differentiation steps (including VDJ joining) for the earliest stages of B cells, resulting first in cytoplasmic μ chains **(C)** and then in surface immunoglobulin M (IgM) **(E)** are shown. The earliest cells expressing surface immunoglobulin M (virgin B cells) are resting cells, unlike their more immature counterparts, and they have switched off expression of c- *myc*. On the right, chromosomal translocation and deregulation of c-*myc* has occurred, with resultant indefinite proliferation of the cells containing the translocation. Normally, such deregulation of c-*myc* would result in diversion to an apoptotic pathway. Other genetic lesions are therefore necessary to permit the cell to survive as a rapidly proliferating lymphoma cell. TdT, terminal deoxynucleotidyl transferase; VDJC, variable, diversity, joining, and constant immunoglobulin gene regions; ∿∿, gene expression.

In BL the breakpoint location on chromosome 8 varies with the geographic origin of the tumor ( Fig. 24-11).[183,184 and 185] In endemic (equatorial African) lymphomas the breakpoint is, in most cases, some distance away from the c-*myc* gene. In this circumstance, however, there are mutations in the first exon of c-*myc*, which appear to contribute to the deregulation of the gene. In sporadic (North American) tumors the breakpoint is usually within the gene or in its immediate upstream flanking sequences, a region that is known to contain sequences involved in the regulation of c- *myc* expression, such that a variable but often considerable portion of the regulatory region of c-*myc* is separated from it.[173] In regions other than equatorial Africa and the United States and Europe, intermediate situations are found with respect to the fraction of tumors with breakpoints in various regions in and around c- *myc* on chromosome 8.[49]

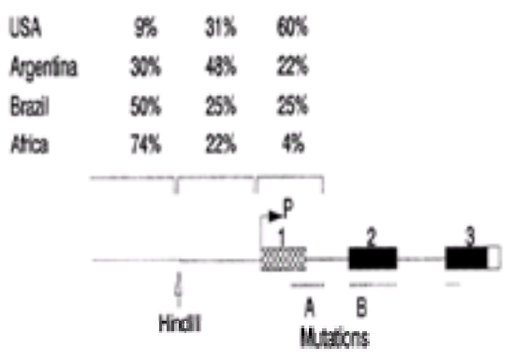

**FIGURE 24-11.** The proportions of Burkitt's lymphomas from different world regions with breakpoints in various regions (shown by square brackets) of chromosome 8

are shown in the table. The diagram underneath the table depicts exons 1 to 3 of the c- *myc* gene and indicates the locations of the breakpoint regions and mutations in regulatory (A) and coding (B) regions. Some tumors from Chile are included in the row labeled “Argentina.” HindIII is a restriction enzyme site that provides a useful marker upstream of the promoter, P.

In addition to the chromosomal translocations themselves, some of which lead to considerable structural changes in the *c-myc* gene, such as detachment of exon one from the coding region, associated point mutations also occur—both in the regulatory elements of c- *myc*, when these are intact (depending on the precise breakpoint location), and in the protein coding region. The former are doubtless associated with altered regulation of the expression of the gene, whereas the latter appear to alter either the half-life of the Myc protein or the ability of another protein, p107, to regulate its ability to function as a transcription factor. [185,186]

BL also frequently contains (in approximately 40% of tumors at presentation) p53 mutations, [187] and recently mutations in the Rb family of proteins, including p130 and p107, which may differ in sporadic versus endemic tumors have been reported. [188]

**Burkitt's-Like Lymphoma and Large B-Cell Lymphomas**

BLL, as previously discussed, is likely to comprise a mixture of BL and LBCL, and indeed, some of these tumors are associated with the same translocations that occur in BL and some with translocations that occur in a fraction of adult LBCLs. Some cases of BLL may also more closely resemble, immunophenotypically, a subset of LBCL than BL. [189] LBCL in adults is inhomogeneous with respect to the presence of cytogenetic or molecular changes, manifesting, in different tumors, various cytogenetic lesions, particularly 14;18 translocations and translocations involving *bcl*-6. [80,153] In LBCL in children, there are very limited data, although a recent report was consistent with the probability that at least some cases of LBCL in children are similar to those in adults. [189a] BLLs that contain both 8;14 and 14;18 translocations have also been described, and it has been suggested that possession of both translocations, at least in adults, is a poor prognostic sign. [190]

**Lymphoblastic Lymphomas**

Although nonrandom chromosomal abnormalities have been found in LLs, unlike BL, many different translocations can be found. Those that occur, as with many of those present in lymphoid neoplasia, frequently involve the BCR and TCR genes. In the case of T-cell LL, the Ta/d locus situated on chromosome 14q11 is frequently involved in, for example, 11;14, 1;14, 8;14, and 10;14 translocations. These findings strongly suggest that the rearrangement of genetic material occurred close to the time when rearrangements of T-cell receptor gene subunits normally occur. However, chromosomal translocations that do not involve the antigen receptor loci have also been described in T-cell LLs and leukemias.

Insights into the pathogenetic mechanisms relevant to T-cell lymphoblastic neoplasia have been gained by molecular cloning of the genes located at translocation breakpoints. In two cell lines that contain 8;14(q24;q11) translocations, for example, the Ta constant region has been shown to be translocated from its location in chromosome 14 (the breakpoint being in the J region of the Ta gene) to a point distal to c- *myc* on chromosome 8. [191,192 and 193] This type of translocation is analogous to the variant translocations observed in BL and, similarly, results in deregulation of c- *myc*. A particularly common molecular abnormality in T-cell lymphoid neoplasia is overexpression of the Tal-1 or Scl gene, as occurs in the 1;14 translocation, but resulting more often from a deletion on chromosome 1 that juxtaposes the *scl* or *tal*-1 gene, which is not normally expressed in lymphoid cells, to another gene, which is normally expressed, Sil-1. [192,194] There is evidence that the chromosomal deletion that results in this particular genetic rearrangement is also mediated by VDJ recombinases. [194] There can be little doubt that, as in B cells, the consequences of the translocations associated with neoplasia in T cells are to alter the differentiation and apoptotic patterns normally found in T-cell precursors. [195,196 and 197]

**Anaplastic Large Cell Lymphomas**

In children, the majority of ALCLs (approximately 80%) contain 2;5 translocations, [198] which despite a few reports to the contrary appear to be largely confined to ALCL lymphoma of the T-cell or null cell type. [88,198 and 199] This translocation does not appear to be associated with the rare subtype of ALCL (occurring predominantly in adults), which involves only the skin. The 2;5 translocation juxtaposes the tyrosine kinase ALK to a widely expressed gene known as *nucleophosmin* such that ALK is inappropriately expressed. [88,199] Recently a number of variant translocations that are also associated with inappropriate expression of ALK, but not with the fusion protein NMP-ALK have been described. [200,201,202,203 and 204] The NMP-ALK fusion protein is expressed in the nucleus, because NMP is a nucleoprotein, as well as in the cytoplasm, but in the variant translocations, which do not involve NMP on chromosome 5, ALK protein expression is confined to the cytoplasm. [204] At present, the mechanism whereby inappropriate expression of the ALK tyrosine kinase is relevant to pathogenesis is unknown. The ALK protein, however, whose xpression normally appears to be confined to the nervous system, has transforming properties *in vitro* and NMP-ALK can cause large cell lymphoma when transfected into murine bone marrow. [88]

## CLINICAL PRESENTATIONS

Patients with NHL present, for the most part, with a limited number of clinical syndromes, which correlate reasonably well with the histologic category, although there is significant overlap. Childhood lymphomas are much more often extranodal than are adult lymphomas, the most frequently involved sites being intraabdominal (B-cell lymphomas) and intrathoracic (precursor T-cell lymphomas). The involvement of some sites, for example, lung, skin or muscle, is sufficiently uncommon to raise questions about a diagnosis of lymphoma, although these sites may be involved in patients with ALCL [205] or in lymphomas arising in patients with HIV infection in whom atypical presentations are common. Although systemic symptoms including weight loss and fever may occur, these are relatively uncommon, except in ALCL or, in the case of weight loss, in circumstances in which there are mechanical reasons for poor food consumption.

**Burkitt's Lymphoma**

***Sporadic Burkitt's Lymphoma***

A large proportion of children with BL in the United States and Europe present with abdominal tumors that give rise to abdominal pain or swelling, sometimes with a symptom complex caused by intussusception, a change in bowel habits, nausea and vomiting, evidence of gastrointestinal bleeding or, rarely, intestinal perforation. [206,207 and 208] Presentation with a right iliac fossa mass is common, occurring in 25% of patients in the NCI series, [41,209] and can be confused with an inflammatory appendiceal mass. Frequently at surgery there are multiple enlarged mesenteric lymph nodes that may or may not contain microscopically visible tumor, and multiple peritoneal plaques of tumor may be observed. Involvement of retroperitoneal structures, including kidneys and pancreas, is frequent, whereas liver and splenic involvement are seen somewhat less frequently. Ovarian involvement is common. Pleural effusions and ascites, which nearly always contain BL cells, and bone involvement (not infrequently multiple) are often present. Pharyngeal or nasopharyngeal sites of disease as well as paranasal sinus involvement are all occasionally seen. Thyroid and salivary gland involvement is uncommon. Unusual presentations of BL include isolated tonsillar (uni- or bilateral) involvement, sometimes only recognized after tonsillectomy for presumptive tonsillitis, and isolated cervical adenopathy. Testicular involvement at presentation occurs in a few percent of patients and skin and mediastinal involvement is very rare, but not unknown. Breast involvement, although rare, occurs nearly always in pubertal girls and pregnant or lactating women in both sporadic and endemic BL. [210,211,212 and 213] Jaw involvement in sporadic BL, in contrast to endemic BL, occurs in less than 10% of patients at presentation and is not age related. [214] Such patients frequently have involvement of other bony sites or of the bone marrow, suggesting that jaw involvement arises for quite different pathobiological reasons than it does in African patients. [215]

Bone marrow involvement is perhaps more common in sporadic BL than had previously been thought. At presentation, marrow involvement occurs in 20% of patients, [206,216] but there is evidence from *in vitro* culture and karyotyping of microscopically uninvolved bone marrow that occult involvement occurs in another approximately 20% of patients. [217] Some patients present with a clinical syndrome consistent with leukemia without any solid lymphomatous masses apart from lymphadenopathy and hepatosplenomegaly. These patients, in the past, constituted 2% to 5% of most large series of patients with ALL, and were referred to in the French-American-British classification as *L3 ALL*. These and all other patients with greater than 25% bone marrow involvement have been more generally referred to as having *acute B cell leukemia* in more recent years, and might better be referred to as *Burkitt's leukemia* to prevent the misconception that such patients should be treated with ALL therapy. If such cases are taken into consideration, involvement of the bone marrow in BL occurs in a rather high fraction of cases in the United States and Europe (in published series from other countries, however, bone marrow involvement is quite uncommon [60,62,219]). Furthermore, in BL in the United States,

involvement of the bone marrow is frequently observed at relapse such that the majority of patients who die from tumor progression have had bone marrow involvement at some time in the course of their illness. It should be pointed out, however, that not all acute leukemias that conform to the criteria of L3 morphology or express surface immunoglobulin have the phenotypic and genetic changes of BL. [220,221,222 and 223] Conversely, there are occasional reports of leukemias with an 8;14 translocation and precursor B-cell morphology. [224,225]

In contrast to endemic BL, CNS involvement and epidural tumor is quite uncommon at presentation in sporadic BL but is distinctly more common in the presence of bone marrow involvement.[216,226,227] Approximately two-thirds of patients with bone marrow disease may have simultaneous CNS involvement. Compression of the inferior alveolar nerve as it passes through the mandible, with resultant numbness of the lip and chin, occurs quite frequently in patients with widespread bone marrow disease, and this, as with compression of cranial nerves by orbital tumor, is not a sign of CNS involvement, although such patients are at high risk to develop CNS disease. Presentation with cranial nerve involvement is occasionally observed, along with cerebrospinal fluid (CSF) pleocytosis, and the latter may be the only indication of CNS (meningeal) disease. Involvement of cranial nerves without evidence of systemic disease is remarkably uncommon but has been described, [228,229] as has a syndrome of multiple peripheral nerve involvement. Intracranial tumor, when it does occur, is more likely to be extradural, although it can be within the brain parenchyma.[230]

### *Endemic Burkitt's Lymphoma*

In patients with BL in equatorial Africa, jaw involvement of multiple jaw quadrants in a large proportion, is the most frequent site of tumor, although it is very much age dependent, occurring particularly in young children ( Fig. 24-12). In an early series collected by Burkitt,[7,231] 70% of children younger than 5 years with BL had jaw involvement as compared to 25% of patients older than 14 years.[28] In very young children, orbital involvement is often present in patients who do not have jaw tumors, although at least some of these orbital tumors arise in the maxilla. Maxillary tumors are twice as frequent as mandibular tumors in endemic BL. In the endemic region of Africa itself, the percentage of patients with jaw tumors appears to be inversely proportional to the incidence of the disease. In addition, the median age of patients tends to be higher in lower incidence areas such as highlands or arid regions. [232] Abdominal involvement is also frequent in endemic BL, being present in just over half the patients and frequently invading the mesentery and omentum, but involvement of the right iliac fossa (appendiceal/cecal region) is uncommon. [28,232] Liver and spleen are not frequently involved. Thyroid and salivary gland involvement is not uncommon, and adrenal gland involvement is occasionally seen. [28,231,232] Isolated lymphadenopathy, tonsillar (or any form of pharyngeal tumor), and splenic involvement are all extremely rare in African BL. Involvement of the ovary is frequent, but testicular involvement is uncommon. Breast involvement, as in sporadic tumors, occurs almost exclusively in pubertal girls or lactating women. [234,235] Involvement of the skin, testis, and pericardium is occasionally observed, but mediastinal tumor is essentially unknown. [28,231,232]

**FIGURE 24-12.** An African child with Burkitt's lymphoma that involves the maxilla.

Bone marrow involvement occurs in only approximately 8% of patients with endemic BL at presentation, but there are no estimates of the proportion of patients who have occult bone marrow involvement, nor is the frequency of L3 or acute B-cell leukemia, presenting as ALL, known in Africa. [28,216] The rarity with which BL recurs in the bone marrow in African patients, even after multiple relapses, further confirms, however, its lack of predilection for the bone marrow. It is worth pointing out that in patients with jaw tumors the marrow of the jaw is clearly infiltrated at a microscopic level, whereas diffuse marrow involvement is seldom observed.

CNS disease, either CSF pleocytosis or cranial nerve palsies, is much more frequently observed in endemic BL than in the sporadic variety, occurring in approximately one-third of patients at presentation in one Ugandan series. [236] Any cranial nerve can be involved, but the ophthalmic nerves and the facial nerve are more often affected.[28,236] Very rarely, cranial nerve involvement and CSF pleocytosis have been the sole sites of disease [237] and peripheral neuropathy is occasionally seen.[238] Also rare, even in the presence of other cranial neuropathies, the optic nerve may be infiltrated giving rise to blindness. In Uganda, approximately 15% of patients present with isolated epidural lymphoma and paraplegia, requiring laminectomy for diagnosis. [28,233,236] Intracerebral disease has been described but is usually diagnosed only at recurrence.[239]

A comparison of sites of disease at presentation in endemic (Ugandan) and sporadic (United States) BL is shown in Table 24-4. In addition to the differences in jaw involvement, there are striking differences in the frequency of involvement of the bone marrow (higher in sporadic); CNS, including spinal epidural disease (higher in endemic); and other sites (those involved in mucosa-associated lymphoid tissue lymphomas, such as the thyroid and salivary glands).

| Site[c] | Uganda (percentage of 224 patients) | United States (percentage of 135 patients) |
|---|---|---|
| Jaw | 58 | 14 |
| Abdomen/pelvis | 58 | 60 |
| Cerebrospinal fluid/cranial nerves | 19 | 11 |
| Paraspinal sites | 17 | 2 |
| Orbit | 11 | 5 |
| Bones | 9 | 24 |
| Thyroid | 8 | 0 |
| Bone marrow | 7 | 21 |
| Salivary glands | 5 | 0 |
| Peripheral lymph nodes | 4 | 42 |
| Pleural effusion | 3 | 26 |
| Skin/soft tissues | 3 | 5 |
| Testis | 2 | 6 |
| Breast | 2 | 4 |
| Mediastinal nodes | 1 | 12 |
| Nasal sinuses | <1 | 3 |
| Pharynx | 0 | 10 |

[a]Uganda Cancer Institute series.
[b]National Cancer Institute, Bethesda, series.
[c]Detection of sites differed in the African series largely by clinical examination supplemented by chest x-ray films, intravenous pyelogram, bone marrow, and cerebrospinal fluid examination. In the U.S. series, computed tomography and nuclear medicine scans were performed, as well as cerebrospinal fluid and bone marrow examination.

**TABLE 24-4. RELATIVE FREQUENCY OF INVOLVEMENT OF DIFFERENT SITES AT PRESENTATION IN ENDEMIC BURKITT'S LYMPHOMA[a] VERSUS SPORADIC BURKITT'S LYMPHOMA[b]**

### *Other Populations*

Patients with BL in North Africa, the Middle East, and South America appear to have a spectrum of organ involvement that more closely approximates that of the sporadic disease rather than the endemic form—that is, jaw tumor is infrequent, and most patients present with abdominal tumor, [219,240,241,242,243,244,245,246,247 and 248] although higher percentages of patients with jaw tumors have been reported in some Asian countries, South Africa (in which both whites and nonwhites appear to have as high a frequency of jaw tumors as that in the endemic form of the disease), Turkey, Japan, and equatorial Brazil. [28,245,247,248 and 249] Paraplegia occurs occasionally, again suggesting that the “endemic form” of BL may occur at low incidence outside Africa. [250] Bone marrow involvement has been reported to occur with lower frequency in several series from outside the United States or Europe, as is the case in equatorial Africa. [60,62,251] These differences may be real or due to exclusion (or referral to a different specialist) of cases with overt leukemia from series of patients with BL, although the latter explanation is unlikely to account for the

finding in Africa, in which childhood leukemia is itself uncommon.

### Burkitt's-Like and Large B-Cell Lymphomas

In spite of the problem of reproducibly separating BL from BLL and BLL from LBCL,[252] there is no doubt that BLL and LBCL have a broader range of presentations than BL. Because BLL includes at least a proportion of cases that resemble, at a molecular genetic level, LBCL,[189] and this proportion increases with age, it is probably true that the older the patient, the more likely the presentation to resemble that of LBCL rather than BL. In addition, there is considerable overlap in the sites of disease at presentation even in classic BL and classic LBCL. Nonetheless, BLL and LBCL much more frequently involve lymph nodes than does BL, whether peripheral, intrathoracic, or intraabdominal, and these sites, as well as liver and spleen, appear to be more often involved in older than in younger individuals. BLL and LBCL also present quite frequently with extranodal disease in sites typical of BL, particularly in the abdomen (bowel, mesentery and retroperitoneum), and involvement of almost any of the sites listed above for BL has been observed. Some sites, such as the mediastinum, are considerably more frequently involved than in BL. The majority of such lymphomas falls into the special category of LBCLs of the mediastinum,[253,254] and[255] and these tumors, which may be associated with superior vena caval (SVC) obstruction and pleural and pericardial effusions, rarely involve lymph nodes. If spread beyond the mediastinum, they are more likely to involve kidneys, adrenals, liver, and ovaries, although bone marrow involvement is uncommon. In BLL and LBCL, bone marrow involvement is quite common, but CNS disease may be rather less commonly present than is the case for BL. In the immunosuppressed individual, isolated involvement of the brain by LBCL is frequent.

### Lymphoblastic Lymphomas

Patients with LLs of precursor T-cell origin most commonly present with intrathoracic tumor, particularly a mediastinal mass (50% to 70%) frequently associated with pleural effusions.[112] Symptoms may include pain, dysphagia, dyspnea, or swelling of the neck, face, and upper limbs from SVC obstruction. Inferior vena caval obstruction occasionally occurs due to compression of the vein as it traverses the diaphragm, but it is rarely symptomatic. In Europe and the United States, if patients with intrathoracic LL have lymphadenopathy (which occurs in 50% to 80% of patients), it is likely to be above the diaphragm, in the neck, the supraclavicular regions, or the axillae. Pericardial tumor or effusion can occur, sometimes with significant cardiac tamponade. Abdominal involvement is quite uncommon and almost never massive, being more likely to be manifested simply as hepatic or splenic enlargement, or a retroperitoneal mass detected with special imaging techniques. LL arising in the retroperitoneum is more likely to have immunophenotypic features consistent with NK cells.[256] Generalized peripheral lymphadenopathy is occasionally seen but should raise suspicions of bone marrow involvement. These and other “peripheral” sites of disease, including bone, testis, nasopharynx, and skin are not usually associated with a large mediastinal mass, suggesting biologic differences between clinical subtypes of LL.

LL of precursor B-cell phenotype nearly always presents with limited disease, with frequent involvement of bone, isolated lymph nodes, or soft tissues, including skin.[257,258,259,260,261] and[262] More extensive disease would almost certainly include diffuse bone marrow involvement—that is, would be diagnosed as ALL.

In LL it is difficult to give a figure for the frequency of bone marrow involvement because this depends entirely on the definition of the disease. In the United States and United Kingdom, T-cell ALL accounts for 12% to 15% of all cases of ALL, and this form of T-cell acute lymphoblastic neoplasia is more common than LL when the latter is diagnosed on the usual basis of having less than 25% of blasts in the bone marrow. In earlier series of patients with LL (i.e., treated inadequately by today's standards), bone marrow involvement occurred at some point in the course of the disease in more than 50% of cases,[20,263] but CNS involvement, including CSF pleocytosis, cranial nerve involvement, or the rare intracranial disease, is present in less than 10% of patients with LL at presentation.

### Anaplastic Large Cell Lymphoma

Unlike the other NHLs of childhood, ALCL can present with a slowly progressive, even waxing and waning course. This is often associated with systemic symptoms such as fever and weight loss. Among the most frequent sites of involvement (again, in contrast to other childhood NHLs, which are predominantly extranodal) are lymph nodes, both peripheral and intrathoracic or intraabdominal.[264,265] Skin involvement is much more frequent than in other childhood NHLs, particularly the skin of the lateral thorax. Involvement of lymph nodes and skin was a prominent feature in the first series of children recognized as having this disease.[205] Bone involvement is also common and often multiple, and some patients present with primary bone involvement.[266] Primary cutaneous ALCL is less common in children than in adults, but has been described.[267] Mediastinal involvement and hepatomegaly or splenomegaly are often present, and the tumor may also involve unusual sites for lymphoma, such as muscle, lung parenchyma, and other soft tissues. In contrast, the gastrointestinal tract is rarely involved and the CNS and bone marrow are both unusual sites of disease, although several cases of the small cell variant of ANLC in which there was a leukemic presentation have been recently described.[268]

## METHODS OF DIAGNOSIS

Histologic analysis remains the primary mode of definitive diagnosis for a child with a suggestive clinical syndrome or, less frequently, persistent lymph node enlargement, but it is important to supplement this information with phenotypic and, wherever possible, cytogenetic examination. Distinction between lymphomas and other “small round blue cell tumors,” which include round cell sarcomas (e.g., Ewing's sarcoma and some rhabdomyosarcomas) and neuroblastoma, is usually not difficult on histologic grounds alone, but where there are difficulties, immunophenotyping, if necessary coupled to molecular studies, is nearly always sufficient to resolve diagnostic problems. The presence of the leucocyte common antigen CD45,[269] which is not present on nonhematologic neoplasms provides sufficient confirmation of a lymphoid cell population. Relatively specific markers now exist for many of the round cell tumors, but care is required in the overall interpretation. For example, the MIC-2 protein that is expressed by Ewing's sarcoma and primitive neuroectodermal tumors may also be expressed on NHLs, particularly LL, although rarely on BL.[270,271] Detection by PCR of the fusion genes generated by chromosomal translocations in Ewing's sarcoma, primitive neuroectodermal tumor, and alveolar rhabdomyosarcoma, has essentially eliminated the diagnostic problem of the small blue round cell tumor. The examination of CSF by PCR may also reveal unsuspected CNS involvement, and the detection of EBV DNA in CSF has been used to confirm the presence of CNS lymphoma in acquired immunodeficiency syndrome patients.[272,273,274] and[275] Tests for the presence of EBV in tumor cells by *in situ* hybridization, generally by detecting the presence of the highly expressed small EBV RNAs, can also be helpful in the diagnosis of other lymphomas, particularly posttransplant and HIV-associated lymphomas.

The distinction between lymphoma and a non-neoplastic lymphoproliferative process is rarely difficult, particularly when immunophenotyping results are available. Occasional diagnostic problems may occur with ACLC, particularly in those with a null phenotype. The presence of CD30 is insufficient evidence of this disease—mediastinal LBCL, for example, quite frequently expresses CD30, albeit usually at a lower level than in ALCL.[276] Although expression of EMA may be helpful, the demonstration of a 2;5 translocation or, more rapidly, expression of the protein product of this translocation, p80, by immunohistochemistry, is diagnostic, although the latter is not present in 100% of ALCLs. Lymphomatoid papulosis, a generally benign disease confined to the skin, does have somewhat different histologic characteristics, but it is cytologically indistinguishable from ALCL and is a trap for the unwary. It may have a waxing and waning course, uninfluenced by chemotherapy, and only occasionally develops into ALCL. As with ALCL confined to the skin, however, lymphomatoid papulosis does not generally contain 2;5 translocations, although some authors have found such translocations in approximately 10% of both lymphomatoid papulosis and the form of ALCL confined to skin.[277,278] and[279]

One area in which there is often difficulty in deciding whether the condition is a malignant lymphoma or benign lymphoproliferative condition is in the child with an underlying immunologic disorder that may include long-standing lymphadenopathy. Demonstration of clonality (by detecting the expression of a single light chain by immunophenotyping, or the presence of immunoglobulin or T-cell receptor gene rearrangements at a molecular level) is helpful, and detection of a specific translocation, diagnostic in making this distinction. It should be recognized that even so-called benign lymphoproliferative syndromes can be lethal, however, and in some circumstances a clinical trial of therapy (e.g., interferon-a or a B-cell monoclonal antibody) may be appropriate while assessing the clinical course. Rapidly progressive disease may be an indication for therapy with cytotoxic drugs.

At the time of biopsy of a suspected pediatric neoplasm, tissue should be provided, unfixed, to the pathologist so that some can be frozen, some used for immunologic and molecular studies, and some processed for karyotyping. The material used for these special studies must contain minimal amounts of normal tissue unless molecular or combined morphologic and phenotyping studies are to be performed, in which circumstances clonal populations can be detected even if representing only a small percentage of the total number of cells. Southern blotting, for example, can distinguish a clonal population representing only 5% of the cells present, whereas PCR can detect a specific translocation even if only a single translocation is present in the DNA sample used for the test. As microarray techniques develop, it is probable that new genes of diagnostic significance, whether single or multiple (“signature sets”), will be identified and used in diagnosis either via small arrays or in the context of standard immunohistochemistry or PCR.

Serum studies cannot provide diagnostic information for lymphomas, but they may provide evidence of a nonlymphoid origin when, for example, there are high levels

of catecholamines or their metabolites, or other tumor markers such as alpha-fetoprotein or carcinoembryonic antigen. Lactate dehydrogenase elevations are nonspecific, and this, or the detection of high serum levels of soluble interleukin-2 receptor and other molecules associated with lymphoid cells, such as $b_2$-microglobulin, are generally more useful in the provision of prognostic rather than diagnostic information because of their nonspecificity. [280,281]

## MANAGEMENT

The management of children with NHL includes initial assessment, to determine whether emergency measures are necessary; the determination of the extent and sites of disease, to assess prognosis and to determine optimal therapy; and the initiation, at the earliest time after diagnosis, of specific therapy.

### Staging

Staging systems for childhood NHL were designed to identify patients who fall into different prognostic risk categories. The major determinants of prognosis in childhood NHL are the treatment given, the biology of the tumor, and the extent or volume of tumor. Tumor biology is reflected in histology so that tumors of different histologic types often differ in their responses to various treatment approaches, even when tumor volume is taken into consideration. Of course, even tumors of the same histology and tumor burden may have very different responses to therapy, because one may prove resistant to treatment. At the present time, there is no way other than initial response to therapy [poor response to pre-therapy is used, for example, by the French Society of Pediatric Oncology (SFOP) to identify high risk patients who then receive more intensive therapy] to definitively identify patients destined to relapse or die from progressive disease when further treated with the same therapy, although the *risk* of relapse and survival is correlated with the tumor burden. Perhaps in the future, the identification of sets of signature genes (e.g., by microarray or proteomics) that, when expressed (or not expressed), are associated with a poor prognosis (in the context of a specific treatment protocol) may markedly improve the ability to predict differences in outcome stemming from tumor biology. Other than this, tumor volume, as measured by staging and biochemical measures such as lactate dehydrogenase (LDH) (or in the African patient, anti-EBV antibody titers) remains the most important determinant of response to a given therapy.[282] Comparison of tumor burden by staging and LDH is, therefore, essential if the results of one therapy are to be compared with another (in the same histologic category of tumor), particularly when the series is not large.

The most widely used staging classification today is that introduced by the St. Jude Children's Research Hospital, a scheme based on the Ann Arbor staging system for Hodgkin's disease, modified for NHL. The St. Jude system is applicable to all histologic types of childhood lymphoma and separates patients with limited-stage disease (i.e., one or two masses on one side of the diaphragm) from those with extensive intrathoracic or intraabdominal disease, although the meaning of *extensive* is not defined. Perhaps the biggest problem with this staging system is that stage III encompasses patients with a wide range of tumor burdens. Indeed, various attempts have been made to distinguish subtypes of stage III in B-cell lymphomas. Recently, the Berlin-Frankfurt-Münster (BFM) group showed that a serum LDH level above 500 U per L is an important negative prognostic factor, and that by treating such patients with ten times the dose of MTX, markedly improved results could be achieved[283] Patients with bone marrow infiltration with less than 25% tumor cells seen on aspirate and patients with involvement of the CNS are separated into the worst prognostic group, stage IV (Table 24-5), although the very intensive therapy regimens used today have resulted in markedly improved results for such patients, often not significantly different from those of stage III.

| Stage | Description |
|---|---|
| I | A single tumor (extranodal) or single anatomic area (nodal), excluding mediastinum or abdomen |
| II | A single tumor (extranodal) with regional node involvement<br>On same side of diaphragm:<br>(a) Two or more nodal areas<br>(b) Two single (extranodal) tumors with or without regional node involvement<br>A primary gastrointestinal tract tumor (usually ileocecal) with or without associated mesenteric node involvement, grossly completely resected |
| III | On both sides of the diaphragm:<br>(a) Two single tumors (extranodal)<br>(b) Two or more nodal areas<br>All primary intrathoracic tumors (mediastinal, pleural, thymic)<br>All extensive primary intraabdominal disease; unresectable<br>All primary paraspinal or epidural tumors regardless of other sites |
| IV | Any of the above with initial central nervous system or bone marrow involvement (≥25%) |

**TABLE 24-5. THE ST. JUDE STAGING SYSTEMS FOR CHILDHOOD NON-HODGKIN'S LYMPHOMA**

Because of the rapidity of tumor growth in children and adolescents with NHL, it is important to expedite staging procedures and other investigations indicated by the history and examination of the patient, because delay increases the risks of a complication due to compression of adjacent anatomical structures. It is inappropriate to delay therapy to identify sites of additional disease that would not influence the approach to therapy. Staging laparotomy is not advocated for patients with NHL, although a fraction of patients will have had laparotomy for diagnostic purposes. The first component of staging is the history and clinical examination, supplemented when appropriate by special procedures such as endoscopic examinations—for example, for pharyngeal tumor or upper gastrointestinal bleeding. Additional components include imaging, examination of the bone marrow and CSF, and biochemical and hematological tests.

Modern imaging methods, including ultrasonography and computed tomography (CT) provide adequate means of evaluating disease sites. [284,285] Ultrasonography has advantages over CT scanning when retroperitoneal fat is minimal, as in small children, and in most cases may provide sufficient information for determination of the appropriate treatment group. It may also be useful in defining or detecting testicular masses, but the rarity of testicular involvement at presentation argues against its routine use for this purpose. CT scans may be particularly useful in determining the presence of residual disease after surgery if this is a critical factor in assignment to treatment groups (as it usually is). Gallium scanning provides a useful whole-body screen, particularly for BL and BLL, which avidly take up the isotope. Scanning techniques have been improved considerably in recent years, and both the administration of higher doses of gallium and the use of single-photon emission CT scanning has considerably increased the value of this procedure. [286,287 and 288] Moreover, gallium uptake provides additional information useful for determining response to treatment, because it is not normally taken up by nonviable tumor such that the clinical significance of residual masses identified on radiological imaging can be better assessed.[287,288,289 and 290] A bone scan is the most sensitive means of detecting bony involvement, but it often adds little to the information provided by a gallium scan. Radionuclide liver and spleen scans also add little to CT and ultrasound images. Magnetic resonance imaging has some advantages with respect to imaging certain sites or organs and is particularly useful for evaluating the CNS, but because CNS involvement is rare at presentation, it is generally not included as part of a standard staging system (although it should be performed in the presence of symptoms or signs suggesting CNS disease).

Bone marrow and CSF examination are an essential part of staging, although when prophylactic intrathecal drug administration is simultaneously initiated with systemic therapy, the initial CSF examination can be carried out at that time. Bilateral bone marrow aspirates and biopsies are superior to a single aspirate in detecting bone marrow disease because of frequent discrepancies between aspirates and biopsies and between left and right samples, [291] although because with most modern treatment protocols the presence of limited bone marrow disease has no measurable impact on outcome in patients who would otherwise be stage III, its value in this context is questionable, and many would not advocate multiple biopsies on a routine basis.

Quantitative biochemical (e.g., serum LDH) or immunochemical measurements, as implied, provide a simpler and more objective measurement of tumor volume, although occasionally, patients with extensive disease do not have an elevated serum LDH level. Such measurements should be included in the evaluation of the patient at initial presentation, and serum LDH has become an accepted component of risk assessment for treatment assignment in BFM protocols.

Abnormal liver function tests suggest hepatic involvement, and renal function tests (including assessment of urine output) and measurement of serum uric acid level are essential for determining the presence of uric acid nephropathy as well as the likelihood of the development of a tumor lysis syndrome (see the section on hyperuricemia and the acute tumor lysis syndrome). Renal function tests are not usually helpful in assessing the presence of renal involvement because of the high likelihood of uric acid nephropathy in patients with very extensive disease even in the absence of renal involvement, but they are essential to patient management. An acceptable list of investigations for staging purposes is shown in Table 24-6.

| | |
|---|---|
| ***Important investigations*** | |
| Physical examination | |
| Complete blood cell count | |
| Chemistries | |
| Serum electrolytes | |
| Liver and renal serum chemistries | |
| Serum lactate dehydrogenase | |
| Serum uric acid | |
| Imaging studies | |
| Chest x-ray | |
| Chest CT scan (if chest x-ray film abnormal or suspiciously abnormal) | |
| Thoracic ultrasound (e.g., for following thoracic tumor) | |
| Abdominal ultrasound examination (include liver/spleen, kidneys, abdomen, pelvis)[a] | |
| Gallium-67 scan | |
| Abdominal CT scan (can be waived if ultrasound and gallium scan performed) | |
| Bone marrow examination (bilateral biopsy and aspirates) | |
| Cerebrospinal fluid examination (cytology) | |
| ***Useful or sometimes indicated investigations*** | |
| Serum lactate (especially in the presence of a large tumor) | |
| Bone scan (for more precise documentation of bony lesions) | |
| Magnetic resonance imaging scan for suspected central nervous system disease or if indicated | |
| Endoscopy (e.g., for gastrointestinal bleeding) | |

CT, computed tomography.
[a]MRI be the better study in children with little intraabdominal fat and can be useful in differentiating between bowel and tumor.

**TABLE 24-6. INVESTIGATIONS REQUIRED FOR ACCURATE STAGING OF CHILDHOOD LYMPHOMAS**

## Risk Assignment

Modern protocols divide patients into at least two, and more often three or four groups for the purposes of assigning them to an appropriately intensive therapy arm (Table 24-7, Table 24-8, and Table 24-9). Patients with minimal disease require less intensive therapy than do patients with extensive disease, and because of the risks of therapy—both acute and chronic toxicities, as well as the inconvenience and discomfort related to more intensive therapy—it is important not to administer more intensive therapy to patients than they need. At the present time, however, risk group assignment, although following similar principles, differs in different protocols and in different cooperative groups. In general, patients with B-cell tumors in which all disease has been surgically removed, particularly if of small volume (nearly always the case) before surgery, are considered to be in the lowest risk group. Typically, such patients receive only two or three therapy courses. Patients with extensive disease, as measured by stage and serum LDH level, as well as the presence of CNS disease are generally considered to be in the highest risk group and are treated with the most intensive therapy, usually involving more than six drugs and four or more cycles of therapy. Patients with bone marrow involvement are also at high risk but are sometimes (e.g., in SFOP studies) subdivided according to the extent of bone marrow involvement; in the latter case, only patients with more than 70% tumor cells in the bone marrow were, until recently, classified as being in the highest risk category. Patients not in the lowest or highest risk groups are assigned to intermediate risk groups.

| Therapy group | Definition |
|---|---|
| A | Complete surgical resection stage I or abdominal stage II |
| B | All patients not eligible for group A or C |
| C | Any central nervous system[b] involvement or bone marrow involvement ≥25% blasts |

In patients with ALCL or LL, risk group assignment is less well studied, but patients with ALCL are usually divided in a way similar to those with B-cell lymphomas. Patients with LL rarely have limited disease, because the majority is of T-cell origin, and have "extensive" mediastinal masses. Those with limited disease, for example, localized bone or skin involvement, generally prove to have precursor B-cell LL, and many would advocate treatment with a protocol designed for low-risk ALL, with relatively prolonged therapy. In the Pediatric Oncology Group, patients with limited LL have been shown to require more prolonged therapy than do patients with limited B-cell lymphomas,[38,39] but they are sufficiently few in number that good data regarding the optimal duration of therapy are not presently available.

## Emergency Management

The need for emergency management arises quite frequently in pediatric NHL, because these tumors have very high growth fractions and doubling times. African BL has been estimated to have a potential doubling time as short as 24 hours, and cutaneous tumors have been observed to double in volume in 3 days. [292] Life-threatening complications may develop as a consequence of the physical encroachment of tumor masses on vital structures or because of high cell turnover in a large tumor, with resultant biochemical disturbances.[208] Airway obstruction may result from pharyngeal or intrathoracic masses; SVC obstruction and esophageal

compression from mediastinal masses; respiratory compromise from massive serous effusions related to involvement of the pleurae or peritoneum; cardiac tamponade or arrhythmias from pericardial tumor, pericardial effusion, or even myocardial involvement; paraplegia from epidural tumor; raised intracranial pressure and neurologic deficits from intracranial lymphoma; obstructive jaundice and pancreatitis from compression of the bile or pancreatic ducts; gastrointestinal bleeding, obstruction of the bowel, and rarely, perforation, from intestinal involvement; renal failure from renal outflow tract obstruction or, rarely, massive renal involvement; and inferior vena caval obstruction and lymphedema from retroperitoneal tumor. Severe pain may result simply from rapid expansion of tumor growing within a confined space, including the abdomen (particularly when there is massive ascites), breasts, brain, or a limb compartment (uncommon). Although venous obstruction of the great veins is relatively common, obstruction of peripheral veins or arteries is rare but not unknown (e.g., from tumor in the popliteal fossa), and occasionally peripheral neuropathy can result from compression of nerves by a mass or from direct infiltration of nerves, particularly nerve roots in the brachial and sacral plexuses. This may be associated with pain as well as motor and sensory impairment.

Involvement of the bone marrow can give rise to anemia, neutropenia with a consequent risk of infection, or thrombocytopenia and a risk of bleeding. Electrolyte or biochemical abnormalities of serious consequence (e.g., uricocemia renal failure, lactic acidosis) may be associated with large tumor volumes. Rarely, because of the production by tumor cells of molecules with hormone-like activities, hypoglycemia or hypocalcemia may lead to a medical emergency. [208] Fever, weight loss, and night sweats are occasionally caused by the tumor itself, rather than infection, particularly in the case of ALCL.

Because of the differences in the patterns of presentation of different types of lymphoma, the pattern of complications is, to a considerable extent, contingent on histology. Thus, compression of intrathoracic structures is much more likely with LL than with BL or BLL, whereas the reverse applies to intraabdominal complications. Large cell lymphomas, however, may occur in either the chest or the abdomen, and ALCL is more likely than are the other major histologic types of NHL to involve unusual sites, including skin. In addition, because the doubling time of BL tends, on average, to be shorter, and possibly because of biochemical differences, BLs are much more likely than are other tumors to present with electrolyte or biochemical abnormalities than other NHLs. [293]

Although immediate intervention may be required in some circumstances (e.g., tracheotomy, establishment of a diuresis, or hemodialysis) it must be emphasized that all of these complications can ultimately be dealt with only by reduction of tumor bulk, and delay will compound the problem, so the initiation of specific therapy as rapidly as possible must always be a primary goal. Clearly, in high-risk patients, even in the absence of overt complications, induction therapy is best administered in an intensive care unit. The management of the some of the more frequently encountered complications at presentation is discussed further in the sections that follow.

***Management of the Complications of Mediastinal Lymphoma***

The most serious complications of mediastinal masses are airway obstruction and cardiac tamponade. SVC obstruction is relatively frequent but is not, per se, a life-threatening complication, although its presence should lead to a careful assessment of airway competence. Dysphagia from esophageal compression may occur and can lead to discovery of a mediastinal mass but rarely becomes sufficiently severe as to require intervention, and is usually a less prominent symptom than is airway or SVC obstruction at the time of presentation, presumably because of anatomical considerations. Although clinical symptoms and signs are present with severe airway obstruction, narrowing of the trachea or major bronchi can occur without significant compromise of breathing while at rest. The most accurate method of assessing the anatomical degree of compression of the major airways is by CT scan. Severe airway obstruction is usually best managed by the institution of specific therapy, although in urgent situations before the establishment of a diagnosis, the institution of corticosteroid or radiation therapy may be indicated. Every effort should be made to establish a diagnosis before the institution of therapy, but general anesthesia and even heavy sedation should be avoided in patients with large mediastinal masses or airway obstruction (sudden death associated with anesthesia has been reported), and in this circumstance, bone marrow examination, biopsy of a peripheral lymph node, or examination of pleural fluid for tumor cells using only local anesthesia may permit a diagnosis to be established. SVC obstruction from a wide range of tumors has been traditionally treated with radiation therapy, but in highly chemotherapy-responsive tumors such as LL, irradiation increases toxicity without therapeutic gain. In the event that no symptomatic improvement (or worsening) is observed within a few days of the initiation of specific chemotherapy in patients with large mediastinal masses and serious respiratory compromise, mediastinal irradiation can be considered, but this circumstance is rare indeed, and augers poorly for the long-term outcome. If radiation therapy must be used, relatively low-dose therapy (e.g., to a total of 1,200 cGy) is preferable, because radiation does not improve the long-term outcome but may decrease marrow tolerance to chemotherapy and will increase the risk of pulmonary and cardiac toxicity, especially in the presence of anthracyclines.

Cardiac tamponade from pericardial tumor or pericardial effusion is best managed by the rapid institution of specific therapy coupled to pericardial paracentesis when necessary. The insertion of a catheter suitable for continuous drainage into the pericardial sac may be appropriate if the reaccumulation of fluid is rapid, but other measures, such as the construction of a pleuropericardial window or pericardiodesis with sclerosing agents, is not recommended at the time of presentation or remission induction, because the problem will normally be resolved as soon as there is sufficient tumor regression. Similar considerations apply to the management of massive pleural effusions. Rarely, antiarrhythmic drugs may be required because of myocardial infiltration or compression.

***Management of the Complications of Intraabdominal Lymphoma***

Massive intraabdominal lymphoma is nearly always of B-cell type in children and is most likely to be diagnosed as BL or BLL. Obstruction of the bowel, ureters, inferior vena cava or other retroperitoneal veins and lymphatics, and intraluminal bleeding or perforation of the bowel from tumor necrosis are the most frequently encountered complications. Intestinal obstruction is most commonly due to intussusception resulting from the intraluminal projection of a small tumor mass, and some patients present with symptoms of acute appendicitis. An acute abdomen is a relatively common presentation of NHL in children and will dictate laparotomy, which both establishes the diagnosis and, in the majority of patients, also leads to complete resection of the tumor. Such patients, particularly those who undergo emergency surgery, enjoy an excellent prognosis because they usually have very little tumor. In patients with gastrointestinal bleeding, surgical intervention should be strongly considered before specific treatment because tumor necrosis after chemotherapy is likely to considerably worsen the bleeding. However, surgical resection to *prevent* gastrointestinal bleeding or perforation in patients with extensive bowel disease is not recommended because both complications are rare, and perforation after chemotherapy may be *more* likely in patients who have been operated on or are malnourished. [294]

Ureteric obstruction (rarely, urethral obstruction) which is, again, a problem that is appropriately managed by the institution of specific therapy, has additional implications because if associated with a large tumor burden, it is likely to be accompanied by hyperuricemia and occurrence of an acute tumor lysis syndrome (see the section on hyperuricemia and the acute tumor lysis syndrome) after the initiation of therapy. The major treatment strategy for dealing with hyperuricemia is the establishment of a substantial diuresis—something that may be impossible in the presence of ureteric obstruction, particularly if bilateral—accompanied by the administration of allopurinol to reduce serum uric acid or, if available, urate oxicase. [295,296] The latter enzyme has been available for the treatment of hyperuricemia for many years in France[297] and is probably the major reason that serious electrolyte imbalances, potentially resulting in death, have not been a significant problem in the SFOP series (see the section on hyperuricemia and the acute tumor lysis syndrome). When acute renal failure cannot be alleviated by the above measures, and particularly when severe obstruction is a major component of the problem, it is appropriate to initiate hemodialysis (or, if feasible, peritoneal dialysis) until uric acid, electrolytes, urea, and creatinine are approximately normal, followed by immediate initiation of specific chemotherapy. Continue dialysis as necessary according to serum chemistries. Although ureteric stents or nephrostomy have been successful in bypassing ureteric obstruction, such measures are potentially hazardous, because the risk of perforating a ureter during placement of a stent or leakage of urine from a nephrostomy (particularly if tumor is in close proximity) are significant. In countries with limited resources and no access to hemodialysis, however, the use of urinary bypass may permit the establishment of a diuresis and initiation of chemotherapy.

Venous obstruction within the abdomen is a potential problem from two perspectives. First, intraluminal thrombosis may be present, necessitating consideration of anticoagulation or physical containment of thrombus to prevent pulmonary embolus. Anticoagulation can be hazardous because of the accompanying risk of gastrointestinal bleeding from involvement of bowel or the presence of thrombocytopenia from bone marrow involvement or chemotherapy. Further, oral anticoagulation with coumadin is difficult to control when potentially hepatotoxic chemotherapeutic agents, for example, MTX, are to be administered, such that heparin is preferable (where available, low-dose heparin may be an appropriate choice). In patients with intraabdominal lymphoma and venous thrombosis, pulmonary embolus (which is certainly a significant risk) may be prevented by the emergency placement of an intraluminal filter below the renal veins in the inferior vena cava.

The second potential consequence of intraabdominal venous or lymphatic obstruction is the inability to establish an adequate diuresis to deal with associated hyperuricemia and to avoid the development of a tumor lysis syndrome after the initiation of chemotherapy because of the tendency of administered fluid to accumulate in the lower limbs. Careful management of fluid balance and appropriate use of diuretics will usually permit the establishment of a diuresis, but recourse to hemodialysis may, on rare occasions, be necessary.

***Hyperuricemia and the Acute Tumor Lysis Syndrome***

The extremely high growth fraction and cell turnover rate of the childhood lymphomas, which are higher in B-cell lymphomas than in T-cell neoplasms, [298] although possibly accounting for their high sensitivity to chemotherapy, leads to the potential for the development of renal complications resulting from the increased solute burden on the kidneys. Both uric acid nephropathy occurring before the commencement of chemotherapy, and the development, immediately after chemotherapy, of an acute tumor lysis syndrome are correlated with the tumor burden and do not occur in patients with completely resected or minimal disease. [293,299,300] Acute tumor lysis syndrome refers to the occurrence of acute oliguric renal failure caused by the high urinary concentrations of phosphates and oxypurines and by their precipitation in the renal tubules when their solubility products are exceeded ( Table 24-10).

| | Acute uric acid nephropathy | Phosphate nephropathy | Xanthine nephropathy |
|---|---|---|---|
| Potassium | ↔ | + | ± |
| Urate | ↔ | + | ± |
| Phosphate | + | ↔ | ± |
| Predisposing factors | Aciduria | Alkaluria | Allopurinol |
| Time of onset | Before and after starting therapy | Within 48 h after starting therapy | After starting allopurinol |
| Prevention | Hydration, alkalinization, allopurinol or urate oxidase | Hydration | Hydration |

+, increase in plasma level; ↔, marked increase; ±, slight or no increase.

**TABLE 24-10. CLINICAL CHARACTERISTICS OF RENAL FAILURE ASSOCIATED WITH TUMOR LYSIS SYNDROME**

Although it is important to initiate specific therapy as soon as possible, the administration of chemotherapy in the presence of a markedly elevated uric acid and impaired urinary output would be highly likely to result in the death of the patient, probably from profound hyperkalemia—it was this complication that originally led to the recognition of the syndrome.[301] Therefore, the biochemical abnormalities must be corrected before the initiation of specific therapy. This period of biochemical correction by means of intensive diuresis (up to 250 mL per $m^2$ per hour in patients at highest risk) accompanied by allopurinol or urate oxidase should be completed as expeditiously as possible, preferably within 24 to 48 hours, because continued tumor growth is likely to compound the problem. The avoidance of potentially fatal hyperkalemia, hyperphosphaturia and renal failure—which will compound both problems—is best accomplished by ensuring a high urine volume before the initiation of chemotherapy. In French and German pediatric cooperative group protocols (both of which are now used in many other countries) a prephase of low-intensity chemotherapy (cyclophosphamide with vincristine and corticosteroid) is given during the first week of therapy based on the hypothesis that it will reduce the rate of response and thereby lessen the risk of acute tumor lysis. In some patients, for example, those recovering from major surgery, such an approach may have additional advantages—that is, allow improved wound healing. Response to this phase of therapy also appears to be predictive of the ultimate outcome of therapy and has been used by the SFOP as a means of identifying high-risk patients (see below).[302] Tumor lysis may occur, however, despite the administration of such a prephase[293] and the low incidence of metabolic complications in the SFOP protocol appears to be largely due to the use of urate oxidase in French studies. [302] For these reasons, the use of a prephase should not be interpreted as lessening the need for hyperhydration before and during initial chemotherapy in patients with a moderate to large tumor burden. Because of the relatively poor solubility of phosphates in alkaline urine, it is preferable to maintain the urine pH at approximately 7 and not to administer bicarbonate during chemotherapy. At pH 7 uric acid is 10 to 12 times more soluble (solubility is 150 mg per L at pH 5) and xanthine more than twice as soluble (solubility at pH 5 is 50 mg per L) than at pH 5. The solubility of hypoxanthine differs little at either pH (140 to 150 mg per L). The administration of high-dose allopurinol (e.g., 10 mg per kg) ensures that a significant proportion of purine metabolites is excreted as xanthine and hypoxanthine. It is inadvisable to completely prevent uric acid production because it is more than ten times as soluble in urine than is xanthine and slightly more soluble than is hypoxanthine. The objective of allopurinol therapy, therefore, is to increase the total amount of oxypurine that can be excreted in a given volume of urine rather than to prevent uric acid formation. Urate oxidase can very rapidly decrease uric acid levels by conversion to allantoin, more than ten times as soluble, and simplify the management of patients with a high tumor burden. This enzyme is gradually being introduced into standard practice in other countries, [295,296] and the development of recombinant versions should make it more widely accessible.[297]

Because of the risk of sudden death from hyperkalemia, which may occur within hours of the initiation of therapy, [301] it is important to avoid potassium supplements shortly before and during the first few days of therapy except in exceptional circumstances. Ideally the patient should be mildly hypokalemic before the commencement of chemotherapy. Hyperkalemia, similar to the other complications of acute tumor lysis, is extremely unlikely to occur in the presence of a high urine output. Hypocalcemia, a consequence of hyperphosphatemia, should not be treated unless symptomatic, and intravenous calcium chloride should be given with great caution, if at all, because of the risk of extraosseous calcification in the presence of a high serum phosphate level. Systemic alkalinity increases the possibility of symptomatic hypocalcemia, including tetany, and this is another reason that alkalinization of the urine is recommended only before chemotherapy, not during therapy. Rarely, hemodialysis may be required for symptomatic hypocalcemia. Because of the quantity and type of monitoring required, it is preferable to manage patients at high risk for acute tumor lysis syndrome in a critical care unit.

### *Management of Neurologic Emergencies*

The primary neurologic emergencies encountered in children with NHL include paraplegia, cranial nerve palsies, meningeal disease, and intracerebral tumor. Although radiation would at one time have been considered appropriate therapy for each of these problems, this is no longer necessarily the case. Given the generally excellent responses to chemotherapy in all childhood lymphomas, there is no reason to presume that tumor will respond more rapidly to radiation. In fact the reverse is usually the case, although radiation response is histology dependent. Reversal of neurologic complications, including dense paraplegia (but only when of brief duration) as well as cranial nerve palsies, has been observed frequently in African BL treated with chemotherapy alone, [28] but radiation response, at least to standard fractions, is generally poor in BL.[36] Extradural disease, the usual cause of paraplegia, and cranial neuropathy, is amenable to standard systemic therapy, and emergency radiotherapy for these forms of CNS disease is not necessary. Failure of paraplegia to resolve may be due to compression of the arterial blood supply to the cord. In BL, there is also no evidence that irradiation is of value in the presence of CSF malignant pleocytosis, which in emergency situations can be effectively managed by intrathecal therapy,[227] although magnetic resonance imaging should be performed to exclude raised intracranial pressure before performing a lumbar puncture in suspected cases. Radiation, although it may have little effect on response rates, is likely to increase the risk of late complications. [303,304 and 305] This, coupled to the success of high-dose systemic cytarabine (Ara-C) and MTX in the treatment of patients with the most advanced disease has led to a significant trend away from the use of radiation for patients with BL and CNS disease at presentation. The role of radiation in the treatment of CNS involvement in other histologies is less clear, and unfortunately, there are too few patients in this situation for randomized studies to be conducted. [306] As with BL, the pros and cons include the curative potential of purely chemotherapeutic approaches weighed against the potential for increased acute and late toxicity of cranial irradiation in association with chemotherapy, particularly when high-dose systemic and intrathecal MTX or Ara-C are used. [305] It is of interest that even in the treatment of primary CNS lymphoma in adults, radiation gives very poor results when used alone, significantly worse than those achieved with high-dose MTX, providing further support for the omission of radiation therapy even for the emergency treatment of patients with CNS lymphoma.[307]

### Relative Importance of the Primary Treatment Modalities

The primary therapeutic modality for the NHLs of childhood is chemotherapy, regardless of stage or sites of disease. Theoretically justified on the grounds that the NHLs are disseminated diseases, this statement is also firmly rooted in empirical clinical experience. The average survival in a combined analysis of eight published series of children with localized NHL—a total of 370 patients—treated with radiation, surgery, and single-agent therapy was 18%. [308] Yet patients with a similar tumor burden treated with combination drug therapy with or without radiation have enjoyed a cure rate usually in excess of 90% for many years. [309,310,311 and 312] These data, coupled to data from Africa, in which poor response to radiation was documented (although there was evidence in these studies that hyperfractionation would be beneficial[36,313]), were sufficient to convince most that radiation probably has no role in the modern therapy of early stage disease, but confirmation has come from a randomized trial conducted in the United States in which radiotherapy was shown not only to have no advantage but also to be associated with a significant toxic cost when combined with a drug combination that cured approximately 90% of patients.[38,39] The lack of benefit of radiation in patients with localized disease would suggest strongly that patients with extensive disease would not benefit from radiation to sites of bulky disease either, and indeed, modern multidrug therapy protocols that do not include radiation clearly produce markedly better results in all histologies [302,314,315] than those of earlier protocols in which local irradiation was used in addition to combination chemotherapy.[305] Even patients with bony disease or testicular involvement do not appear to profit from radiation therapy to these sites. [215,316,317,318 and 319]

In light of these data and taking into consideration the acute toxicities, particularly injuries to skin and mucous membranes (worse in the presence of doxorubicin and MTX), as well as the late effects of radiation, including second malignancies, [304,320] it can be confidently stated that radiation has no *routine* role in the treatment of children with NHL, and its use *in any circumstance*, not excluding emergency therapy, must be clearly justified.

Similarly, surgery, although important to diagnosis and, where indicated, in dealing with the complication of therapy, has no other defined role in the treatment of childhood NHL when a highly effective, modern chemotherapy protocol is used. In few patients with LL is surgery even an option, and the potential for benefit lies largely in patients with abdominal tumor, the majority of whom has BL, BLL, or LBCL—that is, B-cell lymphoma. Early studies in African BL suggested that complete resection of bulky abdominal BL (readily accomplished in patients with, for example, isolated ovarian tumor, even if bulky) before chemotherapy was beneficial to survival.[40] It has been suggested that any apparent benefit of surgery, however, at least in sporadic BL/BLL is more a function of the smaller size, in general, of resectable tumors, than to the fact that the tumor has been completely excised. Retrospective studies in patients treated in the 1980s in the United States or Europe have shown that complete resection is much more likely to be accomplished in those presenting with an acute abdomen than in patients undergoing elective surgery who tend to have more extensive disease.[41,42] This is because the primary causes of an acute abdomen in patients with B-cell intraabdominal tumor are intussusception, which is caused by a small tumor partially projecting into the bowel lumen and "appendicitis" caused by occlusion of the appendiceal lumen by, again, a small volume of tumor. In view of this, it is not surprising that the treatment outcome in these retrospective studies was better in patients in whom all disease had been resected, because this group would include patients with smaller tumor bulk, many of whom presented with a surgical emergency. In the absence of a controlled study, however, it is not possible to determine the role of the surgical resection itself, and indeed, it may vary according to the chemotherapy subsequently instituted. Today, even patients with extensive intraabdominal disease, which would not be amenable to resection, enjoy an excellent prognosis with the most successful chemotherapy regimens so that there is no reason to advocate elective surgical resection. However, the original study of surgical resection conducted in Uganda [40] does suggest that in patients receiving what might today be considered minimal therapy (e.g., two standard doses of cyclophosphamide), a marked reduction in tumor burden is beneficial. In this study, although numbers were small, patients in whom only one of two massively involved ovaries were resected (by choice, to avoid sterilizing the patient) had a worse outcome than patients in whom both involved ovaries were resected. It remains possible, therefore, that in circumstances in which modern intensive chemotherapy cannot be given (e.g., in some developing countries), complete surgical resection may provide therapeutic benefit.

There appear to be no grounds for believing that surgical resection will reduce the low risk of bleeding or perforation associated with gastrointestinal tumor. In fact, the reverse is the case; in addition to the potential for delaying the institution of chemotherapy, there is a significant risk of fistula or perforation occurring in the postoperative period, not infrequently when the patient is granulocytopenic. [294]

The role of "second look" laparotomy has also been studied in B-cell lymphomas, particularly by the BFM group. [42,314] Because patients with viable tumor at the time of second look surgery did poorly regardless of the treatment modality used (usually, if localized, complete extirpation or radiation therapy), whereas those with no demonstrable viable tumor did well, second look surgery with or without complete resection cannot be recommended. Doubtless this is a consequence of the fact that B-cell lymphomas are disseminated from the outset such that evident residual disease represents only the tip of the iceberg and cannot be successfully treated by local therapy alone. Indeed, in patients treated with a very intensive regimen such as that used by the BFM group, patients in whom complete remission was not achieved had a very poor prognosis regardless of the salvage treatment used. It seems that the identification of residual tumor late in the course of therapy is unlikely to be of major value because therapeutic options are by then limited. On the other hand, the identification of slow responders very early in therapy, particularly if such patients are in what would otherwise be considered a low or intermediate risk group, may be beneficial because there is an opportunity to give such patients much more intensive therapy.[314]

**Specific Therapy**

Treatment protocols in childhood NHL, as with all treatment protocols, are designed to maximize benefit and minimize toxicity. Because patients with smaller tumor burdens, that is, at lower risk, require less "intensive" therapy, where *intensity* refers both to the number of milligrams of drug delivered per unit time and to the number of drugs incorporated into the regimen, it is critically important to identify the risk group into which the patient falls in order to tailor therapy accordingly. This process is generally referred to as *risk adaptation*. Any of the prognostic factors mentioned in the sections on staging and risk assignment may be used in this process of assigning patients to a specific treatment group, but in the end, the best indicator of the ultimate outcome of therapy is the response to treatment itself, such that a measure of the response to therapy in the early treatment cycles can be used, and has been successfully used, to identify patients who may benefit from more intensive therapy than that which their risk group dictates. The SFOP, for example, has used response to the prephase element, that is, the first week of treatment, as a factor in determining subsequent therapy.[302]

All childhood NHLs respond to a wide range of chemotherapeutic agents, partly because of their high growth fraction. Results in recent years using combination chemotherapy regimens have improved to the point that the most effective protocols are producing overall survival rates in the region of 90% for BL, BLL, and LBCL (70% to 90% for Burkitt's cell leukemia) and 80% to 90% for LL and ALCL. [26,255,264,265,283,302,305,314,315,321,322,323,324,325 and 326] It has become widely accepted that patients with B-cell lymphomas—namely, BL, BLL, and LBCL—require intensive, short-duration (3 to 6 months) therapy with multiple drugs, whereas those with LL are optimally treated with chemotherapy protocols based on the therapy of ALL. Patients with ALCL are usually treated with protocols identical to, or slightly modified from, those used for the therapy of B-cell lymphomas.

In pediatric NHLs, prophylaxis against the spread of tumor to the CNS is an essential component of therapy for the majority of patients. At the present time, the only patient groups that do not routinely receive prophylaxis against CNS disease are those with minimal disease, for example, patients with intraabdominal B-cell lymphomas that are completely resected, or patients with all histologies and stage I disease that is not in proximity to the CNS (i.e., not in the head and neck region or epidural), in whom CNS spread is a extremely rare. In a CCSG study, for example, none of 55 patients with resected abdominal disease treated with COMP developed a CNS recurrence.[34,327] Similarly, the SFOP LMB 89 protocol does not include any CNS prophylaxis for patients with stage I or II completely resected B-cell lymphoma, and no cases of isolated CNS relapse in this group have yet been observed. [302] However, isolated cases of CNS recurrence after complete resection of all abdominal tumor (B cell) have been occasionally observed, and because of the minimal increase in toxicity associated with the administration of a small number of doses of intrathecal MTX or Ara-C (e.g., four to six), some protocols do not omit CNS prophylaxis, even for this group. The balance here is the very small potential benefit weighed against the very small risk of severe neurotoxicity, such as myelopathy, that may occur after intrathecal therapy.

It is, of course, possible, that certain specific entities, for example, ALCL or subtypes of LBCL that have a much lower tendency to spread to the CNS than do BL or LL, do not require CNS prophylactic therapy, but this has yet to be shown in children, and unless demonstrated by carefully conducted clinical trials to be unnecessary, the majority of patients should continue to receive CNS therapy because the potential for harm (i.e., severe neurotoxicity) would appear to be greatly outweighed by the risk of the development of CNS recurrence if such therapy is not given. Intrathecal therapy with either MTX alone or MTX and Ara-C is usually the mainstay of CNS prophylactic therapy, but in patients with extensive disease, high-dose intravenous infusions of S-phase specific agents such as MTX and Ara-C are administered in the most effective protocols, whether for BL, BLL, and LBCL or for LL. Such agents probably benefit the patient both because of their effect against systemic tumor and because of their role in preventing CNS spread or dealing with occult CNS involvement.

Radiation of the cranium or craniospinal axis is generally not considered to have an advantage over chemotherapeutic CNS prophylactic therapy in children with NHL, and in some studies in patients with B-cell lymphomas, it has been shown to be ineffective. [329,330] Moreover, prophylactic cranial irradiation in ALL, in which there is considerably more experience with this approach, has been associated with significant toxicity, including impaired growth, intellectual impairment, and secondary brain tumors.[331,332,333,334,335 and 336] However, cranial radiation has continued to be used by the SFOP for the treatment of patients with CNS disease at presentation and as preventative therapy for patients with LL in the BFM and United Kingdom CCSG groups. [302,326,337] The value of radiation in these situations is currently being studied by randomized clinical trials.

***Chemotherapy of B-Cell Lymphomas***

For treatment purposes, children and adolescents with B-cell lymphomas (BL, BLL, and LBCL) may be considered together because there is no convincing evidence that, within this group of lymphomas, histology is an important determinant of outcome. Even subgroups of large cell lymphomas, for example, mediastinal LBCL, although comprising a small subset of most protocols, appear to have a similar outcome. Consequently, most cooperative groups use the same protocol for the full histologic spectrum of B-cell lymphomas. This has the major advantage that the treatment regimen employed is not dependent on the arbitrary and poorly reproducible separation of these entities on histologic grounds. In the B-cell lymphomas, short-duration, intensive therapy has clearly been shown to be superior to less intensive but longer duration treatment. Prolonging therapy beyond a few months at most (and a few weeks in patients with limited disease) appears to have no value, although longer therapy durations clearly have a potential for increased toxicity (early or late), increased expense, and increased inconvenience to the patient. There is no doubt that treatment protocols based on the principles used effectively for ALL, such as the LSA $_2$L$_2$ or the BFM 1976–81 regimens (which are several

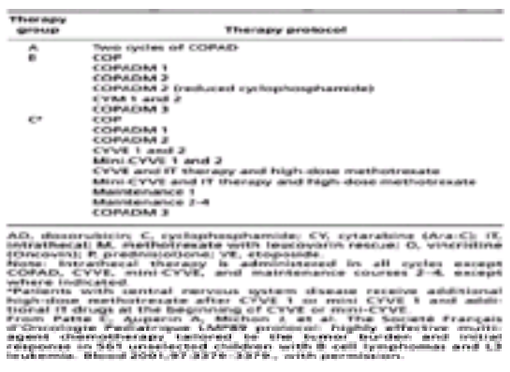
years in duration) are suboptimal for the treatment of patients with BL.[309,310,327] Even patients who present with diffuse bone marrow involvement, whether or not there is a high peripheral white count, have a poor prognosis with conventional therapy for ALL and a much better prognosis when treated with a protocol designed for B-cell lymphomas.[302,322,323,338,340]

The basic four-drug regimens used in the 1970s, consisting of cyclophosphamide, vincristine, prednisone, and MTX (generally low or intermediate dose) or doxorubicin, although still providing effective therapy for patients with minimal disease, cure only 50% to 75% of patients with more extensive disease.[310,324,327,340,341] A regimen known as APO [doxorubicin (Adriamycin), prednisone, vincristine (Oncovin)], based on ALL therapy, has met with similar success in large cell lymphoma in general, but this is probably because both B and T (predominantly ALCL, which can be reasonably well managed with ALL therapy, see below) have been included in series of patients treated with this regimen.[343] For patients with extensive disease, the basic drugs have been supplemented with higher dose MTX (5 to 8 g per $m^2$) and, frequently, high-dose Ara-C as well, in addition to other drugs, such as etoposide and sometimes ifosfamide.[302,314,315,323,328] These added drugs, higher dosages, or drug combinations were first shown to be effective in patients with recurrent disease.[344,345,346,347 and 348] Variations in individual and cumulative drug doses, timing, and total treatment duration exist among the several protocols in use, and present emphasis is on “fine tuning,” that is, refining drug dosage and administration. The optimal duration of MTX infusions is a major study question in the present BFM trial for B-cell lymphomas, whereas the French-American-British protocol for B-cell lymphomas, based on SFOP 89, is designed to determine whether reduction in dosage and in the total duration of therapy for specific patient subgroups can be safely achieved. In these multidrug protocols, the relative value of each drug cannot be determined, and in this respect it is of interest that corticosteroids are not included in the NCI protocol,[315,323] which appears to be as effective as SFOP and BFM protocols, both of which include corticosteroids, whereas anthracyclines have been shown in an as-yet unpublished, randomized study conducted by the CCSG to add no therapeutic value to the four-drug regimen, COMP. Because anthracyclines have the potential for acute or late cardiac toxicity[304] and certainly add to the acute toxicity of combination regimens (particularly with respect to myelosuppression and stomatitis), further studies to determine their utility in the present day 6 to 8 drug regimens may be warranted.

To minimize the possibility of tumor regrowth between treatment cycles and to achieve high-dose intensity, sequential cycles are usually begun as soon as there has been sufficient recovery from the toxicity of the previous cycle—usually when the granulocyte count reaches 500 or 1,000 per $mm^3$. Toxicity is minimized by adjusting the intensity of therapy to the risk category into which the patient falls. This process of patient stratification by risk group is one of the most important aspects of modern protocol design. Inappropriate assignment could lead either to some patients receiving less therapy than they require, with a resultant worse outcome for these patients, or to some patients receiving more therapy than they require, with a greater risk of toxicity than necessary. Since toxicity even with the most intensive therapies is acceptable, however, if there is doubt as to which group a patient fits into, it is reasonable to opt for the higher risk treatment arm. It is necessarily the case that many patients, such as that fraction of patients with extensive disease who would have been cured with one of the earlier four-drug regimens, do in fact receive more therapy than they require. In the absence of a more accurate means to identify such patients, there is no other alternative.

It has become clear that stage is an insufficient means to stratify patients for therapy. Occasional patients with stage I disease have quite extensive tumor, for example, a localized mass of more than 10 cm, and although there is insufficient published data on which to draw solid conclusions, it would seem that such patients ought to be included in a higher risk category than would be the case if stage alone were the determinant of therapy. Serum LDH levels are used by the BFM group as a determinant of risk group based on their earlier finding that stage III patients with a serum LDH higher than 500 U per L had approximately double the survival rate when the MTX dosage was increased from 0.5 g per $m^2$ to 5 g per $m^2$.[283]

The results of several protocols in which the principle of risk stratification is used demonstrate that excellent results can be achieved, overall approximately 90% event-free survival (EFS) (Table 24-11, Table 24-12, Table 24-13, and 24-14). In particular the SFOP LMB 89 and the German BFM 90 protocols have been used in more than 1,000 patients each, with EFS rates of more than 90% for all patients, 76% in patients with the most extensive disease (leukemic patients) treated on BFM 90, and 98% to 100% for stage I and II patients.[283,302] Comparable results have been obtained by the U.S. NCI protocol 89-C-41, but the number of patients accrued is much smaller.[315,323] The U.S. Pediatric Oncology Group (POG) results are also not greatly different ( Table 24-15). In each of these protocols, the significance of prognostic factors has largely been lost. Even patients with stage IV disease do not have a significantly worse prognosis, although CNS disease may still be associated with a somewhat worse outlook. Thus, at this point, the major questions to be asked in the treatment of these diseases is whether equally good results can be achieved with less toxicity and whether further improvements in risk stratification can be made. A means of identifying precisely patients destined not to achieve complete remission could permit even more intensive therapy or perhaps the substitution of drugs, particularly in the event that resistance to one or more of the agents in the planned protocol could be identified in advance. It is possible that newer techniques, such as microarray analysis or proteomic analysis of gene expression patterns, or methods of measuring more precisely the rate of response of tumors to therapy, could lead to such precision.



| Therapy group | Therapy protocol |
|---|---|
| A | Two cycles of COPAD |
| B | COP |
| | COPADM 1 |
| | COPADM 2 |
| | COPADM 2 (reduced cyclophosphamide) |
| | CYM 1 and 2 |
| | COPADM 3 |

**TABLE 24-15. RESULTS OF VARIOUS PROTOCOLS IN THE TREATMENT OF B-CELL LYMPHOMAS**

Patients with CNS disease have long been considered to have a particularly poor prognosis. There are several possible explanations for this. Such patients could have biologically different disease, which is more resistant to the particular chemotherapy in use; CNS disease may be associated with particularly extensive systemic disease; or the therapy used is less effective, for reasons of drug distribution, against CNS disease. Of interest in this context is the observation, published many years ago, that African patients with BL and CNS disease did not have a worse prognosis than other patients. Indeed, even with the therapy delivered in the 1960s and 1970s, often single-agent therapy, 50% could be expected to achieve long-term survival. [236,349] This is probably related to the fact that in endemic BL, CNS disease is frequently associated with rather small tumor burdens. In contrast, CNS disease in sporadic BL is associated with extensive systemic disease, frequently including bone marrow involvement.[218,226,227] Based on evidence from two different series, it seems probable that CNS disease in sporadic BL previously had a poor prognosis because of its association with a high tumor burden, perhaps coupled to the earlier, inadequate therapeutic approach to CNS disease. [218,226] The use of high-dose S-phase agents—that is, MTX and Ara-C, both of which are highly active in BL, and which provide effective drug levels in the spinal fluid and CNS parenchyma—has dramatically improved the results of therapy in patients with CNS disease. Both high-dose Ara-C and high-dose MTX are potential neurotoxins, and this must be taken into consideration in protocol design because neurotoxicity may be considerably increased if other potential neurotoxins are used. [350] This is an additional reason to avoid the use of radiation in patients with CNS disease or those at risk of developing it.

With the improved outcome of patients with B-cell lymphomas, an interesting change in the pattern of failure has occurred. Most failures, although few (approximately 10% of patients), are now caused by primary resistance to therapy, that is, the patient achieves only a partial response, or by toxic death. Recurrent disease has become rare and is almost never observed beyond 1 year after the initiation of therapy. Patients who remain in their first disease-free remission at this time may, as has always been the case, be considered cured. Late relapse (beyond 1 year) has been reported only in a small percentage of African patients with BL; in such patients there is evidence that “relapse” is, in reality, a new neoplasm. [351] Presumably, this results from the significantly higher risk in African children of developing BL, but it may also indicate the presence of genetic factors that markedly increase the risk of developing BL in specific individuals. The identification of familial cases of BL provides some support for the influence of a genetic factor of this kind. [59,352,353] This observation has a parallel in acquired immunodeficiency syndrome patients, also at particularly high risk for the development of B-cell neoplasms, in whom “late relapse” has been shown to be caused by the development of a clonally distinct neoplasm rather than recurrence of the original clone. [354]

***Chemotherapy of Lymphoblastic Lymphoma***

In the randomized trial completed by the Children's Cancer Group more than 15 years ago in which ALL-type therapy ($LSA_2L_2$) was compared with the COMP regimen for all NHLs, the $LSA_2L_2$ regimen, although clearly inferior for non-LLs, proved to be superior for LL. [327] Consequently, because the results of this study became widely know, the treatment of LL has been largely limited either to variants of $LSA_2L_2$ itself or to other treatment protocols designed for ALL. Such protocols include induction, consolidation, and maintenance elements lasting for a total of between 1 and 3 years. [325,326,337,355,356,] Although regimens similar to protocols used for patients with B-cell lymphomas have been used in LL and have resulted in the cure of a reasonably high fraction of patients, [342,355] the results of these protocols in patients with bone marrow disease were quite poor. It is possible that more intensified versions of these protocols, such as those used for B-cell lymphomas (perhaps followed by a maintenance therapy), would achieve better survival rates, but results in LL with therapies used for ALL are sufficiently good and sufficiently well tolerated that there is little incentive to test alternative treatment approaches. The best reported results to date are those of the BFM group, which has achieved an estimated EFS rate at 5 years of 92% for patients with T-cell LL. [326] It is important to note that these excellent results have been obtained without the use of local radiation.

In LL, patients with limited disease (localized or multiple disease sites outside the thorax and on one side of the diaphragm) as well as patients with stage IV disease (i.e., CNS disease or less than 25% of blasts in the bone marrow—with a higher percentage, patients would be considered to have ALL) are uncommon. Thus, many investigators have divided LL into two risk groups, limited (stages I and II) or extensive (stages III and IV), or have not divided them at all and used the same therapy for all patients. In part this is because the infrequency of patients with limited disease has led to a lack of information with respect to the most appropriate therapy to use. It would seem logical to base therapy on that used for precursor B-cell ALL, because LL patients with limited disease more often have LL that is immunophenotypically identical to precursor B-cell ALL. The ability to detect bone marrow involvement by flow cytometry in some of these patients (in whom the bone marrow is generally microscopically normal) suggests that such cases are unusual manifestations of ALL. In the CCSG study conducted with $LSA_2L_2$, children with limited-stage LL had an identical outcome (approximately 80% long-term survival) whether treated with $LSA_2L_2$ or with COMP, although there were only 11 such patients,[327] which is similar to the result that might have been expected in ALL. In this trial COMP was given for 18 months, and the study included local irradiation. A subsequent study demonstrated that 6 months of therapy was as effective as 18 months in patients with limited-stage disease. [357] Using a shorter duration of therapy [9 weeks of CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], prednisone), with or without local radiation], POG reported approximately 70% EFS rates using the same treatment approach as that used in patients with limited B-cell NHL. [39,358] This result would appear to be unsatisfactory when compared to results of 80% to 90% being achieved today in patients with stage III disease, but whether the lower survival rate is due to differences in the drug combinations (e.g., lack of MTX, asparaginase, or Ara-C in the treatment regimen) or to an inadequate duration of therapy is unknown. In protocol LMT81 used at the Institut Goustave Roussy,[325] which included ten administrations of high-dose MTX in conjunction with the $LSA_2L_2$ protocol, there were only eight stage I and II patients, and two died in

remission from measles (all the remaining patients achieved long-term survival). No meaningful conclusion can be drawn from this small number of patients as to the added advantage of the infusions of high dose MTX in patients with limited disease. Similarly, in the BFM-NHL 86 protocol, there were only six evaluable patients with limited-stage (I or II) disease out of a total of 73 patients with LL treated with BFM protocols for ALL (two relapsed). [314] In the more recent BFM 90 protocol, there were four patients with T-cell LL, none of whom relapsed.[326]

At the present time, although it is clear that a high fraction of patients with limited-stage disease can be cured, optimal therapy has not been identified. Based on small numbers, it would appear probable that short-duration therapy is inadequate, although it is unclear whether ALL-type induction is superior to CHOP- or COMP-type inductions. Nor is it known whether precursor T-cell LL requires different therapy from precursor B-cell LL. The answers to these questions will only be obtained by conducting clinical trials involving patients from several countries.

Although LL can be effectively treated using ALL protocols, not all such treatment protocols are equally satisfactory. Some years ago, T-cell ALL had a significantly worse prognosis using the protocols then extant, and because LL is predominantly of T-cell immunophenotype, these earlier protocols may be inadequate for LL as well. The St. Jude Study VIII protocol, for example, produced very poor results in LL, with only 10% of patients surviving at 2 years. [359] $LSA_2L_2$ itself has produced long-term EFS rates of only 64% for patients with disseminated disease in the Children's Cancer Group protocol [327] and less than 60% when modified slightly and used by POG.[355] These results would seem to have been improved by the addition of ten administrations of high-dose MTX by the group at Goustave Roussy, [325] which reported an EFS at 5 years of 78% in 84 patients, 79% for stage III patients, and 72% for stage IV patients. Because randomized comparison was not performed, the conclusion that high-dose MTX adds therapeutic efficacy to $LSA_2L_2$ must be considered tentative. Although the BFM 90 protocol was also a single arm study, the EFS rate of 92% at 5 years in 101 evaluable patients and no significant difference between stage III (91%) and stage IV (94%) patients is considerably greater, suggesting that the protocol is truly superior to $LSA_2L_2$. This will become apparent if the results of the next BFM protocol are similar.

BFM 90 consisted of relatively intensive initial therapy lasting 30 weeks that, except for patients with limited-stage disease, included two “induction” regimens separated by four cycles of high-dose MTX. The “late” intensification, in fact a repeat induction cycle, has been shown to be an important component of this protocol when used for the treatment of ALL,[360] and it improves EFS rates even in patients with good-risk ALL.[361] Asparaginase is likely also to be an important component of this regimen, and the POG recently showed that repeated doses of high-dose asparaginase (25,000 IU per $m^2$ intramuscularly weekly for 20 weeks) early in therapy improved the outcome for patients with LL from 64% to 78% continuous complete remission at 4 years.[362] CNS prophylaxis in BFM 90 included intrathecal therapy, high-dose MTX, and radiation therapy. The value of the radiation therapy, as alluded to earlier, is questionable in this context, and its use is being formally examined in the successor study, BFM 96.

Patients with LL who have not relapsed after 30 months from the start of treatment have a very high probability of remaining in complete remission and in fact, no relapses were observed after 12 months from diagnosis in the BFM 90 protocol. [326] With so few relapses, it is perhaps not surprising that prognostic factors could not be identified. Even the rate of response to therapy was not predictive of outcome, although the rate of response was an important prognostic factor in a United Kingdom CCSG study.[363] Differences of this type may related to differences in the patient population or the treatment used, or may arise by chance.

***Chemotherapy of Anaplastic Large Cell Lymphomas***

ALCL is a relatively recently recognized entity, and as such, optimal therapy has yet to be defined. Reasonably good results have been obtained with a variety of regimens, whether treatment strategies have been based on treatment designed for ALL/LL or for B-cell lymphomas. An Italian group, for example, used $LSA_2L_2$ and, in some patients, local irradiation and observed 5-year survival and progression-free survival of 84% and 72%, respectively. [364] Similar results have been obtained by the SFOP using a protocol based on its successful therapy for B-cell lymphomas. In the latter protocol, two cycles of COPADM [cyclophosphamide, vincristine (Oncovin), prednisone, doxorubicin (Adriamycin), MTX] were followed by 5 to 7 months of maintenance therapy. [365] Seventy-eight patients out of 82 (95%) achieved a complete remission and 21 relapsed. Survival and EFS at 3 years were 83% and 66% respectively, with a median follow-up of 49 months. This result, although promising, appears to be poorer than that achieved in patients with LBCL, as has also been reported by the POG, [366] but in the case of the SFOP, at least, the therapy delivered was less intensive than that delivered for B-cell lymphomas. The BFM group has also demonstrated the efficacy, in ALCL, of the type of therapy designed for B-cell lymphomas. Patients with ALCL were enrolled onto successive BFM protocols that specified a slightly modified version of the standard protocol for B-cell lymphomas.[265,324] Survival and EFS probabilities at 9 years were both in excess of 80% and, unlike the French series, there was no significant difference between survival and EFS. Skin and mediastinal involvement appeared to be negative prognostic factors in the first 62 patients, [265] but these factors could not be shown to be significant prognostic factors when more patients were accrued.[324] The BFM results appear to be among the best reported in children to date, and this protocol will be adopted more widely in Europe in the future.

ALCL has also been shown to respond well to the ABVD [doxorubicin (Adriamycin), bleomycin, vinblastine, dacarbazine] regimen, a protocol used widely for the treatment of Hodgkin's disease. In a randomized study conducted in a small number of patients (40), ABVD was compared to MACOP-B [MTX-leucovorin, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), prednisone, bleomycin], a treatment regimen used in adult patients with “diffuse aggressive lymphomas.” Similar results were obtained with both treatment approaches[367]: 90% of patients treated with MACOP-B and 91% of those treated with ABVD achieved a complete response. The probability of relapse-free survival, projected to 32 months, was 94% for patients treated with MACOP-B and 91% for those treated with ABVD. These results must be considered as preliminary because of the small size of each arm of the study.

In summary, there is no doubt that a variety of regimens can be successfully used for the treatment of ALCL, but at the present time therapeutic protocols designed for B-cell lymphomas are the most widely used in children. Stratification for treatment arms has generally been similar to that used in B-cell lymphomas, although patients with bone marrow and CNS disease are uncommon. There is also some evidence that ALK-positive ALCL, which tends to occur more often in children and young adults, has a better treatment outcome than ALK-negative ALCL.[368] The level of soluble CD30 antigen in serum is also correlated negatively with survival, possibly because it binds CD30 ligand, preventing it from interacting with CD30, a receptor that is a member of the tumor necrosis family of receptors involved in the induction of apoptosis.[369]

**Treatment after Partial Response or Relapse**

Partial response, in the absence of clear-cut regrowth of tumor, should be documented by biopsy because of the frequent persistence of abnormalities due to non-viable tumor on imaging studies. Gallium-67 or positron emission scintigraphy may help in determining whether residual abnormalities are composed of viable tumor, but such studies, too, are not specific. True partial response indicates that the tumor is primarily resistant to the chemotherapy regimen being used; it follows that if all elements of the planned regimen have been employed immediately before a partial response is declared, then continuation with the same therapy is unlikely to be successful. The options for further therapy, to a degree, depend on the number of drugs and the doses used up to that point, and on the histologic subcategory of the disease. Because primary regimens have been changing, and many drugs that were originally used in salvage regimens have now been brought into primary therapeutic protocols with resultant higher cure rates, the approach to the management of the small number of patients in whom primary therapy does not result in cure must also change, and it is to be anticipated that the results of therapy in such patients is likely to be very poor.

***B-Cell Lymphomas***

In patients with B-cell lymphomas, partial response has become a more frequent cause of failure than recurrent disease after a period of complete remission. Because relapses, if they do occur, do so (with rare exceptions) 6 to 8 months after the cessation of therapy, it is also likely that the recurrent tumors are chemotherapy resistant, differing perhaps only with respect to the proportion of primarily resistant cells present at the time of commencement of therapy. As such, in the absence of treatment with non–cross-resistant therapy, it is unlikely that a significant response (i.e., more than a transient response) will be achieved. In general, radiotherapy is not helpful in these patients, primarily because it is not a very effective modality (see above) but also because patients usually have disseminated disease at the time of relapse. An approach that has been quite successful in the past, particularly with less intensive primary therapy, is the use of high-dose therapy with stem cell rescue, usually autologous bone marrow transplantation (ABMT). ABMT was developed at the NCI using BACT (bischloroethylnitrosourea, Ara-C, cyclophosphamide, 6-thioguanine), a regimen that had been used to prepare patients with aplastic anemia for allogeneic transplantation. [370] In this first series, 4 of 19 patients were cured after relatively nonintensive cyclophosphamide-containing regimens. BACT was modified by Philip and colleagues by the substitution of etoposide for 6-thioguanine (BEAC) or etoposide and melphalan for 6-thioguanine and cyclophosphamide (BEAM). [371,372] This approach has subsequently been shown to be effective only in patients with documented chemotherapy-sensitive tumors—that is, patients in whom a second regimen produces a good response—and to be of no benefit to patients with primary refractory disease or resistant relapse. [371,372,373 and 374] Consequently, the usual approach is to first treat patients in whom only partial response is achieved or in whom relapse occurs with a drug combination that includes drugs previously not used and selected in the hope that they will be non–cross-resistant. In patients

whose tumors respond well, additional high-dose therapy with stem cell rescue is given. In a recent report, in patients treated between 1979 and 1991, approximately one-third of patients who failed to achieve remission or who relapsed were salvaged by ABMT, although there were no survivors among patients who had primary refractory disease or resistant relapse.[374] As therapy has continued to evolve since this time, treatment failures (a smaller and smaller number) fall more and more into these two categories, whereas the results of salvage therapy, presumably because of the previous intensive therapy, become worse and worse. In addition, the small numbers of patients requiring salvage therapy make studies of the most effective therapy in such patients difficult. This difficulty, however, reflects the success of primary treatment regimens.

The choice of a salvage regimen is not easy. Because platinum compounds are generally not used in primary therapy, either cisplatin- or carboplatin-containing regimens are frequently used. A popular “salvage” regimen for a variety of tumors in recent years, including NHL in adults and children, has been ICE, a combination of ifosfamide, carboplatin, and etoposide,[375,376,377 and 378] although this regimen is unlikely to be effective in patients who have previously received full-dose ifosfamide and etoposide. ICE represents one of the combinations based on etoposide and ifosfamide that have been shown to be active agents in children and adults who have previously been unexposed to these drugs.[379] A number of ICE regimens, differing with respect to the doses of the constituent agents, have been used, some at sufficiently high dosage that stem cell rescue is required (or advisable), in which case, the regimen becomes one of repeated rounds of ICE and stem cell rescue rather than ICE followed by another high-dose regimen and ABMT. ICE has also been used with additional agents, for example, paclitaxel, with promising results,[380] and other platinum-containing regimens have also been used, particularly in adult patients with recurrent lymphoma.[381] The choice of a conditioning regimen for ABMT (if ICE itself is not used) is also difficult. The traditional regimen—high-dose cyclophosphamide with total body irradiation—has evolved into a broad range of regimens,[382] although few comparative studies of the pros and cons of these various protocols have been conducted.

Patients with isolated CNS relapse, including both African and U.S. patients may achieve long-term survival when treated with conventional systemic therapy and intrathecal chemotherapy.[28,218,227,236] Although bone marrow transplantation has sometimes been advocated in such patients, extrapolating from European Bone Marrow Transplant Lymphoma Registry data, which includes predominantly adult patients, the presence of active CNS disease at the time of ABMT was associated with a poor prognosis, although a small number of patients (probably less than 10%) may achieve prolonged disease-free survival. The presence of CNS involvement before ABMT did not adversely affect the outcome, so that CNS involvement at some time before high-dose therapy should not be considered a contraindication to ABMT.

Allogeneic bone marrow transplantation following high dose chemotherapy, with or without total body irradiation, has also been explored in relapsed patients with B-cell NHL, and overall results are quite similar to the ABMT experience, although data is much more limited.[383] The possibility of a graft-versus-tumor effect, based on the generally lower relapse rate with allogeneic rather than autologous transplant, makes this more attractive on theoretical grounds, and considerable effort has been expended in recent years on the identification of alternative sources of stem cells, including the use of haplotype mismatched donors, unrelated donors, cord blood cells, and positively selected stem cells, because of the limited availability of sibling donors and the complications of graft-versus-host disease.[384,385,386 and 387]

### *Lymphoblastic Lymphoma*

Because LL is generally treated with protocols closely modeled on therapy designed for ALL, recurrent disease is also usually managed on principles that have been largely derived from the management of recurrent ALL. As with B-cell lymphomas, partial responders have an extremely poor prognosis, as do patients who relapse on or shortly after the completion of therapy. In the latter case, standard (although intensive) reinduction therapy may be used if the patient has not received such therapy for some time, and such patients have a high chance of achieving remission, although the remission is likely to be of short duration. Alternatively, an intensive protocol using at least some drugs not previously received by the patient (e.g., ICE therapy) may be used. Patients who respond to such salvage therapy would be candidates for allogeneic bone marrow transplantation (if a sibling match is unavailable, a haplotype-mismatched parental graft, cadaveric graft, or autologous transplant may be considered). For patients who relapse off therapy (i.e., more than 6 months after the cessation of chemotherapy), reinduction with a similar regimen to that used before, followed by intensified consolidation and maintenance therapy is more likely to be successful. The role of transplantation in such patients is less clear and depends to a large extent on the duration of complete remission before relapse—the later it is, the better the prognosis. Although many would advocate bone marrow transplantation for patients who relapse “off therapy, too,” the longer the duration of remission before relapse, the more likely is conventional therapy to offer as effective an approach as bone marrow transplantation.[388 and 389]

### *Anaplastic Large Cell Lymphoma*

As noted above, many patients with ALCL who relapse respond well to a variety of salvage therapies. In perhaps the largest series of children with recurrent ALCL,[390] 28 patients received lomustine, vinblastine, and Ara-C, with or without bleomycin, and the remaining 13 patients received a variety of salvage therapies. Eighty-eight percent achieved a complete second remission. Fifteen of these patients underwent bone marrow transplant (autologous in 14); 44% remained disease free and 69% were survived at 3 years. ABMT in second remission appeared to provide no advantage. In 8 of 13 patients treated for a relapse (not necessarily the first relapse), prolonged remission was achieved with weekly vinblastine as the sole therapy (six of these patients had relapsed after ABMT). In other studies, some patients have achieved prolonged remission with *cis*-retinoic acid or *cis*-retinoic acid and interferon-a.[391,392] Thus, patients who relapse with ALCL should not automatically be referred for high-dose therapy with stem cell rescue. In fact, although such therapy has been successful, as demonstrated by the French experience, it is not clearly superior to other treatment approaches for patients with recurrent ALCL. This situation is reminiscent of African BL, in which a high proportion of long-term survivors have relapsed, sometimes on multiple occasions.[28,236] It is unclear why African BL and ALCL should differ with respect to the sensitivity of recurrent disease, and our concepts of the underlying biology or recurrent disease are challenged by these observations. It is also important to note that even patients who have more than one relapse may benefit from chemotherapy, even single-agent chemotherapy such as vincristine, *cis*-retinoic acid, or interferon-a.

## LONG-TERM COMPLICATIONS OF THERAPY

The long-term complications of the treatment of NHL in children have become less of a problem as treatment has been refined. The potentially serious consequences of radiation therapy on growth and development (including psychological development in patients undergoing cranial irradiation or bone marrow transplant[393]), on fertility, and as a potentiating factor in second malignancies have diminished as this modality has diminished in importance in therapeutic strategies.[304] The trend toward shorter therapy durations in the B-cell lymphomas will almost certainly further reduce the likelihood or seriousness of long-term complications relating to drug therapy, such as impaired reproductive function, the adverse effects of anthracyclines on the heart, and the risk of second malignancies. When combined-modality therapy (chemotherapy and radiotherapy) is used, the risk of many of these complications is significantly increased. Late cardiotoxicity relating to anthracyclines, however, has become an important problem as more patient survive long-term. It occurs at much lower cumulative doses than does acute cardiotoxicity—indeed, it has been suggested that there may not be a “safe level” at which no late cardiotoxicity occurs—and may affect as many as 25% of children with cancer treated with an anthracycline.[394]

Reproductive function is normally severely impaired in males, even prepubertal males undergoing chemotherapy, particularly when high doses of alkylating agents or radiation are used (even scatter from cranial irradiation may impair fertility[395,396 and 397]), but a significant fraction of patients retain the ability to reproduce. In women treated before age 20 years who do not receive abdominal irradiation, reproductive function later in life appears to be normal, and regimens based on acute leukemia therapy are relatively benign with regard to reproductive function, even in males,[396] although once again, due attention must be paid to the particular chemotherapy regimens used. In a recent study of reproduction after chemotherapy in young patients treated with regimens for non-LLs in use 10 to 25 years ago, the effect on reproductive function in both males and females appeared to be rather mild,[304] although precise fertility rates are difficult to obtain in small series of patients of varying age. Nonetheless, the available data serve to demonstrate that fertility can be retained (or returns) in a significant fraction of patients.

In contrast to the situation in Hodgkin's disease and the solid tumors of children, second malignancies have not been a significant problem in the majority of studies reporting on this complication in patients with NHLs,[304,398] although it is highly probable that the incidence of second neoplasms will vary with the specific protocol being used. This may be the explanation for a report from the United Kingdom in which a frequency of 8.6% of second malignancies was described. Six of the eight patients who developed a second tumor had received adjuvant radiotherapy.[399] Even secondary leukemias, often associated with 11q23 chromosomal abnormalities, which have been reported to occur relatively soon (usually within 2 years) after the administration of etoposide[400] do not appear to be a problem with modern regimens, presumably because of the dose and schedule of etoposide used.[304]

In all, late effects of treatment appear to be relatively mild in comparison, for example, with those encountered in Hodgkin's disease, and are likely to be fewer than in the past, as surgery and radiation are no longer primary treatment modalities. Nevertheless, the potential for late effects is a major consideration in the design of new

chemotherapy protocols, precisely because the results of modern therapy are so good.

## FUTURE CONSIDERATIONS

The treatment of NHLs in children has improved greatly in the last 15 years. The best reported results indicate that approximately 90% of all patients can be cured when treated optimally. Even the majority of patients in developing countries can be cured, although only in centers in which the cost of the drugs is met and there is reasonable supportive care. This result has largely been achieved by the refinement of chemotherapy protocols. The emphasis for the near future is on further refinement of risk groups such that patients are not over- or undertreated. It should be remembered, however, that overtreatment is deleterious only to the extent that it is toxic (whether acutely or in the long term) such that the risk of toxic side effects must be weighed against the risk of undertreatment, which has the tragic consequence of disease recurrence. Of particular importance is the identification of patients destined to do poorly so that they can receive more intensive or experimental therapies, preferably before disease progression has occurred. Because myelosuppression is the major acute toxicity, which can be associated with life-threatening infection, a number of investigators have explored the role of colony-stimulating factors in reducing these side effects. Although these agents clearly are effective at reducing the duration of neutropenia, there is less clear-cut information as to their value in reducing the risk of febrile neutropenia or overt infection. [323] The use of prophylactic antibiotics should be carefully researched in view of the ever-increasing risk of emerging resistant organisms, but in situations in which the majority of patients requires antibiotics because of fever, the risk of the development of resistant organisms, although real, may not be enhanced by this practice and could well reduce the in-hospital time and risk of septicemia. Indeed, there is considerable evidence from the bone marrow transplantation literature that patients undergoing intensive therapy and experiencing severe neutropenia can be largely treated as outpatients with judicious use of colony-stimulating factors and oral antibiotics.[401,402] Thrombopoietics (or combinations of colony-stimulating factors that influence megakaryocyte differentiation), although just beginning to be examined in the clinical setting,[403] are likely, at best, to lessen the need for platelet transfusions and will probably have little or no impact on toxic death rates. Thus, major progress is likely only to be made by the development of therapy that is more directly targeted to the tumor cell, such that side effects are minimized. Such approaches are presently being extensively studied and are made possible by the ever increasing knowledge of the molecular genetic and resultant biochemical abnormalities that underlie the pathogenesis of lymphoid neoplasms.[404] This information is also likely to be valuable to the improvement of diagnostic techniques and to the identification of prognostic subgroups. Highly specific (i.e., targeted) therapy is likely to be much less toxic and is likely to eventually replace conventional cytotoxic therapy, although the excellent results currently being obtained with the latter make it difficult to depart from accepted practice, and early trials are likely to include a combination of standard and targeted therapy.

Recently, promising results have been obtained with the use of monoclonal antibodies directed against B-cell antigens, particularly CD20, which is not modulated from the surface of tumor cells.[405,406] and [407] Such approaches appear to be much more successful in the more indolent lymphomas, but their use in targeted radiotherapy, including treatment of meningeal infiltration, [408] ombined with standard chemotherapy or radiolabeled in conjunction with stem cell rescue [409] show considerable promise, and such approaches are worthy of further exploration. Monoclonal antibodies may also prove to have an important therapeutic role in posttransplant B-cell lymphomas.[410,411]

A potential therapeutic target in BL worthy of special mention is EBV, because targeting viral proteins gives rise to a high degree of specificity (the few normal cells bearing EBV are likely to be eliminated with impunity). Indeed, if the property of the virus to induce cell lysis when the replication cycle is initiated could be taken advantage of therapeutically, the virus could actually be made to induce cell death. This has been shown to be possible *in vitro*.[412] Another potential target is the modified *myc* gene itself. Some years ago, proof of principle was established by demonstrating that antisense molecules could be directed toward RNA sequences present only in cells with a particular type of 8;14 chromosomal translocation, with resultant cell death. [413]

Doubtless other highly specific tumor targets will be identified in the future, and the potential of relatively nontoxic, highly specific therapy more than justifies the efforts expended on understanding the pathogenesis of the childhood NHLs. It may be some time before cancer will be treated as easily and with no more toxicity than bacterial diseases, but new approaches to the synthesis of drugs directed toward highly specific targets have brought this possibility into the realm of the thinkable. The demonstration, for example, of inhibitory effects of peptides on specific molecular targets *in vitro* can be followed by the development of peptomimetic drugs. Combinatorial chemistry allows modification of a standard chemical scaffold into millions of agents from among which structures with the desired effects can be selected—much of the process being done by computer modeling. Both approaches could lead to inhibition of genes responsible for drug resistance or nullification of the genetic defects that lead to malignancy. These advances make it highly likely that during the course of this century it will become possible to cure close to 100% of children with reduced toxicity—eventually, perhaps, if highly targeted therapy can be developed, with no more toxicity than present-day antibiotics. There remains a long way to go, however, in identifying molecular mechanisms of drug resistance and pathogenesis, and in the development of highly specific agents, although new technology and high-throughput assays are likely to greatly speed up this process. Thus, despite the exciting advances made in the treatment of childhood NHL in recent years, there is considerable room for refinement of therapy and for the introduction of newer, more highly selective approaches to treatment. This will necessitate the continued conduct of carefully designed clinical trials—the strategy that has led to the major advances made with conventional chemotherapeutic approaches.

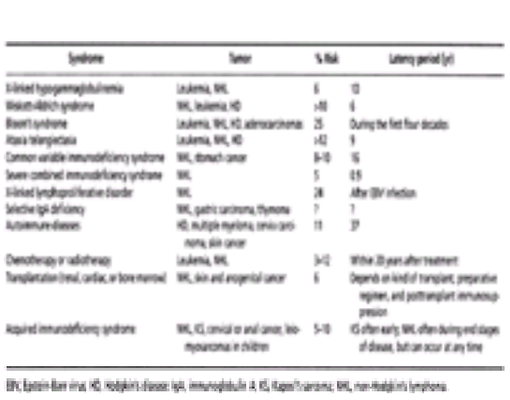
# LYMPHOPROLIFERATIVE DISORDERS AND MALIGNANCIES RELATED TO IMMUNODEFICIENCIES

BRIGITTA U. MUELLER

## INTRODUCTION

The number of children and adults surviving despite a disturbance in their immune system is growing. Due to the success of bone marrow and solid organ transplants, and the improved prevention and treatment of infections, many children with congenital, iatrogenic, or virus-induced immunodeficiencies survive into adolescence or even adulthood. However, a prolonged immunodeficiency that is congenital, acquired, or iatrogenically induced increases the risk for the development of cancers in these children.

Estimates of the cancer incidence in patients with immunodeficiency diseases vary widely. The severity and duration of the immune defect, as well as the concurrent or preexisting infection with certain viruses, especially Epstein-Barr virus (EBV), greatly influences the likelihood of developing a malignant process. An incidence of up to 25% has been reported for patients with Wiskott-Aldrich syndrome (WAS), ataxia telangiectasia (AT), and common variable immunodeficiency (CVID) as well as for patients infected with the human immunodeficiency virus (HIV). A lower incidence has been observed after solid organ or bone marrow transplantation and patients with autoimmune disorders (Table 25-1).[1,2,3,4,5,6,7,8,9,10,11,12 and 13]



| Syndrome | Tumor | % Risk | Latency period (yr) |
|---|---|---|---|
| X-linked hypogammaglobulinemia | Leukemia, NHL | 6 | 10 |
| Wiskott-Aldrich syndrome | NHL, leukemia, HD | >10 | 6 |
| Bloom's syndrome | Leukemia, NHL, HD, adenocarcinoma | 25 | During the first four decades |
| Ataxia telangiectasia | Leukemia, NHL, HD | >32 | 9 |
| Common variable immunodeficiency syndrome | NHL, stomach cancer | 8–10 | 16 |
| Severe combined immunodeficiency syndrome | NHL | 5 | 0.5 |
| X-linked lymphoproliferative disorder | NHL | 24 | After EBV infection |
| Selective IgA deficiency | NHL, gastric carcinoma, thymoma | ? | ? |

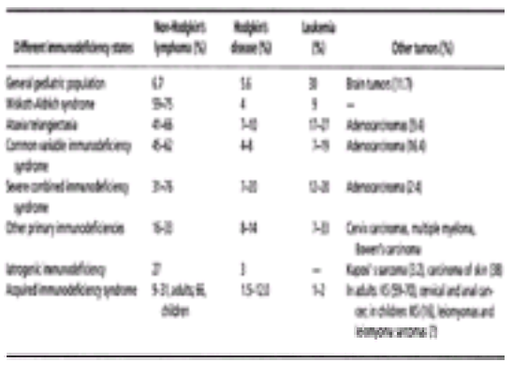
| Chemotherapy or radiotherapy | Leukemia, NHL | 3–12 | Within 20 years after treatment |
| Transplantation (renal, cardiac, or bone marrow) | NHL, skin and anogenital cancer | 6 | Depends on kind of transplant, preparative regimen, and post-transplant immunosuppression |
| Acquired immunodeficiency syndrome | NHL, KS, cervical or anal cancer, leiomyosarcoma in children | 5–10 | KS often early, NHL often during end stages of disease, but can occur at any time |

EBV, Epstein-Barr virus; HD, Hodgkin's disease; IgA, immunoglobulin A; KS, Kaposi's sarcoma; NHL, non-Hodgkin's lymphoma

**TABLE 25-1. INCIDENCE OF MALIGNANCIES IN IMMUNE DEFICIENCY DISORDERS**

Lymphoproliferative disorders (LPDs), or, in the case of transplant patients, posttransplantation lymphoproliferative disorders (PTLDs), predominantly of B-cell origin, are the most common neoplasias in patients with congenital or acquired immunodeficiencies (Table 25-2).[8] They represent a heterogeneous group of diseases that can range from reactive polyclonal hyperplasia, which, in the presence of severe immunosuppression can be fatal, to true monoclonal malignant lymphomas. There is often no clear distinction made between non-Hodgkin's lymphoma (NHL) or Hodgkin's disease (HD), which need to be treated with chemotherapy, and the polyclonal or oligoclonal lymphoid proliferations, which tend to respond to a decrease in immunosuppression. Although this chapter tries to distinguish between the two presentations where deemed appropriate and necessary, they probably represent a spectrum of the disease, and considerable overlap is to be expected.



| Different immunodeficiency states | Non-Hodgkin's lymphoma (%) | Hodgkin's disease (%) | Leukemia (%) | Other tumors (%) |
|---|---|---|---|---|
| General pediatric population | 4.7 | 3.6 | 38 | Brain tumors (11.7) |
| Wiskott-Aldrich syndrome | 59–75 | 4 | 9 | — |
| Ataxia telangiectasia | 41–66 | 1–10 | 11–27 | Adenocarcinoma (3.4) |
| Common variable immunodeficiency syndrome | 8–42 | 4.4 | 1–19 | Adenocarcinoma (16.4) |
| Severe combined immunodeficiency syndrome | 31–78 | 1–10 | 12–28 | Adenocarcinoma (2.4) |
| Other primary immunodeficiencies | 16–33 | 8–14 | 1–13 | Cervix carcinoma, multiple myeloma, Bowen's carcinoma |
| Iatrogenic immunodeficiency | 27 | 3 | — | Kaposi's sarcoma (3.2), carcinoma of skin (38) |
| Acquired immunodeficiency syndrome | 9–31 adults; 66, children | 1.5–12.3 | 1–2 | In adults: KS (59–78), cervical and anal cancer; in children: KS (16), leiomyoma and leiomyosarcomas (7) |

**TABLE 25-2. DISTRIBUTION OF NEOPLASIAS ASSOCIATED WITH DIFFERENT IMMUNODEFICIENCY STATES**

Also clearly increased is the incidence of Kaposi's sarcoma (KS) (especially in HIV disease and after solid organ transplantation), adenocarcinomas (in patients with CVID or AT), and leiomyosarcoma (in children with HIV infection or after solid organ transplants). Furthermore, bone marrow transplant recipients remain at an increased risk for the development of secondary cancers, even after the immunosuppression has been reversed (see Chapter 49).

Several registries and collaborative groups have begun to focus on malignancies in immunocompromised hosts. The immunodeficiency cancer registry collects data

on neoplasms occurring in patients with primary immunodeficiencies.[14] The national and international bone marrow and solid organ transplant registries keep track of the development of cancers in transplanted patients (e.g., Cincinnati Transplant Tumor Registry), and the National Cancer Institute supports the AIDS (acquired immunodeficiency syndrome) Malignancy Consortium and its AIDS malignancy tissue bank.[13,15,16] and [17]

## EPIDEMIOLOGY AND CLINICAL PRESENTATION

### Inherited Immunodeficiency Syndromes

Primary, congenital immunodeficiency disorders include a heterogeneous group of syndromes, which can become clinically manifest as early as at birth, but also not until adulthood. Abnormalities in the humoral immune system are due to a defective development of B cells, whereas disturbances in the maturation of T cells lead to defects in cellular immunity.[18] Morbidity and mortality are mainly due to infections or to a malignancy. [8] Because primary immunodeficiency syndromes are rare, and each treatment center will only diagnose a few cases of associated cancers, an international registry of these cases was established in 1973 supported by the National Cancer Institute.[14]

It has been estimated that patients with inherited immunodeficiencies are almost 10,000 times more likely to develop cancer, especially neoplasia of the lymphoreticular system.[19] Between 1% and 4% of patients with inherited immunodeficiencies develop lymphomas. A recent review of the Immunodeficiency Cancer Registry in Minneapolis, Minnesota, revealed that NHL constituted 50.4% of the reported tumors, followed by leukemia (12.6%), adenocarcinoma (9.2%), and HD (8.6%). Almost 20% of the patients had “other” tumors.[8] A prevalence of NHL over the leukemias (65% versus 8%), a distribution that is markedly different from the general pediatric population, is observed in children with primary immunodeficiencies. [20]

#### *Wiskott-Aldrich Syndrome*

WAS is an X-linked recessive disorder characterized by immunodeficiency, profound thrombocytopenia with small platelets, and eczema. [21] In the past, most of these boys died during the first decade of life from hemorrhage or infection, but recently life expectancy has increased due to better supportive care. [18] Both the humoral and cellular immune system are affected, reflected by low serum immunoglobulin M (IgM) levels, elevated IgA and IgE levels, and a progressive loss of T cells combined with an expansion of the B-cell pool. The gene that is defective in WAS has been identified and maps to Xp11.23. [22] WAS is caused by mutations in an intracellular protein (WASP) that is involved in signal transduction and regulation of the rearrangement of the actin cytoskeleton.

The risk of developing a malignancy approaches 100% by 30 years of age in patients with WAS. [2] Up to 75% of the cancers in WAS are NHL, and 50% of patients have widely disseminated disease at diagnosis.[2] In a multi-institutional survey of 154 pediatric patients with WAS, Sullivan, et al. [1] documented 21 patients (13%) with a malignancy. The average age of onset was 9.5 years, and the majority of the malignancies involved the lymphoreticular system. Burkitt's lymphoma (BL), and lymphoblastic lymphomas are the predominant tumor types, but in contrast to NHL in patients with a normal immune system, these tumors occur more frequently in extranodular sites. HD, mostly of the nodular sclerosing type, is approximately ten times less frequent than NHL. Other malignancies, including myelogenous leukemia, cerebellar astrocytoma, and smooth muscle tumors, have also been described in patients with WAS.

The etiology of the malignancies in WAS remains unclear, but viral stimulation, such as with EBV, and defective intracellular signaling have been postulated. [22,23] Recent data also suggest a pivotal role for WASP in normal hematopoiesis, but it is not yet clear whether a disturbance will increase the risk for the accumulation of potential oncogenic mutations.[24]

#### *X-linked Lymphoproliferative Disorder*

X-linked LPD (XLP) or Duncan's syndrome is characterized by a striking predisposition to fatal EBV infections. [25] A mutation at Xq25 impairs the ability of males to mount an effective immune response to EBV. As of 1995, more than 270 affected males within 80 unrelated families have been reported to the XLP disease registry. [26] Fulminant infectious mononucleosis (IM) with a typical virus-associated hemophagocytic syndrome was seen in 80% of the boys (median age of onset, 5 years). This is a highly fatal disease, with only 5 per 132 (4%) surviving. Eighty-two (30%) of the boys developed an LPD with a median age of onset of 6 years, and only one-third of patients survived this manifestation.[26] A small subgroup of patients develop vasculitis and pulmonary lymphomatoid granulomatosis, which appears to be a T-cell process (see below).[27]

The gene defect responsible for XLP has been cloned. The SH2-domain–containing gene 1A (SH2D1A) encodes a small protein of 128 amino acids containing a single SH2 domain, which is thought to play an important role in signal transduction in activated T cells. [28]

#### *Hyper-Immunoglobulin M and E Syndromes*

X-linked hyper-IgM syndrome is a heterogeneous immunodeficiency disorder characterized by decreased serum IgG and IgA levels, whereas IgM levels are markedly elevated. Clinically, it is manifested by frequent respiratory infections, diarrhea, and liver infections with parasitic and opportunistic organisms. [29] Benign and malignant lymphadenopathy is observed in a substantial subgroup of patients, and several patients have been described who developed tumors of the pancreas, liver, and biliary tree.[8,29,30] The disease is caused by a mutation in the gene encoding the CD40 ligand, an integral transmembrane glycoprotein, which is expressed mainly in CD4-positive cells.[31,32] This protein plays a crucial role in B-cell activation and isotype switching. [33]

The hyper-IgE syndrome, a disease characterized by eczematous skin rash, recurrent staphylococcal abscesses, and purulent otitis media, has also been associated with an increased incidence of lymphoid tumors.[8,34,35] These patients appear to have an underlying dysfunction of the interleukin 12 (IL-12)/interferon-gamma (IFN-g) pathway.[36]

#### *Selective Immunoglobulin A Deficiency*

Unlike most immunodeficiency disorders, selective IgA deficiency is not associated with an increase in lymphoid but rather with an excess of epithelial malignancies.[8,19,37,38] The Immunodeficiency Cancer Registry lists 38 patients with IgA deficiency and cancer, but only six (15.8%) had NHL and three (7.9%) had HD, whereas the predominant tumors were adenocarcinomas, including gastrointestinal carcinomas.[8] This is probably an inaccurate estimate of the true incidence of cancers, as IgA deficiency occurs in approximately 1 in 600 people but is rarely diagnosed. [21]

#### *Severe Combined Immunodeficiency and Common Variable Immunodeficiency*

Severe combined immunodeficiency (SCID) and CVID include a broad range of immunodeficiency diseases affecting both the humoral and cellular systems. NHLs account for 75% of the malignancies in patients with SCID; HD accounts for an additional 10%. [8] Median age at diagnosis for NHL is 1.6 years and 0.3 years for HD, contributing to the high mortality rate in early childhood of this disease.

CVID is the most common immunodeficiency syndrome and has a broad spectrum of clinical manifestations, including late-onset hypogammaglobulinemia, recurrent sinopulmonary infections, and autoimmune disorders. The incidence of cancers has been estimated to be 2.5% in patients with onset of the disease before the age of 16 years, with an increase to 8.5% in patients with later onset. [39] Forty-six percent of the malignancies in CVID are NHL, 7% each are HD and leukemias, and approximately 17% are adenocarcinomas, but a variety of other tumors has also been reported. [10,40,41]

Cartilage-hair hypoplasia, an autosomal-recessive metaphyseal chondrodysplasia, is one of the most common immunodeficiency syndromes in Finland, occurring in 1 in 23,000 live births.[42] Patients not only exhibit lymphopenia and decreased *in vitro* lymphocyte reactivity, but have recently also been found to have an increased incidence of cancers, mainly of the NHL type, and of basal cell carcinomas. [43]

#### *Chediak-Higashi Syndrome*

Chediak-Higashi syndrome is a functional disorder of granulocytes, with autosomal recessive inheritance. [21] It is the only primary phagocyte defect that has been associated with an increased risk for the development of neoplasms. Partial oculocutaneous albinism, photophobia, and increased susceptibility to pyogenic infections characterize the disorder. Laboratory evaluations show abnormally large lysosomal inclusions in monocytes, neutrophils, and lymphocytes, as well as impaired chemotaxis and bactericidal activity and abnormal natural killer cell function. [44] The majority of patients enters an accelerated and usually fatal phase during the first decade of life manifested by pancytopenia, fever, jaundice, hepatosplenomegaly, lymphadenopathy, and neurologic changes. Histologically, a diffuse mononuclear cell infiltration, reminiscent of a virus-associated hemophagocytic syndrome, is observed. [8]

### *Bloom's Syndrome*

Bloom's syndrome is an autosomal-recessive disorder characterized by short stature, pigmentary changes (e.g., café-au-lait spots), immunodeficiency leading to repeated infections during infancy and childhood, chronic lung disease, and a strong predisposition to cancer. Chromosomal instability, typically with an elevated level of sister chromatid exchanges, is seen on cytogenetic examinations. Bloom's syndrome (similar to Fanconi's anemia) is a clastogenic disorder.

As of 1996, 100 cases of cancer occurring in 71 of 168 patients followed through the Bloom's Syndrome Registry had been observed. [45] The predominant neoplasms are skin cancers (with unusual locations) and leukemias, but a variety of other malignancies are also observed. [46] The age of onset for carcinomas is exceptionally early.

### *Ataxia Telangiectasia*

AT, inherited as an autosomal-recessive disorder with an incidence of approximately 1 in 300,000, presents in early childhood with progressive cerebellar ataxia, oculocutaneous telangiectasia, radiosensitivity, and immunodeficiency, with defects in both cellular and humoral immunity. [47] Patients with AT represent approximately 30% of all cases of cancers reported to the Immunodeficiency Cancer Registry. [8] A review of 263 patients noted a 252-fold excess of lymphomas in white patients with AT, whereas black patients had a 750-fold higher incidence than the normal population. [3]

An estimated 12% to 40% of patients with AT develop a malignancy.[4,48] Children with AT have a predisposition to B-cell malignancies, whereas T-cell malignancies are prominent in adults.[5,6] Overall, there is a predominance of T-cell malignancies over B-cell lymphomas (6:1), which is different from the general population. [5] HD tends to occur in a younger age group (mean age, 7.8 years versus 11.5 years), and a large proportion of patients have HD of the mixed cellularity (42%) or lymphocyte depleted type (33%), whereas the nodular-sclerosing type is most commonly seen in the general pediatric population. [49,50] However, 31 solid tumors (e.g., brain tumors, gastric carcinomas, ovarian, and uterine tumors) were noted among 119 patients with AT and a malignancy. [4] Heterozygotes (approximately 3% of the population) may also be at increased risk for cancer, as demonstrated in patients with breast cancer. [51]

At least four complementation groups have been identified, and all map to the ATM gene on chromosome 11q22-q23. [52] AT cells are abnormally sensitive to killing by ionizing radiation, and abnormally resistant to inhibition of DNA synthesis by ionizing radiation. Recent evidence suggests the presence of a tumor-suppressor gene localized in 11q22-q23, important at least for the development of B-cell chronic lymphocytic leukemia. [53] Furthermore, the 11q22-q23 deletions appear to define a subset of B-cell chronic lymphocytic leukemia characterized by extensive lymph node involvement, rapid disease progression, and poor survival. [54]

## Iatrogenic Immunodeficiency States

### *Transplant Patients*

In 1997, the Cincinnati Transplant Tumor Registry contained data on 512 pediatric patients who developed 527 tumors, and 9,639 adults who developed 10,286 neoplasms after solid organ transplantation. [55] The most common tumor (52%) in pediatric transplant recipients was PTLDs, and these were relatively more common in nonrenal transplant patients compared to renal patients (81% to 31%). [55]

Skin cancer, an extremely rare occurrence in the general pediatric population, comprised 19% of all tumors (31% in renal versus 6% in nonrenal patients), but the majority presented 10 years after transplant, beyond the pediatric age group. [55] Other tumors included sarcomas (with a preponderance of leiomyosarcomas and KSs), carcinomas of the vulva, cervix and perineum, and liver or thyroid. A minority of patients developed the more “typical” malignancies of childhood, leukemias or brain tumors (the latter only in bone marrow transplant patients). The majority of tumors became manifest during childhood (before 18 years of age), and 40% were diagnosed in former pediatric transplant recipients when they were between 19 and 40 years old. [55]

Although it is clear that EBV infection plays a major role in transplant-associated LPDs (see following sections), these patients also experience an excessive number of EBV-negative NHLs.[56,57] These EBV-negative tumors tend to occur mainly in adults, and there is no correlation with the time elapsed since transplant, although they are more common a year or more after transplant.[56,57 and 58]

### Renal Transplants

Posttransplant LPDs develop in approximately 1% of renal allograft recipients and are usually manifested during the first few years after transplant, involving the allograft in up to 18%.[13,55,59,60] In a group of 81 children followed at Children's Hospital of Pittsburgh, 19 (23%) developed symptomatic EBV infection. [61] Of these, seven had IM, ten developed a PTLD, and two a malignant NHL. Transplantation of a kidney from an EBV-positive donor into an EBV-negative recipient correlated with a very high probability for seroconversion and for the development of a PTLD or malignancy ( $p$ <.001).[61] Although some studies have indicated no association with the immunosuppression regimen,[62] others have found an increased risk for the development of malignancies in patients who received tacrolimus posttransplant.[61,63]

### Cardiac and Pulmonary Transplants

Almost 4% of heart transplant patients develop a malignancy during their first year after transplant (32% lymphoid, 34% skin, and 27% other). More than 8% developed a malignancy within the first 4 years, mainly nonlymphoid tumors (12% lymphatic, 54% skin, 30% other). [16] In fact, the nonlymphoid tumors represent the second most common cause of death 4 and 5 years posttransplant (18.6%), whereas lymphoid malignancies (NHL and PTLD) account for only 3% to 4% of the deaths 1 year or later after transplant.[16] Pediatric heart transplant patients have a lower risk of malignancies (1.4% after 1 year and 2.0% after 3 years of follow-up). [15,56]

A similar distribution is also observed after lung transplants, although the overall incidence of malignancies is lower (4.8% within the first year and 4.3% within 4 years of transplantation). Lymphoid malignancies predominate during the first year (56%), whereas skin cancers become the most common neoplasm (56%) 4 years after lung transplantation.[16] Children had a slightly higher incidence of malignancies within the first year (7.6%) but a similar rate after 3 years of follow-up (2.1%). [15]

The clinical presentation of tumors after cardiac or lung transplants depends on the localization of the tumor and can be associated with lymphadenopathy and splenomegaly, gastrointestinal symptoms (sometimes even perforation of gut), nasopharyngeal obstruction, respiratory distress with pulmonary infiltrates, fever of unknown origin, anemia or neutropenia, skin lesions, or neurologic symptoms. [64,65]

### Gastrointestinal Transplants

The most common malignancy after gastrointestinal transplants is PTLD, followed by nonmelanoma skin cancers. [66] In 1999, the Intestinal Transplant Registry listed an 8% incidence of LPDs in patients after intestinal transplantation, and a 14% and 15% incidence, respectively, after liver and intestine or multivisceral transplant. NHLs were the cause of death in 14% of patients. [17] Among children undergoing intestinal transplantation, the incidence for PTLD is between 8% and 20%. [67,68 and 69] The main locations for PTLDs are the allograft (liver), abdominal or peripheral lymph nodes, and the lungs. [67,68,70] An increase in gammaglobulin levels and the appearance of mono- or oligoclonal Ig production or hypoalbuminemia have been recognized as early warning symptoms. [68,70]

### Bone Marrow Transplants

In addition to immunosuppression, a number of factors contribute to the risk of malignancy after bone marrow transplantation. Among almost 20,000 bone marrow transplant recipients, a marked increase in risk was related to age at the time of transplant. Children younger than the age of 10 years had a 36.6 times higher risk, whereas adolescents and young adults between 10 and 29 years old had a 4.6 times higher risk, with a close to expected risk in patients transplanted at older than 30 years of age.[71] The same investigators evaluated the risk for PTLDs after bone marrow transplantation and documented 78 cases among 18,014 patients (0.4%). [71] The majority occurred during the first year after transplant; in fact, the highest incidence was seen during the first 5 months (120 cases per 10,000 patients). [71]

Whereas PTLDs are much more common in patients after allotransplantation, solid tumors occur both after allogeneic and autologous transplants. [72] Total body irradiation clearly plays an important role, but at least one study also found a correlation with the use of antithymocyte globulin and the risk of malignancy. [73,74] Not surprisingly, patients with Fanconi anemia have the highest incidence of malignant tumors after transplant. [72] Patients with aplastic anemia have been shown to have a comparable risk for secondary cancers with immunosuppression alone [relative risk (RR) = 5.15] and bone marrow transplant (RR = 6.67) compared with a normal population; however, the cumulative risk after 10 years was markedly higher after immunosuppression alone (18.8% versus 3.1%). [75]

Twenty-five solid tumors and 20 cases of PTLDs were documented among 3,182 children who received an allogeneic bone marrow transplant. [76] Risk factors for PTLDs included chronic graft-versus-host disease (GVHD) (RR = 6.5), unrelated or HLA-mismatched donor (RR = 7.5), T-cell depleted graft (RR = 4.8), and antithymocyte globulin therapy (RR = 3.1).[76] The PTLDs occurred a median time of 1.5 years after transplantation, and all patients with PTLDs died. Solid tumors occurred most frequently in patients who had received high-dose total body irradiation (RR = 3.1) and in children transplanted at a younger age (RR = 3.7). The median time from transplantation was markedly longer (6 years; range, 0.3 to 14.0 years), and the predominant tumors were brain and thyroid cancers. [76] The excess of these tumors is probably at least in part a consequence of irradiation (see Chapter 13), but the four cases of melanoma and three cases of squamous cell carcinoma of the tongue may have been due to the immunosuppression.

#### *Chemotherapy-Induced Immunosuppression*

Second malignancies due to certain chemotherapeutic agents and radiation are discussed in Chapter 49 and are thought to be the result of DNA damage or the acquisition of mutations. The relationship between the chemotherapy-induced immunosuppression and de novo malignancies has been less well studied, although it is well known that chemotherapy leads to a prolonged state of lymphopenia, especially affecting the T-cell numbers. [77] Malignancies (especially NHL) have been described to occur at a higher incidence in patients treated with either cyclophosphamide or azathioprine for rheumatoid arthritis. [78,79,80 and 81]

### Autoimmune Disorders

Autoimmune disorders have been associated with an increased incidence of malignancies, but it is not entirely clear whether this is due to the underlying disease or the treatment for it (e.g., immunosuppressive chemotherapy). Patients with lupus erythematosus have been described to develop lymphoid malignancies (e.g., Castleman's disease and reticulum-cell sarcoma), and women have a slightly increased risk to develop carcinomas of the cervix, lung, and breast. [82,83 and 84] Patients with systemic sclerosis had an increased risk for lung cancer [standardized incidence ratio (SIR), 4.9], nonmelanoma skin cancer (SIR, 4.2), and primary liver cancer (SIR, 3.3).[85] The incidence of hematologic cancers, especially NHL, is elevated in adult patients with Sjögren's syndrome. [86] Rearrangements of both the heavy chain and light chain Ig genes were found in the salivary glands of these patients. [87]

### Acquired, Virally Induced Immunodeficiencies

#### *Human Immunodeficiency Virus Type 1*

The Joint United Nations Programme on AIDS (UNAIDS) estimates that more than 5.4 million new infections with HIV-1 occur every year (including 620,000 children), and that currently 1.4 million children younger than the age of 15 years and 34.7 million adults are living with HIV/AIDS (UNAIDS; http://www.unaids.org/). As of June 2000, more than 8,800 children younger than 13 years had been diagnosed with AIDS in the United States. [88]

Each year, approximately 130 cases of cancer are diagnosed per million non–HIV-infected children (0.013%). The classification of pediatric AIDS includes (as in adults) primary brain lymphomas, small noncleaved cell (BL) NHLs, immunoblastic or large cell lymphoma of B-cell or unknown immunologic phenotype, as well as KS, as AIDS-defining events (category C), whereas leiomyosarcomas are included in category B as a sign of a moderately symptomatic stage. [89]

AIDS-defining malignancies have been reported to the Centers for Disease Control and Prevention in approximately 2% of all HIV-infected children, compared to 10% to 15% of adults. The cumulative statistics in children list BL and immunoblastic NHL in approximately one-third of cases each, followed by primary lymphoma of the central nervous system (CNS) (19%) and KS (17%).[90] However, because only the initial AIDS-defining event is reported, this probably represents an underestimate of cases of cancer in children with more advanced disease. A survey conducted by the Children's Cancer Group and the National Cancer Institute identified 57 HIV-infected children diagnosed with cancers between July 1982 and January 1997. Twenty-five (44%) of these children would not have been captured through the current Centers for Disease Control and Prevention classification system. [91] In a study of men with, or at risk for, HIV infection conducted in southern Europe, a total of 19,609 person-years of observation among HIV-positive men were compared with 7,957 person-years among HIV-negative men. A statistically significant increase for HD (SIR = 8.7) and liver cancer (SIR = 11) was observed in the HIV-positive cohort. [92] Neither disease is currently included in the list of AIDS-defining malignancies.

The incidence of HIV-associated tumors appears to be different in developing countries. An increasing number of KSs have been reported to occur in both children and adults in Africa, whereas the number is decreasing in the United States and Europe, most likely due to the introduction of highly active antiretroviral therapy, including protease inhibitors. [12,93,94,95,96 and 97] Furthermore, a trend to an increase in retinoblastomas, nasopharyngeal carcinomas, and rhabdomyosarcomas, pediatric tumors not commonly associated with immune deficiency states, has been described.[93,94] Seventy-six consecutive newly diagnosed malignancies were evaluated for HIV infection in a study from Zimbabwe.[98] Twenty-seven of 64 children were HIV seropositive (seroprevalence = 42.2%), and the most common malignancies were NHL (22.4%), acute lymphoblastic leukemia (19.7%), Wilms' tumor (19.7%), and KS (15.8%). Nine of 17 patients with NHL and all 12 patients with KS were HIV positive.

### Kaposi's Sarcoma

In the United States, KS is most prevalent in homosexual or bisexual HIV-infected men (95% of adult KS cases) and is rare in men or women infected through heterosexual contacts, intravenous drug use, or transfusions.[99] It has been estimated that the risk for developing KS is 13,000 times higher for an HIV-infected person.[11,12,100,101] The proportion of patients with KS as an AIDS-defining diagnosis has decreased in the United States and Europe from more than 30% of newly diagnosed AIDS cases in the early 1980s to less than 5% in the late 1990s since the advent of highly active antiretroviral therapy. [90] However, a continued increase in the incidence of KS is observed in both sexes in Africa, and KS is now the second most common tumor in African women.[95]

KS is the AIDS-defining illness in less than 1% of children younger than 13 years of age in the United States, and only 3% of adolescents between 13 and 19 years of age, but the incidence increases to 9% in young adults between 20 and 24 years of age, and to 13% in adults older than 25 years of age. [90,102] However, a significant increase in the incidence of KS has been reported to occur in children from African countries. [93,94,103] In Zambia, KS comprised 6% of all childhood cancer cases before 1986 and increased to 19.3% between 1987 and 1992. Furthermore, the male to female ratio has changed from 3:1 before the AIDS epidemic to approximately 1.7:1.0.[94] In another study from Zimbabwe, KS comprised 10.3% of all childhood tumors.[95]

The age of onset of KS in childhood is variable. The median time of onset in vertically infected children is 33 months (range, 2 to 98 months), with a peak incidence in young children (mean, 5.6 years; range, 7 months to 14 years).[93,94] In contrast to adults, KS is rarely the first presentation of HIV disease in children, but follows symptoms of failure to thrive, recurrent infections, and hepatosplenomegaly. [93]

### Non-Hodgkin's Lymphoma and Hodgkin's Disease

The relative risk of developing NHL has been estimated to be 200 to 300 times higher in HIV-infected patients. [104] In a study of 1,255 patients (906 males and 349 females) followed by the HIV Italian Seroconversion Study Group, a 157-fold increase in NHL was observed. [105] The absolute risk for brain NHL is even higher, and has been estimated to be 3,600-fold (incidence of 0.5% to 1.0%). [106] Only approximately 1% of children with AIDS younger than the age of 4 years will ever have NHL, but this number increases steadily with age, and almost 6% of AIDS patients older than 60 years will develop an NHL.

In one study of HIV-infected homosexual men, an excess incidence of 19.3 cases of HD per 100,000 person-years was documented. [107] A similar result was published by Lyter et al.[108] in patients followed as part of the national Multicenter AIDS Cohort Study. The ratio of NHL to HD appears to be influenced by the route of acquisition of HIV disease, with a ratio of 2:1 for intravenous drug users and a ratio of 12.4:1.0 in homosexual men. [107,109,110] HD is relatively rare in children younger than the age of 15 years, although several cases have been described in young HIV-infected children. [91,110,111 and 112]

### Smooth Muscle Tumors

Smooth muscle tumors (leiomyomas and leiomyosarcomas) are more common in HIV-infected children compared to adults.[91,112,113,114,115,116,117 and 118] These tumors are rare in otherwise healthy children, accounting for less than 2% of all childhood cancers, and are much less common than other soft tissue tumors (e.g., rhabdomyosarcomas). The annual incidence is estimated to be eight cases per million children. However, an increased number of leiomyomas and leiomyosarcomas has been described in HIV-infected children, [91,113,114 and 115,119,120] and this tumor is now included as a category B symptom in the revised 1994 classification of pediatric HIV disease.[89] In our survey of the cases reported to the Children's Cancer Study group and the National Cancer Institute, 17% of all reported tumors (eight) were either leiomyomas or leiomyosarcomas, and we are aware of at least 20 cases that have occurred in HIV-infected children in the United States. [91,114] To date, no similar increase in incidence has been observed in adults, but several case reports of smooth muscle tumors occurring in unusual locations (e.g., brain, spleen, and lungs) have been reported. [120,121]

### Cervical and Anal Neoplasms

An increased incidence of cervical pathologies has been noted in HIV-infected women, and the revised classification for HIV-infected adults from 1993 includes cervical dysplasia (moderate or severe) as well as cervical carcinoma *in situ* as an AIDS-defining diagnosis in HIV-infected women and adolescents.[122,123,124,125,126,127 and 128] The prevalence of cervical dysplasia has increased in all adolescents, and human papillomavirus (HPV) infection is found in 15% to 38% of sexually active adolescents and in up to 77% of HIV-infected teenagers. [129,130] In one study, more than 30% of 133 HIV-infected girls (age 13 to 18 years) had squamous intraepithelial lesions, three times more than in an HIV-negative control group. [130] An invasive cervical carcinoma has been described in a 16-year-old girl with HIV infection.[125] At the same time, the incidence of anal cancers appears to be increased in homosexual males with HIV infection. [131,132]

### Other Tumors

Although not part of the AIDS definition, it is notable that other tumors occur with an increased frequency as well. Studies from Zimbabwe and Uganda not only reported a marked increase in the incidence of KS and NHL but also of squamous cell tumors of the conjunctiva. [95,96] Whether this is a true manifestation of the AIDS epidemic or a phenomenon associated with better surveillance and reporting remains to be determined.

#### *Human Immunodeficiency Virus Type 2*

HIV-2 is only superficially related to HIV-1 and is most prevalent in West and Southern Africa, with a seroprevalence in the population of up to 8%. [133,134,135,136 and 137] Modes of transmission are the same as for HIV-1, but the onset and progression of immunodeficiency and associated diseases is markedly slower. Although patients often are co-infected with human herpesvirus 8 (see section on Human Herpesvirus 8 or Kaposi's Sarcoma–Associated Herpesvirus), development of KS occurs at a lower frequency than in HIV-1 infected patients.[138] However, women are still at an increased risk to develop cervical neoplasia. [139]

#### *Human T-Cell Lymphotropic Virus Type I*

Infection with human T-cell lymphotropic virus type I (HTLV-I) is endemic in the Caribbean, Central and South America, certain areas of Africa, and Japan. [140] The virus is transmitted sexually, from mother to child, through transfusion of infected blood products, and by sharing used needles. [140,141 and 142] More than 98% of all infected persons remain asymptomatic, but HTLV-I myelopathy or adult T-cell leukemia can develop in a minority of patients. [140,141] Adult T-cell leukemia usually occurs after 20 to 30 years of infection, and it is therefore not surprising that only a few case reports in children and adolescents have been published. [143,144]

## PATHOGENESIS

The understanding of the pathogenesis of tumors in immunocompromised patients is still evolving. A single event rarely leads to the emergence of a malignancy, but when a degradation of host defense mechanisms permits infection with ubiquitous viruses, the potential for malignancy increases. Indeed, insights gained in studying immunodeficiency disorders has provided an appreciation of the immune surveillance system and may lead to new therapeutic approaches.

### Genomic Instability

Chromosomal translocations occur in the majority of NHLs and in many leukemias. This is probably a product of the genetic variability of lymphocytes to create and maintain antigen receptor diversity.[145] Patients with AT have an increased susceptibility to chromosome translocations, but only a subgroup of these result in the activation of an oncogene.[48,146,147] Cells from patients with Bloom's syndrome show a chromosomal instability that leads to a number of spontaneous chromosomal abnormalities.[45,145] Almost 100% of mice with both the *Scid* and p53-null mutation (*Scid* p53–/–) develop disseminated lymphomas, and they have been found to have a chromosomal translocation involving the IgH locus near the telomere of chromosome 12.[148,149] The loss of p53 control allows unrestricted growth of this abnormal clone. The continued stimulation by certain viruses (e.g., HIV and EBV) increases the stochastic possibility that such an event will occur.

The etiology of malignancies in WAS remains unclear, but viral stimulation (e.g., EBV) and defective intracellular signaling have been postulated. [22,23] Recent data also suggest a pivotal role for WASP in normal hematopoiesis, but it is not yet clear whether a disturbance increases the risk for the accumulation of potential oncogenic mutations.[24] Patients with XLP mount an uncontrolled polyclonal proliferation of T and B cells after exposure to EBV. It is currently thought that a defect in cytotoxic T cells leads to uncontrolled B-cell proliferation. [150,151]

### Immunosuppression and Iatrogenic Factors

One major risk factor for the development of a malignancy is clearly the degree of immunosuppression. In a review of 89 pediatric liver transplant recipients who received tacrolimus for immunosuppression, there was a 20% incidence of PTLDs, compared to 3% in a historical control group who received cyclosporin. [68] Among 298 children undergoing liver transplantation, the incidence for PTLD was 8.4%. [67] The risk of developing a PTLD went up to 28% when both OKT3 and tacrolimus were used simultaneously. In this series, children who developed a PTLD had a mortality rate of 60%. [67] Bone marrow transplant recipients who received an HLA-mismatched or T-cell–depleted allograft, or patients who were treated with antithymocyte globulin or anti-CD3 antibody for prophylaxis of GVHD, are at highest risk for the development of PTLD.[71] Late-onset PTLD, on the other hand, is most closely related to continued immunosuppression for the treatment of chronic GVHD. In summary, commonly recognized risk factors for the development of a PTLD include donor-recipient mismatch or severe GVHD (both necessitating more aggressive immunosuppression), T-cell depletion of donor marrow, or the use of anti–T-cell monoclonal antibodies or high-dose antithymocyte globulin for GVHD prophylaxis.

The risk for an HIV-infected patient to develop a cancer increases with the progressive weakening of the immune system. [152] However, the CD4 count alone is not an absolute determinant for a child's risk to develop a tumor, because HIV-infected children can develop a malignancy when their CD4 count is only moderately depressed. The duration of immunosuppression might play a role, and if so, this could have an important impact on the number of HIV-associated malignancies in the

future as children live longer with HIV infection.

It is currently recommended that all pregnant HIV-positive women receive zidovudine during pregnancy and birth, and that their infants be treated for the first 6 weeks of life to decrease the risk for transmission of HIV infection.[153] Zidovudine given during gestation is incorporated into the DNA of newborn mice and monkeys, as well as into the nuclear DNA of cord blood samples drawn from children whose mothers had been treated with the drug. An increased risk to develop liver and lung tumors, as well as tumors of the reproductive organs, has been observed in the offspring of mice that were treated with zidovudine during the last trimester.[154,155] However, to date there is no indication that children exposed to zidovudine *in utero* are at an increased risk to develop a malignancy, and the benefit of perinatal treatment with zidovudine currently outweighs the risk. Continued vigilance and follow-up observation of all children exposed *in utero* or postnatally to zidovudine is clearly necessary.

## Infection with Viruses

Virus-induced cancers account for approximately 15% to 20% of all cancers worldwide.[156] Although infection with viruses is usually well tolerated and associated with self-limited disease in otherwise healthy hosts, it can have devastating effects in the immunocompromised patient, by triggering an uncontrolled lymphoproliferative process, or, as in the case of HIV and HTLV-1 infection, by inducing an immunocompromised state.

### *Epstein-Barr Virus*

EBV is a ubiquitous human herpesvirus that primarily results in asymptomatic infections or IM during childhood and adolescence. Infected individuals become life-long carriers of the latent form of the virus. EBV has the capability to infect epithelial cells, documented by positive cultures from patients with IM, undifferentiated nasopharyngeal carcinoma, and patients with hairy leukoplakia, an AIDS-associated epithelial lesion of the oropharynx.[157,158] However, chronically infected B lymphocytes are the main reservoir, and the magnitude of this reservoir is closely related to the degree of immunodeficiency, or, more specifically, the capability of memory T cells to mount an EBV-specific cytotoxic T-cell response.[159]

EBV is capable of transforming normal B lymphocytes into continuously proliferating cell lines *in vitro*. Such cell lines produce little or no virus because virus replication results in cell death, and the viral information persists as circular DNA episomes located in the cell nucleus. Latently infected lymphocytes express at least nine viral proteins, including six EBV nuclear antigens (i.e., EBNA-1, -2, -3a, -3b, -3c, and leader protein) and three latent membrane proteins (i.e., LMP-1, -2a, and -2b), as well as two small nonpolyadenylated EBV-encoded RNAs (i.e., EBER-1 and -2). LMP-1 has potent transforming effects both in cell cultures as well as in animal models and plays an essential role in the transformation of B cells.[160,161] Both EBNA-2 and EBNA-3c (and probably also EBNA-3a) activate LMP-1 and therefore have oncogenic potential.[156,162,163] LMP-1, in turn, enhances bcl-2 expression (an anti-apoptosis gene) and activates natural killer NK-kB and c-jun, protecting EBV-infected cells from cell death.[164,165]

By providing the targets for immune recognition by EBV-specific T cells, the EBV-latent genes ensure that transformed cells will be destroyed by the normal immune system. Although nuclear antigens, they are processed by the cell and expressed at the cell surface in the context of HLA class I molecules. Immunodeficient individuals are unable to mount an immune response against EBV epitopes, and EBV-transformed cells, which, although cytogenetically normal, are able to undergo indefinite, unrestricted proliferation, which can be life-threatening.

The role of an unbalanced cytokine response due to the uncontrolled B-cell proliferation is also being explored. Serum levels of IL-4, an inflammatory marker, are elevated in patients with PTLD as well as in healthy but immunosuppressed transplant recipients, compared with normal controls, whereas levels of IFN-a were significantly depressed.[166] Furthermore, tissues of patients with PTLD express significantly lower levels of IL-18 and IFN-g compared to tissue obtained from patients with primary IM.[167] The monokine induced by IFN-g (Mig) and the IFN-g–inducible protein-10 (IP-10) are also expressed at higher levels in tissue from patients with EBV-induced LPDs.[168]

EBV infection is associated with various forms of human lymphoid malignancies, including the sporadic and endemic forms of BL, LPDs in congenital and acquired immunodeficiency states, and posttransplant lymphomas.[169] EBV also plays a role in the development of smooth muscle tumors (i.e., leiomyomas and leiomyosarcomas) in immunocompromised hosts, and has been implicated in the pathogenesis of certain gastric carcinomas, and is recognized as the etiologic agent for the development of nasopharyngeal carcinoma.[115,170,171,172 and 173]

As shown by Purtilo in patients with XLP, primary EBV infection (e.g., IM) can become a fatal disease in patients with congenitally abnormal T-cell function.[174] Most lymphoid tumors are of B-cell phenotype, but both polyclonal and monoclonal lymphomas (of B- or T-cell phenotype) can be found, possibly representing a progression in development.

Several studies have shown that rising EBV titers in the posttransplant period can help with early identification of patients at risk for the development of PTLDs, and it has become standard of care to follow EBV titers, either by serology or by polymerase chain reaction (PCR.)[175] Furthermore, there appears to be a difference between primary EBV infection and reactivation. In a group of 50 children followed before and after heart transplant, 13 developed a PTLD, but 12 of them had evidence for primary EBV infection.[65] A similar observation has been made in pediatric liver and kidney transplant patients.[61,176] This could be the reason for the higher incidence of PTLD in children compared to adults.

In a study of 35 biopsy specimens obtained from patients with progressive generalized lymphadenopathy and HIV infection using PCR and sentence hybridization a positive correlation was seen between EBV positivity (35%) and the development of EBV-positive NHLs at another site, or the subsequent development of a lymphoma.[177] None of the patients whose biopsies were negative for EBV went on to develop a lymphoma. EBV has also been found in some patients with multicystic thymic tumors, and EBV DNA has been associated with at least 80% of lesions found in lymphocytic interstitial pneumonitis (LIP), usually in the absence of other pathogens.[178] Approximately 40% of the systemic and close to 100% of the CNS NHLs associated with HIV disease contain EBV sequences.[178,179 and 180] A third of AIDS-associated BLs show evidence for EBV infection, whereas more than 80% of AIDS-associated large cell NHLs are EBV positive.[181,182,183 and 184]

Although not true in immune-competent individuals, leiomyosarcomas from patients posttransplant as well as from HIV-infected children have been shown to be positive for EBV by *in situ* hybridization.[115,185] Quantitative PCR showed relatively high levels of EBV in tumor tissue (as many as 4.3 genome copies per cell), and discrete episomal EBV clones were present in lesions taken from different sites in the same patient, indicating simultaneous emergence of separate clones.[115] Higher numbers of EBV receptors are found on tumor cells from HIV-infected individuals compared to cells from HIV-negative patients. Jenson et al.[186] were able to demonstrate monoclonal EBV infection and replication in smooth muscle cells obtained from an HIV-infected patient with leiomyosarcoma.

### *Human Immunodeficiency Virus*

HIV-1 and HIV-2 are RNA retroviruses and belong to the family of lentiviruses. They preferentially infect macrophages, monocytes, and lymphocytes, by binding to at least two distinct chemokine receptor sites, CCR5 and CXCR4.[187,188] Infection with HIV results in both a latent and lytic infection, associated with a decline in lymphocyte numbers, especially the $CD4^+$ cells.

HIV does not appear to be directly involved in the malignant transformation of B lymphocytes, and there is a lack of integrated HIV genomic sequences into most hyperplastic lymphoid tissues or NHL. The results of PCR analysis of AIDS lymphoma tissue are consistent with the presence of HIV in infiltrating T cells within these tissues as opposed to actual HIV infection of the B-lymphoma cells.[189] However, a few cases of large cell lymphomas have been described, in which HIV integration was found upstream to the oncogene *FES/FPS*.[190] These tumors had an extremely high expression of the HIV p24 antigen.

Infection with HIV leads to the release of a number of cytokines, some of which may increase the replication of HIV, whereas others may be responsible for producing a state of B-cell growth (and hyperproliferation), activation, and differentiation.[191] HIV may, however, participate indirectly in the development of lymphomatous disease in several different ways, including the release of cytokines. Among others, several ILs (i.e., IL-1, IL-2, IL-6, IL-7, and IL-10), as well as IFN-g and tumor necrosis factor, are stimuli responsible for the proliferation and differentiation of B cells, which ultimately increase the likelihood of genetic mutations resulting in neoplasia.[192,193,194,195 and 196] For example, IL-6 has been classified as a differentiating factor for B lymphocytes, and has been shown to function as an autocrine growth factor in tumor cell lines derived from non-HIV and non-EBV–related malignant lymphomas, acting, together with IL-10, as an autocrine growth factor for

AIDS-associated primary effusion lymphomas.[197]

The HIV Tat gene is a potent transactivator of viral and cellular genes, including the gene for IL-6 and IL-10. Transgenic mice that express the Tat gene develop splenomegaly, often containing malignant B-cell clones.[198] In these mice, the messenger RNAs encoding IL-6 and IL-10 were up-regulated. In another study, Tat significantly increased the motility of AIDS-related NHL cell lines by enhancing the adhesion of lymphoma cells to the endothelium.[199] HIV infection stimulates surface expression of CD40 on endothelial that in turn triggers the preferential induction of the vascular adhesion molecule VCAM-1.[200] Extracellular Tat protein has also been found to have angiogenic properties, to promote KS, to cause normal vascular cells to migrate, and to stimulate new vessel growth.[201,202] Vascular endothelial growth factor (VEGF-A) concentrations are higher in sera of HIV-positive patients with and without KS compared to uninfected individuals.[203] Stimulation of vascular permeability by VEGF has been found to be important in the pathogenesis of AIDS-associated primary effusion lymphomas.[204]

Infection with HIV leads to an up-regulation of preexisting mechanisms. Non-immortalized peripheral B lymphocytes from EBV-positive, HIV-negative donors can be infected with HIV, and a subset will then develop enhancement of EBV DNA and RNA as well as deregulation of c-*myc* transcripts and protein.[205]

The likelihood to develop a chromosomal translocation could be increased in HIV-infected individuals due to the probable accumulation of a significant number of mutations in tumor suppressor genes that occur due to the continued proliferation of B cells secondary to immunosuppression. It has been shown for example, that the failure of p53 to permit DNA repair during the cell cycle can permit mutations to persist in successive cell generations. Progression from oligoclonality to monoclonality, associated with the occurrence of chromosomal abnormalities in immunodeficient individuals, has been demonstrated in reactive lymphadenopathy by the presence of multiple clonal B-cell expansions as multiple Ig gene rearrangements.[206,207] However, only one of these clones has been found to have a c-*myc* rearrangement, suggesting that only one clone carries the genetic abnormality associated with a B-cell lymphoma, whereas the other B-cell expansions only represent precursor lesions. Inactivation of p53 is one of the most common genetic abnormalities associated with human cancers. In HIV disease, it is exclusively associated with AIDS-BL (60%), which is more common than in sporadic or endemic BL (30%), although it is not found in AIDS-related diffuse large cell lymphomas (DLCLs) or primary effusion lymphomas.[184,208] Although deletions of 6q are common in B-cell NHL of immunocompetent hosts, it is only found in approximately 20% of AIDS-DLCLs but is absent in other AIDS-associated lymphomas.[184,209]

Translocations affecting 8q24 t(8;14)(q24;q32), the c-*myc* locus, and an Ig locus, are commonly seen in BL. Adults with AIDS-BL typically show c-*myc* activation (in 100% of cases) and often a disruption of p53 function (in 60%).[182,184,210,211] Clones of circulating peripheral lymphocyte with Ig chain and c-*myc* abnormalities can be found in HIV-positive homosexual men without a clear correlation to the subsequent development of NHL.[212] In children, the frequency of c-*myc* mutations is lower, although translocations clearly do occur. One study found known mutations of c-*myc* in only 2 of 13 small non-cleaved cell lymphomas, whereas 8 of 11 tumors showed translocations of the Ig gene/c-*myc* region.[178]

AIDS-associated DLCLs show *bcl*-6 rearrangements in 20% of cases compared to 40% of DLCLs occurring in immunocompetent hosts.[184,213] Mutations can also occur in the 5' non-coding region of *bcl*-6, and are seen in 60% of systemic NHLs, especially the AIDS-BLs and AIDS-DLCLs (70%), but less commonly in body cavity–based lymphomas (20%).[213] Expression of the bcl-6 protein varies as well between the different types of AIDS-associated NHL. It is expressed in all AIDS-BL but only in one-half of the AIDS-DLCLs, and only if there was no concurrent LMP-1 expression.[214]

***Human Herpesvirus 8 or Kaposi's Sarcoma–Associated Herpesvirus***

In 1994, a unique DNA sequence was found within KS lesions and identified as protein genes of a new gamma herpesvirus, now called *human herpesvirus 8* (HHV-8) or *Kaposi's sarcoma–associated herpesvirus*.[215] HHV-8 has been shown to be present in close to 100% of all KS lesions, and has also been found in AIDS-related body cavity NHL, lymphomatous effusions without tumor mass, and Castleman's disease, as well as some cases of multiple myeloma.[216,217,218,219] and [220] Only a few cases of childhood KS have been studied for the presence of HHV-8, but the herpes virus was present in all of them.[93] It has recently been shown that HHV-8 can be propagated from AIDS-associated KS lesions.[221]

Multicentric Castleman's disease, an atypical LPD, has been strongly linked to the presence of HHV-8, which might explain the coexistence of KS in many patients.[222,223] A correlation between the HHV-8 viral load and progression of disease has recently been established.[224] HHV-8 is more commonly found in multicentric Castleman's disease than in the form with an isolated lesion, and more frequently in HIV-infected patients, but has also been described in PTLDs.[225,226] and [227]

Primary effusion lymphomas comprise approximately 5% of all HIV-associated lymphomas, and they have a strong association with HHV-8 infection (as well as with EBV infection).[226,228,229] and [230] A recent study demonstrated the high levels of nerve growth factor are secreted in an autocrine fashion by the HHV-8–infected cells and are essential for virus maturation and survival.[231]

More than 80% of all patients with KS (HIV-positive or -negative) have specific serum antibodies to HHV-8–related antigens, often detectable before the clinical onset of KS lesions.[103,219,232,233] In the general U.S. population, approximately 25% of adults have HHV-8–related antibodies, compared to 18% in adolescents and less than 4% in children younger than 13 years of age, indicating sexual transmission as the most likely mode of infection.[234,235,236] and [237] However, in African countries such as Nigeria or Zaire, the seroprevalence is much higher (56% and 82%, respectively).[238,239] Seroprevalence for HHV-8 was also found to be increased in immunosuppressed renal allograft recipients (50%) compared to healthy adults (7%) and to reach similar levels as in an HIV-infected control group (73%).[240]

Several potential oncogenes have been identified that might play a role in the development of HHV-8–associated malignancies.[241,242] and [243] They appear to disturb both the retinoblastoma (pRb) and p53 tumor suppressor and cell cycle pathways, as well as interfere with the IFN signaling pathways.[243,244]

***Human Papillomavirus***

Malignant melanoma after renal transplant has been shown to frequently arise from precursor nevi, associated with an abnormal host response to the tumor (i.e., absence of lymphocyte and macrophage infiltrates).[245] HPV DNA, mainly belonging to the epidermodysplasia-verruciformis subgroup, is commonly found in premalignant and cancerous skin lesions of renal transplant patients. However, the prevalence of epidermodysplasia-verruciformis-HPV DNA is equally high in patients with or without a history of skin cancer, indicating that other factors contribute to the development of a malignant lesion.[246]

There is a strong correlation between infection with HPV, especially types 16 and 18, and the development of cervical or anal neoplasms.[122,127,130,132,139,246,247,248] and [249] Immune status and co-infection with HIV or other sexually acquired organisms appear to play a role as well.[122,126,130,250]

***Other Microbial or Viral Pathogens***

Several microbiologic agents have been implicated in the pathogenesis of LPDs. Mucosa-associated lymphoid tumors (MALTs), both in HIV-negative as well as in HIV-infected patients, have been shown to be associated with the presence of *Helicobacter pylori* in the gastric mucosa.[251,252,253] and [254] It is thought that the continuing inflammatory reaction and antigen exposure predisposes the patient to the development of a mucosal tumor, often associated with an accumulation of p53 abnormalities.[255]

The roles of HHV-6 and HHV-7 in the pathogenesis of LPDs are not yet completely resolved.[256,257,258,259] and [260] Infection with HHV-6, the cause of roseola infantum (exanthema subitum) is common. In the immunocompetent host, it causes a self-limited disease and then remains in its latent form. In immunocompromised patients, however, HHV-6 can cause transplant rejection, bone marrow failure, pneumonitis, or encephalitis, as well as hepatitis and various skin rashes.[260] HHV-6 is found in some lymphoproliferative processes in these patients, however, whether it is just ubiquitous or whether it has an oncogenic role is not clear. Some cases of chromosomal integration of HHV-6 into lymphoma cells have been described.[256,261] HHV-7 has selective tropism for $CD4^+$ lymphocytes and appears to be able to reactivate HHV-6. It has not yet been associated with a human disease but is suspected to have a potential role in the pathogenesis of LPDs.[257,258,262]

**Cytokines and Other Pathogenetic Factors**

Abnormalities in the expression of cytokines are commonly found in many patients with LPDs or malignancies associated with immunodeficiency, but we are only beginning to understand the complex regulatory mechanisms that are involved.

Cytokines and angiogenesis factors play a dominant role in the pathogenesis of KS. [201,202,263] KS cell growth is sustained *in vitro* by basic fibroblast growth factor, IL-1, IL-6, oncostatin M, and other cytokines. [263,264] The angiogenic basic fibroblast growth factor acts synergistically with the HIV-1 Tat protein, enhancing endothelial cell growth and type-IV collagen expression. [202] AIDS-KS cell lines also express VEGF/vascular permeability factor, as well as the receptors for VEGF (i.e., Flt-1 and KDR), indicating that VEGF is yet another autocrine growth factor for KS cells promoting neo-angiogenesis. [264]

Chemokines and variants of chemokine receptor genes influence the risk for the development of NHL in HIV-infected children and adults. The stromal cell–derived factor 1 chemokine variant is associated with a twofold increase of the NHL risk in heterozygotes and roughly a fourfold increase in homozygotes. [265] In particular, the stromal cell–derived factor 1-3' A variant was associated with BL and Burkitt's-like NHL, the same tumors that also show c- *myc* activation.

## PATHOLOGY AND TREATMENT

Tumors in immunocompromised patients often display a unique pathology. The border between “benign” cellular proliferation and overt malignancy is intertwined, as demonstrated by the LPDs and the smooth muscle tumors. The interaction between concurrent viral infections and the underlying inability of the immune system to mount an appropriate response leads to typical cytopathogenic changes. Treatment includes improvement (if possible) of the underlying immunodeficiency, treatment of concurrent viral infections, and tumor-specific treatment that is tailored to the diminished capability of these patients to tolerate aggressive interventions. A problem inherent in treating patients with immunodeficiencies and malignancies is that the risk to develop a new tumor continues as long as the immune system is abnormal. This chapter emphasizes the differences in pathology and treatment of tumors occurring in immunocompromised patients; for more detailed review of pathology and treatment, please refer to the disease-specific chapters.

### Non-Hodgkin's Lymphoma

Although most lymphomas seen in immunocompromised patients can also be found in otherwise healthy hosts, there are some distinct features. Nevertheless, an international panel of experts recently determined that no separate classification is needed for lymphoid tumors occurring in immunocompromised patients, with the exception of PTLDs (Table 25-3). [266]

| | |
|---|---|
| Early manifestations | Reactive plasmacytic hyperplasia |
| | Infectious mononucleosis-like |
| Polymorphic PTLD | Polyclonal (rare) |
| | Monoclonal |
| Monomorphic PTLD (classified according to lymphoma classification) | B-cell lymphomas |
| | Diffuse large B-cell lymphoma (immunoblastic, centroblastic, or anaplastic) |
| | Burkitt's or Burkitt's-like lymphoma |
| | Plasma cell myeloma |
| | T-cell lymphomas |
| | Peripheral T-cell lymphoma, not otherwise categorized |
| | Other types (hepatosplenic, gamma-delta, T cell/natural killer cell) |
| Other types (rare) | Hodgkin's disease–like lesions (associated with methotrexate therapy) |
| | Plasmacytoma-like lesions |

**TABLE 25-3. SUGGESTED WORLD HEALTH ORGANIZATION CLASSIFICATION OF POSTTRANSPLANTATION LYMPHOPROLIFERATIVE DISORDERS (PTLD)**

The majority (>90%) of NHLs in immunocompromised patients are high-grade B-cell malignancies. [8,97,104,152,267] Although most NHLs in HIV-infected adults and children are of B-cell origin, there is an increasing number of case reports of T-cell tumors, especially Ki-1 $^{+}$ (CD30$^{+}$) anaplastic large cell lymphomas. A similar observation has been made in NHL occurring after solid organ transplants. [64]

Extranodal sites are involved in the majority of HIV-positive patients (87%), and approximately 34% have bone marrow infiltration at the time of diagnosis. [268] Other commonly involved extranodal sites are the gastrointestinal tract, liver, CNS, lungs, and bone, but almost any organ can be affected. [91,178,268,269] Primary CNS lymphomas account for 4% to 40% of the NHLs in HIV-infected adults and have also been described in children with AIDS. [112,178] A similar incidence of primary CNS lymphomas (20% to 40%) has been reported in the posttransplant setting and some congenital immunodeficiency disorders. [8,55,65,206] Body cavity and primary effusion lymphomas are relatively recently recognized manifestations of NHL in immunocompromised hosts, but have so far only been seen in adults. [178,218,270]

#### *Systemic Non-Hodgkin's Lymphoma*

The clinical presentation of systemic NHL in the HIV-infected child is somewhat different from tumors seen in HIV-infected adults. Patients can have marked variability in age, sites of presentation, and CD4 count at diagnosis. [91] A similar variability has been observed in patients with congenital or iatrogenic immunodeficiency states. [8] Extranodal involvement (including lungs, liver, bones, and meninges) is common and may result in vague and difficult to evaluate symptoms such as refusal to walk, pleural pain, or hepatomegaly. [8,111,112,271] Nonspecific complaints, including fatigue, loss of appetite, and night sweats, are common.

When a lymphoma is suspected, a careful staging should include radiologic studies with computed tomography or magnetic resonance imaging, a gallium and bone scan, a bone marrow examination, and a lumbar puncture. Because the underlying disease (e.g., HIV infection) or its treatment (e.g., transplantation) often result in multi-organ problems as well as the use of several different drugs, it is important to assess hepatic, neurologic, renal, bone marrow, and cardiac function as best as possible before intervention.

The treatment of systemic NHL in immunocompromised patients is still evolving. In general, older (adolescent and adult) patients often have difficulties tolerating aggressive chemotherapeutic regimens. HIV-infected adults with systemic NHL have a median survival of 5 to 8 months, and only 10% to 20% remain disease-free for more than 2 years. [272,273 and 274] An initial attempt to use more intensive chemotherapy based on the more aggressive nature of the HIV-associated NHLs proved unsuccessful because of a high mortality due to opportunistic infections. [272,275] Subsequent trials using reduced-dose regimens yielded better results in regard to treatment-associated hematologic toxicity with similar disease-free survival rates. [273,276] The standard of care is still evolving, but m-BACOD (methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, and dexamethasone) at low or standard dose levels is commonly used in adults. HIV-infected children have successfully been treated with a simpler regimen of cyclophosphamide (day 1) and methotrexate (day 10), combined with intrathecal cytarabine (days 1 and 3) and intrathecal methotrexate (day 10), administered for three cycles (unpublished results). Because BLs or Burkitt's-like lymphomas are the most common NHL type in HIV-infected children, shorter and therefore better tolerated chemotherapy regimens can be used. Regardless of the age and chemotherapy used, it is important to continue to treat the underlying HIV infection, and, if possible, to choose drugs with non-overlapping toxicities. [273,276,277 and 278]

Even in the presence of a monoclonal malignant lymphoma, it might be worthwhile to decrease the degree of immunosuppression in patients with posttransplant NHL. [279] If this alone is not sufficient, chemotherapy may be used and is usually relatively well tolerated. [64,65,280,281] A newer approach is the use of monoclonal B-cell antibodies directed against surface antigens on tumor cells, including CD20, CD21, and CD24 for the treatment of posttransplant malignant LPDs. [282,283 and 284] Rituximab (anti-CD20 antibody) is licensed in the Unites States for the treatment of NHL in adults, and preliminary results support its use in CD20-positive PTLD as well. [285,286,287 and 288] Studies are currently under way to evaluate safety and efficacy of rituximab in pediatric patients.

#### *Primary Central Nervous System Non-Hodgkin's Lymphoma*

Primary CNS lymphoma occurs both in immunocompetent and immunocompromised patients, but survival is markedly different.[289] For unknown reasons, the incidence of primary CNS NHL is not only high in patients with AIDS but also steadily increasing in immunocompetent patients, becoming one of the most common primary malignant neoplasms in the brain in adults.[290,291]

Patients with primary CNS lymphoma are generally symptomatic for several weeks before diagnosis, and may show symptoms of confusion, lethargy, memory loss, seizures, hemiparesis, or other focal neurologic signs, as well as signs suggestive of increased intracranial pressure.[289,292,293] Radiographic imaging by computed tomography or magnetic resonance imaging typically demonstrates an isodense or hypodense single lesion that enhances with contrast, although multiple lesions are present in almost one-half of the patients with AIDS, compared to only 25% of immunocompetent patients.[289,292,293] Ring enhancement is seen in approximately one-half of the patients with AIDS-associated NHL of the brain, whereas it is rare in immunocompetent hosts.[289]

The differential diagnosis of a parenchymal brain lesion in an immunocompromised patient includes neoplasm (usually lymphoma), infection (usually toxoplasmosis, but rare in children), and hemorrhage (Fig. 25-1). The clinical, histologic, and radiographic findings in children are similar to the adult population. In children, however, in whom CNS toxoplasmosis is rare, the most likely diagnosis of an intraparenchymal brain lesion is lymphoma or another brain tumor. Abnormalities of cerebrospinal fluid, with mild mononuclear pleocytosis, slightly elevated protein, and occasional decreased glucose, have been described, and malignant cells were found in approximately 25% of the patients in whom it was considered safe to perform a lumbar puncture.[289,294]

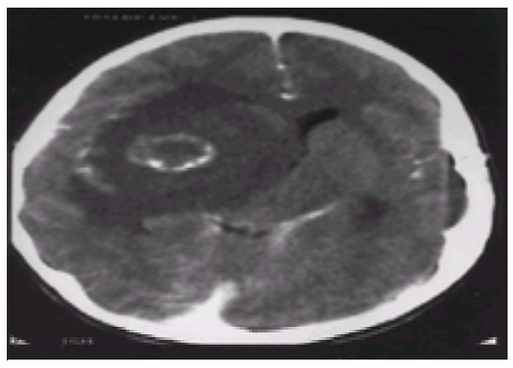


**FIGURE 25-1.** Mass lesion in the cerebrum of a 12-year-old hemophiliac. The differential diagnosis includes malignant lymphoma and central nervous system toxoplasmosis. This child responded well to treatment with pyrimethamine and sulfadiazine, the standard therapy for toxoplasmosis.

The CNS lymphomas in immunocompromised patients are intracranial intraparenchymal tumors, characterized by frequent histologic multifocality, indistinct borders, and often an angiocentric arrangement.[295] They are generally high-grade tumors, mostly large cell immunoblastic lymphomas (in 35% to 45%) and small non-cleaved lymphomas (in 25% to 36%), which is different from immunocompetent hosts in whom only 22% have high-grade morphology (18% immunoblastic and 4% small non-cleaved cell type).[289,296] Most tumors are of B-cell origin; in immunocompromised hosts, virtually 100% of all CNS NHLs are EBV positive, whereas this is rare in immunocompetent patients.[289,297]

Treatment of primary CNS lymphomas consists mainly of radiation with or without chemotherapy. Patients with AIDS who develop a CNS NHL often have far advanced HIV disease, making a more aggressive intervention difficult.[271,272,289,294,298]

### Hodgkin's Disease

Clinically aggressive types of HD are more common in HIV-infected patients and probably in other immunocompromised populations as well.[299] More than 80% of HIV-infected patients with HD present with systemic symptoms, and disseminated stage III or IV disease occurs in approximately 75% to 90% of patients: bone marrow involvement is common (in 40% to 50%).[110] In an Italian study that compared the presentation of HD in infected and non–HIV-infected adults, HIV-associated HD occurred in younger patients (29 years versus 38 years); had a male predominance (90% versus 56%); and presented more often with stage IV disease (63% versus 29%), B symptoms (77% versus 35%), and extranodal disease (63% versus 29%).[300] In contrast to NHL, there is no clear correlation between the occurrence of HD and CD4 counts. Most patients with HIV-related HD did not have a prior diagnosis of AIDS, but a substantial proportion had a history of generalized lymphadenopathy (in 36% to 83% of patients).[110,300,301]

Mixed cellularity and lymphocyte depletion are the most common histologies in HIV-infected patients (66%), compared to lymphocyte predominance and nodular-sclerosing types in HIV-negative patients (71%).[110] Reed-Sternberg cells, the presumed neoplastic cells of HD, are more prominent in HIV-related HD.[302] Evidence for latent EBV infection is demonstrated in the majority (78%) of patients with HIV-associated HD, and 80% of these tumors contain monoclonal EBV genomes.[300]

The optimal chemotherapy for HD in immunocompromised patients has not yet been established. HIV-negative patients with stage III and IV disease achieve cure rates of more than 70% with either a mechlorethamine, vincristine, procarbazine, and prednisone regimen (MOPP), or a doxorubicin, bleomycin, vinblastine, and dacarbazine regimen (ABVD); however, HIV-infected patients have a much poorer outcome.[110,303,304] In a recent study of epirubicin, bleomycin, vinblastine and prednisone, combined with antiretroviral therapy and granulocyte colony-stimulating factor, the median survival was 16 months, with a survival rate of 32%.[304]

### Lymphoproliferative Disorders

LPDs in immunocompromised patients are commonly of the B-cell type, although T-cell tumors have been described as well. They can range from asymptomatic hypergammaglobulinemia (especially in HIV-infected children) to generalized lymphadenopathy with hepatosplenomegaly. The transition to a malignant process is not clearly defined, because even a low-grade, polyclonal process can become life-threatening due to its location. Polyclonal LPDs, especially if EBV associated, can evolve into a rapidly progressive monoclonal process.[305] However, as shown in PTLDs, decreasing the degree of immunosuppression can cause regression in some patients even if they have monoclonal tumors.[279,281]

#### *Lymphadenopathy and Hypergammaglobulinemia*

The lymph node architecture is preserved in HIV-related lymphadenopathy with hypergammaglobulinemia and typically shows polyclonal follicular (B-cell) hyperplasia.[112,306] However, hyperplastic lymph nodes can occasionally contain occult clonal B-cell populations.[207] This lymphadenopathy either resolves spontaneously or responds to initiation or optimization of antiretroviral therapy. Atypical lymphoid hyperplasia or reactive lymphoid hyperplasia are the most common lymphoproliferative lesions in patients with congenital immunodeficiencies such as CVID, WAS, or SCID.[41,268]

A monoclonal gammopathy can precede the development of an EBV-associated PTLD. In a study of 201 patients after liver transplant, 57 (28%) showed a monoclonal urine or serum protein after transplantation, including five of seven patients (71%) who developed a PTLD and 27% of patients who did not.[307] The authors identified cytomegalovirus (CMV) positivity or postoperative CMV infection as the major risk factors ($p$ <.02).

#### *Lymphocytic Interstitial Pneumonitis and Diffuse Infiltrative Lymphocytosis*

LIP is a typical finding associated with HIV infection in children.[306,308] It can remain a radiographic finding only or become clinically problematic because of the development of oxygen dependency. Histologically, both B and T cells (especially CD8+ T cells) are present in either nodular or interstitial distribution.[308]

A diffuse infiltrative lymphocytosis syndrome, consisting of bilateral parotid enlargement, cystic enlargement of the salivary or lacrimal glands, has been described in HIV-infected adults and children.[112,309,310] The patients described by Kontny et al.[117] who presented with multiple cystic lesions in their grossly enlarged thymus, may also belong in the same group (Fig. 25-2).

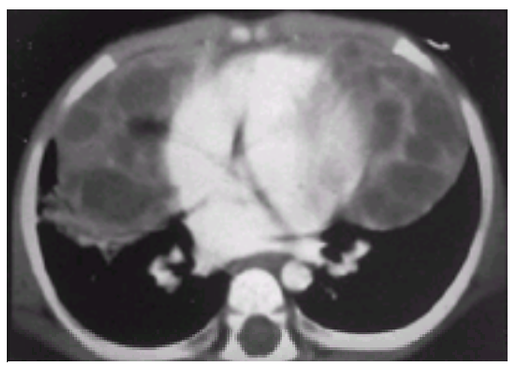

**FIGURE 25-2.** Cystic mediastinal mass in a child with human immunodeficiency virus infection. Histologically, the mass was a polyclonal, Epstein-Barr virus–positive lymphoproliferative process within the thymus, consisting of B and T cells forming distinct lymphoid follicles with germinal centers.

### *Mucosa-Associated Lymphoid Tumors*

MALT lymphomas are at the interface between LPDs and malignant lymphoid tumors and tend to occur in the lungs, the gastrointestinal tract, and parotid and salivary glands.[178,254,311,312] They can occur both in immunocompetent and immunocompromised patients. MALT lymphomas comprised 10% of all NHLs in our series of HIV-infected children with tumors and have also been described in posttransplantation patients.[91,313] Several cases of pulmonary MALT have been associated with LIP, and a pathogenetic link is currently being investigated.[254,314] Immunoproliferative small intestinal disease is another form of MALT especially prevalent in the Mediterranean region, and has been described in some children as well.[315]

MALT lymphomas are monoclonal B-cell tumors that can display cytogenetic abnormalities (e.g., trisomy 3), and may be heterogeneous for *bcl*-2 expression and p53 mutations, which are markers for blocked apoptosis.[254,312,316,317] A translocation between chromosomes 11 and 18, t(11;18)(q21;q21), is commonly found in MALT lymphomas.[318,319] Most MALT lymphomas are low-grade tumors and remain localized at their sites of origin for many years, although transformation to high-grade malignancies can occur.[254,320,321]

Surgical excision, especially of pulmonary lesions, is often all that is needed for successful treatment, and survival seems to be favorable because all children from our series are alive 17 to 36 months after cancer diagnosis.[91,312] Gastric MALT tumors have been shown to be strongly linked to a local infection with *H. pylori* and often respond to antimicrobial therapy (e.g., amoxicillin and metronidazole) combined with omeprazole or bismuth, and some patients with immunoproliferative small intestinal disease respond to treatment with tetracyclines.[252,253,315,322] If this does not eradicate the tumor, single-agent chemotherapy with oral cyclophosphamide or chlorambucil can be tried.[323]

### *Posttransplant Lymphoproliferative Disorder*

As mentioned, lymphoproliferative processes in the posttransplant period range from lymphoid hyperplasia to malignant NHL. Although the majority of PTLDs are of B-cell origin, occasional T-cell tumors have been observed, especially in late-occurring tumors.[71] Simultaneous occurrence of clonally distinct lesions is possible.[324] Non-lymphomatous PTLD can present as plasmacytic hyperplasia or a polymorphic lymphoid process (Table 25-3). Plasmacytic hyperplasia is often confined to the tonsils or adenoids, whereas polymorphic lesions can occur in lymph nodes or extranodular sites, including the allograft.[58,65,67,282,325,326,327] and [328] Neither lesion shows any alteration in oncogene or tumor suppressor gene expression, and most patients respond to a decrease in immunosuppression.[328] This regression might be associated with an expansion of $CD8^+$ T cells.[329] Tonsillar or adenoid lesions can often be treated with excision alone.[330]

Decreasing the degree of immunosuppression often results in a marked regression of a PTLD. The use of intravenous Ig and IFN-a have been effective in some patients, but no controlled studies have been performed.[331,332] and [333] Although acyclovir or ganciclovir are commonly used in patients with EBV-related PTLD, their efficacy is doubtful, because EBV in its latent form is less accessible to therapy. Furthermore, the EBV thymidine kinase does not phosphorylate the two drugs, a necessary step for activation.[334] Several new and exciting therapeutic approaches are being studied, including immunotherapy with infusion of donor T lymphocytes, adoptive transfer of gene-modified virus-specific T lymphocytes, and the use of monoclonal antibodies such as rituximab (anti CD20).[283,284,335,336] and [337]

### *Castleman's Disease*

Castleman's disease, also called *giant lymph node hyperplasia* or *angiofollicular hyperplasia*, is rare in children.[338] The disease is usually localized. A hyalinovascular type is seen in 54%, whereas the plasma cell type is encountered in 24% of cases.[338] Multicentric Castleman's disease is seen more commonly in HIV-infected adults and other immunocompromised patients.[82,223] This systemic lymphoproliferative process, probably originating from plasma cells, often presents with hypergammaglobulinemia, has a frequent association with KS (in 75% of cases), and is, in some patients, associated with the development of NHL at a later time.[223,227,339,340] Like KS, it has a strong association with HHV-8 infection.[222,225,226] and [227,241,341] In the immunocompetent patient, treatment may consist of surgery only, or include steroids and other immunosuppressive agents, whereas low-dose and single-agent chemotherapy (mainly vinblastine) has shown some success in HIV-infected patients.[223,342]

### *Angioimmunoblastic Lymphadenopathy with Dysproteinemia*

Angioimmunoblastic lymphadenopathy with dysproteinemia (AILD) is a rare systemic LPD, presenting with diffuse lymphadenopathy, hepatosplenomegaly, fever, pulmonary infiltrates, or pleural effusions, as well as autoimmune hemolytic anemia with positive Coomb's test and a polyclonal hypergammaglobulinemia.[343,344] This disease is extremely rare in childhood, but a few cases have been described.[345,346] The lymph node architecture shows effacement, prominent neovascularization, and a diffuse infiltration by immunoblasts and plasma cells. The majority of AILDs are clonal T-cell processes, with prominent CD4 positivity.[344] Clonal abnormalities, especially trisomies 3, 5, and X, have been described.[347] Spontaneous regression of the lymphadenopathy has been observed, but AILD is often a rapidly progressive disease. Treatment has not been very successful, and only approximately 25% of patients achieve prolonged remissions even with aggressive multi-agent chemotherapy.[344]

### *Lymphomatoid Granulomatosis*

Lymphomatoid granulomatosis is an LPD that often presents in extranodal sites, especially the lungs, liver, kidneys, skin, and CNS.[348,349] It can occur both in immunocompetent and immunocompromised patients, but has only rarely been seen in children.[350,351,352] and [353] Histologically, lymphomatoid granulomatosis is an EBV-positive B-cell proliferation associated with an exuberant T-cell reaction.[349] Approximately 60% of cases show clonal rearrangements of the VDJ region. Spontaneous regression is possible, but a rapidly fatal course with development of a malignant lymphoma is more common. Treatments include chemotherapy with steroids and cyclophosphamide, or a trial with IFN-a.[349,354]

### *Lymphomatoid Papulosis*

A rare cutaneous T-cell LPD, lymphomatoid papulosis, is mainly seen in elderly adults, but a few pediatric cases have been described. [355,356,357 and 358] Patients may experience a waxing and waning course, with involuting and recurring cutaneous papules, plaques, and nodules, sometimes followed by the emergence of a cutaneous $CD30^+$ NHL.[356,358,359]

### *Autoimmune Lymphoproliferative Syndrome*

Massive nonmalignant lymphadenopathy, a variety of autoimmune manifestations, and an expanded population of $TCR^-CD3^+CD4^-CD8^-$ (double negative) lymphocytes characterize the recently recognized autoimmune lymphoproliferative syndrome (ALPS). [360,361,362,363,364 and 365] Patients typically present with lymphadenopathy, splenomegaly, autoimmune hemolytic anemia, autoimmune neutropenia, and thrombocytopenia. Lymph nodes show marked paracortical hyperplasia due to infiltration by plasma cells and double-negative lymphocytes. [362]

Most patients with autoimmune lymphoproliferative syndrome have been found to have heterozygous mutations in the lymphocyte surface protein Fas, leading to impairment of the apoptotic pathway.[360,361,364,365 and 366] A similar clinical phenotype is typically seen in *lpr* and *gld* mice, in which homozygous mutations of the Fas or FasL gene impair Fas-induced apoptosis, leading to lymphoproliferation and generalized autoimmune disease. [367]

Splenectomy may be required to control the autoimmune thrombocytopenia and hemolytic anemia. However, the benefit from this procedure may be only transient, and postsplenectomy sepsis is not uncommon in these patients. Intermittent treatment with steroids for severe episodes of hemolysis or thrombocytopenia have also been tried.[362]

## Kaposi's Sarcoma

Three distinct forms of KS have been recognized, including an endemic African form, KS occurring mainly in elderly men in the Mediterranean regions, and KS observed in patients after transplantation or affected with HIV disease ( Table 25-4).[12,368,369]

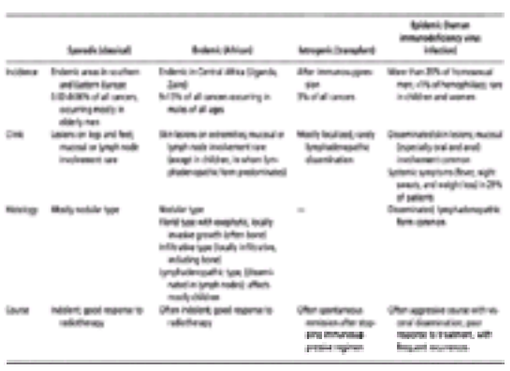

**TABLE 25-4. CLINICAL AND PATHOLOGIC FEATURES OF KAPOSI'S SARCOMA**

AIDS-associated KS occurs in a mucocutaneous and a lymphadenopathic form. Cutaneous lesions can occur in many locations, including the palms and soles, eyelids, scalp, and auditory canal. Mucous lesions can easily be detected in the oral cavity or during endoscopy. A severe but rare presentation of the mucocutaneous variant is involvement of the lungs, leading to respiratory distress. [370] The lesions have a purple or brown color, can be macular, plaque-like or nodular, and are often associated with edema due to venous congestion.[93,368] The lymphadenopathic form is the predominant form in Africa.[93,94] Three distribution patterns have been observed among 100 childhood KS cases in Uganda: an oro-facial distribution (in 79 patients) with regional (86%) or generalized (60%) lymphadenopathy and variable skin involvement (39%); an inguinal-genital distribution (in 13 children) with inguinal lymphadenopathy (100%), skin (57%), and ano-genital (14%) involvement; and a less common pattern with solitary tumors in the extremities or visceral organs (8%). [93]

KS presents as a proliferation of spindle cells surrounded by a network of reticulin and collagen fibers, as well as more or less extensive vascularization. KS cells are positive for a wide range of markers, including vimentin, von Willebrand factor, macrophage-specific CD68 and CD14, and smooth muscle (e.g., alpha-actin). [101] KS-like spindle cells have been cultured from peripheral blood, and some data support a monoclonal origin of multicentric KS lesions. [371,372]

The Oncology Committee of the AIDS Clinical Trials Group has specified criteria for the evaluation, staging, and response determination in AIDS-associated KS. [373] The staging system used by the AIDS Clinical Trials Group considers extent of the tumor, immune status (CD4 count), and signs of systemic illness to categorize patients into good and poor risk groups. Untreated KS, especially of the lymphadenopathic form or in the presence of involvement of internal organs, usually follows a rapidly progressive course.[374] In adults, KS has been treated with a variety of modalities, including local or systemic chemotherapy, radiotherapy, antiviral treatment, and, more recently, anti-angiogenesis therapy. There is limited information available regarding the treatment of children with KS. [93]

## Smooth Muscle Tumors

In children without immune compromise, leiomyosarcomas are most commonly found in the retroperitoneum and gastrointestinal tract. [375,376,377 and 378] In contrast, in HIV-infected children and otherwise immunocompromised patients, unusual localizations, such as the subcutis, spleen, pleural space, adrenal glands, lungs, and even the brain, have been described.[91,113,115,116,121,185,379,380,381 and 382] As previously mentioned, latent EBV infection is found in leiomyosarcomas from immunocompromised patients but not in tumors from otherwise healthy people.[115,119,185]

The course of disease is highly variable, with indolent tumors (more likely leiomyomas) often detected as incidental findings on routine radiographic examinations or at autopsy. However, some children present with very aggressive, widely disseminated tumors. Leiomyomas and leiomyosarcomas can be found to occur concurrently in the same patient.[379] However, smooth muscle tumors are in general not very sensitive to treatment. Decreasing the immunosuppression does not provide a clear benefit in the case of smooth muscle tumors. Local excision is the first line of therapy in non–HIV-infected children followed by chemotherapy with or without radiotherapy (see Chapter 34). Chemotherapy commonly consists of 12 months of cycles of vincristine, adriamycin, cyclophosphamide, and dactinomycin, alternating with ifosfamide and etoposide. Such a regimen is too intensive for the vast majority of immunocompromised children, but novel approaches using anti-angiogenesis drugs or methods of affecting the underlying EBV infection should be explored.

## Cervical and Anal Neoplasms

Cervical malignancies are usually detected by visual or colposcopic examination (with Pap smear) and present as multifocal lesions, not uncommonly extending to adjacent areas of the vagina, vulva, and anus.[122] Anal cancer can occur in both men and women, and the diagnosis is made by cytology, although the sensitivity of this test appears to be lower than for cervical cancer. Cervical intraepithelial neoplasia is considered a precursor lesion for invasive disease; however, this correlation is less well established for anal squamous intraepithelial lesions. [247,249] Immunocompromised patients who present with a more advanced stage of disease tend to follow a clinically aggressive course. [125,132]

The best intervention is clearly to regularly screen patients at risk, including sexually active adolescents. A discussion of the treatment options for cervical and anal malignancies is beyond the scope of this chapter. In the HIV-infected patient, it may be of benefit to improve the antiretroviral treatment in the hope of improving local immune surveillance mechanisms.[383] Both cervical and anal intraepithelial lesions that present as local disease are amenable to local excision. However, patients with more advanced disease often respond poorly to therapy.

### Skin Cancers

Squamous and basal cell carcinomas occur in a substantial number of adult patients who have undergone bone marrow or solid organ transplants. Not surprisingly, patients with fair skin and blue eyes have a higher risk for the development of skin cancers, because most lesions occur in sun-exposed areas. [384] The ratio of squamous cell carcinomas to basal cell carcinomas is reversed compared to the general population. Carcinomas of the skin and lip were the second most common tumors seen in pediatric transplant recipients. [55]

Cutaneous malignancies have a tendency to aggressive behavior, manifested by local invasion, regional metastases at diagnosis, and regional or systemic relapse after therapy.[385] The most common aggressive tumor is a poorly differentiated squamous cell carcinoma (55%) and malignant melanoma (30%). Malignant melanoma is more common in patients undergoing transplants during childhood (12% of all skin cancers, compared to 5% in adults). Furthermore, lip malignancies were twice as common in children than in adults (23% versus 12% of all tumors). [55]

### Other Malignancies

A variety of other tumors have been described in patients with weakened immune surveillance. Whether their incidence is truly increased and pathogenically linked to the immunosuppression remains to be seen.

A number of miscellaneous tumors have been reported to occur in HIV-infected children, including leukemia, Ewing's sarcoma, rhabdomyosarcoma, and ependymoblastoma.[91,296,386,387,388 and 389] As HIV-infected children survive longer and in better health, it is possible that more will develop the “normal” pediatric malignancies in the future, especially leukemia and brain tumors.

Nephrogenic adenoma of the bladder has been described in renal transplant patients and is presumably due to mechanical trauma, chemical and irradiation-induced damage, as well as viral and bacterial pathogens. In a study of seven renal allograft recipients, no correlation with immunosuppression, CMV infection, or ganciclovir therapy was found, and none of the lesions became malignant, although a recurrence was detected in five patients. [390]

Renal cortical neoplasms were found at autopsy in 32 of 1,325 solid organ transplant patients, almost 50% in renal transplant recipients (only one in an allografted kidney).[391] This represents a ninefold increased risk compared to an age-matched control population, but was mostly evident in long-term survivors. These tumors are often small and not clinically detectable. Their significance is unclear, and their pathogenesis remains to be elucidated (e.g., a history of prolonged dialysis in renal transplant patients or the degree and kind of immunosuppression).

## CONCLUSIONS

LPDs are diseases at the borderline between benign and malignant stages. An underlying immunodeficiency, whether congenital, iatrogenic, or acquired, increases the risk to develop an LPD. However, immunocompromised patients are also at risk for nonlymphoid malignancies, partly due to the fact that they are not able to contain otherwise harmless infections, such as infection with EBV, HHV-8, or other viruses. It is likely that the number of patients who develop such diseases will increase in the future, due to the still expanding AIDS epidemic in adults and children in developing nations, as well as the more prevalent use of transplantation as a therapeutic modality. These diseases present a unique opportunity to study the pathogenesis of neoplastic transformations, and are a perfect target for the evaluation of noninvasive therapies, such as anti-angiogenic drugs or cytokine regulators.

# HISTIOCYTOSES

STEPHAN LADISCH
ELAINE S. JAFFE

## INTRODUCTION

The childhood histiocytoses are a rare and diverse group of disorders that have presented great difficulties for pediatricians in diagnosis and treatment. This has been true for nearly a century, since the first clear description of a childhood histiocytosis, Hand-Schüller-Christian disease. [1] The confusion surrounding the childhood histiocytoses is exemplified by the term coined for one group of these disorders, *histiocytosis X*. This term, with X standing for unknown, was proposed by Lichtenstein[2] in 1953 to underscore the lack of understanding of these disorders. Likewise, the rarity of the histiocytoses has prevented adequate epidemiologic studies to date. The only form of histiocytosis that has a definite genetic component is familial erythrophagocytic lymphohistiocytosis (FEL).

The forms of histiocytosis are frequently difficult to distinguish on a clinical basis. Yet they must be unequivocally differentiated from one another because they require different treatment approaches. Correct and complete pathologic diagnosis is essential. Paradoxically, although the diagnosis and treatment of these disorders are frequently relegated to the pediatric oncologist, the majority of the histiocytoses are not malignant diseases. The actual distinction between malignant and nonmalignant forms of childhood histiocytosis has been difficult in the past. This confusion undoubtedly has led to suboptimal treatment in some cases. In fact, the prognosis of many of the childhood histiocytoses has been considered with more pessimism than is justified. Formulation of an appropriate treatment plan rests on the ability to distinguish among the various severe forms of childhood histiocytosis and to establish an accurate diagnosis. This requires an understanding of the biologic features of this group of diseases and their relationship with the normal histiocytic subsets of the reticuloendothelial system.

## BIOLOGY

The historical association of several childhood diseases and syndromes into the single category of histiocytosis resulted from histopathologic findings that, at least at a superficial level, appeared to be common to all these diseases. The term *histiocytosis* literally signifies an increase in the number of histiocytes, or mononuclear phagocytic cells of bone marrow origin. The diseases and syndromes included under histiocytosis are characterized by an infiltration and accumulation of cells of the monocyte-macrophage series in the involved tissues. Not all diseases in which histiocytic infiltrations are prominent are classified as histiocytoses, however. In some instances, histiocytic infiltration represents a secondary rather than a primary process and one in which the primary process has been clearly defined. Some examples include graft-versus-host disease, X-linked lymphoproliferative syndrome, and certain inherited lipidoses. This implies that in the future, diseases currently classified as histiocytoses of unknown etiology may be found to have a cause that establishes the histiocytic infiltration as a secondary process, not a primary one.

An understanding of the histiocytoses requires understanding of the normal histiocyte. The origin of normal histiocytes is the bone marrow, and the differentiation of these cells occurs according to the following sequence. The most primitive precursor of the tissue macrophage is the uncommitted stem cell, found in the bone marrow. Current theory suggests that this stem cell undergoes one differentiation step to become a stem cell committed to further development in the granulocyte-macrophage series. On exposure to colony-stimulating factors, soluble factors promoting bone marrow proliferation and differentiation, the committed stem cell further differentiates into a colony-forming cell or a myeloblast-monoblast. As the next step, this precursor cell matures into the monocyte, which is found in the peripheral blood. This circulating monocyte then undergoes terminal differentiation into cells that are found in essentially every organ of the body. These cells are known by various names according to their tissue location or specialized function (e.g., bone marrow macrophages, Kupffer's cells in the liver, and Langerhans' cells in the skin).

The cells of the histiocytic system can be classified into two major subsets thought to be derived from the same bone marrow precursor: antigen-processing or phagocytic cells, and antigen-presenting or dendritic cells ( Table 26-1).[3,4,5,6 and 7] Dendritic cells are generally not phagocytic and have as their major function the presentation of antigen to both T and B lymphocytes. Follicular dendritic reticulum cells (FDCs) are found in lymph node follicles and present antigen to B lymphocytes. FDCs do not express CD45 (leukocyte common antigen) and may be of stromal, rather than hematopoietic, origin. Interdigitating reticulum cells (IRCs) and Langerhans' cells are functionally related and both present antigen to T lymphocytes. Langerhans' cells are found primarily in the skin but are also present in other organs. They are rare in unstimulated lymph nodes, but their numbers increase in certain reactive conditions. IRCs are found throughout the paracortex of normal and reactive lymph nodes. By incubation with the cytokines granulocyte-macrophage colony-stimulating factor and tumor necrosis factor-a, CD34-positive bone marrow stem cells can be caused to differentiate into Langerhans' cells.[8] Although immunoreactivity of normal Langerhans' cells is well defined, much less is known about their dynamic functional properties. What is known is that they present antigen. Whether they also either release or respond to cytokines is a question that is of more than theoretical interest, because dysregulation of cellular interactions is likely responsible for the pathogenesis of Langerhans' cell histiocytosis (LCH). Therefore, identifying the nature of abnormal cytokine interactions may allow new and specific therapeutic approaches to be developed. In fact, it is now known that the lesional Langerhans' cells in LCH both release and respond to various cytokines (in turn released by other cells, such as T lymphocytes, in the lesions), creating a veritable cytokine storm in the lesion.[9]

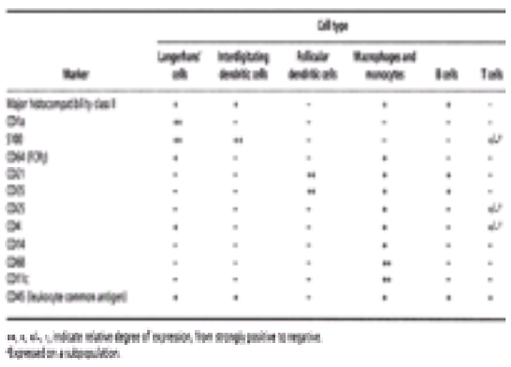
| Antigen-processing cells (phagocytic) | Antigen-presenting cells (dendritic) |
|---|---|
| Tissue macrophages | Follicular dendritic reticulum cell (lymph node follicle) |
| Monocytes | Interdigitating reticulum cell (lymph node paracortex) |
| Tingible body macrophages (lymph node follicle) | Langerhans' cell (skin, etc.) |
| Sinusoidal histiocytes | |
| Epithelioid histiocytes | |

**TABLE 26-1. HISTIOCYTIC AND RETICULUM CELL SUBSETS**

Phenotypically, dendritic cells lack the abundant lysosomal enzymes characteristic of phagocytic macrophages.[10] Both IRCs and Langerhans' cells have small amounts of lysosomal enzyme activity for acid phosphatase and nonspecific esterase. The reactivity generally has a punctate perinuclear distinction and is localized

to the Golgi region. FDCs lack lysosomal enzyme activity. All three dendritic cell types, however, manifest enzyme activity for adenosine triphosphatase.

The dendritic cell types have strong reactivity for HLA-DR, or major histocompatibility class II antigens, on their cell surface membranes ( Table 26-2).[11] Class II antigens play an important role in the presentation of antigen to T and B lymphocytes (see Chapter 5). The CD4-positive subpopulation of T cells recognizes antigen in the context of class II antigens.[11] In contrast, the CD8-positive T-cell subset recognizes antigen in the context of MHC class I antigens.



| Marker | Cell type | | | | | |
|---|---|---|---|---|---|---|
| | Langerhans' cells | Interdigitating dendritic cells | Follicular dendritic cells | Macrophages and monocytes | B cells | T cells |
| Major histocompatibility class II | + | + | - | + | + | - |
| CD1a | ++ | - | - | - | - | - |
| S100 | ++ | ++ | - | - | - | +/-* |
| CD68 (KP1) | + | - | - | + | - | - |
| CD21 | - | - | ++ | + | + | - |
| CD35 | - | - | ++ | + | + | - |
| CD57 | - | - | - | + | - | +/-* |
| CD4 | + | - | - | + | - | +/-* |
| CD14 | - | - | - | + | - | - |
| CD68 | - | - | - | ++ | - | - |
| CDF1c | - | - | - | ++ | - | - |
| CD45 (leukocyte common antigen) | + | + | - | + | + | + |

++, +, +/-, -, indicate relative degree of expression, from strongly positive to negative.
*Expressed on a subpopulation.

**TABLE 26-2. IMMUNOPHENOTYPIC MARKERS OF HISTIOCYTES AND DENDRITIC CELL SUBSETS**

IRCs and Langerhans' cells manifest immunoglobulin G (IgG) Fc receptors and, under some conditions, manifest complement receptors.[13] FDCs strongly express complement receptors (both CR1 or CD35 and CR2 or CD21). FRC is a specific monoclonal antibody that reacts exclusively with FDCs in frozen sections and is useful in their identification in normal and neoplastic lymph nodes ( Table 26-2). IRCs and Langerhans' cells are characterized by strong reactivity for S100 protein, which is totally lacking on FDCs. Smaller amounts of S100 immunoreactivity can be identified in activated monocytes and macrophages.[14]

Langerhans' cells demonstrate immunoreactivity for the CD1a antigen ( Table 26-2).[15] A recently described antibody can detect CD1a in paraffin sections and can thereby aid in diagnosis.[16] This antigen is also expressed on cortical thymocytes. IRCs generally lack the CD1a antigen, but whether CD1a immunoreactivity can be induced on IRCs in certain reactive conditions is controversial. The CD1a immunoreactive cells that appear in dermatopathic lymphadenitis may represent infiltrating Langerhans' cells derived from outside the lymph node, or CD1a immunoreactivity induced on resident IRCs. The normal Langerhans' cell is a resident of the epidermis. Originating from bone marrow precursors (CD34-positive) and possibly maturing or differentiating under the influence of granulocyte-macrophage colony-stimulating factor and tumor necrosis factor-a, this cell is the portal of entry for antigens. After antigenic stimulation, the cell migrates from the epidermis by the afferent lymphatics to the paracortical zone of regional lymph nodes and presents antigen to CD4-positive T cells. LCH cells are strongly reactive for lymphocyte function-associated antigen-3 and intercellular adhesion molecule-1, in contrast to normal epidermal Langerhans' cells, which are not. These findings suggest that abnormal homing of Langerhans' cells may be a component of the disease pathogenesis.[17]

Langerhans' cells have characteristic ultrastructural organelles known as *Birbeck granules*.[18] These rod-shaped structures of variable length contain a central striation and a vesicular expansion, which, when viewed in the appropriate cross section, resembles a racket. Birbeck granules may represent invaginations of the cell membrane and are hypothesized to result from external antigenic stimulation of the dendritic cells, with the granules related to the antigen-processing function of these cells. The granules could also represent exocytosis of intracellular vesicles, however. Which of these explanations is correct has not yet been resolved, and the function of the Birbeck granule is unknown. These granules sometimes appear as rods. When similar structures are seen by electron microscopy, measurement of the diameter of the rod defines the Birbeck granule and excludes possible errors such as the detection of viral particles. FDCs strongly express complement receptors (both CR1 or CD35 and CR2 or CD21). They also are distinguished by staining for the dendritic reticular cell antigen, clusterin, and with the monoclonal antibody CNA.42, none of which are found on macrophages, IRCs, or Langerhans' cells.[19] Finally, these antigen-presenting cell populations of all types in general lack many of the antigens expressed on monocytes and macrophages described later in this chapter.

Tissue histiocytes or macrophages are found in all the major compartments of the normal lymph node. Sinus histiocytes are the principal cells in the phagocytosis of foreign particulate matter and are located predominantly within lymph node sinuses. Tingible bodies macrophages are phagocytic cells found in normal germinal centers. In the presence of a florid follicular hyperplasia, these cells become more numerous. They frequently contain karyorrhectic nuclear debris, derived from apoptosis or karyorrhexis of proliferating germinal center cells. Tingible bodies macrophages are also conspicuous in high-grade malignant lymphomas and are especially prominent in Burkitt's lymphoma, in which they have been described as demonstrating a starry-sky pattern (see Chapter 24). Their role in these tumors is the same as that in the normal lymph node, and they contain apoptotic debris derived from dying lymphoid cells.

Tissue macrophages or histiocytes are also prominent in the paracortex of lymph nodes. In paracortical lymphoid hyperplasias, such as viral lymphadenitis, these histiocytes become prominent and produce a mottled pattern. Epithelioid histiocytes and multinucleated giant cells are associated with granulomatous lesions involving lymph nodes.

The macrophages of the reticuloendothelial system share many enzyme histochemical and immunophenotypic characteristics. They have abundant and diffuse activity for lysosomal enzymes, including acid phosphatase and nonspecific esterase.[20,21] As stated previously, all of these cells can also demonstrate phagocytosis under appropriate conditions. HLA-DR antigens, complement receptors, and receptors for the Fc fragment of IgG are common to all macrophages in lymph nodes. Activity for lysozyme and alpha$_1$-antitrypsin can be seen in all the foregoing subtypes as well, but this activity is most prominent in epithelioid histiocytes.[22] Activity for lysozyme decreases abruptly with phagocytosis, presumably because of its loss into lysosomal vacuoles.

Various monoclonal antibodies have been derived that react with monocytes and macrophages.[23,24] None of these reagents is specific for the mononuclear phagocytic system, however, and all have been shown to react with other hematopoietic cells as well, including myeloid cells, T cells, and B cells (see Chapter 6). Therefore, in the diagnosis of the histiocytoses one must interpret immunostaining and other monoclonal antibody diagnostic methods strictly and only in the context of the histologic or histopathologic features of a given lesion. The CD11c antigen present on monocytes and macrophages is absent from normal T and B lymphocytes but is expressed on the cells of hairy cell leukemia (a B-cell lymphoproliferative disorder), in low-grade B-cell lymphoproliferative disorders, and in some T-cell lymphomas.[25] Similarly, the CD14 antigen is present on monocytes and macrophages, but it can also be seen occasionally on normal and neoplastic B lymphocytes.

Cross-reactivities with T cells are present as well. For example, the CD4 antigen characteristic of the so-called helper T-cell subset is found in normal monocytes and macrophages.[26] Receptors for interleukin-2 (IL-2R; CD25), in addition to being found on activated T lymphocytes, are found on normal monocytes and macrophages.[27,28] Transferrin receptors (CD71), normally a feature of activated or proliferating hematopoietic and nonhematopoietic cells, are strongly expressed on monocytes and macrophages, even if these cells do not appear to be undergoing cellular proliferation.[29]

The monoclonal antibody KP-1, to CD68, is a useful antibody to detect macrophages in both frozen and paraffin sections.[30] CD68 is also expressed in some immune myeloid cells and is positive in granulocyte sarcomas.

That all the macrophage and reticulum cell subsets express the leukocyte common antigen detected by CD45 antibodies attests to their common hematopoietic origin. Many of the antigens expressed on macrophages are involved in triggering of phagocytosis, killing, adhesion and activation. These include CD11a, CD11b, CD11c, CD13, CD14, CD15, CD16 (FcR), CD17, CD18, CD25, CD31, CD32 (FCR), CD35, CD36, CD64, and CD68.

## PATHOPHYSIOLOGY

Several theories have been advanced to explain the pathophysiology of the four major severe childhood histiocytoses. In the case of histiocytosis X (now correctly called *LCH*; see subsequent discussion), it is suspected that immunologic stimulation of a normal antigen-presenting cell, the Langerhans' cell, continues in an uncontrolled manner, resulting in the proliferation and accumulation of these cells. That this results in disordered immunoregulation that may be central to the disease

process is suggested by findings of defective immunologic function in patients with LCH. [31] These patients showed autocytotoxicity, or destruction of their own fibroblasts and antibody-coated erythrocytes by their own effector cells *in vitro*. These immunologic findings were associated with abnormal thymic histology.[31,32] Furthermore, the administration of thymic extract was associated with clinical improvement and reversal of the defective immunologic responses *in vitro*. A continuing issue of controversy is whether LCH is a malignant disease. The demonstration of a clonal origin of lesional LCH cells suggested this possibility, [33,34] although clonality is certainly not a *sine qua non* of malignancy, and these cells are not aneuploid. Finally, that there may be genetic factors contributing to the pathophysiology of LCH is suggested by new evidence of familial clustering of LCH and high LCH concordance rates in presumed monozygotic twins. [35]

Histiocytic reactions that are secondary to known causes and do not result in a self-perpetuating hemophagocytic reaction would be expected to disappear on resolution of the underlying disease process. As discussed in detail later in this chapter, such is the case in the infection-associated hemophagocytic syndrome (IAHS). Thus, in this syndrome, the macrophage is possibly reacting to a foreign antigen adsorbed onto the formed blood elements, including erythrocytes.

An alternate explanation is that the hemophagocytic syndrome may be secondary to excessive cytokine or lymphokine production by normal or neoplastic T lymphocytes.[36] Evidence for increased cytokine production has been shown *in vitro* for cells derived from patients prone to develop hemophagocytic syndromes. [37,38] More recent studies have implicated increased production of gamma interferon, MIP-1 alpha, and tumor necrosis factor in patients with hemophagocytic syndromes.[39,40] Thus, it has been hypothesized that in certain clinical situations, in particular in association with defective T-cell function, a state of abnormal immune regulation exists: A precipitating event such as an infection results in marked stimulation of the immune system. T cells become activated and elaborate cytokines. Cytokine production fails to be shut off, however, possibly because of abnormal feedback regulation. The excessive cytokine production continues unchecked, with marked stimulation of mononuclear phagocytes and the development of a hemophagocytic syndrome.

Additional evidence for excessive immune stimulation in the hemophagocytic syndromes is the marked elevation of serum soluble IL-2 receptor (SIL2-R) levels observed in affected patients with active disease. [41] This molecule, which is a truncated (40- to 45-kd) form of the 55-kd molecule designated CD25, is released by activated lymphocytes. Although high levels of circulating SIL2-R originally had been found in patients with human T-cell leukemia-lymphoma virus–associated T-cell leukemia or hairy cell leukemia, the highest levels of SIL2-R that have been measured occur in FEL. Because SIL2-R binds IL-2, it may interfere with normal immunoregulation in these patients. Finally, although it is tempting to hope that SIL2-R may be the elusive marker for FEL, the normal or near normal levels during clinical remission of the disease, as well as its elevation in IAHS, indicate that this is not the case. The findings do suggest, however, that the T lymphocyte could actually be the central cell in the pathogenetic process seen in the hemophagocytic syndromes and that the monocyte-macrophage proliferation is secondary.

In the case of FEL, the pathophysiology of the disease includes an element of immunodeficiency associated with plasma inhibitory activity. [42] The cell-mediated immune defects may be responsible for the opportunistic infections frequently contracted as terminal events in patients with FEL. The immune defects are secondary, however, because treatment (e.g., plasmapheresis) can remove plasma immunosuppressive activity and can result in complete recovery of cellular immunodeficiency *in vivo*.[43] How this secondary immunodeficiency relates to the underlying genetic (autosomal recessive) disease and to the unknown trigger of the clinical exacerbations of FEL, is unknown. Recently, however, a subgroup of patients with FEL has been shown to have a genetic defect in perforin, [44] a molecule critical to cytotoxic function of both T lymphocytes and natural killer cells. This defect may underlie the defective cellular cytotoxicity [42] in FEL and, in turn, the altered immunoregulation (uncontrolled cellular immune activation), although this remains to be investigated.

The physiology and pathogenesis of IAHS and FEL are similar, if not identical. In recognition of this similarity, these two entities are grouped together under the term *hemophagocytic lymphohistiocytosis*.

Finally, only in the case of neoplastic proliferation of cells of the monocyte-macrophage series (e.g., malignant histiocytosis) is the pathophysiology clearly one of a clonal proliferation of histologically malignant cells.

## PATHOLOGY

The International Histiocyte Society has proposed a system for the classification of the childhood histiocytoses. [45] The basis for classification is the relation of these lesions to normal histiocytic and reticulum cell subsets. This classification system has a pathologic basis because the ultimate diagnosis of all the childhood histiocytoses rests on the findings of pathologic examination. Although this schema does not include all proliferative histiocytic lesions of children or adults, it provides a conceptual approach to the diagnosis and classification of these disorders. The major forms of childhood histiocytosis are grouped into three classes, as presented in Table 26-3. In addition, Table 26-4 summarizes the most recently developed World Health Organization classification of the neoplastic disorders of the histiocytic cell and dendritic cell systems.[46]

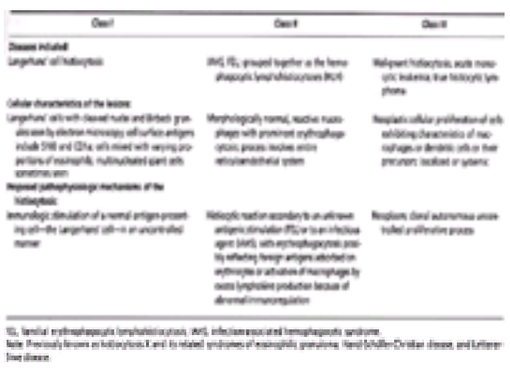


**TABLE 26-3. CLASSIFICATION OF CHILDHOOD HISTIOCYTOSES**

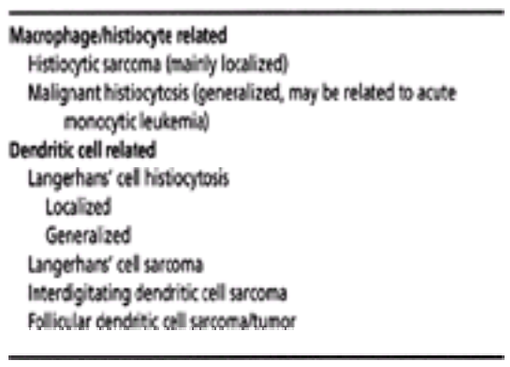

**TABLE 26-4. WORLD HEALTH ORGANIZATION CLASSIFICATION OF NEOPLASTIC DISORDERS OF HISTIOCYTES AND DENDRITIC CELLS**

### Class I Histiocytoses

Class I includes those histiocytoses in which the central cell has the histopathologic features of the Langerhans' cell. LCH, formerly known as *histiocytosis X*, is the principal disease in this class and is also the main proliferative disorder of the Langerhans' cell. LCH replaces the term *histiocytosis X* as well as the syndromes eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease, which had been included under the term *histiocytosis X*.[31,47,48,49,50,51,52] and [53] LCH historically has not been considered a neoplasm but a proliferative lesion, possibly secondary to a defect in immunoregulation. [31,32] The cells of LCH demonstrate the

phenotypic characteristics of normal Langerhans' cells, including S100 positivity, CD1a (OKT6) expression, and Birbeck granules ( Fig. 26-1).[54,55 and 56] However, in contrast to normal Langerhans' cells, the cells of LCH also express leukocyte adhesion molecules, such as CD11 and CD14, typically expressed in greater density on phagocytic histiocytes (Table 26-5).[57,58] Two laboratories[32,33] have demonstrated that the lesional cells in LCH are clonal in origin. This important finding is not yet completely understood. On the one hand, it demonstrates that LCH is a proliferative process, both in patients with only single bone lesions and in those with disseminated disease. On the other hand, the distinction between reactive and malignant causes cannot be ascertained from these findings at this time. Further studies will be necessary to determine whether specific molecular genetic lesions characterize LCH cells.

**FIGURE 26-1.** Electron micrograph of a Langerhans' cell showing Birbeck granules. This cell was obtained by needle aspiration from a patient with lymph node involvement of Langerhans' cell histiocytosis.

| Cell marker | Langerhans' cell histiocytosis | Histiocytic sarcoma | Acute monocytic leukemia | Sinus histiocytosis with massive lymphadenopathy | Follicular dendritic tumor | Anaplastic large cell lymphoma |
|---|---|---|---|---|---|---|
| CD1a | + | - | - | - | - | - |
| S100 | + | +/- | - | + | - | - |
| CD21 | - | - | - | +/- | + | - |
| CD35 | - | - | - | + | + | - |
| CD15 | - | + | + | + | - | +/- |
| CD4 | + | + | + | + | - | + |
| CD68 | - | + | + | + | - | +/- |
| CD45 (leukocyte common antigen) | + | +/- | + | + | - | +/- |
| Lysozyme | - | + | + | + | - | - |
| CD30 | - | - | - | - | - | +/- |
| ALK-1 | - | - | - | - | - | + |

+, +/-, -, indicate relative degree of expression, from strongly positive to negative.

**TABLE 26-5. PHENOTYPES OF HISTIOCYTIC (AND RELATED) PROLIFERATIVE LESIONS**

Grossly, the lesions of LCH are granulomatous and, when visible, appear yellow-brown. As such, they are easily seen in the skin. The hallmark of these lesions is the presence of Langerhans' cells by light microscopy. These cells have deeply indented nuclei and low nuclear to cytoplasmic ratios ( Fig. 26-2). The lesions in LCH may consist of either pure histiocytic infiltrates or mixed histiocytic and eosinophilic lesions, as are commonly seen in lytic bone lesions of this disease. [59,60] In addition to the varying proportion of eosinophils, phagocytic histiocytes and multinucleated giant cells are sometimes present. Necrosis may be evident. In partially involved lymph nodes, the process involves the paracortex. Although cytologic atypia may be observed in Langerhans' cells, this feature is not considered a significant prognostic factor.[61]

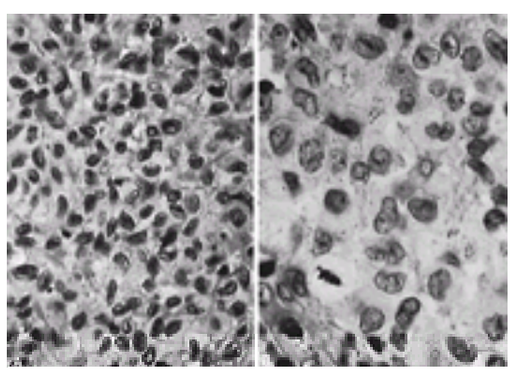

**FIGURE 26-2.** Histopathologic features of Langerhans' cell histiocytosis. **A:** Langerhans' cells exhibit delicate nuclear chromatin with fine nuclear grooves. **B:** Cytologic atypia in Langerhans' cells may be seen in some cases but are not believed to be a significant prognostic feature.

The key pathologic finding in LCH is the presence of Birbeck granules, [17] detected by electron microscopy, in cells of the lesions (Fig. 26-1). The significance of this diagnostic structure is unknown,[12] although it is also found in normal Langerhans' cells of the skin, cells whose role is to present antigens. Investigators have therefore suggested that LCH may represent an uncontrolled immunologic reaction to an unknown foreign antigen. [62] In support of this possibility are the findings of autocytotoxicity and cytokine elaboration in the lesions, previously discussed. The presence of Birbeck granules in cells of the lesions is the diagnostic finding in LCH.

Curiously, however, the cytologic atypia and particularly the Birbeck granules found by electron microscopy usually are not present in brain or liver tissue, even when these organs are clinically involved in the disease process. [63] Therefore, the lesions in these organ systems may possibly result from a different pathogenetic process.

Alternatively, the absence of Langerhans' cells in these organs may possibly prevent the characteristic expression of the granulomas of LCH. As in the analogous situation in hemophagocytic syndromes, in which a T-cell regulatory abnormality may possibly be central to the disease process, it may be that the Langerhans' cell in LCH is not central to this immunopathologic process.

As noted earlier, it has been suggested that LCH may be a malignant disease. The finding of clonality of LCH cells bears on this point, but further studies will be required to resolve this issue. Moreover, lesions with the histologic features of LCH have been described in lymph nodes in association with various malignant neoplasms, most often Hodgkin's disease.[66,67] In this situation, LCH appears to be a finding incidental to a localized process and does not have any independent prognostic importance. Finally, rare malignant proliferations with a Langerhans' cell phenotype have been described, [69,70] as discussed further in the section on class III histiocytoses.

### Class II Histiocytoses

The class II histiocytoses represent the largest group of disorders and include the nonmalignant histiocytoses in which the accumulating mononuclear cell is of the phagocytic (antigen-processing) cell type ( Table 26-1). This finding contrasts these disorders with the class I diseases, which are also reactive histiocytoses but of antigen-presenting or dendritic cell type. In the class II histiocytoses, the normal monocyte-macrophage is the predominant cell, frequently in a mixed lymphohistiocytic infiltrate. The characteristic findings on lymph node biopsy include infiltration of the nodes, especially of the sinusoids, cortex, and paracortex,

without effacement of nodal architecture. Involved lymph nodes may later show lymphocytic depletion with increased numbers of histiocytes.

The striking major histopathologic finding in the class II histiocytoses (FEL and IAHS) is the morphologically normal appearance of the involved cells; no cytologic atypia are noted (Fig. 26-3). Marked histiocytic proliferation is observed throughout the reticuloendothelial system. Sites most markedly affected include the bone marrow, splenic red pulp, hepatic sinusoids, and lymph node sinuses. [36,71]

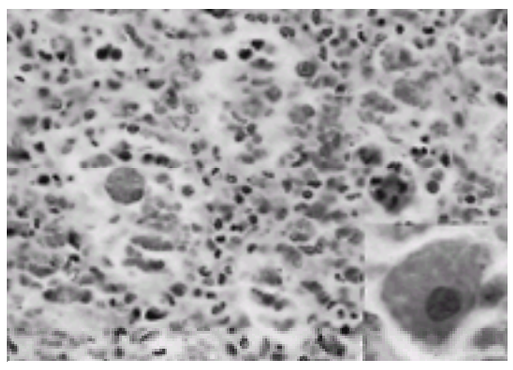

**FIGURE 26-3.** Infection-associated hemophagocytic syndrome. Histiocytic infiltrates with prominent erythrophagocytosis ( *inset*) are characteristic of both this syndrome and familial erythrophagocytic lymphohistiocytosis. Histiocytes are cytologically normal.

Involvement of the bone marrow, always obvious at the time of diagnosis of IAHS, may be delayed in FEL. In FEL, the initial marrow biopsy may show erythroid hyperplasia, without hemophagocytosis. Therefore, other sites should be biopsied to document FEL in an affected child with a positive family history. [72]

Cytologically, the histiocytes appear activated, with abundant cytoplasm and prominent phagocytosis of the formed elements of the blood, including erythrocytes, leukocytes, and platelets. These reactive histiocytes also have low nuclear to cytoplasmic ratios, mature nuclear chromatin, and inconspicuous nucleoli. Striking erythrophagocytosis and, in fact, phagocytosis of all cellular blood elements are characteristic of both IAHS and FEL. On histopathologic criteria alone, FEL and IAHS may be indistinguishable from each other but should be clearly distinguishable from both class I and class III histiocytoses. The striking similarity between FEL and IAHS suggests that one pathogenetic mechanism may be central to both diseases. This possibility remains to be elucidated.

With respect to the evolution of the lesions, resolution of the infection in the case of IAHS sometimes results in complete resolution of the histiocytic infiltration and the erythrophagocytosis. Similarly, apparent clinical remission in FEL is associated with disappearance of the pathologic infiltrates. Thus, the class II syndromes are characterized by a clearly secondary accumulation of histiocytes. The mechanisms causing these accumulations, however, remain unknown. In both cases, electron microscopy is negative for the Birbeck granules that characterize the cells of LCH, and the cellular morphology is also different from that of LCH cells. The mixed lymphohistiocytic infiltrates further help to distinguish the disseminated class II histiocytoses from class I disease, in which either mixed histiocytic and eosinophilic or pure histiocytic infiltrates are seen.

Several other rare class II histiocytoses are mentioned in the next few paragraphs, primarily because these disorders enter into the differential diagnosis of lymphadenopathy or skin lesions in which histiocytic infiltration is prominent. In sinus histiocytosis with massive lymphadenopathy (SHML), affected lymph nodes demonstrate a marked fibrous thickening of the capsule. Residual follicles are usually present and demonstrate a florid follicular hyperplasia. Consistent with the polyclonal hypergammaglobulinemia seen in these patients, a prominent plasmacytosis is present as well. The sinuses and interfollicular regions are expanded by a marked histiocytic proliferation. The histiocytes have abundant clear cytoplasm and distinct cytoplasmic membranes. A characteristic feature is the phenomenon of emperipolesis in which apparently viable lymphocytes and plasma cells are identified within vacuoles within the cytoplasm of the histiocytic cells. The nuclei of the proliferating histiocytes appear activated and may contain small but distinct nucleoli. Cytologic anaplasia indicative of malignancy has not been described, however.

Phenotypically, the cells of SHML demonstrate many of the properties of phagocytic macrophages. [66] The cells contain abundant activity of lysosomal enzymes. They also demonstrate positivity for S100 protein. Although S100 protein is more characteristic of IRCs, weak activity may be seen in normal and reactive sinus histiocytes. The cells of SHML are negative with the dendritic reticular cell antigen and CD1a monoclonal antibodies, but they demonstrate reactivity for CD4, CD11, CD14, CD25, and transferrin receptors. All of the foregoing are present on normal histiocytes and macrophages.

In histiocytic necrotizing lymphadenitis (Kikuchi's disease), histiocytes constitute a significant component of the inflammatory lesion that characterizes this disease.[73,74 and 75] The cause of this reactive lymphadenopathy is unknown. Kikuchi's disease is characterized by a focal necrotizing lesion within lymph nodes, usually located in the paracortex. Although karyorrhexis is conspicuous, neutrophils are absent. The proliferating cells are predominantly histiocytes and immunoblasts. The process is often misdiagnosed as a large cell or histiocytic lymphoma because of the prominent immunoblastic component and partial obliteration of lymph node architecture that may be seen.[67] The disease occurs commonly in young women but is rare in the pediatric age group.

Two pediatric benign histiocytic proliferative disorders are characterized primarily by skin involvement with multiple cutaneous nodules. In juvenile xanthogranuloma (multiple cutaneous nodules), lesions are composed of a monotonous cellular infiltrate of histiocytes with frequent multinucleated Touton giant cells in the subcutaneous tissue. The cytoplasm is abundant and eosinophilic. Cytologically, the cells appear benign. The cells cytochemically and ultrastructurally have the features of macrophages.[76] They are strongly positive for lysozyme.

In self-healing reticulohistiocytosis, the cutaneous nodules are composed of large histiocytic cells that may demonstrate cytologic atypia. This feature distinguishes this disease from juvenile xanthogranuloma, in which cytologic atypia are less prominent. Multinucleated forms may be present and mitotic figures are observed. The cells contain either foamy or eosinophilic cytoplasm that resembles ground glass. Erythrophagocytosis is not a conspicuous feature.

### Class III Histiocytoses

Class III comprises the malignant disorders of mononuclear phagocytes, including acute monocytic leukemia, malignant histiocytosis, and true histiocytic sarcoma. Also included in this class are the rare cases in which the malignant histiocytic cell is the Langerhans' cell. [45]

These three malignancies of mononuclear phagocytes represent a spectrum in terms of their degree of dissemination, and can be conceptually related to different stages of maturation and differentiation in the mononuclear phagocytic series. [57] Acute monocytic leukemia relates to a bone marrow–derived monoblast. This malignancy arises in the bone marrow compartment with secondary involvement of the peripheral blood and usually an elevated white blood cell count. In contrast to acute myeloid leukemia, one sees a higher incidence of involvement of nonhematopoietic sites, with frequent involvement of skin and gingiva. Hepatosplenomegaly and lymphadenopathy are common (25% and 50%, respectively).[77] Acute monocytic leukemia is discussed further in Chapter 20. Malignant histiocytosis represents a malignancy of mononuclear phagocytes that are intermediate in differentiation between monocytes and monoblasts and fixed tissue histiocytes. In many instances, the syndromes of acute monocytic leukemia and malignant histiocytosis merge, and the distinction may be arbitrary and semantic. [78,79]

Malignant histiocytosis is a systemic malignant disease involving the entire reticuloendothelial system. [80,81] Within the lymphoreticular system there is preferential involvement of sites normally populated by histiocytes, such as lymph node sinuses, splenic red pulp, and hepatic sinusoids. Bone marrow involvement is common, and although abnormal cells can be seen in the peripheral blood, if peripheral blood involvement is extensive, a diagnosis of acute monocytic leukemia should be considered. Other frequent sites of involvement include skin and bone. [82]

The cells in malignant histiocytosis have atypical characteristics ( Fig. 26-4). The nucleus is large, with a reticular chromatin pattern and prominent nucleolus. Cells exhibit a basophilic cytoplasm and stain positively for acid phosphatase and nonspecific esterase. [5,14] Erythrophagocytosis may be present but is not prominent, as in the class II histiocytoses. Even when phagocytosis is observed, it is clinically insignificant. Furthermore, on careful examination of cellular morphology, it has been observed that the phagocytosis is generally the result of reactive infiltrating cells within the tumorous lesions. Importantly, particularly in children, most neoplasms

formerly diagnosed as malignant histiocytosis represent anaplastic large cell lymphomas (ALCLs) (see below). The clinical syndrome of histiocytic medullary reticulosis, characterized by hepatosplenomegaly, pancytopenia, and jaundice, once thought to be a variant of malignant histiocytosis, is recognized now as a manifestation of the class II histiocytoses, most often IAHS.

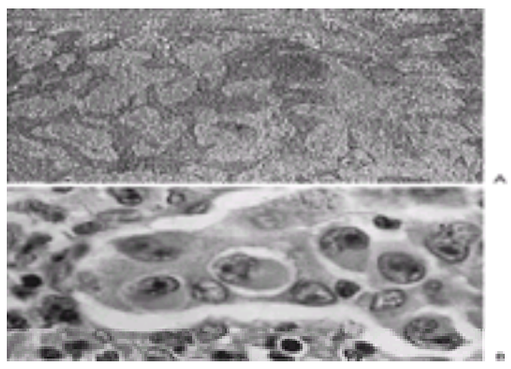

**FIGURE 26-4.** Malignant histiocytosis. Neoplastic cells **(A)** preferentially invade lymph nodes sinuses and, as seen in **(B)**, exhibit cytologically malignant features.

The end point of the spectrum is the rarest form, histiocytic sarcoma, which is a malignancy of the mononuclear phagocytic series at the stage of fixed tissue histiocytes. As such, the lesions in histiocytic sarcoma are localized and discrete. In addition to the reticuloendothelial system, other sites of involvement include skin, gastrointestinal tract, and bone.[83] Cytologically, the cells are unquestionably malignant. Without the benefit of specialized diagnostic tools, these lesions would fall into the category of large cell, immunoblastic lymphomas in the working formulation.[84]

Enzyme cytochemistry and histochemistry remain a reliable adjunct to morphology in the diagnosis of malignant diseases of the mononuclear phagocytic system. The cells have diffuse staining for nonspecific esterase activity, which is usually at least partially fluoride sensitive.[85] Preferable methods for detection of esterase activity include the a-naphthyl butyrate esterase reaction because activity is not observed in myeloid cells.[20] Myeloid cells also contain minimal, if any, activity for a-naphthyl acetate esterase. The naphthol ASD acetate esterase reaction requires the use of fluoride to distinguish myeloid and mononuclear phagocytic cells. Activity for acid phosphatase and b-glucuronidase is usually present as well. In all cases, the activity should be diffuse throughout the cytoplasm and not punctate. Punctate reactivity localized to the Golgi region is more characteristic of lymphoid than of mononuclear phagocytic cells. Caution should be exercised in the use of enzyme cytochemistry because these enzymes are not specific for mononuclear phagocytes and can be seen in certain lymphomas, carcinomas, and sarcomas.[86]

Most malignancies previously diagnosed as malignant histiocytosis in children actually represent ALCLs.[87,88] Indeed, most instances of so-called malignant histiocytosis appear to represent this variant of Ki-1 (CD30)-positive lymphoma. In this tumor, the malignant cells have a propensity to invade lymphoid sinuses. Because of the sinusoidal location of the tumor cells, misdiagnosis as malignant histiocytosis or metastatic carcinoma has been common.[87] In most cases studied, the malignant cells express some T-cell antigens, although the cells have an aberrant phenotype. T-cell gene rearrangement has also been shown in some instances.[89,90] and[91] A consistent feature is the expression of the Hodgkin's disease–associated antigen CD30, detected by Ki-1 and BerH2. This antigen, although present on the malignant cells of Hodgkin's disease, is also found in activated T and B lymphocytes (but not in macrophages).

ALCL has been associated with a common recurring cytogenetic translocation.[92,93] This translocation, t(2;5)(p23;q35), was also described previously in cell lines derived from cases of so-called malignant histiocytosis[94] that in retrospect, were derived from ALCL. The translocation involves the anaplastic lymphoma kinase (ALK) tyrosine kinase gene on chromosome 2, and the nucleophosmin (NPM) gene on chromosome 5. More recently, variant translocations have been identified involving the ALK gene and partners other than NPM. ALK tyrosine kinase is overexpressed in the malignant cells, and now can readily be detected in routine paraffin sections with the ALK-1 monoclonal antibody.[95]

ALCL can occur in all age groups, but it appears to be common in children and young adults.[80] A high incidence of cutaneous disease has been reported. The skin lesions are deep dermal, but ulceration of the overlying epidermis may be seen in larger tumors. The process should be approached clinically as a large cell or aggressive non-Hodgkin's lymphoma. A histiocyte-rich variant has also been described in children and must be distinguished from both class II and III histiocytoses (discussed in Chapter 24).[96]

To summarize, the pathologic classification of the childhood histiocytoses includes LCH in class I, the class II histiocytoses that result from the accumulation of benign histiocytes as a secondary response to disease processes of unknown pathogenic mechanisms, and the class III malignant histiocytic disorders. Histopathologic diagnostic criteria are summarized in Table 26-1. Accurate diagnosis of the childhood histiocytoses is vital. The presence of those pathologic features of definitive value in classifying these disorders must be identified: Birbeck granules uniformly and only in class I histiocytoses; malignant characteristics uniformly and only in class III histiocytoses; and benign reactive histiocytes comprising class II histiocytoses. Attempting to make a clinical diagnosis without these histopathologic findings is inappropriate.

## CLINICAL PRESENTATION AND TREATMENT

### Class I Histiocytoses

#### *Langerhans' Cell Histiocytosis*

The clinical presentation of LCH varies from mild discomfort and irritability to specific lytic bone lesions (Fig. 26-5) that may have been diagnosed only incidentally on a radiograph obtained for another reason.[97,98,99] and[100] Other symptoms may include chronic otitis, diabetes insipidus, or generalized symptoms such as fever and weight loss. This varied clinical presentation may make the diagnosis of LCH difficult. As noted previously, the definitive diagnosis (Table 26-6) rests on confirmation of the presence of the Birbeck granule–positive cells in the lesions of the disease as determined by electron microscopy, or CD1a-positive lesional cells. Other findings include positive immunostaining for S100 protein, which is not present on normal histiocytes.[11] The biopsy sample must be obtained from clearly involved tissue because normal Langerhans' cells containing Birbeck granules are present in the skin as well. Multiple organ systems may be involved in this disorder (Table 26-7).

**FIGURE 26-5.** Langerhans' cell histiocytosis. Radiograph of the characteristic lytic bone lesion, as seen in the skull of a patient whose other findings included exophthalmos and diabetes insipidus.

| Class I (Langerhans' cell histiocytosis) | Class II (infection-associated hemophagocytic syndrome) | Class II (familial erythrophagocytic lymphohistiocytosis) | Class III |
|---|---|---|---|
| **Clinical presentation** | | | |
| Wide spectrum, from mild discomfort related to lesions (lytic bone lesions, chronic otitis, diabetes insipidus) to generalized symptoms, including fever and weight loss | Pancytopenia, hepatosplenomegaly, fever, coagulopathy | Irritability, fever, vomiting, sometimes with a coagulopathy and hepatosplenomegaly | Variable, from systemic disease to acute monocytic leukemia to localized mass in true histiocytic lymphoma |
| **Diagnostic findings** | | | |
| Intact granules and CD1a expression in lesional cells | Morphologically normal macrophages, often showing related infection and negative family history | Morphologically normal bone phagocytes and macrophages, lack of specific infectious etiology, sometimes positive family history | Malignant macrophages or dendritic cells |
| **Prognosis** | | | |
| Variable; may be self-resolving disease process in some cases | Possible resolution if underlying infection is controlled and immunosuppression can be reversed | Extremely poor; uniformly rapidly fatal | Poor for acute monocytic leukemia; improving for MH and HT, up to 75% survival at 4% reported with appropriate therapy |
| **Recommended treatment** | | | |
| None to mild (radiation or chemotherapy limited to one or a few sites), and steroids for certain lesions | Avoidance of immunosuppressive therapy; experimental: etoposide | Experimental: allogeneic bone marrow transplantation | Doxorubicin (Adriamycin) in a combination chemotherapy regimen for MH and HT; appropriate treatment for acute monocytic leukemia |

HT, histiocytic sarcoma; MH, malignant histiocytosis.

**TABLE 26-6. CLINICAL, PROGNOSTIC, AND THERAPEUTIC ASPECTS OF THE MAJOR CHILDHOOD HISTIOCYTOSES**

| Site | Percentage of cases involved (%) |
|---|---|
| Bone | 80 |
| Skin | 60 |
| Liver, spleen, lymph nodes | 33 |
| Bone marrow | 30 |
| Lungs | 25 |
| Orbit | 25 |
| Orodental | 20 |
| Otological | 20 |
| Central nervous system | |
| Diabetes insipidus | 15 |
| Hydrocephalus, nerve palsies | <5 |
| Gastrointestinal tract | <5 |

**TABLE 26-7. ORGAN SYSTEM INVOLVEMENT IN LANGERHANS' CELL HISTIOCYTOSIS**

The clinical hallmark of LCH has been the presence of lytic bone lesions ( Fig. 26-5),[98,101] but clinical involvement may be variable. Formerly, when either single or multiple bone lesions alone were present, the disease was referred to as *eosinophilic granuloma*.[53] When granulomas were more widespread, causing bone lesions, diabetes insipidus (by involvement of the pituitary), and exophthalmos (by the presence of retro-orbital granulomas), the disease was termed *Hand-Schüller-Christian disease*.[48,50] Finally, the disseminated form of LCH was previously called *Letterer-Siwe disease*.[31,51] This last presentation is more commonly seen in infants and in children younger than 2 years and is characterized by wasting, hepatosplenomegaly, generalized lymphadenopathy, anemia, and sometimes pancytopenia. The milder forms of LCH are seen primarily in older children and less commonly in adults. The clinical finding of seborrheic dermatitis deserves special mention. It is often present on the scalp and in infants may easily be confused with a nonspecific dermatitis. As with the other lesions of LCH, however, biopsy and examination by electron microscopy, immunohistochemistry, or both, are diagnostic. In addition to the foregoing clinical findings, virtually every tissue may be involved in LCH, including the lung and gastrointestinal tract. The manifestations of LCH may be protean. No evidence indicates, however, that a given lesion causes another lesion when no physical contact exists. Rather, both in location and in time, the individual lesions of LCH should be considered separate from each other. This consideration has implications for treatment approaches and suggests that clinical classification of the forms of LCH remains to be developed further. A comprehensive approach to the clinical and laboratory evaluation of children with LCH has been suggested by the Histiocyte Society. [102]

Central nervous system (CNS) involvement in LCH has also become increasingly recognized. A long-understood complication of LCH is the development of diabetes insipidus because of hypothalamic and pituitary histiocytic involvement. Less well known are the subtle neurologic defects that may be progressive and may develop years after the initial presentation of LCH. [63] They include hyporeflexia, spastic dysplasia, ataxia, vertigo, dysarthria, nystagmus, tremor, psychomotor retardation, and neuropsychological deficits.[64] The pathogenesis of this aspect of LCH remains enigmatic because characteristic histopathologic features are generally lacking. Understanding of CNS disease has advanced in the last several years, [63] particularly by the use of magnetic resonance imaging. This technique has enabled identification of cerebellar lesions in patients with LCH. The lesions may be mass lesions, but frequently, in the cerebellum, they are only hypodense lesions consistent with demyelination and gliosis of periventricular white matter. [65] These findings have been confirmed by biopsy. The characteristic biopsy findings of LCH, which are Langerhans' cells with Birbeck granules, are absent in these hypodense lesions. These cerebellar pathologic findings parallel the aforementioned symptoms, including ataxia and dysarthria. Clearly distinct from the well-known diabetes insipidus associated with LCH, diffuse CNS disease presents a new challenge in LCH. At the present time, no specific recommendation regarding treatment for this syndrome can be given.

The outcome of LCH varies, but in most cases the disease is a self-resolving process. The two prognostic factors appear to be age at the time of diagnosis and degree of organ involvement.[97,100] Children younger than 2 years at the time of diagnosis have a higher mortality rate than do older children. Likewise, the presence of organ dysfunction (e.g., liver, lungs, and bone marrow) is a poor prognostic sign, with liver involvement at the time of diagnosis indicating a particularly poor prognosis.[103,104] Involvement of multiple organ systems has an additive negative effect on survival. Fortunately, children with these poor prognostic features constitute fewer than 15% of LCH cases. Other than these two factors and the knowledge that the disease usually resolves completely and spontaneously, little is known about the natural evolution of the disease process and the effects of intervention.

The approaches to treatment of LCH over the last century have been as varied as the clinical presentation of the disease. [31,105,106,107,108,109] and [110] Thus, treatment has ranged from antimicrobial therapy, based on the assumption that LCH is an infectious disease, to chemotherapy, based on the belief that this disorder is an aggressive malignancy. Although some reports in the literature had supported a role for chemotherapy by demonstrating improvement in the overall survival rate compared with historical controls, careful diagnosis and stratification for severity of disease were not always applied in these studies. When such analyses were performed on a large number of patients, all uniformly classified, it appeared that disseminated LCH, with multiple-organ involvement, had a poor prognosis that had not been changed substantially by various treatments. [62] In contrast, mild disease has an excellent prognosis that also has not been changed by the administration of any particular therapy. [62,111] These findings suggested that little progress has been made in the development of definitive therapy for LCH. Because this concept is now accepted by pediatric oncologists, current treatment approaches to mild LCH tend to use less intensive therapy, when treatment is indicated. Specifically, this includes use of vinblastine or etoposide, [112] with or without the addition of prednisone, and low-dose radiation therapy. Moreover, long-term steroid therapy should be avoided because of its secondary side effects.

In the absence of a specific, definitive treatment, the therapeutic approach to the child with LCH should be directed toward preventing irreversible damage to normal tissues (permanent consequences) by LCH lesions that eventually spontaneously resolve. Thus, treatment should be directed toward halting or reversing the progression of lesions. This approach has been widely applied to cases of isolated bone involvement in LCH and may also be applicable to more disseminated disease. Even the use of mild therapy remains controversial, however, because of the absence of definitive prospective studies evaluating various treatment approaches to this entity.

Encouraging data about the value of chemotherapy in multisystem LCH came from a large nonrandomized cooperative study of LCH. [104] Patients were stratified according to risk and received mild initial chemotherapy (vinblastine, etoposide, and prednisone) and “maintenance therapy” with the same drugs as well as 6-mercaptopurine and methotrexate. The speed of resolution was rapid (median, 4 months), and the frequency of recurrence after initial resolution was low, ranging from 12% in patients with multifocal bone disease to 42% in patients with organ dysfunction. Overall, 77% of patients have remained free of disease recurrence. Permanent consequences developed after diagnosis in 20% of the patients. A striking finding of this study was the low incidence of sequelae of LCH, especially diabetes insipidus (only 10% after the initiation of treatment). [104] This finding is in contrast to the reported higher incidence of 23% (4% at diagnosis; 19% developing later).[113] The much lower incidence of late development of diabetes insipidus in the former study may reflect the early treatment of all patients, which may therefore be

valuable in reducing the complications and sequelae of LCH, even if overall mortality is not reduced.

To optimize therapy, a sufficiently large, prospective, randomized treatment study is necessary. For this reason, an international randomized trial in LCH was initiated by the Histiocyte Society in 1991. This study (LCH-1) compared etoposide and vinblastine in the treatment of disseminated LCH. Data on the risk of etoposide-associated (therapy-induced) malignancy in the setting of histiocytosis have been reviewed, and the available evidence leads to the recommendation that the study of etoposide in LCH should be continued.[114] LCH-1, now completed, showed vinblastine and etoposide to be equivalent in all respects—response, toxicity, probability of survival, and probability of disease reactivation and development of permanent consequences. The study also identified lack of rapid (within 6 weeks) response as a new prognostic indicator, predicting a high (66%) mortality rate in children with risk organ involvement (liver, lung, hematopoietic system, or spleen).[115] A relatively high rate of disease reactivation suggests that more intensive therapy may be of value for some patients. This is currently being studied, also in a randomized trial (LCH-2) by the Histiocyte Society. In tandem with systematic therapy the use of low-dose radiation therapy to specific lesions that threaten permanent damage is recommended. Doses in the range of 500 to 800 cGy are recommended for such single lesions. Systemic therapy, vinblastine (0.4 mg per kg weekly) or etoposide, with or without corticosteroids, has been used in the case of more widespread disease.

Significant numbers of children, particularly infants with multisystem disease, are “unresponsive” to mild therapy. New treatment approaches should be considered in this group of patients.[105] One such approach is the use of cyclosporine in the treatment of LCH. Several patients treated with cyclosporine had a rapid clinical response.[116] Recrudescence of the disease was observed when the drug was discontinued, however. Investigators have speculated that cyclosporine may act to reduce cytokine production,[117] thereby implicating massive cytokine production as a factor in the pathogenesis of LCH. The eventual value of cyclosporine in the treatment of LCH may lie in its use in combination with mild chemotherapy. Other experimental treatment approaches include bone marrow transplantation, which is considered for severe, unresponsive cases.

The most promising new therapeutic agent for LCH appears to be the antimetabolite 2-chlorodeoxyadenosine (2-CdA), which in addition to being lymphocytotoxic evidences potent cytotoxicity against monocytes.[118,119] 2-CdA has been effective particularly in adult patients with chronic LCH,[119] as well as in some children with refractory or recurrent LCH.[120] Further controlled studies of this agent are therefore warranted and are in progress. Finally, monoclonal antibody therapy, using CD1a as the target epitope, is also being investigated.[121] The effectiveness of these agents remains to be established.

### *Dendritic and Interdigitating Reticulum Cell Tumors*

Although LCH is the major form of histiocytosis included in class I, at least two additional rare lesions are described that have a proposed derivation from FDC and IRC, respectively.[122,123 and 124] FDC sarcomas tend to present as localized lymph node disease. Although local recurrence may occur, systemic spread does not. By contrast, IRC tumors have a more aggressive clinical course and are more appropriately included among the class III histiocytoses—that is, malignancies of histiocytic cells.

## Class II Histiocytoses

Diseases falling into the class II histiocytoses category consist of those in which reactive cells of the mononuclear phagocytic cell series, excluding Langerhans' cells, are found in the lesions. The histiocytic reaction is presumed secondary to a primary underlying disease process. Because the histiocytic proliferation may result from different pathogenetic mechanisms, one can predict that both the prognosis and treatment of the individual diseases in this class would be widely different. This is in fact the case. The two major diseases in this category are FEL and IAHS, grouped together under the common term *hemophagocytic lymphohistiocytosis*, to reflect awareness that the pathogenesis of these two diseases is similar, even though the causes are different.

### *Familial Erythrophagocytic Lymphohistiocytosis*

FEL is characterized by the presence of hemophagocytosis and a positive family history.[125,130] Early in the disease, biopsy of lymph nodes demonstrates lymphoid proliferation. Later, however, lymphoid depletion occurs. Patients exhibit multiple defects in cellular and humoral immunity; a plasma inhibitor of lymphocyte blastogenesis has been demonstrated.[42]

FEL is a rare and almost always rapidly fatal disease. An autosomal recessive pattern of inheritance has been recognized since the initial studies of Farquhar and Claireaux.[126] These findings have led to exhaustive searches for a genetic lesion. Recently, several specific chromosomal abnormalities have been documented in FEL. These include linkage to 9q21.3-22, 10q21-22, and possibly other loci.[127,128 and 129] The heterogeneity of these abnormalities suggests either that FEL is not a single disease or that the abnormalities are secondary. In favor of the former possibility is the recent association of a defect in perforin (the gene for which is mapped to 10q22) with homozygous nonsense or missense mutations in eight 10q21-22–linked FEL patients.[44]

The pathogenesis of FEL is not understood. The clinical presentation of FEL is that of a generalized disease. Affected children, usually younger than 3 or 4 years of age at the time of diagnosis, most often present with weight loss and a fever of unknown origin. They may have the overall clinical appearance of failure to thrive. Physical examination may reveal hepatosplenomegaly and sometimes a maculopapular skin eruption. This eruption is distinguished from the yellow-brown eruption of LCH by its color, which is frequently red to purple. The CNS may be involved, with symptoms including disorientation, seizures, and sometimes coma.[131] Laboratory findings may include marked hyperlipidemia, hypofibrinogenemia, and the cellular immunologic dysfunction mentioned earlier. Although investigators initially thought that some or all of these laboratory findings were related to the underlying primary disease process, this is apparently not the case, because the onset of temporary clinical remission results in normalization of all laboratory parameters.[43] It now appears more likely that these abnormalities are a secondary phenomenon, as is the histiocytic reaction, in this genetic disease of undefined pathogenesis. Chromosomal abnormalities of a nonspecific nature have been reported.[132] Erythrophagocytosis in FEL is marked, particularly late in the course of the disease, and the terminal phase, which resembles the hemophagocytic syndromes, is frequently characterized by pancytopenia and jaundice.[133]

The diagnosis of FEL rests on identification of a lymphohistiocytic infiltrate, often with conspicuous erythrophagocytosis, together with an appropriate clinical and family history. The diagnosis may be made from examination of lymph nodes, spleen, liver, bone marrow, or lungs. The presence of a positive family history is obviously helpful. Because the disease is inherited in an autosomal recessive fashion, however, this history is frequently unavailable. Often, the correct diagnosis is not reached until a second family member is affected. For a review of diagnostic criteria, the reader is referred to the Histiocyte Society's diagnostic criteria and suggested evaluation for the hemophagocytic lymphohistiocytoses (FEL and IAHS) (Table 26-8).[72]

| Required for diagnosis* | Consistent with diagnosis |
|---|---|
| **Clinical** | **Clinical** |
| Fever | Jaundice |
| Splenomegaly | Edema |
| | Lymphadenopathy |
| **Laboratory** | **Laboratory** |
| Cytopenias (affecting ≥2 of 3 lineages in the peripheral blood and not caused by a hypocellular or dysplastic bone marrow): | ↑Circulating soluble interleukin-2 receptors |
| Hemoglobin (<9.0 g/dL) | Hyperferritinemia |
| Platelets (<100 × 10⁹/L) | Cerebrospinal fluid pleocytosis (mononuclear cells) |
| Neutrophils (<1.0 × 10⁹/L) | Hepatic enzyme abnormalities |
| Hypertriglyceridemia or hypofibrinogenemia (fasting triglycerides ≥2.0 mmol/L or ≥3 SD of the normal value for age; fibrinogen ≤1.5 g/L or ≤3 SD) | ↑ Very-low-density lipoprotein<br>↓ High-density lipoprotein<br>↓ Natural killer cell activity |
| Histopathologic criteria: Hemophagocytosis in bone marrow or spleen or lymph nodes; no evidence of malignancy | |

*All are required for the diagnosis of hemophagocytic lymphohistiocytosis. [Infection-associated hemophagocytic syndrome or familial erythrophagocytic lymphohistiocytosis (FEL)]; in addition, the diagnosis of FEL is justified by a positive family history and parental consanguinity is suggestive.

**TABLE 26-8. CLINICAL AND LABORATORY FINDINGS IN THE HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSES**

The rapid and fulminant course of FEL, coupled with findings of marked lymphohistiocytic organ infiltration, has resulted in the erroneous consideration of this disease as malignant. Consequently, cytotoxic chemotherapy has been used in the treatment of FEL.[134] Agents that have been used include vinblastine, etoposide, and other more convenient antileukemic drugs. In general, however, treatment has been unsuccessful, with the usual rapidly fatal course of the disease only slightly prolonged

by the administration of therapy. The lack of definitive benefit from chemotherapy is not surprising given that the disease is histopathologically benign. The extent to which inhibition of the hemophagocytic process may ameliorate the pathogenesis or the evolution of FEL remains to be determined, although clinical improvement is universally associated with quiescence of the hemophagocytic process. Because of the relative lack of success of these treatments, other, more experimental therapeutic approaches have been used. Plasma exchange therapy, consisting of a series of plasmaphereses or plasma exchange transfusions, was based on the findings of circulating immunosuppressive activity in this disease. [43] After exchange therapy, reduction in plasma inhibitory activity and reversal of the depressed cellular immune responses have been observed. Although clinical improvement was noted in an early trial of this approach, the disease subsequently relapsed.

The most promising treatment of FEL appears to be bone marrow transplantation. This approach is based on the hypothesis that the disease represents either an autonomous or uncontrolled proliferation of lymphocytes and histiocytes. Allogeneic bone marrow transplantation may be successful in curing some patients with FEL. According to results of a recent comprehensive study of 122 patients, allogeneic bone marrow transplantation resulted in a 66% estimated 5-year survival versus only 10% for patients treated with chemotherapy.[135] Consequently, a controlled study of chemotherapy and allogeneic bone marrow transplantation for FEL is currently in progress.[136] Although further understanding of the disease process is essential to identify the most effective treatment for FEL, clearly the transplantation results are encouraging.

### *Infection-Associated Hemophagocytic Syndrome*

IAHS was first described as a response to a viral infection in an immunocompromised host.[71] Subsequently IAHS has been reported in association with various infections, including viral, bacterial, fungal, and parasitic infections. [137,138] This hemophagocytic syndrome usually occurs in a setting of immunodeficiency. The immunodeficiency may be iatrogenic, as in organ transplant recipients receiving immunosuppression, or congenital. IAHS has also been seen in association with lymphoid malignant diseases, most often of the T-cell type, such as acute lymphocytic leukemia and the angiocentric immunoproliferative disorders. [36,139,140] and [141] The clinical features of IAHS are similar to those of FEL and include fever and other constitutional symptoms, liver function and coagulation abnormalities, and anemia. The coagulopathy appears to be multifactorial. Coagulation factor levels are depressed, presumably secondary to liver disease, and a component of consumption coagulopathy is also seen.[71] Although the overwhelming nature of the histiocytic proliferation has resulted in confusion of this syndrome with malignant histiocytosis, histopathologic analysis can distinguish these two forms of childhood histiocytosis. Moreover, the clinical features associated with IAHS are not characteristic of the true histiocytic malignancies, malignant histiocytosis and histiocytic sarcoma. [57] One must distinguish the benign IAHS from a true histiocytic malignancy.

The diagnosis of IAHS is most readily made on bone marrow aspirate, in which benign-appearing histiocytes containing platelets and red blood cells are frequently seen. Lymph nodes usually demonstrate lymphoid depletion and marked infiltration by benign histiocytes. Because the histiocytes are normal and reactive, they demonstrate all the phenotypic and enzyme cytochemical characteristics of normal activated macrophages.[36]

As mentioned previously, IAHS usually occurs in a clinical setting characterized by immunodeficiency. If the diagnosis is made, immunosuppression should be withdrawn and supportive care instituted. Treatment for the underlying infection should be instituted. Acyclovir administration has been useful in some patients with Epstein-Barr viral infections and IAHS.[142] Cytotoxic chemotherapy is generally contraindicated for IAHS, although etoposide or another drug that interrupts the pathogenesis of IAHS may be beneficial in reducing the expression of the syndrome while the underlying process (infectious) resolves. Chemotherapy has been found to be very effective in treating EBV-related hemophagocytic lymphohistiocytosis (IAHS) in Japan. [143]

Currently, caution is still suggested in the use of etoposide, both for LCH and for the class II histiocytoses, because of the reported risk of secondary myeloid leukemia in patients treated with the agent (see Chapter 20).[144] Because the secondary leukemias were found in patients with primary malignancies treated with intensive combination chemotherapy (in contrast to use of etoposide as a single agent in the treatment of histiocytosis), whether this drug should be avoided in the histiocytoses, in which etoposide has been found to be a particularly active agent, remains an issue. Evidence available to date [114,115] suggests that the risk of secondary myeloid leukemia in this particular group of patients (those with histiocytosis) is low (on the order of 1%), and therefore use of the agent should be continued, especially given that the mortality rate of the patients treated may be high. Attention to this issue has resulted in the interesting findings of a high association between LCH and malignancies in patients with LCH, with either disease (malignancy or LCH) preceding the other such that a causal relationship between the two cannot be established at this time.[68]

### *Other Class II Histiocytoses*

SHML (Rosai-Dorfman disease) presents primarily in the first two decades of life.[145] It affects boys and girls equally and is seen more often in blacks than in other races. Patients generally present with massive cervical lymphadenopathy, although many other sites can be involved, including skin, orbit, bone, salivary gland, and upper respiratory tract. Patients usually exhibit some systemic symptoms, including fever, increased erythrocyte sedimentation rate, polyclonal hypergammaglobulinemia, and neutrophilic leukocytosis.[146] The etiology of SHML remains obscure. A relation to an underlying immunodeficiency has been postulated. Although SHML is not considered a malignant disorder, considerable morbidity and mortality can result. [147] The lesions are locally destructive and can involve almost every organ system. Both radiation and chemotherapy have been used with some success, and in some cases the lesions spontaneously regress. [148,149]

Histiocytic necrotizing lymphadenitis is a reactive lymphadenopathy, the cause of which is unknown. The disorder usually presents in cervical or axillary lymph nodes. It affects women much more often than men and is more common in Asians than in whites or blacks. The peak incidence is in the third decade of life, but it may be seen in children and adolescents. Clinically, patients exhibit mild constitutional symptoms, fever, fatigue, and localized adenopathy. An infectious etiology is suspected but has not been confirmed. No bacteria or fungi are seen on special stains, and serologic evaluations for toxoplasmosis or Epstein-Barr viral infection have been negative. Because this disorder is entirely benign and has a self-limited clinical course, correct diagnosis is critical. No treatment is indicated.

Juvenile xanthogranuloma is a benign histiocytic lesion of the skin first described by Helwig and Hackney. [150] It occurs predominantly in neonates and young children. The process is characterized by one or more cutaneous nodules, often restricted to the head, neck, trunk, and proximal portions of the extremities. Extracutaneous involvement has also been reported. The lesions usually persist for 1 to 2 years and then spontaneously resolve. [150]

Self-healing reticulohistiocytosis presents in the perineonatal period. [151] Patients have multiple firm cutaneous nodules that range from dark red to dark blue. The nodules resolve spontaneously within 2 or 3 months. In some patients, hematologic abnormalities such as neutropenia, lymphocytosis, or both, have been reported. The process is distinguished from juvenile xanthogranuloma in that more cytologic atypia of the histiocytic cells is evident. The clinical course is benign, and no therapy other than supportive care is indicated.

### Class III Histiocytoses

The histiocytoses that are true neoplasms constitute a minority of the childhood histiocytoses. As noted previously, three major forms are known (acute monocytic leukemia, malignant histiocytosis, and true histiocytic sarcoma). Acute monocytic leukemia, included in this class because of its cell origin, is discussed in Chapter 20.

True malignant histiocytosis is a rare disease. When it occurs, it is usually seen in older children and adults, but it has been described in young children. Affected children present with symptoms of a generalized illness. Clinical symptoms and findings include fever, wasting, lymphadenopathy, and hepatosplenomegaly. Raised skin lesions, peripheral lymphadenopathy, and subcutaneous inflammatory infiltrates also may be seen. Each of these findings represents infiltration by tumor cells. Thus, the clinical presentation may be similar to that of FEL or IAHS. Indeed, some cases diagnosed as malignant histiocytosis in the past may have actually been one of the hemophagocytic syndromes in class II.[152,153]

As discussed earlier in the section on pathology, the diagnosis is best made by lymph node biopsy. Circulating tumor cells are rarely observed in these patients, who nevertheless almost always exhibit some degree of peripheral pancytopenia. Malignant histiocytosis must be distinguished from the other histiocytoses and from disseminated (stage IV) Hodgkin's disease, immunoblastic non-Hodgkin's lymphoma, and immunoblastic lymphadenopathy. In these latter disorders, immunophenotypic characterization may be a helpful diagnostic tool.

True histiocytic sarcomas may involve lymph nodes, the reticuloendothelial system, and skin and bone. When initially confined to the skin, this disease has been reported to pursue an indolent clinical course, with spontaneous regression of lesions observed in some cases. [154] Lesions previously thought to be of histiocytic derivation, such as regressing atypical histiocytosis, [155,156] are now known to be of T-cell derivation, however, and are part of the spectrum of CD30-positive lymphoproliferative disorders of the skin—that is, lymphomatoid papulosis and cutaneous ALCL. Therefore, earlier clinical series of cutaneous histiocytoses must be

reevaluated in light of newer information.

The appropriate treatment of the class III malignant histiocytic disorders of childhood is based on accurate diagnosis. Acute monocytic leukemia should be approached with treatment appropriate for that disorder. Because the diagnosis and classification of malignant histiocytic disorders have undergone such dramatic change in recent years, critical evaluation of previous clinical series is problematic, and conclusions regarding therapeutic efficacy are difficult. As noted earlier, many cases previously diagnosed as malignant histiocytosis represented either hemophagocytic syndromes (a benign disorder) or ALCL (an aggressive non-Hodgkin's lymphoma) (see Chapter 24).[57,89,157,158]

Malignant histiocytosis is one childhood histiocytosis in which treatment has clearly changed the prognosis. Formerly, this disease was considered to be almost uniformly fatal. Survival has now improved, however, apparently because of the addition of doxorubicin (Adriamycin) to the combination chemotherapy treatment regimens for malignant histiocytosis.[62] With the addition of this agent, a median survival of less than 6 months has been increased to one of approximately 40 months. Investigators have recommended that children with malignant histiocytosis receive induction therapy with vincristine, prednisone, cyclophosphamide, and doxorubicin, and subsequent maintenance therapy consisting of vincristine, cyclophosphamide, and doxorubicin.[81] The use of intensive, aggressive, doxorubicin-containing regimens also appears to be effective in the treatment of histiocytic sarcomas.[57]

## CONCLUSION

Most of the childhood histiocytoses have historically been discussed in pediatric oncology textbooks because of their traditional assignment to this subspecialty of pediatrics. Because most of these disorders are not true malignant diseases, however, the use of antineoplastic agents in their treatment should be carefully limited (with the exception of the treatment of class III histiocytoses). Careful documentation of the natural history of the childhood histiocytoses, use of the new system of pathologic classification discussed in this chapter, and careful and complete clinical and laboratory evaluation may help to provide a framework for the development of optimal therapeutic approaches. Ultimately, improvement in the outcome for children with the histiocytoses will benefit from further elucidation of the etiology and pathogenesis of these diseases.

## INTRODUCTION

Tumors of the central nervous system (CNS) on the whole represent the second most common pediatric cancer diagnosed in the United States each year. Depending on the upper age chosen, the number of children, adolescents, and young adults who received diagnoses of a CNS tumor in 1999 ranged between 1,700 (for ages 0 to 14 years) and 2,200 (for ages 0 to 20 years).[1] The numbers are higher if one includes such “benign” diagnoses as craniopharyngioma and choroid plexus papilloma (CPPs).[2,3] Figure 27-1 shows the approximate incidence of the common pediatric CNS tumors.

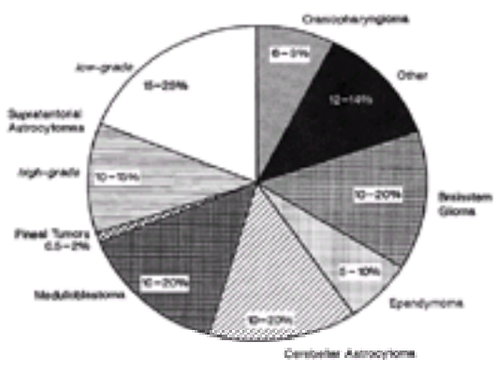

**FIGURE 27-1.** Approximate incidence of common central nervous system tumors in children.

Experience suggests that the morbidity from disease and therapy is significant in terms of physical and intellectual sequelae and, although not quantitated, likely exceeds that associated with other pediatric malignancies. Deaths caused by CNS tumors are the highest among pediatric cancers.[4] Although modest increases in cure rates have been realized, children with a CNS tumor remain a challenge for those who care for them. The authorship of this chapter reflects the multidisciplinary approach required to meet the challenge of increasing cure rates for children with brain tumors. The disciplines represented are by no means comprehensive, however. Optimal care of children with brain tumors involves the contribution of nurses; psychologists; physical, occupational, and speech therapists; and nutritional experts as well. The chapter reviews our understanding of the biology of brain tumors, the principles associated with each of the diagnostic and treatment modalities, management of the more frequently encountered tumors, and long-term effects of both the diseases and their treatment.

## EPIDEMIOLOGY

In the early 1990s, the incidence of CNS tumors in children appeared to be on the increase. Whereas the incidence during the years 1977 to 1981 was 2.7 cases per 100,000 children, from 1990 to 1994, the incidence was 3.3 cases per 100,000 children.[5] Although not definitively proven so, this higher incidence was likely due to the increased use of magnetic resonance imaging (MRI) to evaluate children with neurologic conditions and to an increase in microscopical confirmation of brainstem lesions.[6] Through these changes, the number of brainstem gliomas and supratentorial tumors that were identified increased, primarily as low-grade astrocytomas (LGAs). Other factors also may have contributed to the apparent increased incidence of pediatric brain tumors. Stereotactic biopsies were used more to document histologies of tumors at nonbrainstem sites; in the past, these tumors would not have undergone biopsy. The World Health Organization (WHO) classification of malignant gliomas also changed during this time, resulting in a shift of some diagnoses from benign to malignant. These combined factors affected the detection and reporting of brain tumors.[6] Conversely, ascertaining that the increase in the number of affected children was not, in fact, due to a true, acute rise in the incidence of CNS tumors will require several more years of observation.

The incidence of brain tumors peaks in the first decade of life, then decreases until a second peak in older adulthood. This second peak historically occurred in the seventh decade of life, but recent Surveillance, Epidemiology, and End Results (SEER) data demonstrated a shift in this peak to the eighth decade.[7] The first peak is characterized by a predominance of male patients and by equal incidence rates for whites and blacks, except for the first 2 to 3 years of life, when more whites than nonwhites are affected.[4] The predominance of males is explained mostly by a disproportionate incidence of both medulloblastoma and ependymoma. For other tumor types, the genders are equally affected. During the first 2 years of life, cerebral lesions predominate; cerebellar lesions are more common through the rest of the first decade. The adult pattern of anatomic distribution of tumors is not seen until late adolescence. Within the first decade as well, tumors of embryonal histology are seen much more commonly than in adults. Thus, such tumors as medulloblastoma, supratentorial primitive neuroectodermal tumors (sPNETs), and pineoblastomas occur almost exclusively in children and young adults. High-grade gliomas, including glioblastoma multiforme, are much less common in these age groups than in adults.

Only two factors are consistently noted to place a child at increased risk for a CNS malignancy: various genetic disorders and exposure to ionizing radiation.[8,9]

## ASSOCIATIONS WITH INHERITED SYNDROMES

Fewer than 10% of children with brain tumors will have a syndrome that places them at increased risk for developing a brain tumor. Those syndromes are listed in Table 27-1. Although rare, they place the child at a markedly higher risk for developing other tumors as well. Affected children, therefore, must be monitored closely for evidence of neoplasia both in and outside the CNS.[10] All the syndromes have an autosomal dominant pattern of inheritance, and somatic mutations have been demonstrated in specific genes for each (Table 27-1). Identification of mutations is important to establish cause of the disorders and to provide insights into gene functions.

| Syndrome | Gene(s) | Tumor type(s) | Reference |
|---|---|---|---|
| Cowden | *PTEN* | Dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos) | 29 |
| Li-Fraumeni | *TP53* | Multiple brain tumor types but most commonly astrocytoma and medulloblastoma | 19, 20 |
| Neurofibromatosis type 1 | *NF-1* | Neurofibroma, optic nerve glioma, astrocytoma | 21, 22 |
| Neurofibromatosis type 2 | *NF-2* | Acoustic and peripheral schwannoma, meningioma, spinal ependymoma | 25, 26 |
| Nevoid basal cell carcinoma | *PTCH* | Medulloblastoma | 15, 16 |
| Tuberous sclerosis | *TSC1, TSC2* | Subependymal giant-cell astrocytoma | 27, 28 |
| Turcot | *APC, hMLH1, hPMS2* | Medulloblastoma, astrocytoma | 17, 18 |
| von Hippel-Lindau | *VHL* | Hemangioblastoma | 30 |

**TABLE 27-1. INHERITED DISORDERS ASSOCIATED WITH BRAIN TUMORS**

Fewer than 5% of children with medulloblastomas have inherited disorders. [11] The most common of these are the nevoid basal cell carcinoma (Gorlin) syndrome and Turcot syndrome.[12,13] The Gorlin syndrome has been linked to germline mutations of the Sonic hedgehog receptor *PTCH*.[14,15 and 16] Affected children are born with multiple skeletal anomalies and macrocephaly. They have a 3% incidence of medulloblastoma, which is diagnosed, on the whole, at a younger age than in children without Gorlin syndrome. These children are predisposed to basal cell carcinomas, a risk that is substantially increased in the fields of radiation used to treat medulloblastoma. Children with Turcot syndrome, an autosomal dominant disorder due to mutation of the *adenomatosis polyposis coli (APC)* gene or to one of several DNA mismatch repair genes (*hPMS2* and *hMLH1,* for example),[17] have a high incidence of colorectal adenomas, gliomas, and medulloblastomas.

Multiple cancer types occur in children with Li-Fraumeni syndrome, caused by germline mutation of the *TP53* gene.[19,20] The protein encoded by this gene is multifunctional, having a role in cell cycle control, in ensuring DNA integrity and repair and, in some circumstances, in inducing apoptotic cell death. Children with inherited mutations of the *TP53* gene most commonly develop low- or high-grade gliomas that may be multifocal, medulloblastomas, PNETs, and choroid plexus tumors. They also have increased incidence of sarcomas, leukemia, and adrenocortical carcinomas.

Children with neurofibromatosis type 1 (NF-1), due to mutation of the *NF-1* gene, are at risk for developing dermal and plexiform neurofibromas and have a markedly increased risk for astrocytomas.[21,22,23 and 24] Most commonly, the astrocytomas occur within the optic pathway as low-grade optic gliomas involving both optic nerves, the chiasm, and the optic radiations. Low-grade gliomas may also occur within the cerebral hemispheres, the brainstem, or the cerebellum. Gliomas and plexiform neurofibromas may undergo malignant transformation. Other cancers have been found to occur in association with NF-1, including myelogenous leukemia, rhabdomyosarcoma, and pheochromocytoma.

Neurofibromatosis type 2, due to mutation of the *NF-2* gene, is associated with meningiomas and schwannomas of the cranial nerves and of the peripheral nervous system.[25 and 26] Bilateral acoustic nerve schwannomas are highly associated with neurofibromatosis type 2. Gliomas and ependymomas also occur with increased frequency and tend to be located in the spinal cord.

Finally, several rare tumor types occur most frequently in association with specific inherited disorders. Subependymal giant-cell astrocytomas in the anteromedial aspect of the brain near the foramina of Monroe most often occur in children with tuberous sclerosis. [27,28] Cerebellar gangliocytoma (Lhermitte-Duclos) occurs in the context of Cowden's syndrome, owing to mutation of the *PTEN* gene that encodes a mixed phosphatase.[29] Hemangioblastomas, typically in the cerebellum, spinal cord, or retinas, occur in association with von Hippel-Lindau syndrome, which arises from mutation of the *VHL* gene that appears to have a role in DNA replication. [30,31 and 32]

## OTHER ASSOCIATIONS WITH CENTRAL NERVOUS SYSTEM TUMORS

### Ionizing Radiation

Exposure to ionizing radiation is a well-documented cause of brain tumors. Children treated with radiotherapy for tinea capitis during the 1940s and 1950s were found to have increased risk for the development of gliomas, meningiomas, and nerve sheath tumors 22 to 34 years later. [33] More recently, brain tumors after cranial irradiation for acute lymphoblastic leukemia have been reported. [34,35,36 and 37]

### Other Cancers

With or without radiotherapy, brain tumors may be seen in association with other cancers or with their treatment. Pituitary tumors occur in patients with various forms of the multiple endocrine adenomatosis syndrome (see Chapter 37). The trilateral retinoblastoma syndrome is pineoblastoma in association with bilateral retinoblastoma.[38] Brain tumors may be seen in a minority of patients with malignant rhabdoid tumors of the kidney. [39]

### Immunosuppression

In various immunosuppression syndromes, such as the Wiskott-Aldrich syndrome, ataxia-telangiectasia, and acquired immunodeficiency, and after solid-organ transplantation, lymphoma of the brain occurs at a frequency higher than that in the normal population. [40,41 and 42]

### Familial Conditions

Data are inconclusive regarding less completely understood familial factors outside of known Li-Fraumeni families. Some studies show no influence of family history on the occurrence of brain tumors, whereas others report an increased risk of brain tumors with a family history of bone cancer, leukemia, and lymphoma. The children or siblings of persons with brain tumors may be at higher risk for developing brain tumors themselves. [43,44,45,46 and 47] Reports of familial clustering of embryonal tumors, gliomas, and CPP also exist.[48,49,50,51,52 and 53]

### Environmental Exposures

The effect of environmental exposures, including diet, on the occurrence of brain tumors has been studied by numerous investigators. [8,54,55,56 and 57] The results of these studies are inconclusive for an association.

Several factors confound the epidemiologic study of pediatric brain tumors: First, until recently, etiologic studies considered pediatric cancer a single entity, and brain tumors were not being examined separately. Second, the etiology of brain tumors most likely is multifactorial, and these factors may influence distinct histologic types of tumors to variable degrees. Finally, pediatric brain tumors are rare, and this rarity affects research methodology.

Nearly all studies of pediatric brain tumors are case-control studies in which individuals with and without brain tumors are compared with respect to past exposures. Inaccuracies and disparities in patient or parent recall may limit observations of disease and their associations. [8] Should a link with environmental exposures truly exist, establishing it may be difficult.

## CENTRAL NERVOUS SYSTEM TUMOR BIOLOGY: TUMOR GENETICS AND CYTOGENETICS

Cancers arise as a result of mutations of genes that regulate cell proliferation and death. Gene mutations may originate within the germline or may occur as somatic mutations exclusively within tumor cells. As noted, only a small fraction of children with brain tumors have germline mutations either acquired from their parents (giving them an inherited predisposition to cancer) or as new mutations. Although the causes of the somatic mutations underlying the vast majority of all brain tumors are

unknown, the genetic abnormalities typically associated with childhood brain tumors are being characterized through a growing body of evidence.

Fluorescence-activated cell sorting and direct chromosomal preparations from biopsy specimens have demonstrated that low-grade gliomas, meningiomas, and pituitary adenomas almost universally possess a unimodal diploid DNA content. [58] In contrast, direct biopsy preparations from more aggressive and malignant tumors, such as anaplastic astrocytoma and glioblastoma multiforme, frequently show bizarre chromosomal aberrations and a dominance of triploid and tetraploid cells in the cell lines derived from these tumors. These findings are in agreement with the genetic analyses of cancers arising in other sites, which generally have demonstrated increasingly abnormal genetic content as cancers evolve into high-grade malignancies. Conversely, fluorescence-activated cell sorting and karyotyping performed on freshly prepared tumor cell populations show near-diploid genetic content, possibly as a result of tumor contamination with normal diploid stromal cells. Alternatively, small diploid or near-diploid anaplastic cells may harbor specific mutations that render them both drug- and radiation-resistant, such that their malignant characteristics are not caused by overt loss or gain of chromatin. [58,59,60,61,62,63,64] and [65]

Chromosomal anomalies have been defined further through molecular genetic analyses, including studies of loss of heterozygosity, comparative genomic hybridization, and fluorescence *in situ* hybridization. The most consistent genetic abnormalities have been found in medulloblastomas and atypical teratoid-rhabdoid tumors (AT/RT).

Deletions of the short arm of chromosome 17 (17p) distal to the *TP53* locus occur in 30% to 50% of medulloblastomas. [66,67] Loss of 17p frequently occurs in association with duplication of 17q, which is characteristic of isochromosome 17q, the most common cytogenetic abnormality of medulloblastomas. [68,69] and [70] Trisomy 7 is the second most common cytogenetic abnormality. [68,70] Deletions or mutations of chromosome 9q involving the Sonic hedgehog receptor *PTCH* have been found in association with approximately 10% to 15% of sporadic medulloblastomas. [71,72,73] and [74] A variety of other chromosomal deletions or additions have been found less consistently. [75,76]

The nonrandom occurrence of monosomy 22 is common in several neural tumors, including medulloblastomas, ependymomas, meningiomas, acoustic neuromas, and AT/RT. [63,77] Mutations or deletions of chromosome 22q11.2 involving the *hSNF5/INI1* gene are present in nearly all AT/RT and in rhabdoid tumors outside the CNS. [76,78] The function of the protein encoded by this gene is incompletely understood. It forms part of the SWI/SNF complex that apparently alters chromatin structure to allow gene transcription. [79] In addition to monosomy 22, deletions of 6q in ependymomas have been described by several investigators. [80,81]

A variety of genetic events have been associated with the progression of low-grade gliomas to high-grade glioblastomas in adults: nonrandom loss of chromosome 10 or of portions of 9p, 17p, and others; gene amplifications of, for example, *EGF* or *MDM2*; and mutations of such specific genes as *PTEN* and *TP53*. [58,82,83] and [84] These observations suggest that, as in colon carcinoma, malignant progression of CNS tumors may be a multistep process involving the accumulation of genetic abnormalities that promote activation of multiple dominant oncogenes and inactivation of recessive tumor suppressor genes. [67,85,86,87,88,89,90] and [91]

## PATHOLOGIC CLASSIFICATION OF CENTRAL NERVOUS SYSTEM TUMORS

### Background

Classification of CNS tumors has been a challenge for more than 100 years. Almost from the beginning, several different histologic classifications have coexisted, reflecting a lack of consensus among neuropathologists. Historical details of this problem have been reviewed in detail by Zulch. [92] All classification schemes are basically arbitrary, hypothetical statements that may or may not reflect the natural order of the things being classified. Ideally, however, they change with progress in knowledge, are clinically relevant, and provide a structure within which a subject may be arranged. These goals may not necessarily be achieved by the same scheme.

Classification of CNS tumors became important clinically after successful establishment of neurosurgery as a specialty and received major impetus from Harvey Cushing during the 1920s and 1930s. The classification system proposed by Cushing's student, Percival Bailey, in 1925 has served as the prototype system since then. That scheme was based on the cell-of-origin notion introduced by German pathologists. They suggested that tumors developed from cells arrested at various stages of development; for each putative developmental stage of a cell, a corresponding tumor was identified. Figure 27-2 outlines Bailey and Cushing's basic schema, denoting the different cell types, the developmental stages through which they were said to pass before reaching maturity, and the corresponding tumor types presumed to arise from them (noted in parentheses in the figure). This classification was embraced immediately because it reflected some aspects of clinical behavior and prognosis, corresponding to Cushing's experience, and because of the esteem that Cushing enjoyed.

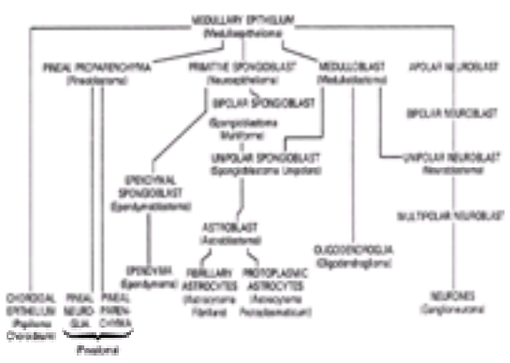

**FIGURE 27-2.** Bailey and Cushing schema of normal developing cells and neuroepithelial tumors derived from them.

### Methods of Classification

#### *Morphologic and Histogenetic Classification*

In addition to their cell-of-origin concept, Bailey and Cushing recognized that tumors were composed of heterogeneous cells. They decided to classify tumors on the basis of the morphology and presumed histogenesis of the *predominant* cell type. Hence, if the majority of cells resembled astrocytes, the tumor was called an *astrocytoma*, even though a small number of other cells (e.g., oligodendrocytes) also were present. Most classifications in current use are based on this concept.

Approximately 60 years ago, Kernohan et al. [93] introduced a grading system based on the concept that glial cells of all types become progressively more anaplastic over time. Criteria were advanced for grading glial tumors on a scale from 1 (most benign) to 4 (most malignant). The scheme was to be applied to astrocytomas, oligodendrogliomas, and ependymomas (Table 27-2). Based on histologic features, it has been adopted readily and is used commonly for astrocytomas for which clinical correlations exist. For the other two tumor types, the scheme has been an awkward fit and, as a result, never has been used consistently for them. Revision of the Kernohan grading system for astrocytomas has been proposed by Daumas-Duport et al. [94]

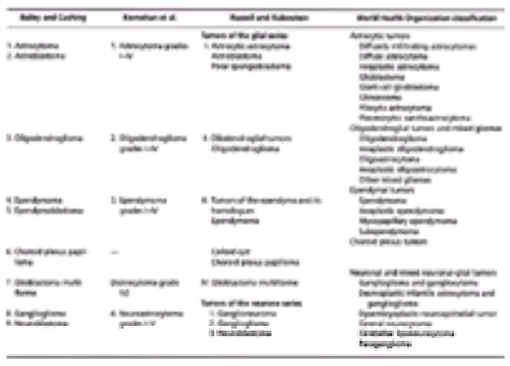

**TABLE 27-2. COMPARISON OF CLASSIFICATION SYSTEMS FOR CENTRAL NERVOUS SYSTEM TUMORS**

An international panel of neuropathologists working under the aegis of the WHO has expanded the concept of grading to all CNS tumors, using the 1-to-4 scale to indicate biologic malignancy.[95] Table 27-2 provides a comparison of four morphologic classification systems: (a) Bailey-Cushing, (b) Russell-Rubinstein, (c) Kernohan et al., and (d) the most recent revision proposed by the WHO.[10] The 1989 Russell-Rubinstein classification is a reorganization of that proposed by Bailey and Cushing. A revision of the Russell-Rubinstein text by Bigner et al.[96] has been advanced too recently to allow its usefulness. Rorke et al.[97,98] proposed and recently modified a classification scheme that recognizes not only morphologic entities and degree of anaplasia but tumor location as well. The proposed histologic reclassification, shown in Table 27-3, is based on advances in identifying cell types by use of immunoperoxidase methods that allow more precision in the categorization of tumors. Tumor location (data not shown) is designated by a Roman numeral and letter: For example, thalamus or basal ganglia (or both) are designated *Ib*, and cerebellum is *Ii*. By considering location, this scheme acknowledges the importance of site of origin as a factor in determining clinical outcome. The most obvious example is the pilocytic astrocytoma; a child with a lesion in the cerebellum generally has a better prognosis than one whose lesion is in the diencephalon.

**TABLE 27-3. PROPOSED MODIFICATION OF REVISION OF THE WORLD HEALTH ORGANIZATION CLASSIFICATION OF BRAIN TUMORS IN CHILDREN (NEUROEPITHELIAL TUMORS ONLY)**

### *Pitfalls of Morphologic and Histogenetic Classification*

It is important to recognize that the histogenetic concepts underlying the morphologic classification schemes are not fully tenable in light of current knowledge.[99,100] It has long been established that cancer is a genetic disease in which the genotypic instability of neoplastic cells may change the histologic features consequent to both time and treatment. At the same time, a large proportion of tumors exhibit relatively characteristic features, allowing easy diagnosis to the trained eye. Until a more accurate basis for classification of CNS tumors emerges, the morphologic approach must be used.

It has been established that cell populations displaying similar, even identical, patterns of differentiation may not have a common embryogenesis as theorized by Bailey and Cushing.[101] Therefore, it is not possible to determine accurately either ancestry or progeny of a tumor cell or cells. Furthermore, the assumption that one or a few histologic features adequately predict clinical behavior of tumors without consideration of other factors, such as site of origin, is untenable. Gilles et al.[102] compared three separate cerebellar tumor types—medulloblastoma, astrocytoma, and ependymoma—with different prognoses and found a broad overlap of multiple, discretely identifiable histologic features.

### *Phenotypic Classification*

An alternative to classification based on histogenetic concepts is the phenotypic approach. Here, immunohistochemistry and techniques of molecular biology are used to assist in identification of cell types comprising the tumor.[103,104] and [105] Use of these techniques to complement standard light and electron microscopy provides more objective identification of cell types, thus allowing more precise classification of CNS tumors. The use of monoclonal antibodies to identify specific antigens, such as cytoskeletal and membrane proteins, hormonal polypeptides, and neurotransmitter substances, has been especially useful in classifying, on routine light microscopy, tumors with unusual morphologic features that previously were relegated to the “unknown” category. In particular, it has allowed greater understanding of the biology of embryonal tumors, as the differentiating potential of the primitive cells can be identified.[106,107]

Use of this phenotypic approach led to identification and separation of the AT/RT from PNET or medulloblastoma, a distinction that appears to have clinical importance.[108] Pathologic features of this tumor are complex and have presented diagnostic challenges to pathologists who most frequently had diagnosed AT/RT as medulloblastoma or PNET or, rarely, as choroid plexus carcinoma (CPC). All tumors in this group, by definition, contain rhabdoid cells. They are round to oval and medium-sized and typically have an eccentric nucleus containing a prominent nucleolus. Cytoplasm is finely granular or homogeneous and sometimes contains a dense, pink, poorly defined “mass” suggesting an inclusion body. Cell borders tend to be distinct. Approximately two-thirds of these tumors contain fields indistinguishable from PNET, and one-third contain malignant mesenchymal elements, whereas one-fourth exhibit fields of epithelial cells that may be glandular or, rarely, squamous. Field necrosis is common, and mitotic figures generally are abundant.

Immunohistochemical features of AT/RT are complex and vary depending on the cellular composition of the tumors. In general, rhabdoid cells express vimentin and epithelial membrane antigen and (less frequently) smooth muscle actin. These cells also may express neurofilament proteins (NFP), glial fibrillary acidic protein (GFAP), and keratin. The cells comprising the PNET component may express NFP, GFAP, desmin, or no antigen, whereas the epithelial portions express keratin and epithelial membrane antigen or vimentin (or both). The mesenchymal cells express vimentin, sometimes smooth muscle actin, and rarely desmin.

Use of immunoperoxidase techniques with various antibodies has forced reconsideration also of the nosology of certain tumors long regarded as astrocytomas, specifically subependymal giant-cell astrocytoma, pleomorphic xanthoastrocytoma, and superficial cerebral astrocytoma. In 1980, Bender and Yunis[109] called attention to the presence in subependymal giant-cell astrocytomas of cells that expressed neurofilament protein, an observation confirmed by Nakamura and Becker[110] and by Bonnin et al.[111] In fact, the majority of cells composing these tumors expresses vimentin, whereas only a few express GFAP, and some tumor cells actually coexpress both NFP and GFAP.[110] The expression of either of the neuronal markers would rarely, if ever, be seen in pure astrocytomas.

Powell et al.[112] documented expression of neurofilament protein in a variable number of cells in pleomorphic xanthoastrocytoma and noted that some of these tumors also contain foci that resemble frank ganglioglioma.[112,113]

It has become apparent that the tumor described by Taratutoet al.[114] in 1984 as a dural astrocytoma and the desmoplastic infantile ganglioglioma (DIG) defined in

1987 by VandenBerg et al.[115] really belong in the same category, as both express GFAP and NFP and exhibit a prominent desmoplastic component.[116] These observations form the basis of Rorke's removal of these three tumors from the astrocytoma category and their placement within the glial-neuronal neoplasms ( Table 27-3).

For optimal study, tumor tissues removed at biopsy and post mortem require special handling. If a tumor is in an accessible location, the surgeon should be encouraged to remove and submit as much tissue as is safely possible; post mortem, generally no limitations apply. At any rate, a fresh sample should be sent for cytogenetic studies, a piece should be frozen, some should be fixed in formalin, tiny fragments should be fixed in glutaraldehyde in the event that ultrastructural study is required, and the bulk of the specimen should be placed in Bouin's fixative. Although this is ideal for preserving cell morphology, fixation in Bouin's creates three disadvantages, including the following: (a) cytogenetic studies cannot be performed, (b) synaptophysin antigen cannot be retrieved, and (c) the tissues cannot be tested for B-cell markers in the event that a lymphoma is suspected.

High-quality technical preparations are of utmost importance in establishing a diagnosis. Use of the microwave enhancement technique for certain antigens is recommended.[117,118] Even under the most optimal circumstances, however, classification based on phenotypes also may be problematic.

Table 27-4 contains a listing of the widely available markers used most commonly and their utility in the differential diagnosis of tumors arising in the CNS. These tumors include primary neuroepithelial tumors, those arising from meningeal coverings, and germ cell tumors.

| Marker | Tumor types containing positive cells |
|---|---|
| Glial fibrillary acidic protein | Astrocytoma, ependymoma, mixed glioma, gliosarcoma, ganglioglioma, gliofibroma, multiforme, glioflorma; positive cells occasionally may be found in oligodendroglioma, capillary hemangioblastoma, choroid plexus papilloma, PNET, AT/RT |
| Neurofilament | Ganglioglioma, gangliocytoma, PNET, neurocytoma, subependymal giant cell tumor, AT/RT |
| Vimentin | Mesenchymal tumors, meningioma, sarcoma, melanoma, lymphoma, ependymoma, astrocytoma, glioflorma, chordoma, schwannoma, hemangioblastoma, carcinoma, PNET, AT/RT |
| S100 and neuron-specific enolase | Positive in a variety of normal and neoplastic cells of neural and nonneural origin; of questionable utility for diagnostic purposes |
| Desmin | Tumors containing muscle (rhabdomyosarcoma, teratoma, etc.), PNET |
| Cytokeratin | Chordoma, choroid plexus tumors, meningioma, certain anaplastic gliomas, nongerminomatous germ cell tumors, PNET, AT/RT |
| Epithelial membrane antigen | Meningioma, ependymoma, epithelial areas of teratomas, rhabdoid tumor (AT/RT) |
| Synaptophysin | PNET, ganglioglioma, gangliocytoma, central neurocytoma, neuroblastoma tumors |
| Smooth muscle actin | Tumors containing muscle, AT/RT |
| Retinal S-antigen | Pineal parenchymal tumors, PNETs, retinoblastoma |
| Alpha fetoprotein | Embryonal carcinoma, endodermal sinus (yolk sac) tumor |
| Human chorionic gonadotrophin | Germinoma, choriocarcinoma |
| Placental alkaline phosphatase | Germ cell tumors |

AT/RT, atypical teratoid rhabdoid tumor; PNET, primitive neuroectodermal tumor.

**TABLE 27-4. COMMON MARKERS FOR DIAGNOSIS OF CENTRAL NERVOUS SYSTEM TUMORS**

### Unsolved Issues in Classification of Embryonal Tumors of Neuroepithelial Origin

From the time that the prototypic CNS embryonal tumor—medulloblastoma—was described by Bailey and Cushing, controversy has swirled around its nature, origin, and name.[119] A historical summary of the issues may be found in a number of papers that interested readers should consult. [120,121,122] and [123]

The essential issue at the heart of the controversy is whether the medulloblastoma is a tumor unique to the cerebellum. If tumors of their histology and biologic behavior occurred only in the cerebellum, no problem would exist. In reality, however, histologically and biologically identical tumors may arise in the cerebrum, the pineal and suprasellar regions, the spinal cord, and the brainstem. Such tumors were well known to Bailey and Cushing who, however, remained ambivalent in regard to what name should be given to the extracerebellar tumors resembling medulloblastomas.[124] In consequence, a large number of diagnostic terms have been applied to medulloblastoma-like tumors that arise outside the cerebellum.

A proposal to resolve the problem in 1983 seemed, instead, to stimulate further controversy.[121] Specifically, it was proposed that tumors composed primarily of apparently undifferentiated neuroepithelial cells be considered a unique diagnostic group regardless of site of origin in the CNS, recognizing that the majority of such tumors do, in fact, arise in the cerebellum. Introduced by Hart and Earle, the diagnostic term *primitive neuroectodermal tumor* (i.e., PNET) was suggested as appropriate for this group, with the addition of modifiers specifying differentiation along one or more lines (e.g., neuronal, glial) if such were identified by use of phenotypic markers (i.e., antibodies for NFP, GFAP, etc.).[125] This proposal was criticized as a “simplistic” approach that would foster intellectual languor among pathologists who would use the diagnosis of PNET as a catchall term for all difficult-to-diagnose tumors primarily composed of poorly differentiated neuroepithelial cells.[126] Also, many were reluctant to abandon the diagnostic term *medulloblastoma* because of its familiarity and association with an enormous body of medical literature.

Conversely, the science on which the term *medulloblastoma* is based is faulty. The practice of using a special diagnostic term for a tumor in a specific location flies in the face of the fact that diagnosis of all other types of CNS tumors generally is based on histologic features and not on the site of origin. For example, a pilocytic astrocytoma in the cerebellum, diencephalon, or spinal cord is called a *pilocytic astrocytoma* regardless of the different locations. In contrast, if a tumor with the histologic features of medulloblastoma arises in the cerebrum or pineal, the current practice is to call it a *supratentorial PNET* (sPNET) or *pineoblastoma*, respectively. However, if the location is not known, a pathologist is forced to make a diagnosis of medulloblastoma, as no distinguishing histologic features separate embryonal tumors of this type, which may occur anywhere in the CNS (including the pineal), from those that arise in the cerebellum.

In 1993, a group of international neuropathologists decided to include the umbrella term *primitive neuroectodermal tumor* as a category under embryonal tumors of the CNS and then designated medulloblastoma as one type of PNET.[95] However, two subsequent revisions of the classification of CNS tumors have undone that categorization, such that the most recent WHO classification of embryonal tumors limits medulloblastomas to the cerebellum and contains a category of sPNET to deal with such tumors in the cerebrum (Table 27-5).[10] Orphaned in terms of diagnostic classification are those rare PNETs that originate in the suprasellar region, brainstem, and spinal cord. Pineal PNETs are still called *pineoblastomas*, and the designation *ependymoblastoma* also has been retained by the WHO committee. The current classification distinguishes the rare variant forms of PNETs, which contain muscle (or at least express muscle antigens) or melanin or both; these tumors are rarely encountered in pediatric neuropathology.

**TABLE 27-5. 2000 CLASSIFICATION OF EMBRYONAL TUMORS OF THE CENTRAL NERVOUS SYSTEM BY A WORLD HEALTH ORGANIZATION COMMITTEE**

Highly likely is that the classification of pediatric CNS tumors will continue to evolve. Expanding studies of tumor cytogenetics raise the hope that CNS neoplasms will be able to be classified on the basis of unique cytogenetic features, leaving aside the difficult issues of morphology. Whereas considerable progress has been made along this path (see Kleihues and Cavanee[10]), a great deal of work remains to be done.

## CLINICAL PRESENTATION: NEUROLOGY OF CENTRAL NERVOUS SYSTEM TUMORS

No single clinical finding is pathognomonic for the diagnosis of a childhood brain tumor. At the onset of illness, the nature of neurologic and systemic dysfunction is varied. The presentation relates mostly to the site of tumor origin, affected children's ages, and their developmental level, but sometimes depends also on the tumor type. Clinical prodromes may include features of increased intracranial pressure (ICP), symptoms and signs of a localizing nature, or symptoms and signs without a localizing quality.

### Increased Intracranial Pressure

Brain tumors cause increased ICP directly by infiltrating or compressing normal CNS structures or indirectly by causing obstruction of cerebrospinal fluid (CSF) pathways and resulting in noncommunicating hydrocephalus. Initial features of elevated ICP often are insidious, nonspecific, and nonlocalizing. Among school-aged children, declining academic performance, fatigue, personality changes, and vague intermittent headaches are common. Over time, morning headaches, vomiting, and lethargy ensue. Papilledema may develop if the pressure is long standing. Rapid progression of symptoms secondary to increased ICP is infrequent but, when such occurs, a quickly growing midline or posterior fossa tumor requiring immediate intervention should be suspected.

Brain tumor headaches frequently have ominous features distinct from tension headaches or migraines.[127,128] When children with a tumor are recumbent, increased ICP often will worsen, and the resulting pain may wake them at night or accompany them on waking in the morning. On arising, vomiting may occur along with some relief of pain. Once such patients are upright, the headache diminishes over the course of the morning. Over time, headaches gradually increase in severity and frequency and clearly differ from any previous pain. The pain, which usually is frontal or occipital rather than temporal, may be exacerbated further with Valsalva maneuvers. The clinical suspicion for tumor should be greatest in those children with recent and continuing complaints of headache, and such should prompt a careful history and evaluation for related symptoms and signs. In fact, by 6 months from headache onset, nearly 100% of children have associated neurologic signs, such as papilledema, strabismus, ataxia, or weakness.[127]

For infants and young children whose skulls may more easily accommodate the growth of a mass lesion, the presentation of elevated ICP may differ. Irritability, anorexia, failure to thrive, and even developmental regression can be frequent early signs. Chronically increased pressure may lead to macrocephaly and splitting of the cranial sutures. An infant ultimately may develop a tense or bulging anterior fontanelle. A baby may develop a shrill, neurogenic cry. Funduscopic evaluation of these patients may reveal only optic pallor and no evidence of papilledema. The setting-sun sign, a seemingly forced downward deviation of the eyes and part of Parinaud's syndrome, may be seen.

Parinaud's syndrome is a collection of ophthalmologic findings stemming from increased ICP at the dorsal midbrain. Beyond the impaired upward gaze seen in infants, older children also display large pupils with impaired reflex constriction to light but not with accommodation. Convergence of gaze may evoke repetitive, bilateral, adducting nystagmus with retraction of the globes in the orbit. A nerve IV palsy, with the affected eye deviated upward and laterally, also may occur. Affected children often compensate for the trochlear nerve palsy by tilting their heads toward the shoulder of the unaffected eye.

A head tilt may occur also with increased ICP because of a stiff neck and cervical root irritation from incipient cerebellar herniation of a posterior fossa mass. Other signs of increased ICP include listlessness and horizontal diplopia from pressure on the long, free intracranial course of the abducens nerve.

### Localizing Symptoms and Signs

Children with supratentorial tumors (i.e., of the cerebrum, basal ganglia, thalamus, hypothalamus, and optic chiasm) may demonstrate various localizing symptoms and signs, depending on the tumor size and its specific origin. Many of these signs precede those of increased ICP. The most common of these signs are hemiparesis, hemisensory loss, hyperreflexia, seizures, and visual complaints.

Vision loss may localize to any location in the optic pathway. Complaints occasionally start insidiously with such events as a failed school eye examination or a need for eyeglasses. Tumors confined to the optic nerve produce monocular vision loss. Chiasmatic tumors present often with a complex visual field loss and decrement in acuity, whereas lesions located more posteriorly, in the optic tract, lateral geniculate nucleus, optic radiations, or occipital cortex, demonstrate some aspect of hemianopsia.[129] A paradoxical increase in pupillary size to light when moving the source from one eye to the other indicates a relative afferent pupillary defect (the Marcus-Gunn pupil), a potential sign of tumor at the optic nerve or chiasm. Among infants, chiasmatic tumors may result in unilateral or bilateral pendular nystagmus, with head nodding and head tilt, a triad known as *spasmus nutans*.[130]

In contrast to the experience in adults, a seizure is seldom the sine qua non of a supratentorial mass in children. Nevertheless, all simple and complex partial (i.e., focal) seizures and most unexplained generalized (grand mal) seizures mandate computed tomography (CT) or MRI of the brain. After a first seizure and subsequent CT, fewer than 1% of patients are given diagnoses of a tumor.[131] Certain features of a seizure or seizures are associated with an increased risk of a tumor. They include a change in the character of the preexisting seizures, status epilepticus as the first seizure, prolonged postictal paralysis, resistance to medical control, and the presence of focal symptoms or deficits.[132,133 and 134] An initially normal CT scan in patients with these seizure characteristics or with persistent epilepsy does not rule out the possibility of a tumor, and repeat imaging with MRI may be indicated.

Other localizing signs for a supratentorial tumor may be subtler. Children with frontal lobe tumors may have a long history of behavioral problems. Tumors that involve the hypothalamus may cause minimal or no motor or visual difficulties. In infants, these tumors may cause failure to thrive and emaciation with a paradoxical euphoric mood and increased appetite, the so-called diencephalic syndrome.[135] By age 18 to 24 months, most children have a right- or left-hand dominance; earlier dominance or subsequent change in handedness implies lateralized disease.

For infratentorial tumors—those arising from the cerebellum and brainstem—localizing features include ataxia, long-tract signs, or cranial neuropathies. Initial cerebellar dysfunction may be insidious, with clumsiness, worsening handwriting, difficulty with hopping or running, or slow or halting speech. Tumors arising in the cerebellar hemispheres more commonly cause lateralizing signs, such as appendicular dysmetria and nystagmus, whereas midline cerebellar masses lead to truncal unsteadiness or increased ICP.

Cranial neuropathies often suggest brainstem pathology. Diplopia, with images seen side by side, is common from invasion of the abducens nerve within the pons. Inability to abduct one or both eyes (abducens palsy), however, can be a false localizing sign, as it may result also from increased ICP trapping of the abducens nerve against the edge of the tentorium. Inability to deviate both eyes conjugately (gaze palsy) or the inability to adduct one eye properly on attempted lateral gaze implies an intrinsic brainstem disorder. These latter findings alone or, more likely, in combination with deficits of the trigeminal, facial, or auditory nerve strongly suggest tumor involving the brainstem. Indeed, masses involving the cerebellopontine angle may result in facial weakness, absent corneal reflex, and hearing loss. Weakness of an entire half of the face (peripheral seventh nerve palsy) suggests a posterior fossa tumor; weakness of the lower face on one side, with spared eyelid closure and forehead movement (central seventh nerve palsy), suggests involvement anywhere superior to the pons. Drooling and swallowing difficulties may arise from involvement of the medulla. A partial Horner's syndrome (ipsilateral ptosis, miosis, and anhidrosis) may be present also in some patients with hypothalamic, brainstem, or upper cervical cord disease, as a result of compromise of the descending sympathetic tracts.

### Nonlocalizing Symptoms and Signs

Some symptoms are characteristic of a brain tumor but not specifically localizing. Affected children may display changes in affect, energy level, motivation, or behavior. They may exhibit weight gain or loss with anorexia. Sexual precocity or delayed puberty, growth failure, somnolence, or symptoms of an autonomic nature may suggest hypothalamic or pituitary dysfunction or may be nonspecific. Vomiting can occur with irritation of the area postrema in the floor of the fourth ventricle from a generalized increase in ICP or from direct irritation by a mass.

As many as 15% of primary CNS tumors, particularly medulloblastoma, germ cell tumors, ependymoma, and high-grade gliomas, have disseminated to other CNS sites by the time of diagnosis.[136] Although such dissemination usually is asymptomatic, neurologic dysfunction from such lesions sometimes overshadows the symptoms of the primary tumor, confusing the localization of tumor origin. For example, spinal cord and cauda equina involvement may cause back or radicular pain, bowel or bladder dysfunction, or long-tract symptoms. Thus, examination at the time of diagnosis should include a search for local tenderness of the spine, focal

extremity weakness, or sensory loss.

### Syndromes Specific to Tumor Types

Although a pathologic brain tumor diagnosis requires tissue biopsy, certain patterns of symptoms and signs are particularly suggestive of specific tumor histologies. In the suprasellar region, pilocytic astrocytomas of the optic pathway and hypothalamus may manifest visual field loss, nystagmus, and diencephalic syndrome but lack any frank endocrinologic abnormality in two-thirds of cases.[137] Craniopharyngiomas also occur in the suprasellar and sellar regions, but these neoplasms present more often with both visual deficits and endocrinopathies.[138] Short stature and diabetes insipidus are frequent disturbances.[139] The endocrinopathies may be obscured, however, if increased ICP and hydrocephalus from obstruction of the third ventricle and foramen of Monro are present.

Germ cell tumors may occur in the anterior hypothalamus as well. These tumors frequently cause long-standing endocrinologic abnormalities, particularly growth failure and diabetes insipidus. Endocrine disturbances may precede the diagnosis by several years. Emotional and behavioral disturbances also can occur.

Germ cell tumors may arise also in the pineal region, as can the pineal parenchymal tumors, pineoblastoma and pineocytoma. All these tumors are apt to be associated with Parinaud's syndrome. Focal motor deficits appear more commonly with infiltrating glial tumors at the pineal region.[140]

In the posterior fossa, brainstem glioma, medulloblastoma, ependymoma, and pilocytic astrocytoma form the oncologic differential diagnosis. Medulloblastoma and ependymoma often compress the fourth ventricle, leading to findings of increased ICP. Vomiting may be extreme with ependymoma because of invasion of the area postrema, an emetic chemoreceptor on the dorsal medulla that protrudes into the fourth ventricle. The classic brainstem glioma, a diffusely infiltrative pontine glioma, presents with a prodrome of less than 6 months consisting of a triad of long-tract signs, ataxia, and cranial neuropathies, particularly an abducens palsy.[141,142] The atypical, focal brainstem glioma presents with a longer prodrome, often without abducens palsy. Cerebellar pilocytic astrocytomas frequently present first with vague symptoms and then with ataxia of long duration, usually a period of 18 months.[143] In the rare cerebellar hemangioblastoma, an elevated hemoglobin level may be noted, secondary to extramedullary hematopoiesis.[144]

Whereas a single seizure seldom is the presenting symptom for histologically malignant cerebral tumors, long-standing epilepsy may be associated with low-grade neoplasms.[132,133] and [134,145,146] In children with long-standing epilepsy found to harbor a tumor, the most common diagnoses are ganglioglioma, dysembryoplastic neuroepithelial tumor (DNET), oligodendroglioma, and LGAs.[147,148] Tumors are found in 12% to 33% of children who undergo surgery for intractable seizures.[149]

Among infants with brain tumors, seizures may occur in conjunction with macrocephaly as the harbinger of DIG, a massive, cystic, and malignant-appearing tumor with a favorable prognosis.[150] CPP presents during infancy with hydrocephalus in nearly all cases. In congenital brain tumors, the most common diagnoses are malignant astrocytoma, teratoma, embryonal tumors, and CPP.[151] For those tumors diagnosed within 2 months of birth, the mass occupies more than one-third of the intracranial volume in 75% of patients.

## NEUROIMAGING IN PEDIATRIC CENTRAL NERVOUS SYSTEM TUMORS: CURRENT STATUS AND FUTURE DIRECTIONS

### Magnetic Resonance Imaging

Preoperative assessment of tumor type and extent, by imaging, is based on the combination of anatomic location, tissue characterization, and enhancement pattern, taken in conjunction with the clinical history. Since its introduction into clinical practice, MRI has superseded CT as the diagnostic tool of choice for pediatric brain and spinal cord tumors. Advantages of MRI include the ease of imaging in three orthogonal planes without the need to move the patient, imaging without the use of x-irradiation, and improved soft tissue contrast. Nevertheless, the clinical presentation of children with brain tumors most often leads to initial evaluation by unenhanced CT. Where MRI is readily available in a timely fashion, CT with iodinated contrast is not recommended because of its inferiority in delineating tumor extent as compared with gadolinium-enhanced MRI.

Routine MRI sequences include T1-weighted imaging (T1WI) before and after gadolinium and T2- and proton density–weighted imaging. Postgadolinium imaging usually is performed with magnetization transfer suppression, which amplifies contrast enhancement by suppressing the signal intensity of normal background brain tissue. As a result, the detection of contrast enhancement is increased by a factor of two to three.[152] This can be useful in demonstrating enhancement within a tumor, extension of the tumor along white-matter pathways, and the subarachnoid spread of tumor. Notable is that contrast enhancement is a reflection not of vascularity but of breakdown of the blood–brain barrier (BBB) and, given this factor, neither CT nor MRI defines the true extent of tumor spread.

MRI offers other advantages over CT scanning. Through the use of the fluid-attenuated inversion recovery sequence, the penumbra of edema surrounding a tumor, which may contain metastatic foci, can be delineated by MRI. This sequence may be useful to the radiation oncologist for targeting focal therapy, although it tends to overestimate the extent of tumor. The introduction of fast-echo planar imaging has enabled the development of diffusion and perfusion techniques, discussed later in this section. Finally, with the advent of frameless stereotaxy, MRI has superseded CT for preoperative planning by virtue of the capability to acquire three-dimensional volumetric data that can be reformatted, in any plane, in the operating room, for tumor localization in relation to markers placed on the skin.

Because it has been replaced by magnetic resonance angiography, conventional angiography rarely is performed in pediatric CNS tumors. Digital subtraction angiography still may be indicated, however, in those cases displaying a mass with blood and a differential diagnosis of vascular malformation versus hemorrhagic tumor. Also, if a highly vascular tumor is suspected, diagnostic angiography may be performed as part of a neuro-interventional procedure before resection to minimize blood loss.

### Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) provides measurement of metabolites within tissue under investigation. For example, proton MRS (HMRS) determines in both a qualitative and a quantitative fashion the chemical environment of the hydrogen nuclei within the tissues targeted. Frequency-domain spectra, which reflect the distribution of resonance frequency of the particular nuclei in the sample, form the data for analysis. Spectra are represented by a series of peaks with positions expressed in parts per million (ppm); the result can be considered a histogram of nuclei with different precession frequencies.

Spectra can be acquired using a single- or multivoxel technique, with short (10- to 30-millisecond) or long (135- to 280-millisecond) echo times. In using a short echo time, more peaks are captured, but the spectrum is superimposed by a complicated baseline, and its analysis is more difficult. With longer echo times, fewer peaks are captured, but the measurement precision is improved. In pediatric brain tumors, the three most important metabolic peaks are, reading from right to left ( Fig. 27-3), *N*-acetyl aspartate (NAA), 2.02 ppm; creatine-phosphocreatine (Cr/PCr), 3.02 ppm; and choline (Cho), 3.22 ppm.

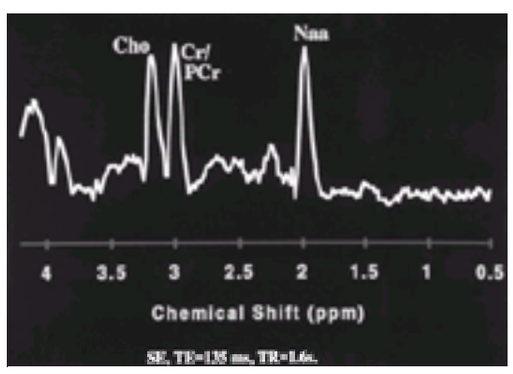

**FIGURE 27-3.** Normal long-echo single-voxel spectrum from the cerebellum of an age-matched control for a patient with medulloblastoma (see Fig. 27-8). Reading from right to left, note normal peaks of *N*-acetyl aspartate (Naa), creatine-phosphocreatine (Cr/PCr), and choline (Cho).

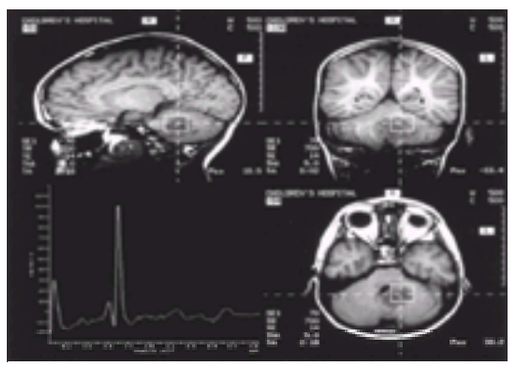

**FIGURE 27-8.** Composite image demonstrating the set-up of a single voxel of interest in all three planes for long echo time (TE) magnetic resonance spectroscopy in a posterior fossa tumor. Note almost complete absence of *N*-acetyl aspartate at 2.02 ppm, loss of creatine-phosphocreatine peak at 3.02 ppm, and gross elevation of choline at 3.22 ppm. Histopathology confirmed a medulloblastoma (primitive neuroectodermal tumor).

NAA is a marker of neuronal and axonal integrity. Cr is a marker for energy metabolism. Cho is a marker for cell membrane turnover and, as such, is elevated in tumors, demyelination, and inflammation; it is decreased in liver disease. Notably, the relative ratios of different metabolites vary, depending on the location of the voxel in the brain and on age during the first 5 years of life, when myelination of the immature brain increases. It is imperative, therefore, to have normal age-matched control data from the same brain region in interpreting the spectra from young children. As a general rule, the NAA increases over time, especially during the first 18 months of life, whereas the Cho slightly decreases over the same period. Creatine-phosphocreatine tends to remain rather stable over time; for this reason, it has been used historically as an internal control when metabolic data are expressed as ratios.

The finding of a lipid-lactate peak usually indicates the presence of ischemia or necrosis. Phosphorus 31 MRS has been used in head and neck tumors, especially in the diagnosis and management of lymphoma. It is more time-consuming and a less generally available technique at present. Fluorine MRS has been used to research tumor drug pharmacokinetics, such as 5-fluorouracil. The uptake of drug in the tissue of interest and its subsequent metabolism can be followed.

Single-voxel MRS can be used to interrogate new tumors having a volume greater than 1 cc. However, a multivoxel technique, such as two-dimensional chemical shift imaging, in which several subcentimeter voxels can be examined simultaneously, can be very helpful in distinguishing recurrent tumor from radiation necrosis. From a compilation of two-dimensional chemical shift imaging spectra, one can obtain a three-dimensional MRS data set. For the future, whole-brain single-metabolite techniques are being developed,[153] which, in addition to double-quantum spectroscopy, will further and more accurately separate out the metabolic peaks.

### Diffusion-Weighted Imaging

Diffusion-weighted imaging (DWI) describes brownian, or random, motion of water molecules. However, in the intracellular and extracellular spaces of the brain, macromolecular proteins, intracellular organelles, cell walls, and myelin sheaths restrict or slow diffusion in certain directions. This restriction results in a new directionality of diffusion within given regions of the brain. This directionality, or anisotropy, is most noticeable in the white-matter tracts in which diffusion tends to be much faster in the direction parallel to myelinated axons. Images can be made for individual directions, usually corresponding to the three orthogonal imaging planes: axial, coronal, and sagittal. Alternatively, the individual directional images can be averaged to produce a relatively direction-independent, or isotropic, diffusion image called a *trace image*. From this, a mean apparent diffusion coefficient (ADC) map can be calculated.

### Magnetic Resonance Perfusion Imaging

In addition to DWI, the development of fast-echo planar imaging has made possible an assessment of the vascularity of tumors using a gadolinium first-pass bolus technique. This relies on changes in the T2 signal of gadolinium-laden blood as it passes through the region of interest. [154] Resulting data, reflected in maps of relative cerebral blood volume, provide some semiquantitative analysis of the blood flow to a particular region. Early work suggested a positive correlation between relative cerebral blood volume and tumor grade.[155] Perfusion imaging may be helpful in targeting a lesion for biopsy. Application of perfusion imaging may be particularly applicable to the study of neovascularization and angiogenesis inhibition.

### Activation Functional Magnetic Resonance Imaging

After the use of a stimulation paradigm or task designed to activate a specific functional area of the brain, the target can be located anatomically by an increase in blood flow to that area. Functional MRI uses the BOLD (*b*lood *o*xygen *l*evel–*d*ependent) technique to generate differential signals based on the relative hemoglobin-oxyhemoglobin content of the blood flowing away from activated brain during an appropriate stimulus. Repetition of the task improves the robustness of the data, and subtraction of rest from activity reduces background signal. Data are presented on maps that outline the activated area of interest in relation to the lesion, and these may be useful in preoperative planning. An example involving finger-thumb opposition and the motor cortex of the hand is shown in Figure 27-4. Different activation tasks can be designed to stimulate other eloquent areas of the brain for vision, hearing, and language.

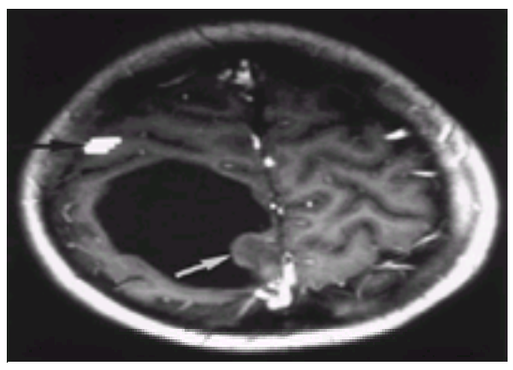

**FIGURE 27-4.** Preoperative functional magnetic resonance imaging in an 11-year-old boy presenting with left-sided focal motor seizures, performed for surgical planning. The bright pixels (*black arrow*) represent the statistical parametric map produced by using a left-sided finger-thumb opposition paradigm. The bright pixels reflect the increase in oxygenated blood flowing away from the right-sided sensorimotor cortex. The white arrow indicates the solid tumor component within a cystic mass displacing the sensorimotor cortex anteriorly. Histopathology demonstrated a cystic dysplastic ganglioglioma that later was removed successfully via a posterior approach without damage to the child.

### Single-Photon Emission Computed Tomography and Positron Emission Tomography

A limited number of reports address the role of thallium 201 single-photon emission CT (SPECT) in pediatric brain tumors. In a heterogeneous and somewhat limited series, although representative of the pediatric population, Rollins et al. [156] failed to establish any clinically useful indication for the test. $^{201}$Tl SPECT was less sensitive and less specific than was gadolinium-enhanced MRI and did not correlate with histologic grade, biologic aggressiveness, or tumor type. In children with brainstem glioma, however, $^{201}$Tl SPECT was able to distinguish persistent or recurrent tumor from radiation necrosis. [157]

Positron emission tomography (PET) adds another dimension to brain imaging. Using the appropriate tracer or combination of tracers, subtle metabolic changes can be measured with a relatively high spatial resolution approximating 3 to 4 mm. Registration of PET with MRI is an issue that will have to be resolved if meaningful

application of this technique using fluorodeoxyglucose and other isotopes is to occur in the clinical arena. [158]

## Imaging Characteristics of Central Nervous System Tumors

### *Posterior Fossa Tumors*

The differential diagnosis of cerebellar tumors in children consists in large part of medulloblastoma, or PNET, juvenile pilocytic astrocytoma (JPA), ependymoma, hemangioblastoma, and exophytic brainstem glioma. Although medulloblastoma tends to be more solid and homogeneously less enhancing and JPA more commonly cystic and typically strongly enhancing, distinguishing one from the other still can be difficult with CT or conventional MRI alone. However, DWI may help in the differential diagnosis preoperatively. Because of the high, tightly packed cellular content of medulloblastoma, a pattern of “restricted” diffusion appears to occur in these tumors, similar to that seen in stroke.[159] This is reflected by a reduction in the ADC. The ADC reflects physical factors, such as temperature and viscosity, in addition to the relative ease or restriction of the motion of molecules through tissues and membranes. The ADC of regions of tumors appears to correlate with cellularity, there being a tendency for lower ADC values to be seen with high-grade gliomas and higher values with low-grade gliomas. In comparing tumor tissue to normal brain, ADC may be important in distinguishing regions of edema from nonenhancing tumor as well. [160]

MRS may help also in the preoperative differential diagnosis of posterior fossa tumors. Using a discriminant analysis, single-voxel MRS of pediatric cerebellar tumors has been proven capable of separating out medulloblastoma (or PNET), JPA, and ependymoma from normal cerebellar tissue based on a plot of Cr/Cho ratios against NAA-choline ratios (Fig. 27-5).[161]

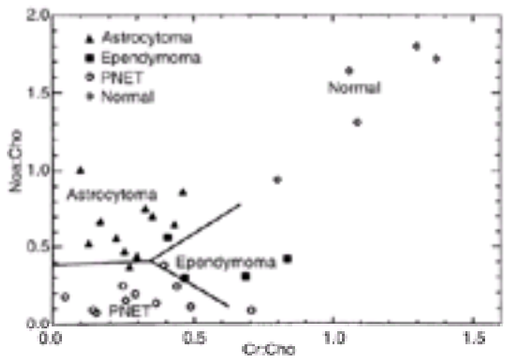

**FIGURE 27-5.** *N*-acetyl aspartate–choline (Naa:Cho) versus creatine-choline (Cr:Cho) scattergram for astrocytoma, ependymoma, medulloblastoma, and normal cerebellar tissue. The straight lines are boundaries between the three tumor types found by discriminant analysis. PNET, primitive neuroectodermal tumor.

Using CT, MRI, and MRS characteristics, the following can be said of posterior fossa tumors: The solid component of *JPA* is hyperdense on CT, hypointense to gray matter on T1WI, and hyperintense on T2WI, demonstrating marked enhancement after administration of gadolinium. DWI usually shows evidence of unrestricted diffusion, especially in the presence of a cystic component. MRS tends to show moderate reduction in NAA and modest elevation in Cho ( Fig. 27-6, Fig. 27-7). *Medulloblastoma* is hyperdense on CT and uniformly hypointense to gray matter on T1WI and tends to be isointense to gray matter on T2WI with restricted DWI, most likely secondary to the tumor's dense cellularity and high cellular nucleus-cytoplasm ratio. MRS tends to show very low NAA with very high Cho ( Fig. 27-8). *Ependymoma* may be distinguished by its different anatomic location and pattern of spread through the foramina of Luschka, but MRS can give additional support to the diagnosis, especially in those cases in which the size and extent of the mass render difficult the identification of its point of origin. Solitary cerebellar *hemangioblastoma* usually will demonstrate serpiginous flow voids, reflecting the vascularity of the lesion, in addition to intense enhancement after intravenous contrast.[162] Intrinsic hemangioblastoma may be seen also in the spinal cord.

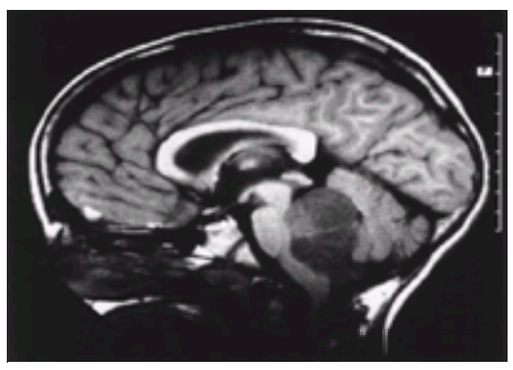

**FIGURE 27-6.** Sagittal T1-weighted midline image demonstrating posterior fossa tumor occupying most of the fourth ventricle extending inferiorly to the obex, with mild prominence of the supratentorial ventricular system. The histopathologic diagnosis was a juvenile pilocytic astrocytoma.

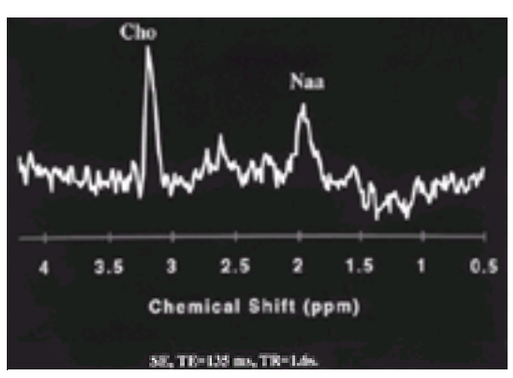

**FIGURE 27-7.** Long echo time (TE) magnetic resonance spectroscopy (135 milliseconds) from the same patient mentioned in Figure 27-6. Note the moderate decrease in *N*-acetyl aspartate (Naa) and moderate elevation in choline (Cho), a typical pattern for low-grade glioma.

Other rare tumors seen in the posterior fossa include AT/RT that are typically rapidly progressive, with surrounding edema and enhancement from breakdown of the BBB.

### *Brainstem Tumors*

MRI is the procedure of choice for identifying brainstem tumors. Some work has shown a correlation between $^{201}$Tl SPECT and gadolinium enhancement, suggesting that, like gadolinium, thallium uptake requires breakdown of the BBB. [157] The only information lacking with MRI is the presence or absence of calcification. Calcification is an unusual manifestation of brainstem tumors. It may occur rarely with oligodendroglioma of the brainstem, occasionally with extension of fibrillary astrocytoma of

the cervical cord into the medulla, or with dystrophic calcification secondary to radiotherapy. CT is superior at demonstrating calcification in these situations and in association with vascular lesions as well.

### *Supratentorial Tumors*

Intra-axial tumors, which usually are low-grade gliomas, are imaged in much the same way as are posterior fossa tumors. Published pediatric data concerning MRS of these lesions are few, but the peak-area ratios or NAA/Cho and Cr/Cho may be prognostic.[163] Experience in this area of imaging is evolving.

Ganglioglioma, DNET, and hypothalamic hamartoma have fairly specific imaging characteristics. Ganglioglioma and DNET tend to be superficial lesions with a predilection for the temporal lobe. Gangliogliomas may be cystic and demonstrate a variable pattern of relatively poor enhancement. DNET classically causes remodeling of the overlying inner table of the skull, a reflection of their natural history of slow growth. The anatomic location, lack of enhancement, and commonly associated history of gelastic seizures, precocious puberty, or other hormonal imbalance in a young child leads to a diagnosis of hypothalamic hamartoma.

Extra-axial sellar and pineal region tumors, together with meningiomas, lack a BBB and therefore enhance avidly after contrast administration. Single-voxel MRS has been used to differentiate large cystic sellar and parasellar masses on the basis of their metabolites.[164] Hypothalamic gliomas have a metabolic profile similar to that of JPAs and other low-grade gliomas, with a moderate reduction in NAA along with a moderate elevation in Cho. This is fairly different from pituitary adenomas, which demonstrate no NAA because they contain no neuronal tissue, a moderate elevation of Cho as a marker of cell membrane turnover, and variable amounts of lipid-lactate, depending on the degree of tissue necrosis. The “crankcase” oily contents of cystic craniopharyngiomas lead to a large lipid peak with little else.

### *Spinal Tumors*

Intrinsic tumors of the spinal cord, such as primary gliomas and ependymomas, are best imaged with MRI. It is also the imaging modality of choice for metastatic disease in the subarachnoid space (e.g., from medulloblastoma). Ideally, time and patient condition permitting, the spine is scanned preoperatively when medulloblastoma or ependymoma is suspected. When such a scan cannot be performed, a baseline study should be performed approximately 3 weeks into the postoperative period to avoid the problems of interpreting the appearances of postsurgical blood and arachnoiditis. Most treatment protocols direct repeat imaging for studies showing and not showing disease. However, it may be reasonable in the nonprotocol setting, when initial spine study results are negative, to repeat the spine MRI after completion of therapy only if new symptoms develop. CSF cytology is complementary to spinal imaging in detecting subarachnoid disease.

## Imaging Characteristics of Neurofibromatosis Type 1 and Associated Tumors

NF-1 frequently manifests as focal areas of signal intensity (FASI) on T2WI. Typical imaging features in affected young children include T2 bright signal returned from the basal ganglia and dentate nuclei, which gradually disappears in young adulthood. Limited histopathology suggests that these lesions may represent spongiform dysplasia.[165] However, it is recognized that some of these FASI grow and start to enhance and are diagnosed ultimately as gliomas, usually of low grade. Tumors identified in patients with NF-1 most commonly are located in the brainstem, optic chiasm, and hypothalamus and, less commonly, below the tentorium. Anomalies of the corpus callosum, including LGAs, have been identified also in children with NF-1.[166] Three-dimensional multivoxel proton MRS has been used in children with NF-1 to interrogate these areas of focal signal abnormality. Proton MRS indicated that FASI (a) are characterized by significantly elevated Cho, reduced Cr, a Cho/Cr ratio greater than 1.3, and near-normal NAA levels; (b) are different from tumors that exhibit Cho/Cr greater than 2 and no NAA; (c) have no lipid or lactate signal; and (d) correlate in spatial extent but are more extensive than indicated by conventional MRI sequences.[167] Use of three-dimensional chemical shift imaging, as opposed to single-voxel imaging spectroscopy, to delineate metabolically the extent and volume of the lesion, may be useful for following the effects of treatment ( Fig. 27-9).

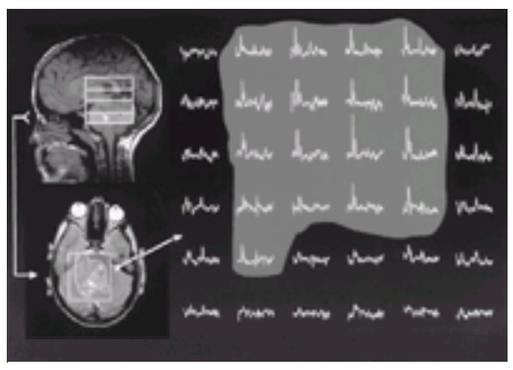

**FIGURE 27-9.** Composite image demonstrating a set-up for three-dimensional chemical shift imaging (stack of two-dimensional slabs), in a patient with neurofibromatosis type 1 complicated by a brainstem glioma. The tumor is outlined from the spectroscopy grid by the extent of the abnormal *N*-acetyl aspartate–choline pattern.

Screening neuroimaging of asymptomatic children with NF-1 has not been shown to improve clinical outcome. Serial ophthalmologic examinations of affected children are critical. Those with unexplained ophthalmologic abnormalities should undergo MRI examination of the head and orbits.[168] Optic nerve lesions seen in association with NF-1 generally are JPAs; they demonstrate enhancement on postgadolinium imaging. Unless directed otherwise by clinical protocol, follow-up imaging of these tumors should be considered only on evidence of deterioration of vision.

### *Tuberous Sclerosis*

In tuberous sclerosis, subependymal giant-cell astrocytoma classically occurs at the level of the foramen of Monro. These lesions often are bilateral, may be calcified, and usually demonstrate marked enhancement with intravenous contrast. They require continued follow-up and repeat imaging, on an annual basis, to track the development of hydrocephalus. Tubers typically demonstrate elevated myoinositol on MRS.

## Radiation Necrosis

Radiation necrosis may demonstrate mass effect, enhance after intravenous contrast, and easily be indistinguishable from recurrent or progressive tumor. Fluorodeoxyglucose PET has been considered the gold standard through which tumor and irradiation-induced necrosis can be distinguished. However, an incidence of false-negative and false-positive results now is recognized.[169] Two-dimensional chemical shift imaging/MRS can be used to interrogate the region of interest on a subcentimeter voxel-by-voxel basis. A reduction or absence of both NAA and Cho, in the presence of lipid and lactate, is found in radiation necrosis. In the presence of recurrent tumor, elevation of Cho occurs.

## Imaging and Radiation Treatment Planning

Many of the techniques described in this section allow for more accurate localization of tumor and tumor extent than was historically obtained with CT imaging. MRI should delineate more clearly between tissue planes and improve image fusion needed for planning radiotherapy. More experience is needed to determine whether this capability will result in improved patient outcome.

## Future Developments

Currently under development is the technique of whole-brain spectroscopy.[153] This modality is performed in conjunction with three-dimensional volumetric imaging of the brain and allows for a quantitative expression of individual metabolites, such as NAA and Cho, expressed per gram of brain tissue. Other advances in MRS include the development of two-dimensional double-quantum spectroscopy, which will further and more accurately separate out the metabolic peaks.[170,171 and 172]

Diffusion tensor imaging is a technique performed using six to nine planes of imaging as opposed to the three that typically are employed for DWI in standard MRI. The data acquired allow the mapping of white-matter tracts and detection of interruptions in them due to infiltrating tumor. [169] The same data can be used to measure fractional anisotropy, and those results may allow further discrimination of differential tissue characteristics.

Finally, the development of pulsed and continuous arterial spin tag labeling as a technique to study perfusion of brain tissue should permit quantitative or semiquantitative analyses of blood flow.[173] This procedure might have application to the assessment of angiogenesis in tumors and effects of anti-angiogenic therapy.

## NEUROSURGERY: DIAGNOSIS AND TREATMENT

For most CNS tumors, surgical intervention forms the initial step in the treatment plan by providing tissue to establish the histologic diagnosis and, when possible, reducing the tumor burden. Notable exceptions to this rule are certain unresectable tumor types, such as diffuse infiltrative brainstem gliomas [174] and globular chiasmatic gliomas in children with NF-1. Each of these tumors has an almost diagnostic MRI appearance in association with consistent histologic features. As surgery has been shown not to improve prognosis in patients with these tumors and the histologic diagnosis rarely is in question, operative intervention is not required. In addition, for certain deep-seated tumors, the risks imposed by a conventional surgical approach to them may be high and, for establishing a histologic diagnosis, stereotactic biopsy techniques provide a reasonable alternative to open tumor debulking. CT- or MRI-guided stereotactic procedures are highly accurate in targeting such deep-seated lesions and are associated with a morbidity of fewer than 5% and a mortality of fewer than 1% of patients. [175,176]

For the majority of pediatric brain tumors, however, open operations are preferred; the goal in such procedures is to remove as much tumor as is safely possible. Although a truly complete tumor resection is feasible only for well-circumscribed benign tumors, such as pilocytic astrocytomas and craniopharyngiomas, an extensive, near-total resection can be achieved with many parenchymal tumors. The limitation to complete resection in such tumors is the imperceptible blending of the neoplasm into the surrounding brain; scattered tumor cells may infiltrate past the margins of the resection into the normal parenchyma. Unlike the situation with solid, non-CNS tumors, it is rarely feasible to resect the tumor with surrounding margins of normal tissue because of the unacceptable risks of producing irreversible neurologic deficits. An outline of the neurosurgical approach and considerations for the most common types of brain tumors is provided in Table 27-6.

**TABLE 27-6. MANAGEMENT SCHEMA FOR PEDIATRIC BRAIN TUMORS[a]**

### Preoperative and Perioperative Considerations

In occasional affected children who present with obtundation from a large mass lesion, resection is performed urgently. In children who are awake and alert but nonetheless harbor a large lesion that is producing substantial mass effect, the tumor resection is performed on the next operating day. Smaller lesions without significant mass effect can be managed more electively.

Because peritumoral edema commonly contributes to the neurologic impairment produced by the tumor, moderate doses of corticosteroids generally are administered preoperatively. For example, 0.1 to 0.5 mg per kg dexamethasone may be given every 6 hours. This dosing often will lead to a dramatic improvement in the patient's symptoms and signs, avoiding the need for emergency surgery in the vast majority of cases. Corticosteroids typically are continued intraoperatively and during the early postoperative period. If a significant reduction in tumor volume has been achieved at the time of operation, corticosteroid therapy is tapered and then discontinued within several days of surgery.

Another factor that commonly contributes to increased ICP in children with brain tumors is the presence of obstructive hydrocephalus, observed most commonly in tumors arising near the aqueduct, such as with pineal region tumors, or the fourth ventricle, as seen with cerebellar vermian lesions. Although resection of the tumor often opens the CSF pathways and leads to resolution of the hydrocephalus, the resection frequently is rendered safer if the elevated pressure is relieved as an initial step. The use of preoperative shunting carries a small risk of upward herniation through the tentorial hiatus. In some institutions, preoperative relief of hydrocephalus is accomplished by endoscopic third ventriculostomy[177,178]; however, a more common approach is to place an external ventricular drain immediately before the craniotomy for tumor resection, which has the advantage of allowing drainage of bloody spinal fluid and debris in the early postoperative period. If the operative procedure opens the CSF pathways and the patient's absorptive pathways remain patent, the external ventricular drain often can be removed within several days of surgery.[179] If the hydrocephalus persists, a third ventriculostomy can be performed or, if the hydrocephalus appears to be of a communicating type, a ventriculoperitoneal shunt can then be inserted. Although in the past a great concern was that shunting would provide a route for systemic dissemination of tumor, more recent studies have failed to show an increased risk of tumor spread via the shunt. [180] Overall, the use of shunts in children with posterior fossa tumors has diminished substantially.

The endocrinopathies commonly manifested by hypothalamic tumors can be exacerbated by tumor resection. Patients undergoing this procedure typically require stress doses of hydroxycorticosteroids before, during, and after surgical intervention. Although thyroid hormone replacement occasionally is instituted preoperatively, it is initiated most commonly postoperatively. Patients in whom the posterior pituitary stalk is sectioned or injured during surgery often manifest a triphasic response of impaired fluid regulation, characterized by an initial period of transient diabetes insipidus lasting 1 to 2 days, a subsequent period of inappropriate antidiuretic hormone release lasting several days, and a final phase of persistent diabetes insipidus. In view of the rapid changes in vasopressin levels during the first several days postoperatively, careful attention to fluid replacement and cautious administration of synthetic vasopressin, where indicated, are essential to avoid potentially deleterious swings in electrolyte levels and fluid balance.

Children with cerebral cortical tumors and those in whom cortical retraction is required in the approach to a deep-seated lesion may be at risk for seizures during the perioperative period. Preoperatively, such patients often are started on an anticonvulsant medication (e.g., phenytoin) that is continued during the postoperative period, even if they have not experienced previous seizures. Patients generally are maintained on anticonvulsants for at least 1 week postoperatively; the decision to continue such therapy in patients without documented seizures is of uncertain benefit. [181] In patients who experience a preoperative seizure disorder from the tumor and have been rendered seizure-free by tumor resection, anticonvulsants often can be stopped within several months after surgery.

### Intraoperative Considerations and Surgical Technique

Recent studies have indicated that the extent of surgical resection has a major impact on the likelihood of long-term survival for children with many types of pediatric brain tumors, particularly ependymomas,[182,183,184,185,186,187 and 188] high-grade gliomas,[189,190,191 and 192] medulloblastomas,[193,194,195,196,197,198 and 199] low-grade gliomas,[200] and choroid plexus tumors.[201,202 and 203] Accordingly, with the exceptions noted earlier, in which surgical resection is not indicated or in which stereotactic biopsy may be a preferable initial step, extensive resection is the goal for many types of pediatric brain tumors.

A major limitation to the widespread incorporation of extensive surgical resections in the management of childhood brain tumors has been the fact that aggressive resections may increase the risk of immediate and long-term morbidity, particularly for tumors in functionally critical locations. Although morbidity generally is less than 10% for polar supratentorial gliomas and less than 20% for cerebellar astrocytomas, more deep-seated lesions, such as ependymomas and craniopharyngiomas,

carry morbidity rates in excess of 40% with extensive resection.[204] Although some studies have observed that morbidity is lower if operations are performed by neurosurgeons who do such operations frequently,[205,206] recent studies also indicate that pediatric neurosurgeons are more likely to attempt extensive removals, on the basis of their recognition that this influences prognosis, and therefore may have overall rates of management morbidity comparable to those of general neurosurgeons, albeit with a higher frequency of complete or nearly complete tumor resections.[207]

During the last 10 to 20 years, a number of intraoperative modalities have been developed or refined to allow tumor resection to be performed more safely and efficiently. Foremost among these are the progressive improvements in operative microscopy, which facilitates illumination and visualization of the interface between neoplasm and normal brain. Localization techniques, such as frame-based and, more recently, frameless stereotactic guidance systems, allow preoperative targeting of the tumor so that the surgical approach can be tailored precisely to minimize manipulation of normal brain structures and to maximize the extent of resection of deep-seated subcortical lesions.[208,209]

Ultrasonographic guidance also is useful in this regard. Recently, intraoperative MRI units have become available in selected centers and may help to refine further the accuracy of intraoperative decision making,[210] provided that issues of cost and the difficulties involved in operating in or adjacent to a high field-strength magnet can be resolved effectively.

In children whose tumors are in and around functionally critical brain regions, intraoperative monitoring of visual, auditory, and somatosensory pathways and direct assessment of motor and speech pathways often are used in an attempt to improve the safety of the tumor resection. In addition, areas of essential cortex overlying a deep-seated tumor may be delineated using cortical stimulation techniques to plan an approach to the tumor that avoids traversing important structures. Functional MRI also provides a useful way of noninvasively localizing important cortical areas[211] to identify a safe trajectory to an underlying lesion. Finally, in children with intractable seizures from cerebral neoplasms, intraoperative or extraoperative electrocorticography (ECOG) may be used to define areas of epileptogenic cortex in and around the tumor to increase the likelihood that seizure control will be obtained postoperatively.[212]

For supratentorial craniotomies, children generally are placed in the supine or lateral position. For infratentorial craniotomies, the prone or lateral position is used more often than the upright position because of concern over potential venous air embolism. Intraoperatively, the head of an infant often is positioned on soft rings rather than being held by pins that can perforate the skull or cause a depressed fracture. For cortical and many subcortical tumors, the surgical approach follows the most direct trajectory to the lesion. However, for deep-seated lesions that are subjacent to functionally critical regions of the brain, alternate approaches often are required. Details of the operative approaches for specific tumor types are provided in subsequent sections of this chapter.

The actual tumor resection often is aided by the use of ultrasonic aspiration, which provides a relatively atraumatic way to debulk many pediatric brain tumors. The surgical $CO_2$ laser also may be used, depending on the consistency and location of the tumor. In general, tumors are resected “from the inside out.” With many extra-axial tumors and a small percentage of intraparenchymal lesions, a clearly defined peritumoral plane is encountered through which the tumor may be dissected carefully from the surrounding brain, cranial nerves, and vessels after the central portion of the mass has been debulked. However, for most intraparenchymal tumors, a well-defined tumor pseudocapsule is not present, and the resection must proceed via gradual internal debulking until the boundary between tumor and normal brain is reached.

Because the extent of resection is so important in defining prognosis and choice of subsequent therapy for many tumor types, objective confirmation of the volume of residual tumor, if any, is essential before embarking on further therapy. Because a surgeon's impression of the extent of tumor resection is subject to error,[213] postoperative confirmation of the extent of resection generally is established by CT or, preferably, by MRI. This imaging typically is performed within the first 24 to 72 hours postoperatively to minimize the impact of postoperative inflammation on the delineation of areas of residual tumor.

A recent trend in the surgical management of selected types of brain tumors has been the concept of second-look surgery. For large, relatively vascular tumors in which an initial complete resection cannot be obtained, the patient is treated with several courses of postoperative chemotherapy in the hope of making the tumor amenable to complete resection at a second procedure. This approach has been applied anecdotally in ependymomas and malignant germ cell tumors, two groups of lesions in which the extent of residual disease before initiation of radiotherapy has a substantial impact on long-term outcome. What remains to be determined is whether patients who undergo a second-stage complete resection have as good a prognosis as those who were amenable to complete resection initially; this issue is being examined systematically in studies of the Children's Oncology Group (COG).

Surgical resection has been used increasingly as a component of the management of recurrent disease, particularly in children without evidence of tumor dissemination. For children with malignant lesions, this relieves mass effect in preparation for additional phase I or phase II chemotherapy. Some recurrent tumors, such as JPAs and craniopharyngiomas, can be treated with reoperation alone, without the need for additional adjuvant therapy, if a gross total resection (GTR) can be achieved.[214] For children with recurrence of other, more malignant tumors that may also be subject to dissemination, data are lacking for a survival benefit from re-resection.

## RADIOTHERAPY

The rational application of radiotherapy in pediatric brain tumors requires an understanding of the development of the brain, the probable biologic effect of ionizing radiation on the brain of a child, the behavior and natural history of the different brain tumors, radiobiology and physics, the techniques and technology of radiotherapy, and the probable interaction of irradiation with other treatment modalities, such as chemotherapy.

### Radiation and the Developing Brain

The development of brain is most rapid during the first 3 years of life. Axonal growth and synaptogenesis are most active during the growth phase.[215] The rate of growth and development slows down after the age of 6. Maturation of the brain, however, judged by degree of myelinization, is not complete until puberty.[216] Hence, radiation-induced brain injury is most pronounced during the early years of childhood. Radiation injury to the brain generally is regarded as one of the most serious complications of radiotherapy of brain tumors and thus constitutes the major limitation in delivering high-dose radiation.

### Effect of Radiation on the Brain

The responses of brain tissues to radiation are classified into three groups: (a) acute reactions, occurring during treatment; (b) early delayed (subacute) reactions, occurring a few weeks to 2 to 3 months after treatment; and (c) late delayed reactions, occurring several months to years after treatment.[217] The pathogenesis of radiation-induced brain injury includes edema formation; damage to oligodendrogliocytes, leading to inhibition of myelin synthesis; and damage to the vascular endothelium, leading to white-matter necrosis. The late delayed reactions, which include focal radiation necrosis, postirradiation diffuse white-matter injury, leukoencephalopathy, neuropsychological effects, cerebrovascular effects, and secondary tumors, can be progressive, irreversible, and potentially fatal. Late neuropsychological effects include intellectual impairment, memory deficits, and inability to acquire new knowledge. Impairment in cognition is most pronounced in children younger than age 4 to 7. Deterioration in intelligence quotient (IQ) is prevalent in children after whole-brain or supratentorial irradiation for primary brain tumors.

The presence and severity of radiation reactions depend on (a) irradiation treatment factors, including total dose, fraction size, interfractional interval, and treatment volume; (b) patient factors, such as age, presence of preexisting brain injury by tumor or surgery, infection, and vascular diseases; and (c) other treatment modalities, most commonly surgery and chemotherapy. Some factors are unavoidable, such as preexisting brain injury or vascular diseases. However, the influence of certain factors, such as fraction size and treatment volume, can be altered to decrease the incidence and severity of brain injury. One of the latest advances in radiation oncology is conformal radiotherapy, which certainly can decrease the irradiated volume and potentially minimize treatment-related toxicity.

### Radiosensitivity of Specific Structures in the Central Nervous System

#### *Brainstem*

The brainstem traditionally was regarded as more radiosensitive than the cerebrum, especially in the era of orthovoltage. However, in the modern era of high-energy radiotherapy, brainstem necrosis is rare. In view of the high concentration of white matter, a reduction of 10% from brain tolerance dose usually is recommended.[218]

Fraction size also is very important. Other influencing factors include chemotherapy and vascular pathology.

### *Spinal Cord*

In view of its location, the tolerance of spinal cord to radiation is a major dose-limiting factor in delivering high-dose radiation not only to tumors involving the cord but to other tumors in the vicinity. In pediatric radiation oncology, craniospinal irradiation is common, especially in the treatment of standard- and high-risk medulloblastoma. Also, in irradiating certain head and neck tumors in childhood, such as rhabdomyosarcoma and nasopharyngeal angiofibroma, the spinal cord usually will receive some radiation. If the spinal cord is overdosed, damage can result in devastating neurologic deficits. Radiation myelopathy can occur from 1 year to several years after cure of the cancer.[219] Instead of tumor cure, quality of life then becomes a very important issue. The traditional dogma concerning the pathogenesis of radiation myelopathy rests on postmitotic cell death in the endothelial cells or oligodendrocytes (or both). The current concepts view radiation as producing cell death that, in turn, induces a complex pathophysiologic reaction in which the response of surviving cells may contribute to determining the impact of radiation on tissue integrity and functions. Cytokines, such as tumor necrosis factor and interleukin-6 (IL-6), appear to play important roles. [219] Also, some researchers suggest that the tolerance of the spinal cord is 5% to 10% lower in children than in adults. [219] Increasing the radiation dose per fraction generally produces a disproportionately larger biological effect on the spinal cord. If the time interval between fractions is less than 8 hours, the repair by the spinal cord of sublethal damage could be incomplete and consequently the biological effect could be magnified. Interfractional interval also plays an important role in radiation myelopathy. Generally accepted is that the dose to the spinal cord should be reduced when the irradiated volume is large. Results of recent primate studies indicated that an increase in treatment volume reduces the threshold and steepens the slope of the sigmoid dose-response curve for myelopathy. [219]

### *Cranial Nerves*

Most cranial nerves are relatively resistant to radiation-induced damage. Two cranial nerves, the second and eighth, are worth mentioning in the radiation treatment of pediatric cancers. The optic nerve and visual pathway can be damaged when delivering therapeutic radiation to periorbital tumors (e.g., orbital rhabdomyosarcoma, optic glioma, paranasal and nasopharyngeal tumors) and suprasellar tumors (e.g., craniopharyngioma, pituitary adenoma, germ cell tumor, hypothalamic-chiasmatic glioma). Recently, a linear-quadratic model yielded an a/b estimate of 1.6 Gy for optic neuropathy. [220] The risk of radiation-induced optic neuropathy is related to total radiation dose, fraction size, and the irradiated volume. It was shown recently that no injuries were observed in 106 optic nerves that received a total dose of less than 59 Gy. The 15-year actuarial risk of optic neuropathy after a dose of greater than 60 Gy was 11% when treatment was administered in fraction sizes of less than 1.9 Gy, as compared with 47% when given in fraction sizes of greater than 1.9 Gy. [221] The vestibular cochlear nerve and auditory apparatus must be considered in the delivery of high-dose radiation to tumors in the posterior fossa, such as medulloblastoma, ependymoma, and astrocytoma. Medulloblastoma therapy often includes cisplatin-based chemotherapy. Cisplatin given after completion of radiotherapy increases further the risk of ototoxicity.

### *Retina*

The retina, a specialized neural end-organ supplied by an end-arterial system, is sensitive to vascular injury and has little ability for repair. [217] It is sensitive to radiation as well. Deterioration of vision, resulting from radiation-induced progressive obliteration of small retinal vessels, can occur 1.5 to 6.0 years after irradiation. The dose-response curve is steep (between 50 and 60 Gy), and 45 Gy produces a 5% risk of visual injury within 5 years. [218] Again, as the fraction size increases up to 2.5 Gy or more, the frequency of injury increases.[222]

### *Lens*

The lens is one of the most radiosensitive organs, even to very low doses of radiation. For example, 1 Gy can lead to cataract formation. From total body irradiation data, the risk of developing a cataract requiring surgery was 20% for fractionated doses of 12 to 16 Gy. [223] Currently, the dose that could produce a 5% risk of damage to the lens within 5 years is 10 Gy.

### *Hypothalamic-Pituitary Axis*

Irradiation of the region of the hypothalamus and pituitary gland can result in significant neuroendocrine abnormalities and long-term sequelae. This is especially important in children. The hormones affected include growth hormone (GH), thyroid-stimulating hormone, adrenocorticotropic hormone, and follicle-stimulating hormone–luteinizing hormone. The largest volume of data concerns the effect of cranial irradiation on GH production and release. The irradiated anatomic site responsible for GH deficiency has been shown to be the hypothalamus.[224] Sixty percent to 80% of irradiated pediatric brain tumor patients ultimately will have impaired serum GH response to provocative stimulation.[224] A dose-response relationship is seen with a threshold of 18 to 25 Gy. The higher the dose of radiation, the earlier the GH deficiency will occur. Deficiencies of other hypothalamic-pituitary hormones also have been described. The responsible irradiated site can be the hypothalamus, the pituitary, or both. Constine et al.[225] have described non-GH abnormalities (thyroidal, gonadal, prolactin, and adrenal) in 20 children with brain tumors not involving the hypothalamic-pituitary region and treated with either cranial or craniospinal irradiation. In patients receiving only cranial irradiation, the hypothalamic-pituitary region is estimated to receive a mean dose of 53.6 Gy (40 to 70 Gy). [225]

## Potential Side Effects of Radiotherapy

Acute and subacute toxicities related to radiation of the pediatric brain and head and neck are mild and usually produce no major consequences. Acute reactions, characterized by symptoms suggesting increased edema and ICP, or deterioration of preexisting neurologic signs, usually can be controlled and reversed by steroids. Subacute reactions, characterized by somnolence syndrome or accentuation of preexisting signs and symptoms, usually are transient and associated with complete recovery. Late sequelae are of major concern. They are discussed in detail in the section Sequelae of Treatment.

## Indications for Radiotherapy

The indications for radiotherapy depend on the histology of the tumor. Therefore, pretreatment histologic diagnosis is necessary in practically all cases. The only exceptions are diffuse pontine glioma and optic gliomas in which a diagnosis can be made with high certainty on the basis of neuroimaging. Specific indications for radiotherapy and controversies concerning its use are discussed later under the headings of the individual tumor types.

## Radiotherapy Volume

Radiotherapy volume is determined by the anatomic extent of the tumor and the potential areas of spread and by the patterns of failure. Advances in MRI and CT have made tumor localization more accurate.

In general, local target volumes are used for tumors that are either confined to, or recur within, a single anatomic area. Whole-brain irradiation is used for multifocal tumors. Craniospinal irradiation is delivered to patients who have tumors with proven or suspected seeding in the subarachnoid space or to those with a reasonable chance of developing subarachnoid disease.

## Radiobiologic Considerations

The biology of fractionation in radiotherapy is based on four *R*s: reoxygenation, redistribution of cells within the cell cycle, repair of sublethal damage, and repopulation. These functions are discussed in Chapter 13.

The effect of radiation on the brain generally is characterized by delayed reactions, because the normal brain parenchymal cells are either slowly or not dividing. As a late-responding tissue, the normal CNS is very sensitive to radiation dose fraction size. Small radiation fraction sizes tend to produce a lesser effect on the CNS than on tumor cells. One can take advantage of this phenomenon by decreasing the fraction size from what is considered conventional and delivering more than one fraction each day. This is called *hyperfractionation*.

Hyperfractionated radiotherapy has several theoretic benefits: (a) the opportunity to escalate radiation dose without increasing damage to late-responding tissues; (b) greater ability to overcome tumor hypoxia that contributes to radioresistance; and (c) increased tumor cell kill by the dose escalation. Generally, a sufficient interval

between fractions is necessary to allow normal tissue repair of radiation-induced damage between the radiation fractions. Six to eight hours commonly is used for the interval. This approach has been tested in the treatment of supratentorial and brainstem high-grade glioma. However, to date, no convincing data suggest any survival benefits with the use of a hyperfractionated radiotherapy approach, probably because the total radiation dose still is insufficient to show a significant increase in tumor cell kill.

Accelerated fractionation radiotherapy is another fractionation technique. The aim with this approach is to deliver the total radiotherapy dose over a shortened period. It involves multiple daily radiotherapy fractions in conventional radiotherapy fraction size (usually 1.6 to 2.0 Gy). The total radiotherapy dose may be equivalent to or less than that delivered with conventional fractionation. Shortening of overall treatment time has the theoretic benefit of overcoming the accelerated repopulation of tumor clonogens between radiation fractions.[226] Again, no convincing data suggest a survival advantage with the use of accelerated fractionation over conventional radiotherapy.

### Techniques in Radiotherapy

#### *Conventional External-Beam Radiotherapy*

Conventional radiotherapeutic techniques remain the most common in use today. These techniques use simple geometric radiation-field arrangements with a small number of treatment fields. Head immobilization is important so that the treatment target is not missed during radiotherapy. A customized head-fixation device, such as an Aquaplast mask, frequently is used. Other immobilization devices, such as the body cast or alpha cradle, may be used when appropriate. Sedation or general anesthesia usually is necessary in the treatment of children younger than ages 3 or 4 years. The advantages of conventional techniques are relative simplicity (except perhaps for craniospinal irradiation) and general familiarity by radiation oncologists and technologists. The major disadvantage is the usual inclusion of more normal brain tissue than necessary in the high-radiation-dose regimen because of the limited field arrangements.

#### *Classic Three-Dimensional Conformal Radiotherapy*

The advances in neuroimaging and computers have rendered possible the delivery of high-dose radiation more precisely to the tumor while significantly sparing the surrounding normal tissues when using three-dimensional conformal radiotherapy (3D-CRT). This technique may involve multishaped fields, arranged in coplanar, nonaxial, and noncoplanar orientation, directed at the tumor, and delivered in either static or dynamic modes. [227] Compared to conventional radiotherapy, 3D-CRT results in the reception of high-dose radiation by approximately 30% less normal brain tissue. [228] This reduction in normal brain irradiation should lead to fewer long-term side effects, particularly in young children.

#### *Intensity-Modulated Radiotherapy*

Intensity-modulated radiotherapy (IMRT), a more complex form of 3D-CRT, combines two advanced concepts to 3D-CRT: (a) inverse treatment planning with optimization by computer and (b) computer-controlled intensity modulation of the radiation beam during treatment. IMRT allows a high degree of flexibility in reducing the dose to the surrounding normal tissues by the creation of so-called avoidance areas during the treatment planning process. The initial experience with IMRT in the treatment of brain tumors has been encouraging.

#### *Stereotactic Radiosurgery*

Radiosurgery can be administered by a gamma-knife unit using cobalt 201 sources or by a modified linear accelerator unit. Either unit is designed to deliver a high radiation dose to a small intracranial target in one sitting by focusing multiple small radiation beams from different directions to the target. The application of radiosurgery usually is limited to tumors measuring 3.5 cm or less in maximum diameter. This limit is held to achieve the steep dose gradient at the treatment-field edge. Radiosurgery commonly is used for the management of brain metastases, acoustic neuroma, and meningioma and is being investigated as a boost treatment for small, high-grade gliomas.

#### *Brachytherapy*

Brachytherapy, or interstitial irradiation, involves the implantation of radioactive sources directly into brain tumors. Iodine 125, iridium 192, and gold 198 are the radioisotopes that have been used for either permanent or temporary implants. Brachytherapy has been used for patients with glioblastoma as an additional boost after external-beam radiotherapy and for selected patients with recurrent high-grade glioma.

## PRINCIPLES OF CHEMOTHERAPY

Specific indications for the use of chemotherapy and the results of current trials for each tumor individually are discussed later. Those issues that relate to the use of chemotherapy for CNS tumors and an overview of new therapeutic approaches are presented here.

### Blood–Brain Barrier and Other Factors Influencing Drug Penetration

The presence of the BBB profoundly influences the penetration of most substances in the CNS. Tight endothelial cell junctions of this structure limit penetration to all but small-molecular-size (200 Da), highly lipophilic compounds, unionized at physiologic pH. [229] The BBB apparently is not uniformly intact in CNS tumors, however, and various degrees of disruption exist in different parts of these tumors. This variability is reflected in the different degrees of enhancement in CNS tumors produced by the water-soluble contrast agents commonly used with CT and MRI. In general, small tumor foci and the peripheral leading edges of larger tumors sometimes appear to have a relatively intact BBB. Furthermore, central portions of larger tumors may have absent BBB characteristics, independent of central necrosis. [230] These findings may be explained by the advancing margins of tumor that initially parasitize normal CNS capillaries that possess an intact BBB and by abnormal tumor-induced vascularity to arise in and dominate more established areas of tumor. [231]

These observations suggest that the commonly held notion that water-soluble chemotherapeutic agents are unlikely to be useful in CNS tumors is not entirely correct. In fact, many such compounds, such as the classic alkylators and the platinums, are of clinical value in these tumors. However, for a greater effect from chemotherapy at the peripheral, advancing areas of tumor in which the BBB is relatively intact, the use of more liposoluble agents may be required.

Other properties of individual agents that influence CNS tumor penetration include the degree to which they are protein-bound and the rapidity with which they are cleared systemically. Clinical variables affecting drug penetration include the use of corticosteroids, anticonvulsants, and concurrent radiotherapy. Steroids both may affect the systemic metabolism of agents and have been suggested to decrease the transcapillary transport of various compounds. Anticonvulsants may accelerate hepatic clearance of agents and, therefore, systemic and CSF levels of drug. [232] Radiotherapy at higher doses may increase transcapillary transport. [233,234] and [235]

### Drug Delivery Strategies

#### *High-Dose Systemic Therapy*

Tumors of the CNS may fail to respond to standard-dose chemotherapy because of inherent or acquired drug resistance. Additionally, treatment may fail because of a relative lack of penetration of agents into the CNS and further into the tumor tissue. In an attempt to overpower these resistance mechanisms, several clinical trials have examined the use of high-dose chemotherapy, with autologous bone marrow or peripheral blood stem cell rescue, to try to improve the response rate of CNS tumors to chemotherapy. Because of their liposolubility, the nitrosoureas were among the first agents so studied. However, because of excessive neurologic toxicity, dose escalation of these agents was not feasible. [236,237] and [238] More recent trials have used classic and nonclassic alkylating agents, often combined with etoposide. Examples of the former include cyclophosphamide, melphalan, and thiotepa; the nonclassic group includes carboplatin. The rationale for these drug combinations is based on their nonoverlapping hematologic toxicities, their propensity to show little cross-resistance, and their maintenance of steep, linear dose-response curves through several logs of cell kill. The approach has been studied most often in patients with recurrent tumors and in infants, for whom postponement of radiotherapy is desirable because of its potential late neurologic toxicities. [239,240,241,242,243,244] and [245] Feasibility has been demonstrated clearly, and encouraging results have been seen in patients with medulloblastoma and germ cell tumors and in infants with embryonal tumors. Clinical trials wherein these regimens are compared prospectively to

those using standard-dose chemotherapy have not been performed. The experience with gliomas, including those of the brainstem, has been less promising. [246,247] and [248] Patients who appear most likely to benefit from this approach are those with minimal disease at entry into myeloablative therapy, those whose tumors have shown response to standard-dose chemotherapy, and those with little prior exposure to chemotherapy. The optimal timing of this approach, either as a consolidative or a salvage treatment, remains uncertain, particularly as primary chemotherapy regimens are intensified. Because it is a feasible approach, high-dose chemotherapy with hematopoietic rescue will continue to be investigated for high-risk tumors. However, such treatment outside a clinical trial is inappropriate.

### *Intrathecal Chemotherapy*

Delivery of drug directly into the intrathecal space through either a lumbar puncture or a ventricular reservoir is a type of regional chemotherapy designed to circumvent limited penetration through the BBB of systemically administered agents. Compared to the result with plasma, the volume of CSF is relatively small and, as a result, high concentrations of drug can be achieved after low doses of intrathecal agents. However, penetration of drugs from the CSF into the parenchyma of the spinal cord and brain is limited severely by the efficient absorption of the compounds by the rich capillary vascular supply throughout the CNS. [249] Therefore, a benefit from intrathecal chemotherapy is likely to be realized only for control or prevention of subarachnoid disease. Mafosfamide and topotecan are two agents currently under investigation by clinical cooperative groups; busulfan will be studied by the Pediatric Brain Tumor Consortium (PBTC). Mafosfamide is the preactivated derivative of cyclophosphamide and has shown cytotoxic activity *in vitro* comparable to or exceeding that of cyclophosphamide and *in vivo* against numerous human solid tumor cell lines.[250,251] Topotecan is a water-soluble analog of camptothecin and an inhibitor of topoisomerase-1. Although the number of agents currently approved for intrathecal administration is limited, the potential utility of this route is being documented for several new agents, including those used in such new approaches as immunotherapy and gene therapy.[252]

### *Intratumoral Chemotherapy*

Another innovative strategy to enhance delivery of a therapeutic agent is direct administration of the agent into the tumor bed. Although this approach has been studied most extensively in adults with recurrent high-grade gliomas, it now is being translated to the pediatric setting. The most experience to date has been gained with interstitial chemotherapy, using polymeric “wafers” impregnated with BCNU (carmustine), which relies on passive diffusion of the nitrosourea from the polymer during a period of several weeks to achieve high drug concentrations around the tumor while keeping systemic exposure at low levels. Studies by Brem et al. [253] and Valtonen et al.[254] have demonstrated a modest prolongation of the survival of adults with recurrent high-grade gliomas, and a recent study of patients with newly diagnosed disease showed a similarly modest but nonetheless statistically significant therapeutic effect. [255]

An alternate approach, better suited for the delivery of larger molecules, involves the direct infusion of a soluble agent into the tumor using an implanted catheter connected to an external infusion pump. This approach incorporates the properties of bulk flow through the interstitial spaces of the brain to provide high concentrations of a therapeutic agent to the tumor and peritumoral brain. Although this approach has been applied anecdotally for the delivery of conventional chemotherapeutic agents, such as BCNU, the most experience to date has been obtained in the delivery of mutated toxin genes conjugated to ligands that target receptors (e.g., epidermal growth factor receptor, transferrin receptor, IL-13 receptor) expressed at levels higher within the brain tumor than in the surrounding normal brain.[256,257] The toxin component of the conjugate, such as diphtheria toxin and *Pseudomonas* exotoxin, contains mutations within the domains necessary for cell internalization, which restricts toxin entry to those cells that express the receptor for the ligand. Because each of the receptors that has been targeted to date is expressed also on cells outside the CNS, the infusion approach to delivery minimizes the concentrations of the toxin that reach those vulnerable non-CNS cells while maximizing the amounts that are delivered to the tumor.

### *Blood–Brain Barrier Disruption*

Osmotic opening of the BBB by infusions of hypertonic arabinose or mannitol can enhance the penetration of different compounds into the CNS. The mechanism appears to involve vasodilation, shrinkage of endothelial cells, and opening of endothelial tight junctions and results in an increased diffusion and bulk flow of water-soluble and large-molecular-size substances that normally are unable to permeate the BBB. [258,259] Although the effect is brief (generally reversible within 10 minutes), increases in CNS and CSF drug levels have been documented and correlated favorably with clinical responses in some instances. [260,261,262] and [263] Phase III studies are lacking, and one published experience showed no benefit from disruption of the BBB. [264] Pediatric experience is fairly limited, and only one study has evaluated the effect of mannitol infusion in a phase II study of an agent (etoposide). [265] In that study, overall response rate was approximately 11%, although it varied with tumor type, and an effect of mannitol infusion was not observed. The study could not determine whether the lack of effect was due to failure to disrupt the BBB or to a low level of activity of etoposide. A number of controversies surround this approach to therapy, including the contribution of the BBB to poor outcome of therapy and the clinical impact of the ability to circumvent this barrier. Furthermore, methodologic standards are lacking. Carefully designed clinical trials are needed to test this treatment approach.

### *Carotid Artery Infusion Chemotherapy*

The rationale for infusion of chemotherapy through the carotid artery is that lower doses of chemotherapy more immediately might be delivered directly to the region of the tumor, resulting in a higher concentration of drug in the tumor bed without a concomitant increase in systemic exposure and toxicity. Agents that penetrate tumor well but have a rapid systemic clearance theoretically are the best candidates for this approach, and increased regional exposure should be possible with lower doses of the agents. The use of nitrosoureas and cisplatin in this manner has resulted in a modest number of clinical responses. [238,266,267] However, drug penetration into normal brain tissue appears to have been increased as well, resulting in focal neurologic toxicity, particularly to the retina. [268,269] Some of the toxicity may have been due to nonuniform mixing of drug and blood at the infusion site, resulting in “streaming” during arterial delivery and to exposure of the brain to alcohol-containing diluents.[269,270]

## Other New Approaches

### *Differentiation Therapy*

The potential utility of differentiating agents, such as retinoic acid and phenylacetate, has received attention in human CNS tumors. Various *in vitro* studies have suggested that these compounds may induce differentiation and suppress growth in human CNS tumor lines, including glioblastoma multiforme and medulloblastoma.[271,272,273,274,275,276,277,278] and [279] The mechanism of these effects remains uncertain. Retinoic acid may modulate autocrine growth loops in some tumors; an inhibition of the kinase activity of epidermal growth factor receptor has been suggested by some investigators. [280] This molecule often is amplified in adult high-grade gliomas and possibly is related to malignant transformation. To date, phase I trials of both *trans*- and *cis*-retinoic acids have been reported preliminarily in adult glioma patients; an objective response rate of approximately 12% and a stable disease rate of 12% to 35% have been reported after oral administration in small numbers of patients.[281,282] and [283] The mechanism of action for phenylacetate has been hypothesized to involve DNA hypomethylation with secondary alterations in cycle-regulatory proteins. The demonstration of some modulation of *in vivo* proliferation and biochemical changes suggests differentiation in some malignant glioma and medulloblastoma cell lines.[274] An adult phase I study of this agent suggested that potentially therapeutic levels of phenylacetate may be achieved. [284] An oral formulation of phenylbutyrate has been studied in adults, also demonstrating that drug concentrations beyond the *in vitro* therapeutic threshold can be achieved.[285] Pediatric investigations are ongoing.

### *Immunotherapy*

The CNS is a relatively immunologically privileged site. The brain lacks defined lymphatic drainage, [286] the expression of major histocompatibility complex antigens is low,[287] and the BBB limits the interaction of the peripheral host immune system and the brain.[288] However, the privilege is not absolute. For example, patterns of allogeneic and xenogeneic tissue transplant rejection from immunologically naïve [289] and nonnaïve brains[290] suggest that peripheral T-cell activity may be carried into the CNS.[291]

Immunotherapy of CNS tumors is based on the hypothesis that stimulation of the immune system, or blocking of the immunosuppressive effects of tumors, might enhance an antitumor response. Immunotherapy has been studied primarily in the preclinical setting but also more recently in adult phase I studies of patients with malignant gliomas. Pediatric data are in their very early stages. Strategies of immunotherapy are based on eliciting systemic antitumor immune responses that are carried into the CNS and on inducing a primary immune response in the brain itself. Adults with malignant gliomas are known to have, to some degree, altered immunity, owing to effects on T-cell proliferation, natural killer cell activity, and immunoglobulin production. The current thought is that these effects most likely are

due to production of transforming growth factor b. These observations form the basis for another immunotherapy strategy, that of decreasing tumorigenicity of malignant gliomas by blocking the immunosuppressive effects of transforming growth factor b. A variety of approaches have been studied: administration of cytokines, such as ILs and interferons; delivery of monoclonal antibodies; and the use of adoptive immunotherapy (i.e., the transfer of immune T lymphocytes). Gene transfer therapy is discussed later.

Interferons show cytostatic and cytotoxic effects on human glioma cell lines and xenografts.[292,293 and 294] However, phase I and phase II clinical trials of interferon-a and interferon-b to boost systemic immune responses against intracranial tumors have yielded clinical responses in only a minority of patients.[295,296,297 and 298] In addition, clinical trials of interferon-g, which is a much more potent inducer of major histocompatibility complex class I and II antigen expression, have demonstrated unacceptable toxicities with little clinical benefit.[299,300] Although the interferons appear to have anti–CNS tumor properties, their clinical potential has not yet been realized.

IL-2, a cytokine that can increase the antitumor activity of T cells and natural killer cells, has been used in the treatment of melanoma and renal cell carcinoma. Systemic and intratumoral administration of IL-2 to boost the antitumor cellular immune response of patients with malignant gliomas has resulted in significant neurotoxicity, primarily from cerebral edema, and in little clinical benefit.[288] Adoptive immunotherapy using IL-2 and lymphokine-activated killer cells has resulted in inconsistent clinical and neurotoxic effects.[301,302] IL-2 and tumor-infiltrating lymphocytes appear to have activity against CNS tumors *in vitro* and in extracerebral sites but not in the brain.[303] In yet another adoptive approach, stable disease and prolonged survival, albeit with disease, were demonstrated in a recent adult phase I clinical trial of cytotoxic T-lymphocyte therapy for patients with primary or recurrent malignant gliomas.[304] Taken together, these data indicate an *in vitro* antitumor potential of adoptive immunotherapy of CNS tumors that has yet to be fully realized in the clinical setting.

A potential role for monoclonal antibodies in the diagnosis and treatment of brain tumors also has been investigated. Systemically administered radionuclide-conjugated antibodies have prolonged survival in mice with human glioma xenografts, but human applications of these products have shown only limited efficacy. Although disrupted by tumor, the BBB may be sufficiently intact as to block penetration of large-molecular-weight antibodies.[305] The application of these products currently is limited by tumor heterogeneity and rapid immune antibody clearance and, for radioconjugated antibody therapy, by dehalogenation and loss of radionuclides[131] and excessive radiation to nontarget tissues.[306] Intrathecal or intraventricular delivery of monoclonal products may bypass some of the limitations of systemic administration. Such studies are limited but promising.[307,308 and 309]

### *Gene Transfer Therapy*

Gene transfer therapy, the process through which genetic material is transferred into cells for the purpose of eliciting a therapeutic response, is a ew and innovative approach to the treatment of brain tumors and of other malignancies and disease processes (see Chapter 17). The gene of interest generally is transferred to the target brain or tumor cell using a virus-mediated delivery system. The postmitotic environment of the CNS tissue may offer an advantage over other tissues in that it may allow more specific targeting of the viral vectors to only mitotically active tumor. Genes that may be transferred may result in cell killing, either directly through cellular toxins or indirectly through the expression of drug-mediating enzymes.[310] The therapeutic response of gene therapy can be through immunomodulation or anti-angiogenesis as well.[291,310,311 and 312]

The herpes simplex virus thymidine kinase type 1 (*HSV-Tk1*) gene is a type of suicide gene that can be transferred to tumor cells. When exposed to systemically administered ganciclovir, the gene causes phosphorylation of the drug that results in death not only of transfected tumor cells but of surrounding tumor cells.[291,313,314] Through a limited institutional phase I study, Packer et al.[315] recently demonstrated the feasibility and safety of *HSV-Tk1* gene therapy in children with recurrent supratentorial malignant brain tumors. Significant toxicities associated with the injected vector or ganciclovir exposure occurred in 4 of 12 treated patients and included seizures, headache, lethargy, weakness, cerebral edema, and symptoms of increased ICP. All these symptoms resolved spontaneously or with a short course of glucocorticoid therapy.

Modulation of the immune response to brain tumors through the use of cells genetically modified for secretion of IL-2, interferon-g, tumor necrosis factor, and IL-4 has been relatively well studied preclinically and with mixed results.[312,316,317,318 and 319] IL-4 has emerged as a particularly potent antiglioma cytokine.[288] In an animal model, the efficacy of an IL-4-transduced 9L glioma cell vaccine in eradicating tumor and prolonging survival has been shown.[320,321] On the basis of these results, adult phase I trials will be initiated. Vaccine therapy using dendritic cells for antigen presentation also is under investigation.[322,323] Preliminary data indicate that such vaccines may be as potent as, or even more so than, those based on cells modified for cytokine production.[322]

Collectively, these preclinical and early clinical data support a continued investigation of the potential role for gene therapy against CNS tumors. The majority of work has been done with adult gliomas. Similar studies with high-risk pediatric brain tumors are eagerly awaited.

### Clinical Trials Groups

The use of chemotherapy for CNS tumors now is commonplace and, for specific tumors, is considered the standard of care (as discussed in later sections). However, for no single tumor can any *specific* regimen be considered standard. The COG, consisting of pediatric cancer programs from North America, Europe, and Australia, conducts numerous clinical trials of chemotherapy for nearly every brain tumor type and for children of all ages. New agents, or new schedules of established agents, are studied in clinical trials for the primary therapy of newly diagnosed disease or as treatment for recurrent disease. Correlative biologic studies are conducted on several tumor types. Similar national and international cooperative groups exist worldwide. In 1999, the National Cancer Institute established the PBTC from nine institutions that collectively diagnose disease in and treat the majority of U.S. children with primary brain tumors. The objectives of the PBTC are to develop pilot data rapidly about new therapeutic agents and neuroimaging techniques and from biologic studies of brain tumor specimens. Results from these studies will be available to the COG and other international cooperative groups for confirmatory testing in larger phase II and phase III studies.

Physicians and interested families can learn more about investigational chemotherapy protocols by contacting any of these cooperative groups or by contacting foundations that support pediatric brain tumor research. Details are presented at the end of this chapter under Information on Clinical Trials.

## TUMORS IN INFANTS AND YOUNG CHILDREN

Because of the special nature of the harboring of a CNS tumor in very young children and of the general practice of treating these children with protocols separate from their older counterparts with the same diagnoses, infants and young children are discussed as a separate group. In practice, the upper age of eligibility for infant studies varies generally between 18 months and several years.

### Demography

Approximately one-third of CNS tumors in children younger than age 15 years are diagnosed before the age of 5.[324] In the most recent SEER registry data reflecting incidence of brain tumors from 1975 to 1995, the annual incidence rates for brain tumors are highest in the first 5 years of life and are fairly constant from year to year.[1] As with other ages, infant boys are affected more commonly than are girls, but the ratio between them is dependent on both tumor type and age. For example, although medulloblastoma occurs overall more commonly in boys, girls are affected more commonly in the first year of life, with a ratio to boys of 1.27. Except for the fifth year of life, brain tumors are more common in whites than in blacks.[1]

### Special Clinical and Pathologic Considerations

Astrocytomas are the tumors that occur most commonly in infants, followed in incidence by PNETs (consisting primarily of medulloblastomas but including pineoblastomas and intracranial neuroblastomas as well), “other gliomas,” and ependymomas.[1] These registry data generally are reflected in the accrual onto the infant brain tumor trials open to all malignant diagnoses; in them, medulloblastoma and ependymoma are most common.[325,326,327 and 328]

Certain CNS tumors have a predilection for infants and young children. Among the low-grade gliomas, these tumors include optic chiasm and hypothalamic gliomas (discussed in the section Tumors of the Optic Pathway). The DIG, a mixed neuronal-glial tumor, frequently is mistaken for a more malignant process. Recognition of this entity is important because, despite its malignant appearance, complete resection alone appears to be curative and chemotherapy is not indicated.[115,150] The

DNET is another of the mixed tumors that occur more commonly in infants. Other less common low-grade tumors encountered primarily in infants and young children are the mature and immature intracranial teratomas.

Among the more malignant tumors, AT/RT primarily occur in children younger than 2 years. They occur more commonly in male children and in the cerebellum. Historically, treatment regimens have varied, but survival is poor. [108,329] Although the tumors are responsive to chemotherapy, the response is generally of short duration. Dissemination of disease along with local recurrence is the most common pattern of treatment failure, and survival generally is less than 1 year.

## Clinical Presentation and Differential Diagnosis

Although the presentation of CNS tumors has been described earlier, a few points concerning very young children bear repeating. The evolving anatomy of the infant skull, together with the predilection for supratentorial sites in the first 1 to 2 years, influences the presentation of these tumors. The principal calvarial sutures do not fuse until approximately 6 months of age. Until that time, tumors may be accommodated easily and not become clinically evident until they have reached a large size. An increasing head size, with or without a bulging fontanel, is particularly characteristic of tumors until the age of suture fusion. General signs of failure to thrive, such as poor feeding, emesis, and lethargy, are common and may precede large head growth. These symptoms may be mistaken for the much more common anatomic problems or infections of the gastrointestinal tract or infections of the ears or sinuses. Loss of developmental milestones, seizures, and hemiparesis can result from perinatal complications and cerebral palsy. A mass lesion can cause a hemiparesis manifested by early hand preference. The same manifestation may result from hypoxic brain injury. Evaluation of these general symptoms, particularly when no obvious cause is found or when they persist despite other intervention, should include imaging of the brain to rule out a CNS tumor.

## Treatment and Prognostic Considerations

### *Surgery*

The surgical management of brain tumors in infants follows the same general approaches as that indicated for the specific tumor types in older children. However, infant brain tumors pose a number of unique challenges that add to the difficulty and potential morbidity and mortality of surgical intervention. [330,331,332,333 and 334] First, these lesions often are fairly large at presentation, as described. Second, infant brain tumors are, as a group, more uniformly malignant than are those observed in older children and tend to be extremely invasive into the surrounding brain, increasing the chances of postoperative morbidity. Third, these lesions tend to be extremely vascular. This factor, coupled with the small blood volume of an infant, increases the risks from life-threatening hemorrhage during the course of the tumor resection. Fourth, because postoperative radiotherapy carries significant long-term sequelae in infants and young children, a greater onus is placed on surgeons to attempt as complete a resection as is safely feasible. The management of these tumors requires not only significant surgical expertise but skilled anesthetic management, with attention to adequate replacement of blood products and clotting factors during the resection.

### *Radiotherapy*

With the possible exception of those in LGAs, the survival rates from other CNS tumors in infants and young children have historically been lower than those in their older counterparts.[324,335] The reason for this finding may be biologically based for certain tumors but probably is due in equal measure to the administration of lower doses of radiotherapy because of concerns about long-term adverse sequelae. [336] Craniospinal irradiation to young children is associated with significant neuropsychological, neurodevelopmental, and neuroendocrine deficits that are more profound with earlier age at irradiation. [337,338,339,340,341 and 342] Recognition of these effects and their relation, in part, to radiotherapy led in the 1980s to investigational treatment approaches that relied on use of postsurgical chemotherapy to obviate the use of radiotherapy in primary therapy, to delay its administration, or to allow concurrent use at lower doses. This strategy resulted in cure rates higher than those in historical reports but, for infants with ependymoma and medulloblastoma, rates still were suboptimal. After progression of disease on chemotherapy, craniospinal irradiation provides control of disease in 25% to 30% of patients. [343] Because most instances of tumor progression or recurrence are at the local tumor site, current studies are examining the earlier use of conformal posterior fossa irradiation to improve local disease control. If chemotherapy can control microscopic disease successfully outside the primary tumor site, conformal radiotherapy offers the potential advantage of decreased neurotoxicity, as less normal brain will be irradiated.

### *Chemotherapy*

Published results of recent infant brain tumor trials using primary chemotherapy are listed in Table 27-7. Results of the first cooperative group [Pediatric Oncology Group (POG)] study to use postoperative primary chemotherapy, POG 8633, recently were updated. [344] For the patients as a whole, the most important prognostic factor was degree of tumor resection accomplished at diagnosis. The 5-year survival for all patients who had a GTR of their primary tumor, as determined by central review, was 62%; for those whose tumors were resected less than completely, the rate was 31%. Similar results were seen in the two most common diagnoses: For patients with medulloblastoma, the 5-year survival rates after GTR and less than GTR were 60% and 32%, respectively; for ependymoma, the corresponding figures were 66% and 25%, respectively. The presence of metastases did not independently predict outcome for either diagnosis. Except for ependymoma, younger age was not a prognostic factor. These and other smaller studies have demonstrated that, for children with medulloblastoma and ependymoma, the use of primary chemotherapy after complete resection of disease, with either delayed or lower-dose radiation, results in survival rates that approach those seen in older children.

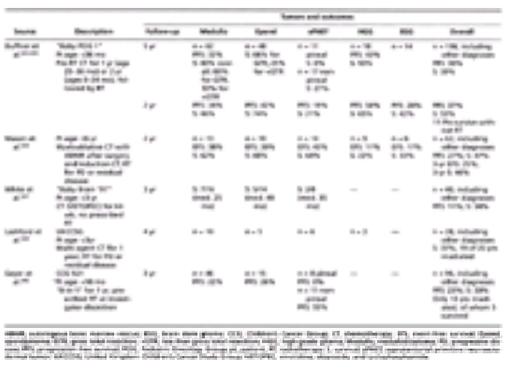

**TABLE 27-7. MULTI-INSTITUTIONAL STUDIES OF CHEMOTHERAPY FOR INFANTS AND VERY YOUNG CHILDREN WITH NEWLY DIAGNOSED BRAIN TUMORS**

Alternatively, chemotherapy has been used after reduced-dose craniospinal irradiation (CSI). In a small pilot study of ten patients, CSI was given with vincristine at 18 Gy to the craniospinal axis and 50.4 to 55.8 Gy to the posterior fossa; this was followed by 48 weeks of vincristine, cisplatin, and lomustine (CCNU) therapy. [345] Seven of the patients survived without recurrence at more than 6 years from diagnosis. The neurotoxicity with this approach was minimal; IQ scores 3 years after diagnosis were within 8 points of baseline scores.

In several noteworthy studies, a small minority of children, mostly with medulloblastoma, apparently were cured with surgery and chemotherapy alone. [325,327,346,347] The oldest of these series was initiated in 1976 and recently was updated by Ater et al. [347] Children who were younger than 3 years and had malignant brain tumors were treated for up to 2 years with mechlorethamine, vincristine, procarbazine, and prednisone; radiotherapy was reserved for recurrent disease. Of 12 patients with medulloblastoma, eight survived at a median of more than 10 years, and six of these never received radiotherapy. Of five patients with ependymoma, two survived, one without having received radiotherapy. Irradiated survivors had a mean IQ of 85, whereas those who were not irradiated maintained a mean IQ of 100.1. These studies, and that of Goldwein,[345] suggest that neurotoxicity can be reduced substantially in a subset of young patients with medulloblastoma by lowering, or even omitting, radiotherapy.

In both the POG and the Children's Cancer Group (CCG) infant brain tumor studies, histology of sPNETs affected outcome. Children with pineoblastoma in either study did not survive, whereas those with nonpineoblastoma, nonmedulloblastoma PNETs had prolonged survivals. [325,346] A similarly poor outcome has been seen with

other primary chemotherapeutic strategies for sPNETs.[348]

More recent U.S. and European clinical trials have incorporated dose-intensified chemotherapy after surgery and have either restricted or withheld radiotherapy. The benefit of this approach has not yet been proven. The second POG “Baby-Brain” study (POG 9233) randomly assigned patients prospectively to standard-dose chemotherapy, as was given in the first such study, or to a dose-intensive schedule of the same agents. Initial results indicate that the dose-intensive approach is feasible, is more toxic than the standard schedule, and does not appear to provide a survival benefit for children with medulloblastoma and ependymoma. [349] Event-free survival was significantly higher on the intensive schedule for infants with ependymoma. Again, complete resection of ependymoma and medulloblastoma was associated with significantly higher rates of event-free and overall survival. Mature data from that study, including those from the companion radiotherapy study, are eagerly awaited. (Dose intensification of chemotherapy with stem cell or marrow support was discussed in the section Drug Delivery Strategies.)

Currently, no chemotherapy approach to infants with malignant CNS tumors can be considered standard. The long-term results of POG 8633 are encouraging but have not yet been duplicated. The value of dose-intensified chemotherapy, as compared to standard doses, is not clear. New agents are sorely needed. The PBTC is studying the addition of intrathecal mafosfamide to a schedule of cisplatin, cyclophosphamide, vincristine, and oral etoposide, similar to earlier trials. Outside the clinical trial setting, the use of chemotherapy in standard doses for a limited period before radiotherapy is a reasonable approach but cannot be considered curative by itself. It appears that radiotherapy cannot yet be avoided. However, using the recent development of highly conformal delivery technology, current studies are testing hypotheses that earlier use of radiotherapy may lead to increased local tumor control rates and perhaps increased cure rates, while potentially decreasing long-term neuro-cognitive sequelae from decreased exposure of normal brain tissues to radiation.

Current infant trials also are seeking to determine whether the benefit of total tumor resection observed in other studies can be expanded to a larger proportion of patients. Limited data suggest that neoadjuvant chemotherapy can render tumors more easily resectable. [350] On the basis of these data and the results of earlier trials, ongoing studies are incorporating second-look operations into chemotherapeutic regimens.

New molecular technologies offer the hope that genetic profiles of tumors will help to guide clinical oncologists in their design of treatment protocols. If inherent tumor biology can be defined through genomic profiling, it might render possible identifying subsets of young children who might be curable with surgery and chemotherapy alone. Those with higher-risk disease warranting innovative treatment approaches also might be described. Ultimately, such molecular genetic analyses may permit more effective and less toxic scheduling of chemotherapy and radiotherapy.

## MEDULLOBLASTOMA

### Demography

Medulloblastoma accounts for approximately 20% of all primary pediatric CNS tumors and for approximately 40% of tumors arising from the cerebellum, and it is the most common malignant brain tumor of childhood. Although the tumor may be diagnosed in teenagers or young adults, most cases of medulloblastoma occur in the first decade of life. The peak age of incidence is between 3 and 4 years, and boys are affected between one and a half and two times as commonly as girls. [1]

### Pathology and Patterns of Spread

The ongoing debate surrounding the nomenclature of medulloblastoma and PNET was reviewed earlier. The most recent WHO classification of brain tumors maintains medulloblastoma as an independent cerebellar embryonal neuroepithelial tumor and classifies separately other similar-appearing embryonal small-cell tumors in other locations.[10]

Medulloblastomas are highly cellular, soft, friable tumors composed of cells with deeply basophilic nuclei of variable size and shape, little discernible cytoplasm and, often, abundant mitoses (Fig. 27-10). Homer Wright rosettes and pseudorosettes are variably present. Various degrees of glial or neuronal differentiation are noted, suggesting that the primitive cell of origin possesses the capacity for bipotential differentiation. [106,107] A histologic variant with an abundant stromal component, desmoplastic medulloblastoma (Fig. 27-11) occurs dominantly in the lateral cerebellar areas of adolescents and adults. [121,351]

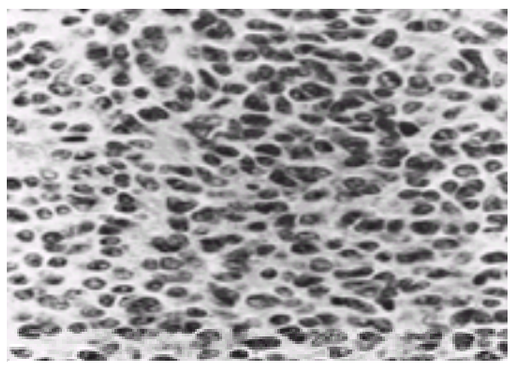

**FIGURE 27-10.** Typical histologic features of medulloblastoma (primitive neuroectodermal tumor). Tumor formed by apparently undifferentiated, basophilic, round to oval nuclei with minimal perceptible cytoplasm. (Hematoxylin and eosin, ×400.)

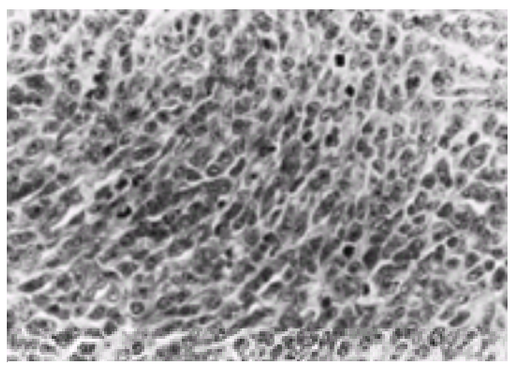

**FIGURE 27-11.** Desmoplastic medulloblastoma showing linear arrangement of cells along delicate background fibers. (Hematoxylin and eosin, ×400.)

An aggressive variant of medulloblastoma, termed *large-cell* and *large-cell anaplastic*, has been described.[352,353] As the names imply, the histologic features that distinguish this subset of medulloblastoma are large round nuclei with prominent nucleoli, frequent mitoses, abundant apoptosis and, in the anaplastic subset, nuclear pleomorphism. These tumors are uniformly positive for synaptophysin; positive staining with chromogranin is common as well. Monosomy 22 has not been seen in the cases described. The large-cell anaplastic variant represented 4% of the nearly 500 cases of medulloblastoma reviewed by Brown et al. [353]

Medulloblastomas often grow to several centimeters and may fill the posterior fossa, invading surrounding CNS structures as they occupy the regional subarachnoid and ventricular spaces. As with other CNS tumors of presumed primitive neuroepithelial origin, widespread seeding of the subarachnoid space may occur ( Fig. 27-12). The reported frequency of CNS spread outside the area of the primary tumor at diagnosis is 11% to 43%, and such spread eventually occurs in as many as 93% of patients who come to necropsy.[354,355]

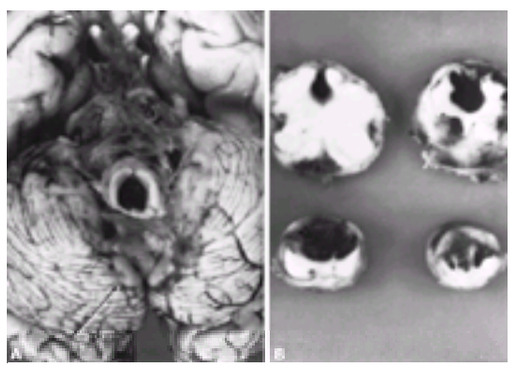

**FIGURE 27-12. A:** Nodules of a medulloblastoma (primitive neuroectodermal tumor) in the cisterna magna (*arrow*). A hemorrhage is present in the medulla. **B:** Transverse section of the medulla and spinal cord showing metastatic deposits of medulloblastoma in the subarachnoid space. Tumor is partially hemorrhagic and has invaded the neural tissue to a variable extent at the different levels.

Of all pediatric CNS neoplasms, the medulloblastoma has the greatest propensity for extraneural spread. Although this has been observed in 20% to 35% of patients in smaller institutional studies, more recent larger series suggest that the rate of such events is less than 4%. [195,356,357,358 and 359] Bone is the most common site, accounting for more than 80% of metastases; bone marrow, lymph nodes, liver, and lung are other common sites.

### Prognostic Considerations

An analysis of prognostic factors is confounded by the rapid diagnostic and treatment modality changes that have occurred over the last two decades. Assessment of biologic factors is only beginning. Some of the clinical and biologic characteristics of the disease that have, or have had, prognostic value in medulloblastoma are discussed here.

#### *Age at Diagnosis*

Determining the influence of age as an independent prognostic factor is difficult because of several observations: younger patients tend to have a higher rate of disease dissemination at diagnosis,[359,360] a lower overall rate of complete tumor resection,[325] and less aggressive radiotherapy.[336] In addition, more aggressive histologic subtypes of medulloblastoma[353] and AT/RT, which might be misdiagnosed as medulloblastoma, occur more commonly in the first few years of life. Nevertheless, children younger than 2 or 3 years have a worse prognosis than do older children. The age at which outcome no longer is affected negatively is not clear. In studies of patients older than 2 to 3 years, for whom radiotherapy generally is used as the primary postoperative treatment modality, younger age has been prognostic of outcome in some series[197,361] but not in others.[362,363]

#### *Tumor Size and Extent*

The Chang staging system, shown in Table 27-8, was developed in 1969 and used preoperative imaging studies, the surgeon's intraoperative impressions, and CSF cytology to assign stages of primary (T stage) and metastatic (M stage) disease. Modifications of the system have been proposed but, in any form, the Chang stage remains the system used most widely for designating the extent of disease.

| Stage | Definition |
|---|---|
| Tumor | |
| T1 | Tumor <3 cm in diameter and limited to the midline position in the vermis, the roof of the fourth ventricle and, less frequently, to the cerebellar hemispheres |
| T2 | Tumor >3 cm in diameter, further invading one adjacent structure or partially filling the fourth ventricle |
| T3 | Divided into T3a and T3b |
| T3a | Tumor invading two adjacent structures or completely filling the fourth ventricle with extension into the aqueduct of Sylvius, foramen of Magendie, or foramen of Luschka, thus producing marked internal hydrocephalus |
| T3b | Tumor arising from the floor of the fourth ventricle or brainstem and filling the fourth ventricle |
| T4 | Tumor further spreading through the aqueduct of Sylvius to involve the third ventricle or midbrain, or tumor extending to the upper cervical cord |
| Metastases | |
| M0 | No evidence of gross subarachnoid or hematogenous metastases |
| M1 | Microscopic tumor cells found in cerebrospinal fluid |
| M2 | Gross nodule seedings demonstrated in the cerebellar cerebral subarachnoid space or in the third or lateral ventricles |
| M3 | Gross nodular seedings in the spinal subarachnoid space |
| M4 | Extraneural metastasis |

**TABLE 27-8. CHANG STAGING SYSTEM FOR POSTERIOR FOSSA MEDULLOBLASTOMA**

Although M stage retains prognostic value (see later), T stage does not in most recent large series. [194,359,364,365] Brainstem involvement by direct infiltration of tumor, designated as Chang T3b, was historically indicative of a worse prognosis. However, with modern treatment regimens employing chemotherapy with radiotherapy, this feature is not prognostic. [193,196,364,366,367]

Extent of disease, or M stage, is consistently predictive of outcome, with two caveats. First, M1 disease, indicating positive CSF cytology without radiographic evidence of disseminated disease, is rare, and its impact on survival is unclear. In CCG study 921, wherein 18% of patients had M1 disease, 5-year progression-free survival (PFS) was 57% (± 10%), a rate lower than that for M0 disease and higher than that for M2 or M3 disease, but not significantly different in either case. [365] In the German HIT '91 trial, 13% of patients had M1 disease, and their survival rate of 65% (± 12%) did not differ from that of patients with M0 disease. [361] A similar rate of survival was found for the low number of M1 patients in the French M7 protocol for metastatic medulloblastoma. [363]

Of note is the observation that sampling of CSF from different sites may lead to discordant results. Positive cytology from ventricular CSF, obtained through ventriculoperitoneal shunts, does not correlate consistently with cytology from the lumbar space, which is more sensitive in detecting malignant cells. [368] Cytologic examination of CSF obtained by lumbar tap remains the standard method for determining CSF disease status.

Additionally, although M2 to M3 disease is prognostic in all series, ascertaining the independent impact of M4 disease, indicating extraneural metastases, is difficult. It is a much less common occurrence than is M1 disease and, in most recent medulloblastoma trials, patients with M4 disease were either excluded from, or not accrued to the study. As a result, M2 disease and M3 disease usually are combined in outcome analyses, often with M1 disease. In all series, a higher M stage of disease correlates with a lower survival rate. [359,361,362 and 363,365]

#### *Extent of Resection*

A near-total resection (generally defined as a more than 90%) can be achieved in approximately 80% of medulloblastomas using contemporary microsurgical techniques.[205] Evidence suggesting that extent of resection correlates with outcome has been provided by several single-institution studies and by a multi-institutional study of the International Society of Paediatric Oncology. [194,195 and 196,198,199,369] For example, Jenkin et al.[369] reported a 5-year PFS of 93% in children undergoing “gross total” resection versus only 45% in those undergoing incomplete resection. These observations were in contrast to older multi-institutional studies that failed to detect an effect of resection extent on outcome.[359,370] In neither of these older studies was M stage assessed uniformly, however. More recently, the CCG study 921 demonstrated a clear relationship between extent of resection and outcome but only in the subset of patients who had no evidence of tumor dissemination. [194] The same study found that, regardless of the surgeon's estimate of disease resection, the presence of less than 1.5 $cm^2$ residual disease on postoperative imaging was

associated significantly with a higher PFS rate in patients with M0 disease; this effect was greatest in children older than 3. [194]

Although the foregoing studies support the performance of extensive surgical resections in children with medulloblastoma, little convincing evidence substantiates improved outcome when gross total is compared with near-total resections. This distinction is important, because these tumors generally infiltrate the floor of the fourth ventricle. The observation that this microscopic residual disease does not affect prognosis adversely provides a strong rationale for avoiding aggressive removal of small components of brainstem disease, thereby minimizing the morbidity of the resection.

### *Shunts*

Although some reports have suggested that shunts placed to relieve hydrocephalus are associated with an increased incidence of systemic metastases, [195,356,371] other studies have cast doubt on this association. [354,372] A more recent review demonstrated fairly conclusively that, in patients with comparable risk factors, insertion of a shunt did not appear to increase the risk of systemic tumor dissemination. [180] Ventriculoperitoneal shunts and alternatives to relieving hydrocephalus have already been discussed.

### *Molecular Markers*

Several recent investigations have identified molecular markers that may be more accurate than clinical criteria for predicting medulloblastoma prognosis. Early flow cytometry studies indicated an association between aneuploidy and a more favorable prognosis. [373] Later cytogenetic studies further refined the link between genomic mutations and tumor behavior, demonstrating that deletions of chromosome 17p were associated with poor outcome. [90] Amplification of c-*Myc* was linked strongly to poor prognosis but was found to occur in fewer than 20% of all medulloblastomas. [374]

Several recent investigations have focused on gene expression as a marker of medulloblastoma prognosis. Expression of the neurotrophin-3 receptor TrkC has been found to be associated with a favorable prognosis. [375,376] and [377] The majority of medulloblastomas expresses both TrkC and neurotrophin-3, suggesting an autocrine or paracrine receptor activation of the TrkC receptor tyrosine kinase. [375,377] Moreover, TrkC activation induces medulloblastoma apoptosis that possibly may contribute to the more favorable prognosis of tumors with high TrkC expression. [377] In contrast, a poorer prognosis has been linked to increased expression of the neuregulin receptors *Erb*B-2 and *Erb*B-4 and of c-*myc*.

These discoveries suggest that inherent biologic differences, reflected in the divergent expression of genes that regulate tumor growth and response to therapy, determine the clinical outcome of morphologically similar-appearing medulloblastomas. Efforts now are under way, through multi-institutional therapeutic trials, to test prospectively molecular markers that might be used for the stratification of patients in future clinical investigations. Furthermore, the molecules identified by these investigations might serve as targets for future, biologically based therapies specifically designed on the basis of molecular mechanisms regulating tumor growth.

### *Risk Groups*

Most clinical trials in the United States stratify patients on the basis of the following factors for treatment strategies: age less than 3 years, M+ disease, and more than 1.5 $cm^2$ disease residual on postoperative images (generally indicating higher-risk disease); and age no younger than 3 years, M0 disease, and less than 1.5 $cm^2$ of disease residual (indicating lower-risk disease). All these factors are clinical and, thus far, biologic characteristics of disease, including histologic variants of medulloblastoma, have not figured into risk classification.

## Treatment

### *Surgery*

A fundamental decision in evaluating a child with a posterior fossa tumor is determining whether the tumor is a mass lesion arising from the cerebellar hemisphere, vermis, or fourth ventricular floor or is an intrinsic tumor of the brainstem. Children with the former lesion types (e.g., medulloblastomas, ependymomas, cerebellar astrocytomas) undergo surgical intervention to allow for diagnosis and to achieve cytoreduction.

In children with a resectable lesion, such as a medulloblastoma, the timing of surgery is determined by the clinical status of the children. If they are alert, high-dose corticosteroids are administered and, if feasible, a spine MRI scan is obtained to determine the presence of evidence of leptomeningeal dissemination; the craniotomy then is performed on the following day. This approach is reasonable also if such children are lethargic but become alert after administration of corticosteroids. However, in the rare situations in which such children are extremely somnolent, urgent surgical intervention is preferred.

A ventriculostomy is placed in most cases for temporary CSF diversion, and this is “weaned” by gradual elevation of the drip chamber during the postoperative period. If affected children need CSF drainage for more than 7 days after tumor removal, permanent CSF diversion usually is performed.

The tumor usually is approached through a suboccipital craniotomy or craniectomy, with the patient in a prone or modified prone (Concorde) position. The dura is opened in a Y-shaped fashion. Cerebellar hemispheric lesions, which are encountered most commonly in older children, are exposed fully by a transverse or vertical incision in the cerebellar hemisphere. The more common vermian and fourth ventricular lesions may be visible within the foramen of Magendie but, if not, are exposed by dividing the caudal 1 to 2 cm of the inferior vermis. Because approximately 10% of patients develop a postoperative syndrome of pseudobulbar symptoms and mutism (the “posterior fossa syndrome”) after vermian tumor resections [378,379] —a reaction possibly related in part to the extent of the vermis incision—an attempt is made to incise only as much vermis as is needed to provide adequate exposure of the tumor. The central portion of the lesion then is debulked using the ultrasonic aspirator. The plane between the tumor and the vermis then is followed rostrally until the roof of the fourth ventricle is reached. Once the tumor has been debulked partially, a cottonoid patty is inserted under the caudal aspect of the tumor along the floor of the fourth ventricle, to minimize the risk of injury to the brainstem as additional tumor is removed from within the fourth ventricle. Some surgeons monitor electromyelograms of the lateral rectus and facial muscles during the resection to reduce the risk of abducens and facial nerve palsies. Next, tumor extending laterally within the foramina of Luschka or the cerebellar peduncles is removed. Finally, tumor adherent to the floor of the fourth ventricle is removed carefully. The aggressiveness of the resection in this region is guided by the frozen-section diagnosis. For medulloblastomas, the tumor can be shaved down to the floor of the fourth ventricle, but removal of tumor below the floor is unnecessary as it does not appear to improve outcome and clearly increases the potential for morbidity. This recommendation contrasts to the same situation for ependymoma (discussed later).

Once the tumor has been removed, the dura is closed, generally with a graft. Because a CSF examination is an important component of the postoperative staging of children with medulloblastomas and because blood and debris can settle in the lumbar thecal sac within several hours of surgery, complicating interpretation of the cytology for several weeks, many groups either perform a lumbar puncture immediately after the tumor resection or delay the puncture until the third postoperative week. Currently available data are insufficient to judge whether intraoperative CSF sampling from the cisterna magna is adequate for staging of disease.

### *Radiotherapy*

Medulloblastoma is radiosensitive; hence, for decades, the standard curative therapy for medulloblastoma has been craniospinal irradiation. Attempts at not irradiating the entire neuraxis or omitting radiotherapy altogether have resulted in compromised survival. [380] Conversely, craniospinal irradiation can produce intellectual and endocrinologic morbidity, most marked in younger patients. Therefore, the desirable approach is to use a minimum craniospinal radiation dose that does not jeopardize the cure rate. A small, prospective, multicenter study in which patients with favorable prognostic factors were randomly assigned to the standard (36.0-Gy) irradiation versus reduced-dose (23.4-Gy) neuraxial irradiation showed an excess number of neuraxial relapses in the reduced-dose arm. However, the difference in survival rates between the two arms was only of borderline statistical significance. [381] Whether the addition of chemotherapy to reduced-dose craniospinal irradiation would result in outcomes similar to standard-dose irradiation is unknown. One randomized study to test this hypothesis was aborted because of insufficient patient accrual secondary to physician and family bias in favor of chemotherapy. Nevertheless, the current COG protocol uses 23.4 Gy and randomly assigns patients to one of two different chemotherapeutic regimens. Hyperfractionated neuraxial irradiation has not been proven to be superior. Undue protraction of the course of radiotherapy has been shown to have an adverse impact on the control of the disease. [382]

The radiation dose to the posterior fossa tumor bed is less controversial. A total dose of less than 50 Gy has been shown to lead to inferior cure rates. The dose used most commonly is 54.0 to 55.5 Gy. The potential benefit of an additional radiosurgical boost in high-risk patients is still under investigation. A current debate concerns

whether the entire posterior fossa or just the tumor bed plus a margin must receive the full dose of radiation. The bulk of medulloblastoma recurrence is in the posterior fossa or adjacent to the original tumor site. Therefore, a reasonable approach is to deliver the full dose to the tumor bed plus a 2-cm margin only. Modern conformal techniques, such as IMRT, can deliver the full dose to such a target while reducing the radiation dose to the cochleas and hypothalamic-pituitary axis. A preliminary study using IMRT has shown a significant reduction of ototoxicity despite the addition of cisplatin chemotherapy (S. Woo, unpublished data).

The technique of craniospinal irradiation is well-known. However, ensuring at least a 5-mm margin of coverage of the cribriform plate is important, as inadequate irradiation of that area can lead to an increase in recurrence at this location. [383] Also recommended is MRI of the spine to determine the inferior border of the thecal sac in each patient.

### *Chemotherapy*

The potential benefit of chemotherapy to subsets of patients with medulloblastoma was demonstrated first by the International Society of Paediatric Oncology and was confirmed further in studies by the CCG and the POG.[196,359,370,384] Since those reports, imaging and surgical technology have advanced significantly, and tumor assessment has become more standard. Through a series of subsequent trials, medulloblastoma has emerged as one of the most chemotherapy-sensitive of all brain tumors. The tumor's sensitivity has allowed the investigation of chemotherapy use in different contexts: to increase disease control and patient survival; to decrease adverse effects of radiotherapy; and to postpone or obviate the need for radiotherapy in the very youngest child. Table 27-9 outlines more recent studies that have employed chemotherapy for the treatment of medulloblastoma. The agents used most commonly are the classic alkylators and platinum complexes. For these, issues of timing, use with other agents, and drug schedules are not yet standardized. However, toxicities limit the extent to which these agents can be used, and cure rates remain suboptimal for many patients. New agents that are more effective and less toxic are needed.

**TABLE 27-9. RESULTS OF RECENT MULTI-INSTITUTIONAL CLINICAL TRIALS OF CHEMOTHERAPY FOR NEWLY DIAGNOSED MEDULLOBLASTOMA**

With regard to increasing disease control, chemotherapy has been employed in both neoadjuvant and adjuvant settings. In patients with residual or metastatic disease, studies of neoadjuvant chemotherapy offer the potential advantages of identifying active agents; of delivering chemotherapy to a BBB that is possibly more advantageously disrupted owing to surgery; of treating micrometastatic disease throughout the CNS; and of decreasing gross residual tumor burden before the delivery of conventional radiotherapy. Chemotherapy before irradiation is better tolerated by the nonirradiated bone marrow and hearing apparatus as well. Several active drugs and drug combinations have been identified through neoadjuvant chemotherapy trials: cyclophosphamide [385]; cisplatin and vincristine [386]; "8-in-1"[387]; cisplatin and etoposide [388]; cisplatin, vincristine, and cyclophosphamide [389]; and carboplatin with etoposide.[390] The potential benefit of decreasing tumor burden before craniospinal radiotherapy is accompanied by a risk of disease progression before initiation of radiotherapy. Progressive disease rates of 20% to 30% have occurred during various neoadjuvant regimens.[365,389,390 and 391] Whether progressive disease or disease improvement during neoadjuvant chemotherapy ultimately affects long-term disease control is not known. However, delay of radiotherapy may be detrimental to the outcome of certain patients, as suggested in a study by Kortmann.[361]

Medulloblastoma's sensitivity to chemotherapy has rendered possible the modulation of treatment modalities based on relative risk of recurrence in balance with potential long-term sequelae of treatment. In this context, chemotherapeutic trials generally have employed two risk strata for purposes of treatment: higher-risk disease, defined as that which is resected incompletely or is metastatic, and lower-risk disease, defined as completely resected and without metastases. The goal of adding chemotherapy to low-risk disease is to allow a safe reduction of radiation dose outside the posterior fossa so as to decrease the risk of late, adverse neuro-cognitive effects due to radiation. Available data from the POG/CCG study of standard (36-Gy) radiotherapy versus reduced-dose (23.4-Gy) radiotherapy, without the addition of chemotherapy, for lower-risk medulloblastoma patients indicate that neurotoxicity is indeed lower after reduced-dose radiotherapy. [339] Whether the addition of chemotherapy to irradiation increases the survival of lower-risk patients is not clear. Such a benefit was suggested in Packer's limited institutional study,[362] which used chemotherapy in addition to standard-dose radiotherapy for patients considered at higher risk for disease recurrence. Many patients in that study, including those with M0 tumors and with totally or near-totally resected tumors, subsequently were considered to have lower-risk disease. The apparent benefit of chemotherapy to these patients has not been confirmed in larger controlled clinical trials.

In 1993, the CCG and the POG tried to answer the question through a randomized study of standard radiotherapy versus reduced-dose radiotherapy plus chemotherapy for low-risk patients. The study was stopped early, owing to lack of patient accrual secondary to parental and physician bias in favor of chemotherapy.[392] The current COG trial compares two cisplatin-based adjuvant regimens, substituting cyclophosphamide for CCNU in one arm, after reduced-dose craniospinal irradiation. Future trials will examine further reduction of radiotherapy dose. Outside a clinical trial, the use of chemotherapy for lower-risk patients could be considered a standard of care. However, the lowest, safest dose of radiotherapy to use within this approach has not yet been determined.

Chemotherapy studies for patients with higher-risk disease have focused on increasing tumor control and patient survival. In some series, the addition of chemotherapy to craniospinal irradiation has increased survival rates over those achieved with standard irradiation alone. [196,359,393] Conversely, reduction of craniospinal radiotherapy dose, in conjunction with adjuvant multi-agent chemotherapy, may result in lower survival rates. [394] Ongoing studies for high-risk patients are exploring chemotherapy dose intensification. The feasibility of administering several courses of high-dose chemotherapy with peripheral blood stem cell support after irradiation recently was demonstrated.[395] A similar approach is being studied in the COG as well. The effects of new agents on measurable disease and the addition of intrathecal chemotherapy also are being explored.

## SUPRATENTORIAL PRIMITIVE NEUROECTODERMAL TUMORS

The term *primitive neuroectodermal tumor* was coined by Earle and Hart in 1973. The histologies of all these tumors are similar, but their nosology has been controversial, as noted previously. Various designations of these tumors have been based on the site of tumor origin and by lines of differentiation within the tumor. Thus, the sPNET also has been called *cerebral* or *central neuroblastoma*, *cerebral medulloblastoma*, and *pineoblastoma*. Ependymoblastoma commonly has been included in the sPNET category as well. Medulloblastoma is the designation for PNET of the posterior fossa. In this section, only sPNET is reviewed.

H4>Demography

Collectively, sPNETs in childhood are rare, accounting for only 2.5% to 6.6% of CNS tumors in most series. [338,396,397,398 and 399] These tumors are more common during the early first decade.[330] The median age of onset varies between several months and several years in combined series of patients. [397,400,401 and 402] Many series show a male-female ratio near unity; in others, male persons predominate nearly 2:1. [397,402] Whites appear to be affected much more commonly than are nonwhites.[403]

### Pathology and Patterns of Spread

Despite the presence of considerable microscopic extension, sPNETs generally appear as well-circumscribed masses. Grossly, they are lobulated, soft, hemorrhagic, and often cystic masses. Microscopically, sheets of uniform embryonal-appearing, small, round cells with hyperchromatic oval nuclei and frequent mitoses are noted

(Fig. 27-13). Homer Wright rosettes and perivascular pseudorosettes and areas of necrosis are common. Although foci with various degrees of glial, neuronal, or ependymal differentiation are seen in 70% of tumors, light microscopy and ultrastructural evaluation generally reveal most individual cells to be primitive and undifferentiated.

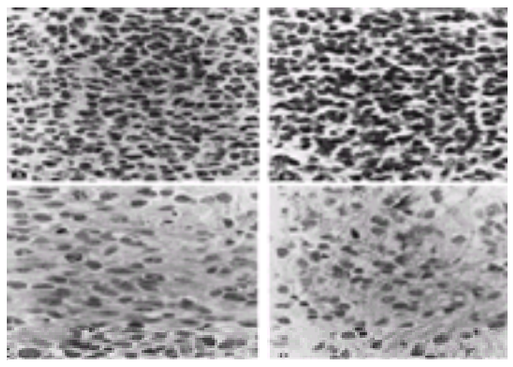

**FIGURE 27-13. A:** Typical field of medulloblastoma (primitive neuroectodermal tumor of the posterior fossa). Tumor is formed by apparently undifferentiated, basophilic, round to oval nuclei with minimal perceptible cytoplasm. (Hematoxylin and eosin, ×400.) **B:** Typical field of pineoblastoma (primitive neuroectodermal tumor of the pineal). Note the similarity to the photomicrograph in **A**. (Hematoxylin and eosin, ×400.) **C:** One of several nests of malignant astrocytes in primitive neuroectodermal tumor of the cerebrum, displaying mild pleomorphism and several mitotic figures. (Hematoxylin and eosin, ×400.) **D:** Another similar field from the same tumor shown in **C** stained with glial fibrillary acidic protein (GFAP) showing a few cells staining for GFAP. (GFAP, ×400.)

Wide local and regional tumor extension is common, and transcallosal extension into the opposite hemisphere also has been reported. [404] Although the incidence of diffuse leptomeningeal or spinal subarachnoid disease was as high as 30% at diagnosis in many early studies, [400,405,406,407,408,409,410,411,412] and [413] reliable statistics for the incidence of metastatic disease are not available, owing to the relative rarity of these tumors and to changes in diagnostic imaging modalities and practice over the last few decades.[414] Despite the initially low incidence of dissemination at diagnosis, the eventual occurrence of leptomeningeal spread may be as high as 70% at relapse. Systemic metastases have not been reported commonly, but they appear to favor bone and lung.

### Prognostic Considerations

Much of what is inferred about sPNETs is derived from the experience with medulloblastoma. In past and current protocols, treatment of these tumors has been similar. Whether such an approach is biologically sound is not known, because treatment outcomes for sPNET appear to be worse than those for medulloblastoma. From various series, different factors affecting outcome emerge. In the CCG 921 study of radiotherapy and two different chemotherapeutic regimens, site of primary tumor and the absence of metastases predicted a higher chance of survival.[403] Children with pineal tumors had a 3-year PFS rate of 61%, whereas for those with tumors of nonpineal origin, the rate was only 33%. Noteworthy is that whereas pineal site is favorable in older children, pineal location in infants portends a dismal prognosis (as noted earlier).[325,346] In the CCG study, PFS for nonmetastatic tumors, when adjusted for site, was 50%; for those with M+ disease, PFS was 0%.[403] GTR of disease, or no residual disease measured by postoperative MRI, is associated significantly with a better outcome in some series, [193,401] but other studies have failed to identify such an association.[346,404,411,412] Given the small numbers of patients with primary pineal sPNET and the inherent risks associated with operation in this area, assessing the benefit of tumor resection conclusively is difficult. [414]

### Treatment

#### *Surgery*

Because sPNETs often are large, highly invasive of functionally important cortex, and fairly vascular, gross total and near-total tumor resection are less frequent for sPNET than for medulloblastoma.[193] Furthermore, as stated, data are mixed with regard to the benefit of GTR of these tumors. Accordingly, the surgical management for sPNETs is similar to that for other cerebral malignant tumors, such as high-grade glioma, in which the primary goal is to relieve local mass effect by removing as much tumor as is safely feasible.

#### *Radiotherapy*

Standard therapy for patients with sPNET is craniospinal irradiation. Current treatment recommendations are craniospinal irradiation to 36 Gy with a boost to 54 Gy to the area of the initial tumor. Radiotherapy alone, as the only postoperative treatment, has been reported in only two retrospective studies; only 1 of 22 patients in the combined studies survived beyond 2 years.[415,416] Most treatment series have used both irradiation and adjuvant chemotherapy. Despite the improvements in survival rates noted with combined-modality therapy, PFS is no better than 33%. [193,396,403,404]

Craniospinal doses of 24 Gy and tumor doses of 45 Gy have been used in children younger than 3 years. As with medulloblastoma, it is uncertain whether the poorer outcome for this group of patients is related to the reduced radiotherapy dose or to more aggressive tumors that appear to have a higher incidence of dissemination at diagnosis.

#### *Chemotherapy*

Various single-agent and combination chemotherapeutic regimens have shown activity against sPNET. [346,388,407,417,418] No study has been designed to compare outcomes of medulloblastoma and sPNET statistically but, in recent series, the outcome for patients with sPNET appears to be inferior. In the CCG 921 study in which neoadjuvant and adjuvant “8-in-1” chemotherapy was compared to adjuvant CCNU, prednisone, and vincristine, each given with radiotherapy, 3-year PFS and survival were 45% and 57%, respectively, for all patients with sPNET and did not differ significantly between the two study arms. [403] Unlike the experience with medulloblastoma, neither degree of surgical resection nor extent of residual disease was prognostic. The authors concluded that the data were insufficient to determine whether the use of chemotherapy increased survival from that historically reported with surgery and radiotherapy alone. [404] Ongoing clinical trials offer combined-modality therapy to infants and older children with sPNET. Identification of either clinical or biologic prognostic factors is needed to redirect therapy in the future.

## EPENDYMOMA

### Demography

According to recent SEER registry data, ependymomas constitute approximately 9% of all primary CNS tumors in children. [1] The tumors usually arise within or adjacent to the ependymal lining of the ventricular system or the central canal of the spinal cord. Ninety percent of the tumors are intracranial, and up to two-thirds of these occur in the posterior fossa.[186,420,421] In children, the highest incidence occurs in the first 7 years of life [1]; the incidence peaks again in the third to fifth decades of life.[422] Whereas in the past, the ratio of male to female patients was reported to be near unity, recent series report a male-female ratio of between 1.3 and 2.0.[1,184,188,423,424] Of note in the potential etiology of these tumors is that DNA sequences identical to the SV40 polyomavirus and the corresponding viral large T-antigen have been found in several tumors; SV40 and related polyomaviruses can induce ependymoma and choroid plexus tumors in monkeys and other mammalian species.[425]

### Pathology and Patterns of Spread

Ependymomas generally are well-demarcated tumors that often display areas of calcification, hemorrhage, and cysts. Although uncommon, the ependymal rosette is a characteristic and diagnostic microscopic feature composed of radially aligned ependymal elements about a central lumen. More common is the conspicuous pseudorosette (Fig. 27-14), an eosinophilic halo composed of cells with tapering processes surrounding a blood vessel.

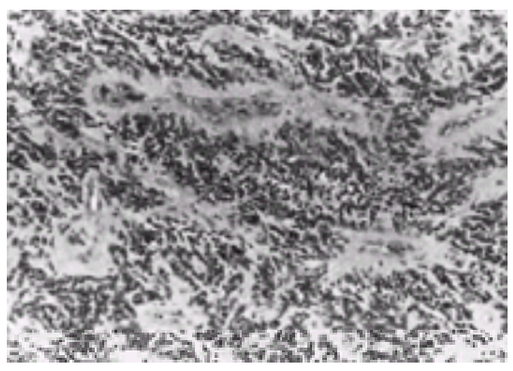

**FIGURE 27-14.** Section from a fourth ventricular ependymoma displaying typical perivascular pseudorosettes. (Hematoxylin and eosin, ×400.)

Ependymomas vary from well-differentiated tumors with no anaplasia and little polymorphism to highly cellular lesions with significant mitotic activity, anaplasia, and necrosis that may resemble glioblastoma multiforme. Ependymomas have been classified descriptively as cellular, epithelial, or papillary. Neither these terms nor a proposed classification that grades these tumors on the basis of their degree of anaplasia has gained wide acceptance, although they often appear in older literature. An exception to the use of such terminology exists for the ependymal tumors arising in the region of the conus medullaris and filum terminale, termed *myxopapillary tumors* because of their unique histologic features. Current terminology for ependymomas located elsewhere distinguishes between benign (low-grade) tumors and malignant (high-grade or anaplastic) tumors. The WHO classification system uses the terms *ependymoma* and *anaplastic ependymoma* to distinguish these two types. Although this division has been thought to correlate well with clinical outcome, its prognostic significance may be an artifact of the inclusion of a different but similar-appearing entity—the ependymoblastoma—within the anaplastic group. When this tumor has been removed from the series of ependymoma, the relationship between histology and clinical outcome generally disappears. [351,424,426,427]

Ependymomas are locally invasive tumors that spread contiguously into adjacent brain. Tumors arising in the posterior fossa frequently infiltrate the brainstem. In as many as one-third of these cases, tumor may project through the foramina to involve the medulla and upper spinal cord. [424] The incidence of spinal subarachnoid dissemination has been estimated to be 7% to 12% in combined patient series. One meta-analysis suggests that such events are potentially most common in high-grade and posterior fossa tumors.[422,428] Systemic metastases are rare and, when present, show a predilection for liver, lung, and bone.

**Prognostic Considerations**

The single most important prognostic factor that emerges from review of single- and multi-institutional experience with ependymoma is the extent of tumor resection.[182,183,185,186,187 and 188,344,420,428,429,430 and 431] Whether gauged by the surgeon's estimate or measured by postoperative MRI, patients whose tumors are grossly totally resected and those who have less than 1.5 $cm^2$ of residual disease on imaging have a rate of survival higher than that in children whose tumors are resected less than completely. The rates of survival after complete and less-than-complete resections range from 66% to 75% and 0% to 11%, respectively. [182,183,184,185,186,187 and 188] Perhaps related to degree of resection has been the finding in some series that location of primary intracranial tumor and patient age are prognostic. [432,433] However, these data are inconsistent except that the best prognosis is associated with ependymomas of the spinal cord. Younger children are more likely to have tumors arising from the posterior fossa and, in this location, tumors tend to be more invasive, and removing them entirely is more difficult. When lower age (usually younger than 2 to 4 years) has been found to have a negative impact on survival, this finding also has been attributed to the delivery of lower radiation doses. Another inconsistent prognostic factor is histology of the tumor; in some series, anaplastic or malignant histology predicts a poorer prognosis than does well-differentiated ependymoma,[182,420,428] although other series show no difference in outcome between the two histologic types. [183,186,187,424,426,434,435 and 436]

**Treatment**

***Surgery***

Techniques for the resection of posterior fossa ependymomas are similar to those used for resecting medulloblastoma, although the rationale for intraoperative monitoring of evoked potentials and cranial electromyography may be even greater because of the higher frequency of brainstem infiltration. Supratentorial ependymomas, often located subcortically, are resected in a fashion similar to that used in other deep-seated gliomas (described later).

The prognostic benefit of complete tumor resection has been stated. However, such a result has been feasible in only approximately 50% of ependymomas in most series. GTRs generally are more difficult for posterior fossa ependymomas than for supratentorial ependymomas because of the propensity for infratentorial lesions to infiltrate the brainstem and to surround cranial nerves and vessels lateral and ventral to the brainstem, precluding complete removal without unacceptable neurologic morbidity. Infants are particularly likely to have large infratentorial ependymomas with significant ventrolateral extension, which in part accounts for their less favorable prognosis in most series. [421,437,438,439 and 440] In such patients, multiple lower cranial nerve palsies as a result of both tumor and surgery often necessitate a tracheostomy and gastric feeding device. Resolution (if any) of neurologic impairment may be delayed for several weeks to months. [438,441] Because the prognosis in children with incompletely resected ependymomas is so poor, several recent treatment protocols have selectively incorporated second-look surgery in children with objective evidence of residual disease after an initial procedure. This generally has been attempted after a short course of neoadjuvant chemotherapy, administered in the hope of reducing the vascularity and invasiveness of the residual disease. A multi-institutional study, designed to examine the ability of this approach to improve outcome in such children without an unacceptable trade-off of morbidity, is currently being developed in the COG.

***Radiotherapy***

Local postoperative radiotherapy increases the overall survival rates of patients with ependymoma from between 15% and 25% to between 35% and 63%. Patients with supratentorial lesions should receive wide local treatment to 50 to 55 Gy. Because the tumor may spread by the subependymal route, the target volume for at least part of the treatment should include the wall of the lateral ventricles if the tumor involves any part of the ventricular wall. Posterior fossa tumor often extends down the cervical spinal cord, and careful attention should be paid to cover the involved upper cervical spine in the treatment fields.

Although a debate still questions the need for routine craniospinal irradiation, most investigators agree that patients without evidence of subarachnoid disease at diagnosis do not need craniospinal irradiation. Recent retrospective studies did not demonstrate a significant impact of prophylactic craniospinal irradiation on the rate of subsequent spinal dissemination or survival, regardless of tumor differentiation or primary site. [182,424,442] In intramedullary spinal cord or cauda equina ependymomas, postoperative radiotherapy could be withheld if complete surgical excision is accomplished.

***Chemotherapy***

Single- and multi-agent chemotherapeutic regimens have been used in ependymoma therapy. In clinical trials, the platinum agents appear to have the greatest activity. (For a comprehensive review of chemotherapeutic experience with ependymoma, the reader is referred to a review by Bouffet and Foreman. [443] The use of chemotherapy for infants with ependymoma is discussed earlier.) Despite the demonstrated activity of various regimens, the use of chemotherapy has not improved the survival of patients with either completely or incompletely resected ependymoma in any multi-institution series. For older children, chemotherapy is recommended only as part of a clinical trial.

## LOW-GRADE SUPRATENTORIAL AND CEREBELLAR GLIOMAS

Low-grade glial neoplasms are a diverse group of tumors that include JPA, fibrillary (also called *protoplasmic* or *diffuse*) astrocytoma, oligodendroglioma, ganglioglioma, and such mixed tumors as oligoastrocytoma. Their unifying features are their generally slowly evolving, nonaggressive clinical behavior and relatively benign histologic appearance. Generally high rates of long-term survival are characteristic as well, despite low but steady rates of disease progression even after 10 years from diagnosis.

### Demography

Cerebellar astrocytomas are the most prevalent, representing 15% to 25% of all CNS tumors, followed in prevalence by cerebral hemispheric astrocytomas and tumors of deep midline structures (each representing 10% to 15% of all CNS tumors) and tumors of the optic pathway (accounting for approximately 5% of all CNS tumors).[444] Seventy to seventy-five percent of cerebellar astrocytomas occur in childhood, [445,446] most commonly in the first decade of life. The average age at diagnosis ranges from 6.5 to 9.0 years. [143,446,447,448,449 and 450] Boys are affected more commonly than are girls.[451] Neuraxis dissemination of low-grade gliomas from any location in the brain is distinctly uncommon, occurring in only approximately 5% of cases. [452,453,454,455 and 456] Tumors arising from the hypothalamus and periventricular areas may be more likely to disseminate.

### Pathology and Patterns of Spread

Classifications, such as that of Kernohan, St. Anne/Mayo, and WHO, identify low-grade tumors primarily on the basis of their grade or degree of anaplasia rather than on histologic type.[95] Neoplasms that are only modestly cellular and contain few or none of the histologic criteria of malignancy are designated as low-grade or grade I and grade II lesions in these classifications. The WHO classification uses the grade I designation for the typical pilocytic astrocytoma and grade I or grade II for the mixed neuronal-glial tumors. The low-grade fibrillary astrocytomas that make up most adult low-grade lesions are designated as grade II. Grade III and grade IV tumors are high-grade lesions characterized by aggressive clinical behavior and malignant histology (considered separately in the section, Supratentorial High-Grade Gliomas). Although the utility of such grading systems has been questioned because of their subjective nature and their reliance on often small biopsies from tumors that may be heterogeneous, these systems remain popular because applying and understanding them is simple and because they have some prognostic value.

#### *Supratentorial Low-Grade Gliomas*

Most supratentorial low-grade gliomas are astrocytomas, a diverse group of neoplasms generally composed of GFAP-positive bipolar or stellate cells. Such designations as *fibrillary*, *protoplasmic*, *gemistocytic*, *xanthomatous*, and *pilocytic* often are used to describe the appearance of the astrocytes and their various histologic patterns.[95,457] Only the pilocytic and fibrillary varieties are seen commonly in children. Anaplastic transformation of these tumors leading to more malignant-appearing and clinically aggressive entities, such as anaplastic astrocytoma and glioblastoma multiforme, a common event in adults, occurs less frequently in children and young adults.[351,458,459 and 460]

Oligodendrogliomas, a separate category of glial neoplasms, are characterized by a generally monotonous collection of uniform spheroidal cells with more homogenous nuclei than are seen in the fibrillary astrocytoma, the tumor that represents the principal diagnostic alternative. An abundant clear cytoplasm surrounding a dark nucleus produces the appearance of a perinuclear halo that gives a distinctive fried-egg appearance. As in astrocytomas, grading of oligodendrogliomas appears to identify groups with differing prognoses. Although several schemes for grading have been proposed, no consensus over which tumor features are the most prognostically significant has emerged. Most investigators reserve the use of the terms *high-grade* and *anaplastic* oligodendroglioma for tumors with increased cellularity, mitotic activity, and other features of more malignant glial tumors (outlined earlier and in the section dealing with malignant gliomas). [461] In children, at least one-half of oligodendroglial tumors occur as a part of mixed astrocytic-oligodendroglial tumors. These tumors have a predilection for the frontal and temporal lobes. [462]

Mixed neuronal-glial cell neoplasms, such as ganglioglioma, gangliocytoma, DNET, and DIG, are grouped for convenience with the low-grade gliomas (discussed in the section, Supratentorial Low-Grade Gliomas). Gangliogliomas are the predominant type of mixed tumors, and they are composed of glial tissue and a disorderly array of binucleate ganglion cells that must be distinguished from normal neurons in the area involved. The glial component most commonly is astrocytic, but it may be oligodendroglial. Although anaplastic gangliogliomas are uncommon, when they do occur, they usually involve anaplasia within the glial component; anaplastic involvement of the neuronal component is unusual.[463]

#### *Low-Grade Cerebellar Tumors*

Low-grade gliomas occurring in the cerebellum typically are astrocytomas. Two principal histologic variants have been described. The classic, or pilocytic, astrocytoma accounts for 80% to 85% of these tumors (Fig. 27-15), and it is composed of fusiform astrocytes loosely interwoven with a fine fibrillary background and no (or rare) mitoses. A frequent microcystic component and the presence of Rosenthal fibers, thought to represent degenerative changes in astrocytes, also are common. Large macrocystic structures filled with proteinaceous fluid and containing a mural nodule are seen in as many as 50% of patients. The walls of these cysts may be highly vascular, leading to occasional instances of spontaneous hemorrhage. Even though this tumor often displays features otherwise associated with malignant behavior, such as nuclear atypia and focal leptomeningeal invasion, it rarely behaves in other than a benign fashion. [143,351] Although most tumors remain confined to the cerebellum, direct extension through the cerebellar peduncles to involve the brainstem may occur. On rare occasions, both pilocytic and fibrillary cerebral astrocytomas have demonstrated neuraxial dissemination or late malignant transformation, a behavior that belies their typically low-grade histologic features.[464] In contrast to supratentorial astrocytic tumors, high-grade astrocytomas, such as glioblastoma, are uncommon in the cerebellum.

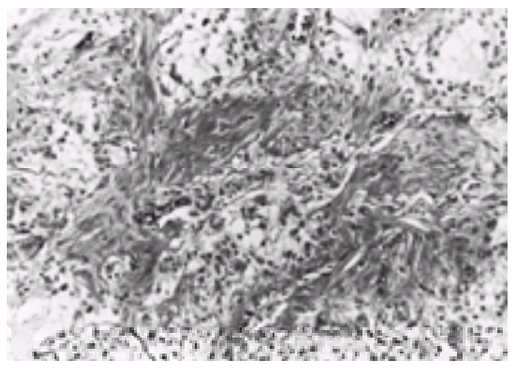

**FIGURE 27-15.** Typical biphasic pattern of a pilocytic astrocytoma. Note the dense, relatively anuclear fibrillar areas alternating with looser honeycombed fields. (Hematoxylin and eosin, ×250.)

The second variety of cerebellar astrocytoma is the diffuse or fibrillary astrocytoma, which accounts for 15% of cerebellar astrocytomas and is similar to the diffuse LGA of the cerebral hemispheres. This tumor is more densely cellular, lacks the microcysts and Rosenthal fibers common to the pilocytic tumors, is more widely infiltrative, and is more likely to undergo anaplastic change than is its counterpart. [351]

### Prognostic Considerations

Published reports of the management of LGA in children are complex, and the identification of consistent prognostic factors is difficult. Most reports include adult and pediatric cases, tumors from all sites, and patients treated over several decades, during which time diagnostic and therapeutic techniques have changed. The very good outcome reported by most authors and the indolent natural history of these tumors confounds analysis as well. Even so, certain factors consistently emerge in analyses but with inconsistent results. Complete resection of tumor seems most important for achieving prolonged disease-free survival in most, but not all,

series.[200,445,446,449,451,467,468] After a radical resection (i.e., greater than 90% of tumor resected), 5-year PFS rates for cerebral astrocytomas exceed 75% [145,467,469] (Table 27-10) versus less than 50% after incomplete resections.[145,146] However, the amenability of these tumors to second surgical explorations results in survival rates that may not differ from tumors completely resected at diagnosis.

| Treatment | Survival in yr (%) | | | Study |
|---|---|---|---|---|
| | 5 | 7 | 10 | |
| Complete resection | 76-100 | 86<br>60 (d) | 69-100 | 200, 467, 477 |
| Incomplete resection | 62 | — | 67-87 | 200, 478 |
| Incomplete resection plus irradiation | 80<br>58-93 (d) | —<br>77 (d) | 67-94<br>67 (d) | 200, 478 |

d, diencephalic.

**TABLE 27-10. SURVIVAL RATE ACCORDING TO THERAPY IN LOW-GRADE ASTROCYTOMAS**

The independent influence of the histology of tumors—generally pilocytic versus nonpilocytic—is controversial. Some reports support superior survival rates with pilocytic histology,[449,470,471,472,473] and [474] and others report equivalent outcomes for pilocytic and nonpilocytic tumors.[146,213,451,454] Related somewhat to histology and to the degree of resection is the invasiveness of the tumor into surrounding structures and amount of tumor residual. In particular, pilocytic and oligodendroglial tumors, which often are well circumscribed, appear more often to be amenable to extensive resection and more likely than fibrillary astrocytomas to have a favorable prognosis.[146,200,462,467,475] The tendency toward invasiveness among nonpilocytic astrocytomas is in keeping with the less favorable prognosis that some have reported for these tumors.[470,472] However, separating the effects of histology and the extent of resection is difficult. Invasion into the brainstem is a primary factor limiting complete resection of cerebellar LGA[445,449,476] and is an independent prognostic factor in one of these series.[476] Volume of tumor residual emerged in another series as the most important predictor of cerebellar LGA progression, emphasizing the importance of maximal tumor resection.[449]

Although the benefit of radiotherapy is not entirely clear, higher-dose radiation (i.e., greater than 53 Gy) significantly improved length of survival in Shaw's series.[474] Young age is noted consistently to increase the risk of progressive disease.[445,451,465]

The ongoing CCG/POG natural history study, which has accumulated more than 700 cases of low-grade gliomas with centrally reviewed pathologic material and radiologic studies, may address more conclusively the independent contributions to prognosis of surgery, histology, and tumor location.

## Treatment

### *Surgery*

The goals of surgery for low-grade gliomas are to obtain tissue for diagnosis and to remove as much tumor as is safely feasible. Current operative mortality rates are less than 1%; morbidity depends largely on tumor location and is highest in diencephalic tumors, in which the incidence of hemiparesis or visual field deficits may be 10% to 20%. Although gross total excisions are possible in 40% to 80% of hemispheric tumors, fewer than 40% of diencephalic tumors are similarly resectable.[479,480] However, the use of microsurgical techniques has led to a resection rate of up to 90% in some diencephalic tumors in a single-institution study.[481]

#### Cerebral Hemisphere Gliomas

Although complete resection usually is the operative goal for cerebral hemisphere low-grade gliomas, its achievement may be difficult for nonpilocytic tumors, which rarely have a distinct tumor-brain interface. Because malignant degeneration of nonirradiated cerebral low-grade gliomas is uncommon, lesions that progress after an initial operation often are amenable to repeat resection. This possibility contrasts with the situation in adults, in which the majority of low-grade gliomas exhibits malignant features at the time of progression.[482]

For cortical and many subcortical tumors, the surgical approach follows the most direct trajectory to the lesion. In recent years, a variety of physiologic monitoring tools have been implemented to facilitate extensive resection of gliomas in “eloquent” regions of the brain. These include functional MRI and direct cortical mapping using strip, grid, and bipolar contact electrodes. Although it is difficult to prove that any or all of these modalities are essential to achieving tumor resection, they clearly increase the comfort level of a surgeon attempting resection of a tumor in, or adjacent to, a functionally critical region of the cortex. Similarly, investigators have debated the need for intraoperative ECOG (direct cortical electroencephalographic monitoring) in children with tumor-associated epilepsy; 75% of patients whose tumor resections are performed without ECOG are free of seizures postoperatively, versus 85% of those with ECOG.[212,483,484] If used, ECOG is likely to be of most value in treating those patients with long-standing or severe seizure disorders.

For deep or poorly circumscribed superficial lesions, imaging-based neuro-navigation and intraoperative imaging using ultrasonography and MRI guidance are helpful for planning an approach to the tumor that avoids traversing critical regions and for monitoring the progress of the resection. These strategies are particularly valuable for lesions that arise from or extend into the thalamus and basal ganglia.

The approach to deep subcortical lesions also is influenced substantially by the predominant direction of tumor growth. Lesions deep within the temporal lobe or temporal horn of the lateral ventricle are approached through a corticotomy in the middle temporal gyrus or sulcus. Lesions that grow medially and encroach on or expand within the lateral ventricle can be approached transcallosally or transfrontally, through the middle frontal gyrus, whereas tumors that extend laterally in the nondominant hemisphere may be approached through the insula after the sylvian fissure has been opened. Laterally extending lesions within the dominant hemisphere and tumors that arise more posteriorly within the thalamus may be reached using a posterior parietal approach situated behind the sensorimotor cortex and above the angular gyrus or through a posterior incision in the middle temporal gyrus. Such lesions can be reached also via an occipital transtentorial trajectory via an opening in the pulvinar. Finally, tumors that project anteriorly and laterally can be reached from a paramedian frontal trajectory, provided that care is taken to avoid injury to the motor pathways.

#### Cerebellar Gliomas

As with supratentorial hemispheric gliomas, a close correlation exists between the extent of resection and outcome in cerebellar gliomas. As shown in Table 27-11, complete tumor excision is associated with improved long-term and disease-free survival. Because the survival of patients with GTRs is as high as 90% for up to 30 years, aggressive attempts at resection are warranted, except when the tumor has invaded the cerebellar peduncles or brainstem.[143,448,465,470,478] The operative approach is similar to that described earlier for resection of a medulloblastoma. Data suggest that as few as 36% of patients with subtotal resections remain free of relapse at 6 years, and actuarial survivals similarly may decline with longer follow-up times of 10 to 20 years.[143,213,448,466,485] Thus, the appearance of resectable residual tumor on a postoperative scan frequently is an indication for reoperation.

| Treatment | Survival in yr (%) | | Reference |
|---|---|---|---|
| | 5 | 10 | |
| Complete resection | 76 (n = 64) | — | 143 |
| | 100 (n = 18) | — | 448 |
| | 100 (n = 9) | 100 (n = 9) | 478 |
| | — | 9 (n = 42) | 465 |
| Subtotal resection without radiotherapy | 56 (n = 34) | — | 143 |
| | 36 (n = 14)[a] | — | 448 |
| | 65 (n = 3) | 33 (n = 3) | 448 |
| | 65 (n = 16) | 65 (n = 16) | 465 |
| | — | 69 (n = 13)[b] | 485 |
| Radiotherapy | 92 (n = 12) | 72 (n = 12) | 478 |
| | 70 (n = 30) | 63 (n = 30) | 384 |
| | 88 (n = 30)[a] | 76 (n = 30)[a] | 200 |

[a]Disease-free survival.
[b]Two- to 31-year follow-up.

**TABLE 27-11. SURVIVAL WITH AND WITHOUT RADIOTHERAPY IN COMPLETELY AND INCOMPLETELY RESECTED CEREBELLAR ASTROCYTOMAS**

Most pilocytic astrocytomas have a distinct margin and can be separated from adjacent cerebellum with reasonable safety; currently, as many as 90% of patients have GTRs with an operative mortality rate of less than 1%.[143,470,472,485,486] Although complete resection is feasible also for the majority of nonpilocytic astrocytomas, its achievement is more difficult because these lesions rarely are as well circumscribed as the pilocytic tumors.

### Gangliogliomas and Other Benign Neuroepithelial Tumors

The approach to gangliogliomas is similar to that for other low-grade gliomas. Complete resection of cerebral gangliogliomas may be associated with survival rates in excess of 90% at 10 years, and recurrences are infrequent. The recurrence rate is substantially higher for deep-seated lesions, such as those within the diencephalon, because of the difficulties in achieving a GTR. However, even after partial resection, long-term progression-free intervals may ensue. The response of the desmoplastic mixed neuronal-glial tumors appears similar; GTRs generally are curative, and incomplete removals have been associated with local recurrence or tumor progression.[150,487,488,489,490 and 491]

#### *Radiotherapy*

The role of radiotherapy in patients with low-grade gliomas depends on the degree of tumor resection. As shown in Table 27-10, patients who have had completely resected tumors have survival rates up to 100% and do not require postoperative irradiation. However, the utility of radiotherapy in patients with incomplete resections is debated. Studies from which data can be abstracted frequently include both adult and pediatric patients who are accrued over several decades and in whom all low-grade tumors, regardless of site or histology, are combined. An additional caveat with respect to these retrospective studies is that they probably were biased toward including patients with a less favorable prognosis in those groups who received radiotherapy. Nonetheless, these reports suggest that radiotherapy may improve survival in these patients. In one review, PFS of children who underwent subtotal tumor resection was improved by the administration of radiotherapy, although overall survival was unaffected.[200] Investigators have suggested that irradiation may be associated with late anaplastic transformation of low-grade tumors. Noting the foregoing and recognizing the improvements in neurosurgical techniques, approaches to patients with incompletely resected tumors may reasonably include observation, with further surgery when it is a feasible option, chemotherapy (addressed later), and no immediate adjuvant irradiation.

For patients with progressive or recurrent cerebral low-grade gliomas, evidence suggests that whole-brain therapy is unnecessary and that local treatment is sufficient. Because 90% of recurrences are local, even after prior limited-field irradiation (e.g., conformal therapy), irradiation of the area of the tumor plus a 2-cm margin is adequate. Both interstitial and stereotactic irradiation have been advocated for some selected newly diagnosed and recurrent tumors; however, their ultimate utility remains to be determined.

The role of radiotherapy in incompletely resected cerebellar tumors is unclear. All reported comparisons involve retrospective reviews of patients accumulated over periods as long as 40 years, most of which patients were not treated uniformly with respect to dose and type of radiation. As shown in Table 27-11, some single-institution studies suggest that radiotherapy may improve the survival of these patients. The numbers of patients in these studies are low, however, and more recent studies with larger numbers of patients are unable to demonstrate a significant advantage for such treatment. As suggested for other low-grade gliomas, patients with incomplete tumor resections of cerebellar tumors should be considered for further surgery, and radiotherapy should be reserved for patients with residual or progressive tumor. Intracavitary $^{32}P$ may be useful in some patients with recurrent macrocystic tumors. Although limited-field conventional radiotherapy is effective in producing long-term disease control, single-fraction stereotactic radiotherapy also has produced encouraging initial results.

Irradiation has been proposed for patients who have gangliogliomas and have undergone incomplete resections or disease recurrence. However, the reported numbers of patients treated with radiotherapy are insufficient to estimate reliably the long-term utility of such treatment. Long periods free of tumor progression may follow incomplete resection alone.

#### *Chemotherapy*

LGA is primarily a surgical disease. When tumors recur after complete or incomplete resection, reoperation generally is indicated, and subsequent resection may lead again to prolonged disease-free status. However, aggressive primary or secondary surgery may be unsafe for tumors in deep locations or eloquent structures. In those situations, in cases in which deferring radiotherapy has been desirable, and in children whose tumors have progressed after irradiation, chemotherapy has been explored. Numerous single-agent and combination regimens have been reported in series involving low-grade gliomas of all sites in patients from a few months of age through adolescence.[492,493,494,495,496,497,498,499,500 and 501] Regimens have been based largely on classic alkylators, nitrosourea, or platinum. The most common responses are stable disease and partial remission. Complete remissions are rare, and progressive disease occurs in a subset of patients in many series. Data regarding cyclophosphamide are conflicting. Benefit was seen after a short course of high-dose cyclophosphamide in all four patients with disseminated pilocytic astrocytoma reported by McCowage et al.[494] In a classic phase II study for patients with progressive LGA, however, activity was so low that the study was closed early.[502]

The most promising chemotherapy data come from two reports. In the first, carboplatin and vincristine were administered to 73 patients with newly diagnosed, progressive LGA. Most tumors were in the diencephalon, and the mean patient age was 3 years. Radiographic responses were seen in 56% of patients. Three-year PFS rates were 68%. Histologic type of astrocytoma, location of tumor, or maximum response to chemotherapy did not correlate with the duration of disease control. The only significant factor was age: Children 5 years old and younger had a significantly higher rate of 3-year PFS (74%) as compared with children older than 5 (39%; $p < .01$).[496] The other promising reports come from a chemotherapeutic regimen based on experimental *in vitro* laboratory data showing that chemical interactions could increase nitrosourea cytotoxicity and possibly overcome resistance to that agent. The regimen—6-thioguanine, procarbazine, dibromodulcitol, CCNU, and vincristine—resulted in no complete responses, a definite degree of tumor reduction in 36% of patients, and stable disease in 59%; 5-year survival was 78%.[501] In contrast to the carboplatin-vincristine data, older age was the only factor that improved survival significantly. These two regimens form the basis of an ongoing study within the COG for patients with progressive low-grade glioma.

Although chemotherapy appears to be a viable treatment option for children in whom either aggressive surgery or radiotherapy is inadvisable, the natural history of LGAs, characterized by recurrence or progression rates many years after diagnosis or after irradiation, will require up to 20 years of follow-up to determine its long-term benefit. In the shorter run, comparative activity of various agents will be determined. Biologic factors may guide chemotherapy further in the future.

## TUMORS OF THE OPTIC PATHWAY

### Demography

Optic pathway tumors (OPTs) generally are those tumors that arise in the optic nerves, chiasm, and hypothalamus and may extend from these sites to adjacent brain structures. Together, they represent approximately 5% of pediatric intracranial tumors.[503,504] Nearly two-thirds of OPTs are diagnosed in the first 5 years of life.[504] Seventy-five percent of OPTs will become symptomatic in the first decade of life, and 90% will become so before the age of 20.[505] Boys and girls are affected equally. OPTs are prevalent in patients with NF-1. The incidence of NF-1 in reported series of OPT ranges as high as 28%,[506] and as many as 70% of OPTs may be

associated with NF-1.[168] The sites of OPT involvement appear to differ in patients with and without NF-1. Unilateral or bilateral optic nerve involvement alone is seen almost exclusively in patients with NF-1, whereas chiasmal involvement is significantly more common in patients without NF-1. [506,507]

### Pathology and Patterns of Spread

Histologically, OPTs usually are low-grade pilocytic and occasionally fibrillary astrocytomas with microscopic features virtually identical to those of the classic cerebellar astrocytoma and other midline pilocytic tumors. Malignant degeneration is rare. [508] Although these tumors usually are confined to the structures of the visual pathways and extend in contiguity along them (Fig. 27-16), they may extend also into the frontal lobes, hypothalamus, thalamus, and other midline structures. Such events are more frequent in chiasmal tumors. Overall, tumor growth is slow, although alternating periods of clinical progression and stability suggest an erratic growth pattern.[508,509,510,511,512 and 513]

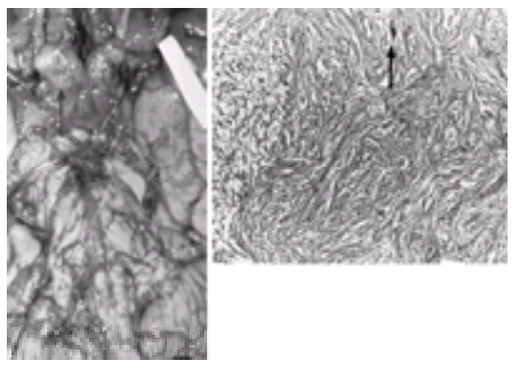

**FIGURE 27-16. A:** Diffuse infiltrating glioma of the right optic nerve (*arrow*). Note the diffuse enlargement of the nerve and absence of a separate mass lesion. **B:** Optic nerve glioma formed by elongated, swirling piloid processes of astrocytes, the nuclei of which are inconspicuous. Note the plump Rosenthal fiber (*arrow*). (Hematoxylin and eosin, ×250.)

### Prognostic Considerations

Three factors appear to have prognostic importance for the outcome of OPTs, although reports are not always consistent. The presence of NF-1 generally is associated with more indolent disease, reflected in longer times to disease progression and higher rates of PFS and survival. [137,477,507,514,515,516,517 and 518] For example, 15-year relapse-free survival in Jenkin's report[518] was 84% for patients with NF-1 and 47% for those without ($p = .0007$). In Imes's series,[517] patients with NF-1 survived their OPT better than did those without NF-1 but died of other causes, including other intracranial tumors and complications of NF-1 resulting in a survival not different from nonneurofibromatosis patients. In other series, NF-1 does not offer a protective effect. [519,520] Tumors involving the chiasm and hypothalamus have a worse prognosis in most (but not all) series.[508,516,518,521] Finally, as with most other CNS tumors, youngest children, generally younger than 3 to 5 years, do worse than do their older counterparts.[516,520,522]

### Treatment

#### *Surgery*

Because of the variability in the growth properties of OPTs, diverse approaches to management have been advocated in different clinical situations and in different institutions. In children with NF-1, the etiology of the lesion rarely is in question. Because the tumor usually exhibits diffuse involvement of the chiasm and nerves, it is not amenable to extensive resection. Often, it is biologically indolent, resection generally is not pursued, [23,523,524], and adjuvant therapy is initiated empirically.

Lesions that seem particularly well suited to radical excision are those that involve only a single optic nerve and produce progressive, disfiguring proptosis or blindness (or both) and those that grow exophytically from the optic chiasm and produce significant mass effect or hydrocephalus. [510,511,522,524] For isolated optic nerve gliomas, which are fairly uncommon, the tumor can be removed with preservation of the globe. In such cases, the resected segment of the optic nerve should be as long as possible, preferably extending close to the chiasm, to diminish the risk of local tumor recurrence. [511] Ruling out the diagnosis of NF-1 before embarking on surgery is essential, because such children commonly exhibit widespread involvement of the optic pathways and may have long-term stabilization of vision without aggressive intervention. For exophytic chiasmatic-hypothalamic tumors, resection often is pursued to relieve obstructive hydrocephalus, to reduce local mass effect, and to establish a tissue diagnosis. For lesions amenable to resection, the tumor is approached via a subfrontal, trans-sylvian, or transcallosal exposure, depending on the pattern of tumor growth. Although a complete resection is not feasible because these lesions infiltrate the optic chiasm or hypothalamus (or both), substantial symptomatic improvement sometimes can be achieved.[522,524] In occasional cases, removal of a significant portion of the tumor may stabilize the disease and delay the need for additional therapy.[522]

Open biopsy also is pursued sometimes for lesions involving the chiasm in which the histologic diagnosis is uncertain, before instituting further therapy. This is especially the case in children without neurofibromatosis or those with isolated chiasmatic-hypothalamic lesions without contiguous optic nerve or optic tract involvement. However, this procedure may further compromise vision in a significant percentage of patients. [129,525,526] Alternatively, some neurosurgeons prefer to perform a stereotactic biopsy and treat with chemotherapy, reserving open resection for lesions that fail to respond or subsequently progress. Although aggressive surgery may be of potential benefit in some patients with large, progressive lesions, it may be associated with significant morbidity, particularly in the youngest patients, and does not convincingly improve survival in comparison to more limited open or stereotactic biopsy and adjuvant therapy. [522,527]

#### *Radiotherapy*

Radiotherapy has been shown to stop the progression of these gliomas, to stabilize and preserve vision and, occasionally, to improve vision. The treatment decision today, however, is dependent on several factors: the degree of vision loss at diagnosis, evidence of progression of the tumor by visual decline or as documented on imaging studies, the age of the patient, and the presence or absence of NF-1. For young patients, the definition of which is not standard but could include children younger than 10 years, primary chemotherapy is reasonable if therapy is in fact indicated. NF-1 is associated with a vascular phenomenon called *moyamoya syndrome*, which appears to be exacerbated by radiotherapy. One should, therefore, be more conservative in recommending radiotherapy as the first treatment in children with NF-1. If irradiation is needed, the usual dose is 45 to 50 Gy, and a conformal technique generally is preferred.

Patients with chiasmal-hypothalamic gliomas have a worse prognosis than those with optic nerve gliomas. In addition, such tumors occasionally may spread along the leptomeningeal space. Although primary chemotherapy is a reasonable option, a significant number of children treated with primary chemotherapy eventually will require radiotherapy for treatment of tumor progression. Ten-year survivals after radiotherapy have been reported as 40% to 93%. [137,514,518,528,529]

#### *Chemotherapy*

The optic glioma chemotherapy experience is greatest for children who are younger than 3 years and for whom delay of radiotherapy is desirable for avoidance of long-term neuropsychological and neuroendocrine effects. Packer's regimen of vincristine and actinomycin-D was the first to defer radiotherapy successfully for children who are younger than 5 and have progressive chiasmatic and hypothalamic gliomas. At a median of 4 years' follow-up, 62.5% of the patients remained free of progressive disease and had not received radiotherapy. [530] By 7 years, however, only one-third of patients were free from progression. Packer also tested a carboplatin and vincristine regimen described for low-grade gliomas. [496] Recently, the POG reported the results of its phase II study of carboplatin for children who are younger than 5 years of age and have progressive OPT. Carboplatin was administered alone every 4 weeks at a dose of 560 mg/m $^2$. After two courses, patients were evaluated, and those with stable disease or better were continued on therapy for 18 months or until disease progression. Of 50 eligible children, including 21 with NF-1, 39 (78%) had stable disease or better, and 34 completed therapy. Six children, of whom only one had NF-1, died of disease. [531] These reports have established

carboplatin as an effective chemotherapeutic agent for OPT.

Petronio et al.[532] reported improvement or stable disease in 15 of 18 patients with progressive OPT using the five-drug regimen of 6-thioguanine, procarbazine, dibromodulcitol, CCNU, and vincristine. Of the 15 patients, 11 had a greater than 50% decrease in their tumor mass. Those children whose tumors progressed on or after completion of chemotherapy were treated successfully with radiotherapy. Using chemotherapy, vision was stabilized in 14 of 18 patients and improved in 2. The ongoing COG study for progressive low-grade gliomas includes children with OPT and is a randomization between carboplatin-vincristine and a modified 6-thioguanine, procarbazine, cisplatin, and vincristine regimen. Future studies will examine the efficacy of other agents for OPT. Already, reports of limited numbers of patients have identified cisplatin and vincristine, tamoxifen and carboplatin, and oral etoposide as having activity against progressive OPT. [533,534 and 535]

Most reports of chemotherapy for low-grade gliomas include patients whose tumors arose from the optic pathway. (See Supratentorial Low-Grade Gliomas for additional chemotherapy data.)

## SUPRATENTORIAL HIGH-GRADE GLIOMAS

### Demography

Anaplastic astrocytoma, glioblastoma multiforme, and mixed glial tumors with a preponderance of malignant astrocytic elements collectively compose malignant or high-grade astrocytic tumors in children. These tumors represent 7% to 11% of childhood CNS tumors. When primary brainstem tumors are excluded, combined series suggest that approximately 25% of malignant or high-grade astrocytic tumors occur in deep midline structures of the cerebrum, not more than 15% occur in the posterior fossa, and the majority occurs in the cerebral hemispheres.[190,191,536,537 and 538] The median age at diagnosis is 9 to 10 years, and the male-female ratio is near unity.[190,537,539]

### Pathology and Patterns of Spread

Various classification schemes have been applied to astrocytic tumors. High-grade lesions, unlike their low-grade counterparts, generally are characterized by the presence of several histologic features of malignancy that include hypercellularity, cytologic and nuclear atypia, mitoses, necrosis, endothelial proliferation, and other anaplastic features; lesions with these features may be termed *malignant* or *high-grade* gliomas. The most common malignant glial neoplasms are the high-grade astrocytomas, such as the anaplastic astrocytoma (Fig. 27-17) and glioblastoma multiforme (Fig. 27-18), which may alternatively be termed *grade III* and *grade IV* astrocytomas, respectively.[95] Similarly, the term *high-grade* or *anaplastic* may be used to describe other, less common glial neoplasms, such as oligodendroglioma, ganglioglioma, or mixed astrocytic-oligodendroglial neoplasms.

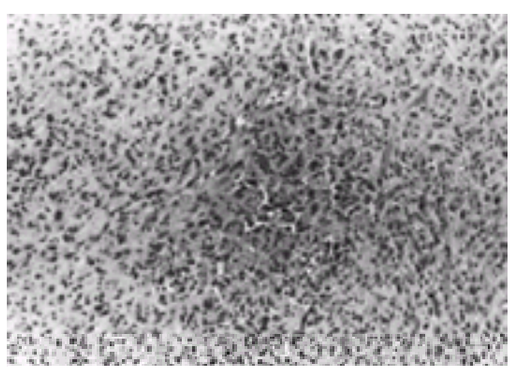

**FIGURE 27-17.** Highly cellular tumor composed of anaplastic astrocytes. A few vessels with compressed lumina are formed by swollen epithelial cells. (Hematoxylin and eosin, ×250.)

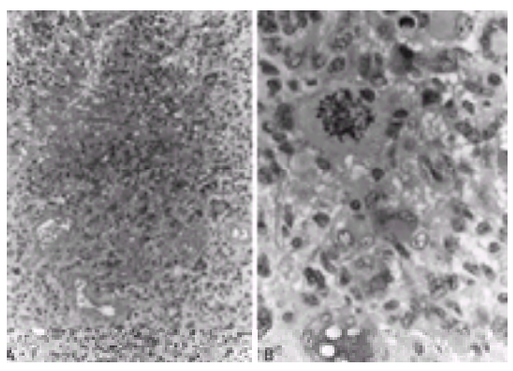

**FIGURE 27-18. A:** Typical field in glioblastoma multiforme showing pseudopalisading ( *upper left*), neovascularity, nuclear anaplasia, and multinucleate giant cells (*lower right*). (Hematoxylin and eosin, ×250.) **B:** Higher magnification of a different field from the same tumor showing cellular anaplasia, multinucleate cells, and bizarre mitosis (*upper left corner*). (Hematoxylin and eosin, ×400.)

The high-grade astrocytomas are clinically aggressive, regionally invasive, and capable of extraneural dissemination to lung, lymph nodes, liver, and bone, particularly in adults. In children, these and the other malignant gliomas occur most commonly in the cerebral hemispheres, in contrast to the more frequent cerebellar and deep midline locations for low-grade tumors. Although the rapid growth and effacement of normal tissue produced by high-grade tumors may produce what appears to be a well-demarcated tumor, microscopical study frequently demonstrates extension for up to several centimeters beyond this margin. Distant neuraxial dissemination, once considered unusual, has been demonstrated in as many as 25% to 50% of high-grade astrocytomas, both at diagnosis and post mortem in carefully evaluated series of patients.[538,539 and 540]

High-grade gliomas may have a histologically heterogeneous nature in that areas of low-grade histology commonly are noted in many high-grade tumors, particularly in small biopsies taken from the more superficial areas of tumor. Diagnostic confusion may be reduced by more generous sampling and by directing stereotactic biopsies toward the contrast-enhancing or more central portions of the tumor.

### Prognostic Considerations

Several series conducted by both institutional and cooperative groups noted the prognostic importance of the extent of surgery, regardless of the primary site of tumor.[189,190,191 and 192,536,537,541,542] In these series, outcome is better with complete or near-complete resection of primary disease. For example, in the CCG-945 study, patients who were reported to have a greater than 90% resection of their tumor had a median PFS significantly longer than that in patients with more limited resections. The difference was more notable for patients with grade III tumors (31 versus 12 months) than for those with grade IV tumors (12 versus 8 months) but was significant for both groups.[190] The relationship may be surprising, given the fact that tumor often extends well beyond the identified central component of tumor [543,544 and 545] and that, even after a radiologically confirmed GTR of all contrast-enhancing tumor, extensive residual tumor is known to remain. A caveat worth emphasizing is that factors specific to the tumor, such as the pattern of growth and degree of infiltration, may determine which tumors are amenable to extensive resection. Thus, tumors that are amenable to resection may constitute a group biologically more favorable than those that infiltrate extensively into the surrounding brain. [546] Insights from genomic analyses of these tumors may provide better understanding of these issues.

In several series, site of disease is independently prognostic of outcome as well, with deep midline tumors showing a survival poorer than that of cerebral hemispheric tumors. However, hemispheric tumors are more amenable to radical resection than are midline tumors.[190] Data are conflicting in regard to the impact of gender and age at diagnosis; however, female gender and younger age have been shown by some investigators to affect outcome favorably.[190,192,538,547] The impact of histology—anaplastic astrocytoma versus glioblastoma multiforme—is debated as well. Anaplastic astrocytoma may be favorably prognostic for subsets of patients[190,191 and 192] or not at all.

### Treatment

#### *Surgery*

The surgical techniques employed for tumor resection are similar to those used for supratentorial low-grade gliomas. As with the latter tumors, malignant gliomas often are amenable to reoperation at the time of disease progression, because most lesions recur at the primary site. Although the majority of children succumbs to further disease progression despite additional intervention, attempted re-resection may be warranted in the selected group of tumors that are amenable to gross total or radical subtotal removal, in view of recent reports of long-term survival after extensive resection followed by high-dose chemotherapy.[548]

#### *Radiotherapy*

In combined series of pediatric patients with malignant gliomas, postoperative local or wide-field irradiation to 50 to 60 Gy after incomplete surgical resection leads to median survivals that uncommonly exceed 1.5 years, with only 0% to 30% of patients surviving beyond 3 years.[384,538,539,547,549,550] Median time to progression rarely exceeds 1 year. The addition of single- or multi-agent chemotherapy in phase II and phase III trials along with irradiation has had little or no impact on the overall survival in patients in this group, despite producing response rates as high as 45%.

An objective analysis of the issue of treatment volume has correlated field size with CT and MRI scans and whole-brain-mount pathologic sections.[545] This study suggests that limited-field irradiation with a 2- to 4-cm margin around the area of “edema” defined by imaging should be adequate to cover the tumor in most cases and should produce survival rates equivalent to those seen after whole-brain treatment. Similar conclusions have been reached in clinical trials in which little or no difference in survival was evident between whole-brain and limited-field treatment volumes. Modern imaging studies, such as PET and MRS, may further improve the targeting of subclinical disease. The corpus callosum and the subependymal pathway along the ventricular wall are the potential routes of spread within the brain and should be included in the treatment volume if the gross tumor involves any part of these regions.

Noting that most recurrences of malignant gliomas are local and occur within the initial treatment volume, attempts to improve local control have focused on techniques that employ locally enhanced radiation doses. Although some reports have suggested that “boosting” the local tumor dose using brachytherapy, offering up to 60 Gy additional dose, may be associated with some increased survival, this advantage may be the result of selection bias and the accrual of patients with smaller tumors and prognostic features better than those receiving standard treatment.[551] Additionally, a substantial incidence (40% to 56%) of radionecrosis is associated with brachytherapy[552,553]; the need for surgical intervention in many such patients suggests that the disadvantages of this technique outweigh its advantages, particularly in patients with anaplastic astrocytoma.

Currently, attention is turning away from brachytherapy and toward the use of stereotactic radiotherapy as a technique to increase local tumor doses. This technique has the advantage of being noninvasive and providing a more focal and homogenous dose that may be associated with a lower incidence of radionecrosis. The benefit of a radiosurgical boost is controversial and is the subject of a current COG trial.

#### *Chemotherapy*

The role of chemotherapy for treatment of high-grade gliomas has yet to be defined clearly. A single prospectively randomized phase III trial was conducted by the CCG between 1976 and 1981. Postoperatively, children who were between the ages of 2 and 21 and had nonbrainstem and non–spinal cord high-grade astrocytomas were assigned randomly to radiotherapy with or without chemotherapy consisting of prednisone, CCNU, and vincristine (PCV). PFS for those children receiving postradiation chemotherapy was significantly higher (46%) than for those who did not receive it (16%; $p = .026$).[537] A significant benefit of chemotherapy was observed in only those patients with glioblastoma; furthermore, chemotherapy did not appear to improve the outcome for any patient whose tumor underwent biopsy only, regardless of histology. For patients who had glioblastoma multiforme and whose tumors were at least partially resected, the addition of chemotherapy significantly improved 5-year event-free and overall survival.[190] The follow-up study by the CCG was again a randomized trial, this time comparing “8-in-1” chemotherapy against PCV. No difference was observed between the two chemotherapy arms, and 5-year PFS rates were 33% and 36% for “8-in-1” chemotherapy and PCV, respectively.[190] Taken together, these studies suggest that the benefit from addition of chemotherapy, when compared to surgery and radiotherapy alone, is modest at best.

In contrast to this experience with anaplastic astrocytoma and glioblastoma multiforme, children in this study, with eligible diagnoses other than anaplastic astrocytoma and glioblastoma multiforme, fared well. Their 5-year PFS and survival rates were 64% and 71%, respectively. Chemotherapy with procarbazine, CCNU, and vincristine has resulted in greater than 50% partial and complete responses in patients with anaplastic oligodendrogliomas and anaplastic mixed gliomas in other studies as well.[554,555] These data suggest that CCNU and vincristine, combined with prednisone or procarbazine and in addition to radiotherapy, probably is the chemotherapeutic regimen of choice for children with these tumors.

Given the poor outcome for children with most high-grade gliomas, numerous single-agent phase II studies have been conducted on cisplatin, carboplatin, CCNU, procarbazine, cyclophosphamide, ifosfamide, etoposide, and topotecan. The data for CCNU and cyclophosphamide have shown the most promise.[498,547,556] To determine the contribution of procarbazine to the results of combination chemotherapeutic regimens for high-grade gliomas, the POG recently completed a phase II evaluation of that agent for patients with newly diagnosed high-grade glioma demonstrating measurable disease. Of 12 evaluable patients, none had a complete response, and only 1 patient had a partial response.[557] Topotecan has been evaluated similarly and was found to have little activity against high-grade gliomas.[558] Initial experience with irinotecan for adults with high-grade gliomas has been reported in abstract form; pediatric studies are ongoing. Temozolomide has generated excitement in adult studies and is under investigation by the COG as well. Combination regimens of BCNU with cisplatin and cyclophosphamide with etoposide have also been evaluated by the POG. Although activity was demonstrated, superiority over CCNU and vincristine has not been determined.[559] Myeloablative chemotherapeutic regimens have shown activity against bulk residual disease but have not demonstrated convincing superiority over standard therapy.[241,243,548,560,561] Clearly, new agents and new approaches to therapy are needed.

## BRAINSTEM GLIOMAS

### Demography

Tumors arising in the midbrain, pons, and medulla oblongata now account for approximately 20% of all CNS tumors among children younger than 15 years.[6] This apparent rise from 10% in the late 1970s does not reflect a truly increased incidence. Instead, this jump stems from the advent of MRI and increased detection of focal brainstem tumors, subsequently confirmed microscopically as low-grade gliomas. The median age of occurrence for all brainstem gliomas is 6 to 7 years.[142] The male-female ratio is near unity. Brainstem tumors are noted to be increasingly frequent among patients with NF-1.[562,563]

### Pathology and Classification

The term *brainstem glioma* is an imprecise descriptor suggesting that all these tumors behave in the same way. As a result of advances in neuroimaging over the last two decades, a plethora of terms emerged to subclassify brainstem gliomas (sometimes confusingly) by site of origin or imaging features. Terms used have included *midbrain tumor*,[564,565 and 566] *tectal glioma*,[567,568,569,570 and 571] *pontine glioma*,[566,568,572] *focal medullary tumor*,[568,573,574] *cervicomedullary tumor*,[573,575,576,577,578 and 579] *diffuse glioma*,[566,568,573,575,576,578] *intrinsic glioma*,[572,575,578,580] *pencil glioma*,[581] *dorsal exophytic brainstem tumor*,[568,573,576,578,580,582,583 and 584] *focal glioma*,[566,574,575,578,580,585] and *cystic glioma*.[580,586] Brainstem tumors are sometimes also subcategorized by pathology, as either low-grade (benign) or high-grade (malignant) gliomas.[580,587,588 and 589] However, brainstem gliomas can be parsimoniously and better biologically classified as diffusely infiltrative brainstem gliomas and focal brainstem tumors, categories

that combine tumor location and histology.[142]

*Diffusely infiltrative brainstem gliomas* are the classic brainstem tumor having a poor prognosis. Most arise in the pons, particularly the ventral aspect, and cause diffuse enlargement of that structure (Fig. 27-19). Engulfment of the basilar artery by tumor is specific for the diagnosis of diffusely infiltrative brainstem glioma but is not seen in all cases (Fig. 27-19B).[142] Axial or exophytic growth is seen in at least two-thirds of cases.[566] Neoplastic infiltration extending into the midbrain, cerebral peduncle, cerebellum, or medulla is exceedingly common. These tumors are generally fibrillary astrocytomas by histology, sometimes well-differentiated, WHO grade II or, more often, high-grade anaplastic astrocytoma (WHO grade III) or glioblastoma multiforme (WHO grade IV). [142] These diffuse gliomas may occasionally show disseminated neuraxis spread.[590,591]

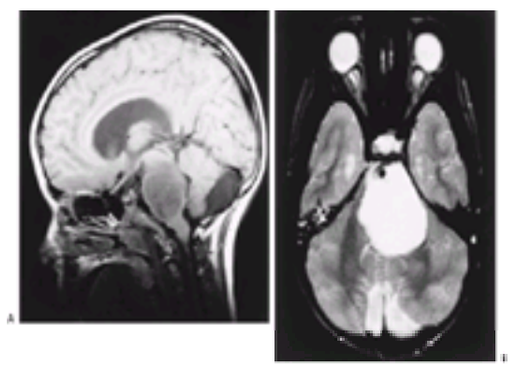

**FIGURE 27-19.** Typical magnetic resonance imaging findings in a diffusely infiltrating brainstem glioma. **A:** T1-weighted sagittal view shows diffuse, fusiform enlargement of the pons with tumor spread superiorly and inferiorly. **B:** T2-weighted transverse view shows engulfment of the basilar artery.

*Focal brainstem tumors* are discrete, well-circumscribed tumors without evidence of infiltration and without edema. These tumors may occur in any level in the brainstem but are most frequently seen in the midbrain or medulla rather than the ventral pons ( Fig. 27-20). More often, focal tumors are dorsally exophytic to the brainstem, sometimes effacing the fourth ventricle. By pathology, focal brainstem tumors are most commonly pilocytic astrocytomas or, rarely, gangliogliomas, both WHO grade I.[142,583] Sometimes these tumors are cystic.[566]

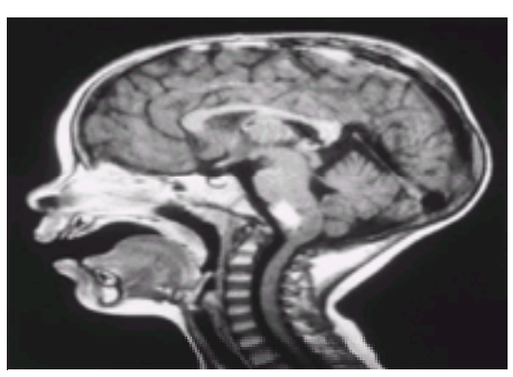

**FIGURE 27-20.** T1-weighted transverse magnetic resonance imaging with gadolinium shows a focal brainstem tumor with acid enhancement at the medulla. Biopsy demonstrated the tumor to be a pilocytic astrocytoma.

Rarely, tumors of histologic types other than gliomas are found at the brainstem. Among infants, the highly malignant AT/RT can arise in the brainstem. [329] Embryonal tumors, or PNETs, can also occur in very young children as localized pontine tumors with an exophytic component and extension beyond the pons, along with a predilection for leptomeningeal dissemination at diagnosis. [592] Hemangioblastoma may arise at the brainstem also, although more commonly during adolescence or adulthood.

**Prognostic Considerations**

Prognosis depends principally on the tumor type but is also influenced by NF-1. Patients with diffusely infiltrative gliomas fare dismally, regardless of therapy. In most series, median survival is less than 1 year, and survival rates at 2 years are lower than 10% to 20%. [593,594] In contrast, the prognosis for patients with focal brainstem tumors may be good after surgery if the tumor is accessible, with or without postoperative radiotherapy, or after radiotherapy alone. Survival for these patients is reported to be between 50% and 100%.[562,566,589] Many patients with small focal tumors in the midbrain, particularly the tectum, may do extremely well after shunting alone and can demonstrate PFS of up to 10 years or more.[567,570,571]

Among patients with NF-1, brainstem gliomas, whether diffuse or focal, display a generally indolent biologic behavior. [562,563] The tumor may stabilize in size or regress without intervention, and survival approximates 90% over 5 years. Thus, intervention should be limited to those lesions that exhibit rapid or unrelenting growth on serial neuroimaging or that produce significant clinical deterioration.

**Treatment**

The choice of treatment depends largely on whether the tumor is a diffusely infiltrative brainstem glioma or a focal brainstem tumor. Even among focal lesions, the site of the tumor affects selection of therapy.

***Surgery***

A major advance in the surgical management of brainstem gliomas followed the recognition that this broad category of tumors encompasses biologically distinct groups that demand individualized therapeutic strategies. At one extreme are the diffuse intrinsic gliomas, which are biologically malignant, highly infiltrative, and not amenable to resection. Although biopsy usually is associated with low morbidity, it no longer is considered necessary because, in the context of a typical clinical presentation and characteristic MRI findings, histologic results do not influence treatment. [174] At the other extreme are the benign intrinsic tectal gliomas, which also are not appropriate for resection because these lesions are extremely indolent and are best treated symptomatically with CSF diversion and observation ( Fig. 27-21).[565,567,570]

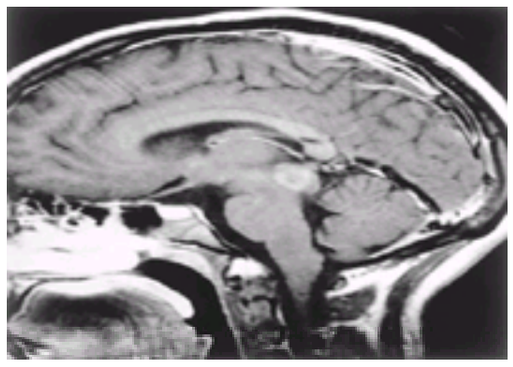

**FIGURE 27-21.** T1-weighted sagittal magnetic resonance imaging with gadolinium of a tectal glioma with minimal contrast enhancement.

In contrast to the preceding groups, and because of improvements in neurosurgical techniques and postoperative care, surgical resection is a reasonable option for focal gliomas that arise at the cervicomedullary junction and for dorsally exophytic gliomas. These lesions are histologically and biologically benign but, unlike tectal gliomas, commonly show gradual enlargement over time. In particular, extensive resection of exophytic tumors, leaving a thin rim of tumor on the surface of the brainstem, frequently achieves long-term PFS without further treatment.[582,583] and [584,589] Some focal intrinsic, cystic, and solid brainstem lesions are likewise surgically resectable, and several authors have suggested that even after only partial resection, many patients require no further postoperative treatment. Although good survival rates have been achieved with surgical resection of symptomatic focal midbrain and medullary lesions, it remains to be determined whether these results represent an improvement over those obtained with stereotactic biopsy and local irradiation, [565,579,595] particularly in view of the potential for significant surgical morbidity from aggressive attempts at resection.[574]

### *Radiotherapy*

Depending on the neurologic status and tumor type of the child with a brainstem glioma, the therapeutic options include observation, radiotherapy, or investigational approaches. Radiotherapy continues to be the mainstay of treatment for most children with diffusely infiltrative brainstem gliomas. Although it rarely produces long-term survival, it frequently affords neurologic palliation, albeit for a relatively short time only.

Because of the poor survival rates that follow standard-dose radiation and the apparent lack of effective chemotherapy, various cooperative groups have studied escalating doses (ranging from 64.8 to 78.0 Gy) of hyperfractionated radiotherapy in a series of phase I and II trials. [596,597,598,599,600,601,602,603,604,605,606] and [607] Collectively, these trials have failed to show any therapeutic benefit from this approach. Median survival was still less than 1 year. However, escalating hyperfractionated radiotherapy did result in increased steroid dependency and clinically significant intralesional necrosis. [599,605,608]

Other treatment approaches have been used for patients with diffusely infiltrative brainstem gliomas. but these too have been largely unsuccessful in achieving cure rates higher than those seen with radiation alone. A CCG phase I and II trial combined hyperfractionated radiotherapy with escalating doses of interferon-b three times weekly. The median time to death was 9 months.[594] A recent POG study randomized patients to either 70.2 Gy hyperfractionated radiotherapy or 54 Gy conventional radiotherapy, with cisplatin infused as a radiosensitizer over 120 hours on weeks 1, 3, and 5 of radiotherapy for both treatment arms. [593] No difference in survival was noted between groups, the 2-year overall survival being just 7%. When the patients who received hyperfractionated radiotherapy with cisplatin were compared to historical controls receiving just 70.2 Gy, the patients who received cisplatin unexpectedly fared slightly less well. [593] In another CCG study, intravenous topotecan used as a radiosensitizer did not appear to alter outcome either, although only limited conclusions about efficacy can be made from this phase I dose escalation trial.[609] Currently, the COG is exploring the effectiveness of gadolinium texaphyrin, another radiosensitizer.

Radiotherapy is used also for patients with focal brainstem lesions that are treated surgically. For those patients with high-grade lesions, radiation is used postoperatively. For those with low-grade lesions, radiotherapy may be delivered postoperatively for symptomatic residual disease, should it exist, or may be deferred until clinical or radiographic evidence of progression is present. [583,584,589] No controlled or prospective trials comparing these two approaches have been performed. If radiation is deferred until progression is seen, additional surgery should be considered as well. As stated earlier, for patients with gliomas confined to the tectum and associated with hydrocephalus, radiotherapy routinely is deferred until there is symptomatic progression after the hydrocephalus has been corrected. [567,569,570] and [571]

### *Chemotherapy*

A role has yet to be established for chemotherapy as standard treatment in the management of patients with brainstem tumors. With focal brainstem gliomas, weekly carboplatin with vincristine has shown activity in a very limited number of patients younger than 5 years. [610]

For diffusely infiltrative pontine gliomas, response rates to various single-agent and multi-agent regimens have been disappointingly low, even when chemotherapy is given as first treatment, before radiotherapy.[325,387,611,612] and [613] Adjuvant chemotherapy using PCV did not improve survival when compared with conventional radiotherapy alone in the only prospective, randomized study that has tested this question. [614] Oral etoposide has been reported to have antitumor activity in a small numbers of patients with recurrent diffuse tumors,[615] and this approach is under investigation in a COG trial that is nearing completion. Approaches that will be investigated in the future will likely include the use of inhibitors of angiogenesis, farnesyl transferase, and epidermal growth factor receptors. As patients with progressive diffusely infiltrative pontine gliomas survive, on average, at least 3 months after their first relapse, they can be candidates for further treatment in clinical trials.[616] Such efforts may delay further disease progression and are requisite for improving the outcome in this disease group.

## PINEAL REGION TUMORS

### Demography

Tumors of the pineal area account for 0.4% to 2.0% of all primary CNS tumors in children. Three principal groups of tumors—germ cell tumors, pineal parenchymal tumors, and astrocytomas—account for most tumors in this location. In combined clinical series, astrocytomas constitute 15%, the pineal parenchymal tumors 17%, and germ cell tumors 40% to 65% of all neoplasms in this area. Of CNS germ cell tumors, two-thirds occur in the pineal region and the remaining one-third in the suprasellar region.[617,618] Pineal parenchymal tumors are more frequent in the first decade of life and have a male-female ratio near unity. Germ cell tumors are most common in the second decade of life or later, have a peak incidence at between 10 and 14 years of age, and are associated with a male-female ratio of at least 2:1 and as high as 9:1. Astrocytomas tend to occur in two separate age groups, 2- to 6-year-old children and 12- to 18-year-old teens, and each group has a 2:1 male-female incidence characteristic of astrocytomas elsewhere in the CNS. [140,619,620] and [621]

### Pathology and Patterns of Spread

### *Pineal Parenchymal Tumors*

Pineoblastoma is a primitive undifferentiated tumor that accounts for approximately 50% of the pineal parenchymal tumors ( Fig. 27-13). Except for its location, this tumor may be indistinguishable from medulloblastoma and is considered by some investigators to be a variant of the PNET. This highly cellular tumor has frequent mitoses and areas of focal necrosis. The occasional presence of Flexner-Wintersteiner rosettes indicates differentiation toward retinoblastoma. [351] Although the histologic appearance of the pineocytoma (Fig. 27-22) may overlap that of the pineoblastoma, the cells generally are larger and have a recognizable relation with blood vessels, and true rosettes rarely are seen. Occasional evidence of astrocytic, neuronal, or ganglion cell differentiation is noted. [351]

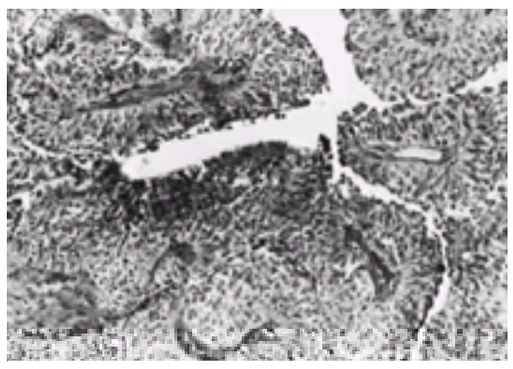

**FIGURE 27-22.** Primary pineal tumor displaying prominent perivascular growth of neoplastic cells characteristic of pineocytoma. Note the papillary pattern. (Hematoxylin and eosin, ×250.)

### *Germ Cell Tumors*

The germ cell tumors include a spectrum of embryonal neoplasms and teratomas believed to be derived from totipotent germ cells that aberrantly migrated to the cranial midline during embryogenesis. The germinoma accounts for approximately 60% of these tumors (Fig. 27-23). Germinomas have a typical two-cell appearance indistinguishable from that of gonadal germinomas and are composed of large, primitive-appearing cells intermixed with smaller lymphoid cells. [140,351,622,623]

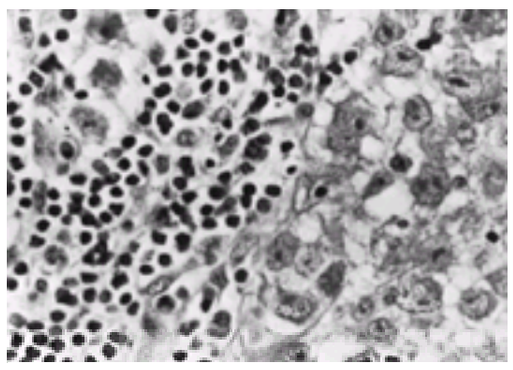

**FIGURE 27-23.** Typical field of germinoma displaying large cells with large nucleoli and focus of lymphocytes ( *right half of field*). (Hematoxylin and eosin, ×400.)

Teratomas and mixed germ cell tumors harboring various mature and immature elements constitute nearly 30% of the pineal nongerminomatous germ cell neoplasms, and the highly malignant embryonal carcinoma, choriocarcinomas, and endodermal sinus tumors constitute the remaining 10%. The histologic appearance of these tumors is identical to that of similar tumors occurring outside the CNS. Teratomas generally remain local, well encapsulated, and noninvasive. However, areas with more primitive germ cell elements may be present and are associated with a more aggressive clinical course that may include neuraxis dissemination. [351,623]

Both contiguous regional extension and distant intra-axial dissemination are common with nonastrocytoma pineal area tumors. The overall incidence of leptomeningeal spread in larger series of patients is approximately 10%, with pineoblastoma and germinoma demonstrating the greatest frequency of such spread.[140,619,622,623] Even pineocytomas, once considered slow-growing, locally infiltrative tumors, may have a high incidence of leptomeningeal seeding. [624,625]

Systemic metastases, although uncommon, may occur with the pineal parenchymal and pineal germ cell tumors. Bone, lung, and lymph nodes are the most common sites of such dissemination.[623] Occasional instances of peritoneal metastasis associated with the use of ventriculoperitoneal shunts have also been noted. [626]

## Prognostic Considerations

Tumor histology has prognostic significance. The germinomas and LGAs have the best overall survival rate and response to treatment, followed by teratomas and pineal parenchymal tumors. Five-year survival rates for intracranial germinomas are as high as 95%, but the remaining nongerminoma germ cell neoplasms have, historically, much poorer survival rates, ranging from 20% to 76%. [627,628 and 629] Disease that has spread regionally, involves the hypothalamus, or has spread along leptomeninges also is associated with a worse prognosis. Although age at diagnosis is variably reported as having prognostic significance, this parameter may not be independent of the finding that very young patients (those younger than 3 years) have a higher incidence of disseminated disease at diagnosis and are frequently treated with reduced-dose irradiation. [140,403,623,630]

## Treatment

### *Surgery*

Because of the diversity in the biologic behavior and response to treatment of different types of pineal area tumors, biopsy is recommended whenever possible to establish a tissue diagnosis, which will help guide subsequent therapy. [140,620,623] One exception is patients with benign intrinsic tectal tumors (discussed earlier) with brainstem gliomas. A second exception is patients with malignant germ cell tumors in which a-fetoprotein or b-human chorionic gonadotropin (or both) is detected at high levels within the blood or CSF, in which case biopsy is considered optional.

Current neurosurgical techniques allow stereotactic or open biopsies in most patients, with morbidity generally limited to transient worsening of prior visual symptoms, although new or permanent losses may occur. The mortality rate is generally less than 2%. Direct visually guided biopsy is preferred by many neurosurgeons because of concern that stereotactic biopsies may injure adjacent deep veins. However, a variety of recent reports have demonstrated that stereotactic biopsy can be performed with acceptable morbidity, provided that a low frontal entry point is used to allow access to the tumor below the internal cerebral veins. [631] This approach also provides CSF for analysis of a-fetoprotein and b-human chorionic gonadotropin, because the biopsy trajectory often traverses the lateral ventricle. Often, it is feasible to achieve CSF diversion using endoscopic third ventriculostomy while the patient is under the same anesthetic; in some instances, the tumor biopsy itself can be accomplished endoscopically. Although these minimally invasive approaches have significant appeal and appear to carry a lower morbidity than conventional approaches, a major concern is the issue of sampling error. As many as 15% of germ cell tumors have mixed histology, which calls attention to the importance of adequate biopsy and of performing CSF and blood marker studies in such patients. [620]

If a stereotactic or endoscopic biopsy is nondiagnostic or equivocal, or if the histology of the lesion suggests that an open surgical resection is likely to be of benefit, as in the case of benign teratoma, tumor removal can be accomplished using one of a variety of operative approaches. An infratentorial supracerebellar approach is used for lesions that exhibit predominant growth below the level of the vein of Galen and basal veins of Rosenthal. A suboccipital transtentorial approach is preferred for larger lesions that extend above the basal veins or down into the rostral fourth ventricle. Both approaches can be accomplished using a prone or modified prone position, which is generally preferred to the sitting position, to minimize the risk of air embolism. After division of the precentral cerebellar vein and surrounding arachnoid, the lesion is subjected to biopsy and then debulked using the ultrasonic aspirator. Great care is taken to avoid injury to the deep veins.

Except for well-encapsulated teratomas, few pineal region tumors are amenable to complete resection, generally because of extensive local or regional disease. Even though subtotal resections are possible for many patients with localized tumors, no evidence indicates that such resections improve outcome. Because many tumors in this area are sensitive to both radiotherapy and chemotherapy, and because aggressive surgery may cause significant morbidity, biopsy alone or limited tumor

debulking to relieve hydrocephalus often is the most prudent approach initially, particularly for patients with germinomas. In addition, a variety of current treatment protocols for nongerminomatous germ cell tumors are employing intensive neoadjuvant chemotherapy after an initial open or stereotactic biopsy, followed by second-look surgery to perform a biopsy or remove areas of residual enhancement. [628,632,633 and 634] In some cases, such reoperations indicate only scar tissue without evidence of viable tumor or foci of mature teratoma that may be amenable to resection, with favorable long-term results.

Pineoblastomas are considered to be PNETs, and their treatment and outcome are comparable to those of high-risk medulloblastomas. However, because these lesions are uncommon, previous studies have contained insufficient numbers of patients to determine conclusively whether extensive resection favorably influences outcome.[401,630]

### *Radiotherapy*

Radiotherapy for pineoblastomas, which generally are not completely resectable, is similar to that for high-risk medulloblastoma—namely, craniospinal irradiation to 36 Gy, followed by additional radiation to the tumor bed to a total dose of 54.0 to 55.8 Gy. For incompletely resected, nondisseminated pineocytomas, local field irradiation to 50 to 54 Gy is appropriate, whereas craniospinal irradiation is indicated for disseminated tumors.

Germinomas are exquisitely radiosensitive tumors. Typically, 10-year survival rates exceeding 90% after operation and radiotherapy can be expected.[617,620,622,623,627,631,635] Patients with germinomas who have evidence of leptomeningeal spread at diagnosis require craniospinal irradiation to 45 to 50 Gy if radiation is the only treatment modality. However, if evidence of leptomeningeal dissemination is absent at diagnosis, the need for routine craniospinal irradiation is controversial. Recent retrospective series have suggested that the cure rates of local field irradiation and craniospinal irradiation are equivalent. [620,621,636,637 and 638] The treatment fields for local field irradiation should include the tumor plus a margin as well as the suprasellar region, including the floor of the third ventricle and the horns of the lateral ventricles, because separate foci of tumor from the primary lesion have been detected in these areas in a few cases, and recurrences at those sites have also been noted if these areas were not irradiated. [637] With conformal techniques, especially IMRT, one can treat the primary tumor to 45 to 50 Gy while simultaneously irradiating the aforementioned suprasellar region to 30 Gy. Recent reports have suggested that a short course of platinum-based, postoperative chemotherapy can produce an excellent tumor response and allow the radiation dose to be reduced to 30 to 40 Gy. [639] No randomized trial has yet compared combined-modality treatment with radiotherapy alone.

In modern studies, craniospinal irradiation is recommended for most nongerminomatous germ cell tumors in conjunction with chemotherapy; the only exception is mature teratoma.[620,625,630,640] For those patients whose tumors lack leptomeningeal spread and who are also treated with chemotherapy, limited data suggest that local irradiation may result in 5-year survival rates equivalent to those achieved with craniospinal irradiation. [641] Unfortunately, even with aggressive therapy, 5-year survival rates are generally less than 50%.[620,627,631,634]

### *Chemotherapy*

Unlike any other CNS malignant tumors, germ cell tumors of the CNS have a model for chemotherapeutic treatment based on histologically similar systemic disease. Outside the CNS, chemotherapeutic regimens based on cisplatin have been very effective in treating disease. This experience, coupled with the mixed response to radiotherapy, prompted the exploration of chemotherapy for CNS germ cell tumors. For patients with germinoma, chemotherapy has been added to decrease deleterious late effects of radiotherapy. For the nongerminomatous tumors, chemotherapy has been added to try to improve cure rates.

There appears to be no question that germinomas are chemotherapy-sensitive tumors. Regimens that use cisplatin, carboplatin, or cyclophosphamide, along with vinblastine or vincristine, bleomycin, and etoposide, are capable of producing complete and partial response rates as high as 90% in newly diagnosed patients.[628,642,643,644,645,646 and 647] In most of these series, patients have had irradiation as part of their treatment; thus, the influence of chemotherapy on survival remains uncertain. Administration of chemotherapy to patients with suprasellar lesions who also commonly have diabetes insipidus may be difficult. Fluid and electrolyte imbalances may result in clinically significant hyponatremia or hypernatremia and dehydration. The use of vasopressin infusions during such chemotherapy may help to avert some of these problems.[648]

With the demonstrated responsiveness of germinomas to chemotherapy, the current debate centers around the optimal balance of chemotherapy and radiotherapy. Recent studies have examined the use of chemotherapy with either reduced-dose radiotherapy or without radiation altogether. [628,646,647] In the largest series wherein chemotherapy was used alone for patients with germinomas, high rates of response were demonstrated to chemotherapy.[628] Despite this, however, 22 of 45 patients ultimately relapsed, a number higher than would have been anticipated after radiotherapy alone. Although a large proportion of the patients who experienced relapse was successfully treated with additional chemotherapy or irradiation, the 2-year overall survival rate for patients with germinoma was only 84%. [628]

Other, smaller studies have examined the use of chemotherapeutic regimens followed by radiotherapy at doses reduced to 30.6 Gy and 40.0 Gy. [646,647] Response rates to chemotherapy have been high, and survival rates in both series are 100%, with median follow-up periods exceeding 32 months. Similar approaches with even lower doses of radiation are being studied by the various cooperative groups. The use of chemotherapy and radiotherapy for intracranial germinomas is rational and effective, although the optimal schedule must be determined. Treatment with chemotherapy alone is not recommended outside of a clinical trial setting.

Similar chemotherapeutic regimens have been applied to nongerminomatous germ cell tumors, with encouraging results. [639,641,649,650,651,652,653 and 654] In these studies, complete and partial response rates to chemotherapy have approached 80%; survival rates several years after diagnosis have similarly ranged from 48% to 80%. Although all patients were treated with radiation as well, the fields varied. Relapse rates appear to be higher in the patients treated with involved fields only. Therefore, craniospinal irradiation for all patients with nongerminomatous germ cell tumors seems advisable.

For a discussion of chemotherapy for pineoblastoma, the reader is referred to the section in which sPNETs are discussed.

## CRANIOPHARYNGIOMA

### Demography

Craniopharyngiomas account for between 6% and 9% of all primary CNS tumors in children. These lesions exhibit a bimodal age distribution, with one peak during childhood at approximately 8 to 10 years of age and a second peak in middle age. [655] This tumor rarely is detected before age 2 years.[447,656] No gender predilection has been noted. Although these lesions are predominantly suprasellar tumors, which involve the pituitary stalk and hypothalamus, they may occur within the sella turcica or third ventricle as well.

### Pathology and Patterns of Spread

Craniopharyngiomas in children are thought to arise predominantly from pharyngeal cell rests left from the embryonic hypophysiopharyngeal duct that connects the infundibular bud with the stomodeum.[657] Although, in adults, these tumors may result from neoplastic transformation of cell rests within the pituitary gland that have undergone squamous metaplasia,[658] this mechanism is less likely in children. [351] Grossly, these tumors are smooth, lobulated masses with both solid and cystic components. The cyst contents may range from gelatinous to viscous oily fluid rich in cholesterol crystals. Rupture of a cyst into the CSF may cause an intense chemical meningitis. Calcification is frequently apparent. Both the cystic lining and the solid portions of the tumor are characterized by squamous epithelium, usually with some evidence of keratinization (Fig. 27-24).

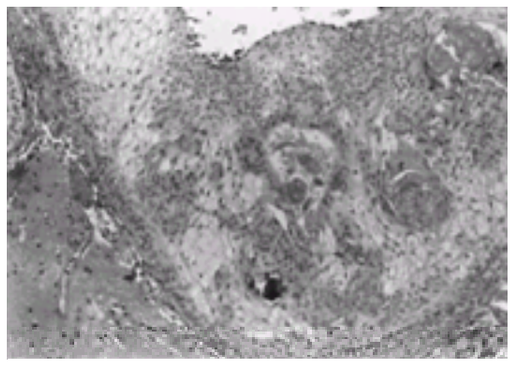

**FIGURE 27-24.** Photomicrograph of typical epithelium found in a craniopharyngioma showing the basisquamous character with incarcerated keratin. Note the honeycombed character of the epithelium in areas. (Hematoxylin and eosin, ×250.)

Although craniopharyngioma is a histologically benign tumor composed of well-differentiated tissue, it may have a malignant clinical course because of its location and its propensity to infiltrate surrounding normal structures. A thick glial layer may encase the tumor, and small islands of epithelial tumor arising within this gliotic scar can extend into adjacent tissues. The tight adherence of this layer to surrounding tissue can make complete resection difficult and hazardous.

### Clinical Presentation

Childhood craniopharyngiomas often manifest with short stature, symptoms of increased ICP, delayed puberty, vision loss, and neurobehavioral abnormalities. Hydrocephalus is observed in approximately 50% of children as a result of obstruction of the third ventricle and the foramen of Monro by superior tumor extension. Because of slow tumor growth, papilledema is less common than optic pallor. Visual field defects of various degrees of severity occur in 50% to 90% of patients, homonymous hemianopsia and bitemporal hemianopsia being the most frequent defects encountered.[656,659] Despite the fact that many children show evidence of vision loss on examination, only approximately 25% present with complaints of visual deterioration.[660]

Various neuroendocrine deficits are present in as many as 90% of patients at diagnosis, decreases in GH and resultant growth delay being the most common findings.[139,659] Diabetes insipidus is seen in fewer than 10% of children in whom craniopharyngiomas are diagnosed in the modern era and, if present in a child with a suprasellar lesion, should raise concern about the possibility of a germ cell tumor or histiocytosis.

### Differential Diagnosis and Evaluation

The differential diagnosis of craniopharyngioma includes intrinsic hypothalamic gliomas, large chiasmal gliomas, Rathke's cleft cyst, and suprasellar germ cell tumors or teratomas. Plain skull radiographs, commonly used before the advent of CT and MRI, often show an enlarged or distorted sella with suprasellar tumor calcification. The CT scan characteristically demonstrates a partially cystic, low-density, contrast-enhancing lesion with calcification.

MRI defines the solid and cystic nature of the tumor, its extent, and its relation to adjacent structures better than does any other modality ( Fig. 27-25).

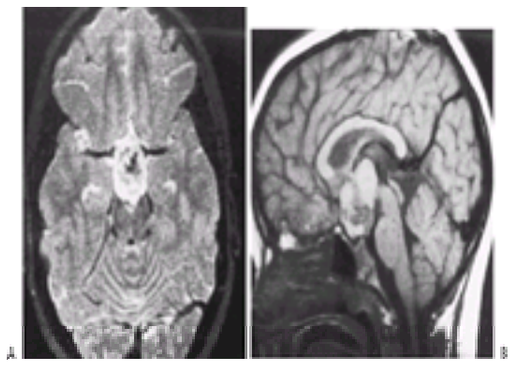

**FIGURE 27-25.** Axial **(A)** and sagittal **(B)** T2-weighted magnetic resonance imaging of mixed-density craniopharyngioma with foci of calcification ( *black*).

Owing to the high incidence of clinical and subclinical neuroendocrine deficits at diagnosis, a thorough evaluation of the hypothalamic-pituitary axis should be undertaken preoperatively. Secondary abnormalities of adrenal function and of the regulation of fluid and electrolyte balance, in particular, can lead to serious perioperative problems if not anticipated. Neuroendocrine evaluations should be repeated postoperatively and periodically thereafter for at least 1 year, because hormonal deficits often increase postoperatively and may take several months to stabilize fully.[661]

### Prognostic Considerations

The extent of tumor resection has been an important factor in series in which the initial treatment has consisted of surgery alone. Patients with totally excised tumors have had considerably better survival rates than those managed by biopsy alone or by subtotal resection.[662] However, several studies have shown that the combination of subtotal resection and radiotherapy achieves survival results that rival those obtained with attempted GTR.[206] The purported prognostic significance of tumor size probably is not an independent variable but rather is related to the ease and extent of resection. Although the data show only a trend, patients with purely cystic lesions appear to survive longer than those with solid or mixed solid and cystic tumors; in addition, children older than 5 years seem to have a better prognosis than do younger patients.[662,663]

### Treatment

#### *Surgery*

Preoperative and perioperative considerations for operation on tumors in the region of the pituitary gland have been reviewed earlier in this chapter. Those considerations specific to craniopharyngioma are discussed here.

Because tumor resection may cause or exacerbate endocrine deficiencies, the management of these problems must begin preoperatively and continue through the postoperative period. Stress doses of hydroxycorticosteroids (e.g., hydrocortisone, 100 mg per $m^2$ intravenously followed by 25 mg per $m^2$ every 6 hours) are administered before, during, and immediately after the surgical procedure, often in addition to dexamethasone, which is used to reduce peritumoral edema. Doses then are tapered but, if postoperative endocrine testing demonstrates a need for long-term steroid hormone replacement, then hydrocortisone is continued at maintenance levels.

Hydrocephalus in patients with craniopharyngiomas generally resolves after the tumor has been resected. If the hydrocephalus is severe, a ventriculostomy can be inserted before the tumor resection is begun and can be removed within several days of surgery if the operative procedure opens the CSF pathways. If the hydrocephalus persists, a ventriculoperitoneal shunt is inserted.

The extent of surgical removal to be attempted is a matter of intense debate: Some authors strongly recommend radical surgery in all cases, [664,665] whereas others suggest partial resection followed by local irradiation. [206] The debate centers around the prognostic advantage gained by complete resection balanced by the morbidity associated with such a procedure. With the use of microsurgical techniques, a radiologically complete resection can be achieved in 60% to 90% of children.[660,664,665,666,667,668 and 669] Under these circumstances, the likelihood of long-term PFS is 80% to 90%. However, significant neurologic morbidity, memory and cognitive dysfunction, and appetite and neurobehavioral disturbances are encountered in 10% to 30% of patients, mortality ranges from 0% to 5%, and panhypopituitarism develops in 80% to 90% of patients. [656,659,664,665,670] The operative morbidity is lower in children operated on by neurosurgeons who perform such procedures frequently.[206] Although morbidity may also be lessened somewhat by more limited resections, the likelihood of long-term disease control is substantially lower than with complete resection. Without radiotherapy, the vast majority of subtotally resected tumors progresses within 2 to 5 years. [671,672] The recurrence rate is diminished significantly with the use of postoperative external irradiation, [206,673] although some studies indicate that the results, in terms of PFS, remain inferior to those achieved with total resection.[671] Although repeat microsurgical resection is feasible in patients with recurrent tumor, morbidity and mortality may be substantially higher than at the primary operation.[664] The primary cause of death in these patients is either recurrent tumor or chronic neuroendocrine problems. [674]

Craniopharyngiomas are extra-axial tumors, tenaciously attached to surrounding structures, such as the optic chiasm, hypothalamus, and vessels of the circle of Willis. These characteristics impose practical limits on a surgeon's attempt at tumor resection. Regardless of the degree of surgical resection intended at the outset, the usual cases are approached via a subfrontal or trans-sylvian exposure, working between the optic nerves, carotid arteries, and third nerves, or through the lamina terminalis. However, other approaches may be used, depending on tumor extent and location. A growing trend is to tailor the treatment strategy based on tumor size and composition. Tumors with a sizable solid component (greater than 3 cm) are treated microsurgically, generally via a transcranial approach; selected lesions that arise within and expand the sella turcica may be amenable to transsphenoidal resection. [675] Thin-walled cystic lesions can be treated using intracavitary techniques; if small residual solid components of the tumor subsequently enlarge, stereotactic radiosurgery or microsurgical techniques can be used. The management of small, solid tumors (less than 3 cm in diameter) remains particularly controversial, with most groups favoring microsurgical resection and others employing stereotactic techniques. For example, tumors located primarily in the sella can be removed transsphenoidally, [675] and large cystic tumors extending to the roof of the third ventricle can be approached through the corpus callosum.

***Radiotherapy***

Radiotherapy can decrease the recurrence rate and enhance the survival of patients with incomplete tumor resections ( Table 27-12). The addition of radiotherapy after subtotal tumor resection may result in a 50% to 80% disease-free survival. Even with minimal surgery, consisting of biopsy and cyst drainage, the survival of patients with both newly diagnosed and recurrent disease is prolonged by irradiation. Recommended doses of external beam irradiation are 50 to 55 Gy to local fields only.

| Treatment | 5 yr (%) | 10 yr (%) | References |
|---|---|---|---|
| Total resection | 58–100 | 24–100 | 662–665, 668, 673, 683, 684 |
| Subtotal resection | 37–71 | 31–52 | 139, 668, 671, 673, 683, 685 |
| Subtotal resection and irradiation | 69–95 | 62–84 | 662, 663, 668, 671, 673, 683, 685, 686 |

**TABLE 27-12. ACTUARIAL SURVIVAL RATES IN CRANIOPHARYNGIOMA WITH SURGERY AND RADIOTHERAPY**

Although a controlled trial has not been done, multiple comparisons strongly suggest that patients treated with incomplete tumor resection followed by irradiation have less neuroendocrine dysfunction and fewer serious sensory, motor, and visual deficits than do those who have undergone aggressive attempts at complete tumor resection. These patients may also have an improved level of function and better quality of life than patients treated with radical surgery alone. [656,670,676] Additionally, neuropsychological function is reportedly better preserved in the combined-therapy group despite the known detrimental effect of irradiation. Modern conformal radiation techniques appear to lower the morbidity also when compared to conventional techniques of irradiation.

Increasing interest has been generated in recent years in the use of stereotactic approaches to treat selected craniopharyngiomas. Predominantly cystic lesions, which account for 20% to 30% of tumors, may be treated with intracystic instillation of yttrium 90 or phosphorus 32 to deliver a cyst wall radiation dose of approximately 20,000 cGy.[677,678,679 and 680] Because of the limited tissue penetration of the radiation from these b-emitting isotopes, radiation exposure to the adjacent hypothalamus and optic nerves is minimized. Involution of the cyst is achieved in more than 80% of patients [678,679 and 680]; morbidity and mortality are lower than with microsurgical resection; and the recurrence rate is comparable to that achieved with attempted total microsurgical removal. [679,680] After intracavitary therapy, small, residual solid-tumor components can be treated with stereotactic radiosurgery. [677,680] This modality has also been used to treat residual or recurrent lesions after an initial microsurgical resection.

***Chemotherapy***

Chemotherapy has no established role in the treatment of craniopharyngiomas. An anecdotal response to a vincristine, BCNU, and procarbazine combination has been described in one patient.[681] Intracystic administration of bleomycin has also led to response and significant second remissions in some patients with recurrent disease,[682] but concerns have been raised regarding local toxicity.

## CHOROID PLEXUS NEOPLASMS

### Demography

Choroid plexus neoplasms constitute between 1% and 4% of brain tumors in children. Seventy percent of these occur during the first 2 years of life; the median age at diagnosis ranges from 10 to 32 months in recent series.[201,202 and 203,687,688,689,690 and 691] CPPs, benign tumors treated only surgically, outnumber the malignant counterpart, CPC, by nearly four to one.[201,687] Tumors arise from the lateral ventricles approximately 75% of the time, from the fourth ventricle and cerebellopontine angle in 15% of cases, and from the third ventricle in 10% of affected children. [688]

### Pathology and Patterns of Spread

Choroid plexus neoplasms generally arise as functioning intraventricular papillomas capable of secreting CSF. Grossly, CPPs resemble coral, fronds of tumor attached to a pedicle float in the CSF. Microscopically, these tumors are similar to normal choroid plexus and have cuboidal or columnar epithelium and a well-preserved epithelial-stromal border overlying fibrovascular septa ( Fig. 27-26). Their neoplastic nature is reflected in the heaping and redundancy of the epithelial component. These tumors tend to be slow-growing and, because of their intraventricular location, often reach a size of 60 to 70 g before they are diagnosed. Fewer than 5% are bilateral.

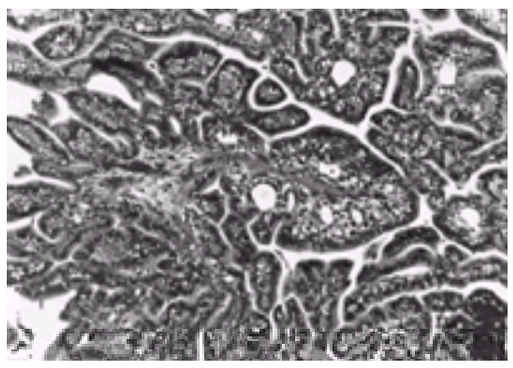

**FIGURE 27-26.** Choroid plexus papilloma. The photograph illustrates the luxurious papillary structures composed of a loose fibrovascular core covered by a single layer of cuboidal-columnar epithelium. (Hematoxylin and eosin, ×250.)

The CPC, a more aggressive and anaplastic tumor, accounts for up to 40% of choroid plexus neoplasms.[688,690,692] This tumor has lost the well-differentiated papillary structure and the epithelial-stromal border of the CPP (Fig. 27-27). It is a hypercellular tumor with pleomorphic cells, frequent mitoses, and foci of necrosis.[693] Both papillomas and carcinomas are capable of leptomeningeal dissemination. In CPPs, the clinical behavior and histology of the isolated and frequently noted deposits are benign, and symptoms are uncommon. Conversely, diffuse and aggressive leptomeningeal spread occurs in CPCs.

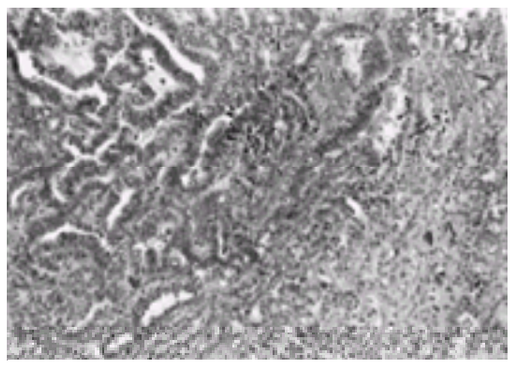

**FIGURE 27-27.** Choroid plexus carcinoma. The papillary character, which is partially retained in tissues on the left side of the field, has been lost in the portion of the tumor on the right side. Note pseudostratified epithelium forming irregular glandular structures on the left and diffuse epithelial growth on the right. (Hematoxylin and eosin, ×250.)

### Prognostic Considerations

Tumor histology and degree of resection are the primary prognostic factors for choroid plexus neoplasms. The long-term recurrence-free survival after complete resection of CPP approaches 100%.[688,694,695 and 696] Even less-than-complete resection is associated with long periods of PFS. The outcome is less favorable in patients with CPC,[202,203,697,698] because these lesions invade the brain parenchyma and are extremely vascular, making complete resection difficult. In addition, these tumors often disseminate within the CSF. Nevertheless, in reviews of experience with CPC, complete resection of disease appears to be the single variable that most affects long-term survival.[201,202 and 203,689,690] In fact, GTR of CPC may be curative by itself in a proportion of children.[692]

### Treatment

#### *Surgery*

Surgical excision is the primary mode of therapy for both CPP and CPC. These lesions most commonly arise in the trigone; tumors in this location usually are approached through a posterior temporoparietal craniotomy, through a cortical sulcus. Tumors of the anterior third ventricle and the body and frontal horn of the lateral ventricle may be approached transcallosally or transcortically through the middle frontal gyrus. Fourth ventricular tumors are approached by the suboccipital route. Intraventricular tumors outside the posterior fossa may be more easily removed if the ventricles are large; for this reason, preoperative shunts usually are not inserted in patients who are otherwise clinically stable. Contemporary surgical morbidity and mortality rates are less than 20% and 5%, respectively. Complete resections are possible in approximately 80% of patients.[688] Even after complete tumor removal, persistent hydrocephalus requiring a CSF shunt is present in up to 60% of patients.[699] If the postoperative MRI scan demonstrates residual tumor, reoperation is indicated. Appreciation for the importance of complete surgical resection has provided an impetus for efforts to perform second-look surgery in those children whose incompletely resected tumors persist after a trial of neoadjuvant chemotherapy.

#### *Radiotherapy*

Postoperative radiotherapy frequently is used to treat CPC, especially if the resection is incomplete or if there is evidence of leptomeningeal dissemination of disease. Although the survival times of some irradiated patients may be marginally better than those of nonirradiated patients, such results are not entirely separable from results with surgery alone. No randomized trial has yet tested the benefit of radiotherapy.

#### *Chemotherapy*

Surgery alone is usually sufficient for cure of CPP; chemotherapy has no role in the treatment of this tumor. As with other uncommon malignant pediatric CNS tumors, however, the role of chemotherapy is difficult to define in the treatment of CPC. Numerous reports of small numbers of patients collectively demonstrate that CPC can respond to different chemotherapeutic regimens at initial diagnosis or following relapse. The regimens given to the highest number of patients were based on platinum[201,687,688] or cyclophosphamide[692] or included multiple agents.[202] However, whereas most patients with CPC treated with GTR and chemotherapy appear to be long-term survivors, cure has been achieved with GTR alone. Furthermore, the majority of children whose tumors are less than completely resected and who also are treated with chemotherapy ultimately die of their disease.[201,202,690] Anecdotal reports, however, suggest that chemotherapy may render CPC less vascular and infiltrative and potentially amenable to complete removal, even if the initial attempt was unsuccessful.[202,687,697] Thus, chemotherapy may potentially contribute to higher chances of survival. Because the number of children with choroid plexus neoplasms is so low, international collaborative clinical trials will be needed to test hypotheses related to outcome of therapy.

## INTRAMEDULLARY SPINAL CORD TUMORS

### Demography

Intrinsic tumors of the spinal cord make up 1% to 10% of pediatric CNS tumors.[700,701,702,703 and 704] These tumors occur throughout childhood, and the median age at diagnosis is 10 years. Male patients are slightly more commonly affected than female patients, in a 1.3:1.0 ratio. Patients with neurofibromatosis appear to have a higher incidence of spinal cord tumors, as they do with other astrocytic neoplasms.

### Pathology and Patterns of Spread

In children, up to 70% of intramedullary tumors are astrocytomas. The remaining 30% are ependymomas (10%), other glial neoplasms such as oligodendroglioma and gangliogliomas (10%), and malignant gliomas (10%). Histologically, these tumors are indistinguishable from their intracranial counterparts. Large cysts, both within the tumor and at the superior and inferior margins, are common. In as many as 60% of cases, extensive involvement by tumor and cysts may be present. Slow and contiguous extension across several vertebral segments, with compression and effacement of normal tissues, is the usual mode of growth. [705,706 and 707] Leptomeningeal dissemination has been reported in as many as 58% of patients with high-grade tumors, but it is uncommon in patients with low-grade tumors. [707,708] The presence of multiple discrete tumors is associated with neurofibromatosis. Tumor location in the spinal cord appears to be random, with the incidence in each anatomic region (cervical, thoracic, lumbar) roughly proportional to the length of that region. The only exception is the myxopapillary ependymoma, which has a predilection for the conus medullaris and filum terminale.

### Prognostic Considerations

Spinal cord tumors in children are rare occurrences. The low number of patients and relative lack of inclusion in clinical trials with prescribed treatment approaches make the identification of published prognostic factors difficult. Bouffet et al. [704] reviewed the experience of 13 French treatment centers with spinal cord astrocytoma and found high-grade histology and short duration of presenting symptoms to be associated with poorer survival. [704] From review of other series, low-grade lesions are compatible with long-term survival, whereas this appears not to be the case with high-grade lesions. Although investigators have suggested that complete tumor removal may be associated with longer survival and less frequent local recurrences, the degree of resection has not been associated with outcome in several studies; however, such a determination is problematic in view of the small sizes of the study cohorts. [707,709,710 and 711] Ependymomas may be an exception to this generalization, in that patients who undergo total tumor resection have fewer recurrences than do those who undergo incomplete tumor resections. [712]

### Treatment

#### *Surgery*

Complete surgical resection is difficult for astrocytoma because a distinct tumor-cord interface often is absent, but extensive subtotal resections may be performed in most instances. Ependymomas are associated with a clearer cleavage plane and can usually be resected completely. Intramedullary tumors usually are approached by an osteoplastic laminectomy, removing as a single unit all laminae covering the solid portion of the tumor. Replacement of the lamina after surgery not only helps to protect the spinal cord but may also diminish the risk of subsequent spinal deformity. Operative mortality is low; morbidity and the amount of neurologic recovery are proportional to the severity of preoperative dysfunction and to the definition of the tumor-cord interface. In one report of 69 patients undergoing operations for intramedullary tumors, at a mean follow-up of 54 months, 17% were better than they had been preoperatively, 56% were unchanged, and 31% were worse. [713] Postoperative orthopedic follow-up and monitoring for spinal deformity are important. In 25% to 40% of children, the development or progression of such deformity occurs within a mean of 3 years.

#### *Radiotherapy*

No controlled trial of radiotherapy has been conducted in patients with intramedullary tumors, and evidence for its utility is inferred from the treatment of similar tumors in other CNS locations. As with low-grade lesions in the cerebrum, irradiation may be unnecessary for incompletely resected low-grade tumors. Evidence also suggests that radiotherapy may be unnecessary for completely resected ependymomas. Although radiation doses of 45 to 50 Gy have been used in patients with high-grade astrocytomas and in patients who have had incomplete resections of both astrocytomas and ependymomas, the effectiveness of this therapy has not been unequivocally documented.[707,709,711,714] These doses are lower than those usually given for gliomas and ependymal tumors in other locations because of the radiation tolerance of the spinal cord. The overall survival rates for LGAs with various degrees of resection and postoperative radiotherapy are 66% to 70% at 5 years, 55% to 73% at 10 years, and 67% at 20 years.[706,711,714] Even so, local recurrence rates have been as high as 33% to 86%. [707,714] Patients with anaplastic or high-grade tumors generally die of their disease within several months of diagnosis. For patients with ependymomas, survival rates of 50% to 100% at 5 years and 50% to 70% at 10 years are reported, and local recurrences are similarly high in patients with subtotally resected tumors. [705,714]

#### *Chemotherapy*

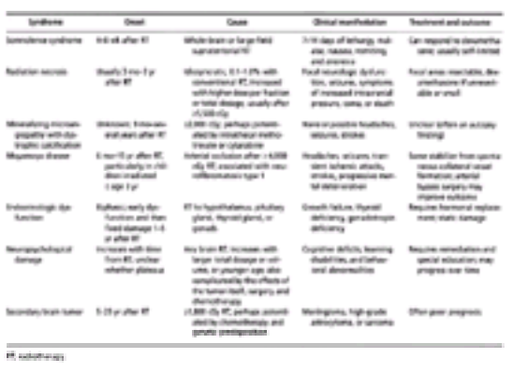
Tumors of the spinal cord have been treated as have their histologic counterparts in other parts of the brain. Chemotherapy has been employed for high-grade lesions at diagnosis, recurrent low-grade lesions, and in very young children in whom the avoidance of radical surgery or radiotherapy has been desired. [700,702,715] The largest of these series involved 13 children with high-grade astrocytoma of the spine who were treated with “8-in-1” chemotherapy along with radiotherapy, postoperatively. The response to pre-radiation chemotherapy was not measurable in three patients, was complete in one patient, partial in two, stable in four, mixed in two, and progressive in one. After completion of therapy, with the time of median follow-up not stated, 2 of the 13 patients were alive without disease at the report, and 5 were alive with disease. Five-year PFS and survival rates were 46% and 54%, respectively. [702]

Until biologic factors or other clinical trial results indicate otherwise, it seems rational to use chemotherapy for tumors of the spinal cord only as would be used for tumors of like histologies in other areas of the brain.

## SEQUELAE OF TREATMENT

Mortality rates for children with brain tumors have declined less rapidly than those of other cancers. [716] Nevertheless, the 5-year overall survival for children with brain tumors, aside from the favorable, LGAs, has improved to 60%.[5] Even when therapy is successful, these patients, unlike other long-term cancer survivors, often never overcome the symptoms and signs manifest at their tumor's clinical presentation. As a result, brain tumor survivors suffer physical, cognitive, neurologic, endocrinologic, and other deficits as sequelae of both their cancer and its therapy. These patients function at lower intellectual, social, and physical levels than their peers, leading to significant handicaps and diminished quality of life. The eventual magnitude of these problems may be greatest in patients who are the youngest at diagnosis (see Chapter 13, Chapter 15, and Chapter 49).

The acute and late effects among pediatric brain tumor patients arise from several sources. Before diagnosis, the tumor mass distorts and even destroys normal brain tissue and increases ICP, which sometimes is associated with hydrocephalus. Surgical trauma, postoperative meningitis, shunt infection, or repeat surgery can also cause some degree of irreversible neurologic damage.[717,718] Likewise, chemotherapy may be capable of producing encephalopathy. [719] Radiotherapy has been implicated as the chief cause of many adverse sequelae, which are listed in Table 27-13. Early on, irradiation may cause transient vasogenic edema, which exacerbates neurologic abnormalities and may require dexamethasone to alleviate symptoms. Other consequences are not apparent for years.



RT, radiotherapy

**TABLE 27-13. SYNDROMES OF POSTRADIATION DAMAGE WITH CHILDHOOD BRAIN TUMORS**

Cognitive impairment is among the most frequent and devastating problems of the child treated with radiotherapy. Although a drop in IQ is the most often cited effect of radiotherapy for a brain tumor, it is unclear whether IQ loss ultimately plateaus with age or continues longer. [720,721,722,723,724 and 725] This controversy is likely confounded by the lack of sensitivity of IQ testing to measure some neuro-cognitive effects. In fact, some children may maintain normal range scores because of intelligence and academic achievement before treatment. Scores within the average range of IQ do not necessarily indicate the child's level of adaptive functioning. More specific assessment of neuropsychological function usually will illustrate multiple areas of damage in information processing. Some studies have identified specific neuro-cognitive deficits in attention, memory, coordination, fine motor speed, visual motor processing, mathematics, and spatial relations. [721,725,726 and 727]

Extent of damage from irradiation is a complex function of the volume and dose, tumor location, and age at treatment. Even though IQ is an imprecise descriptor, reports agree that most young children receiving brain irradiation have a moderate to severe IQ drop, more striking with diminishing age of the child. [340,727,728] In one series of 29 survivors of medulloblastoma diagnosed at a median age of 2.5 years and treated with chemotherapy and then craniospinal irradiation at time of disease progression or completion of chemotherapy, the children had severe intellectual deficits. [729] IQ was 62 at a median follow-up of 5 years, as compared with a baseline of 88 at diagnosis. Although the loss of roughly 4 or more IQ points per year is startling, more alarming is that the cognitive losses had yet to plateau. Even among older children undergoing whole-brain irradiation, a linear decline in IQ is apparent, dependent on radiotherapy dose and age at treatment. [730] In one follow-up assessment of children with noncortical brain tumors receiving 24 to 36 Gy craniospinal radiotherapy, all patients younger than 7 years at diagnosis were receiving special education, and half of those patients older than 7 years were receiving supplemental educational services. [720]

The contribution of the volume of irradiation to cognitive deficits is perhaps more clear. Whole-brain irradiation appears to be linked to the greatest IQ decline and is more detrimental as a function of lower age of the child. [339,340,723,731] Supratentorial irradiation, which exposes the frontal and temporal lobes, hippocampus, and limbic structures, also leads to a significant IQ decrease. [732] Radiation fields limited to the posterior fossa appear to be associated with less intellectual damage, although IQ still drops. [728,731,732 and 733] When medulloblastoma patients who received 25 to 35 Gy craniospinal irradiation along with a boost to the posterior fossa totaling 45 to 55 Gy were compared to ependymoma patients receiving only the same posterior fossa doses, the differences were striking. [724] At 5- and 10-year follow-up, results remained stable for children with ependymoma, approximately 60% having an IQ in excess of 90. In contrast, medulloblastoma patients had progressive deterioration, 20% having an IQ of greater than 90 at 5 years after therapy and only 10% having this IQ at the 10-year follow-up.

The dosage of irradiation also clearly influences the development of cognitive deficits, with more severe sequelae occurring at higher doses. Patients who receive a dose of 36 Gy to the whole brain are estimated to score 8 points lower on IQ testing than those receiving 24-Gy doses, although both groups are subnormal on average. [339,730] Although the exact relationship of dosage to detrimental effect is not well defined, variable intellectual deficits and CT abnormalities of the brain occur regularly in young children with leukemia who are given doses of 24 Gy to the whole brain, and such abnormalities have been variably demonstrated even with lower whole-brain doses of 18 Gy. [345,722]

As another consequence of radiotherapy to whole brain, hypothalamic-pituitary region, or spine, growth failure occurs commonly among brain tumor patients. Irradiation along the spinal axis retards the growth of the vertebral column and spinal cord, leading to a child with a short trunk and disproportionately longer extremities. [719] Spinal irradiation alone has been associated with a decrease in eventual height of 9, 7, and 5.5 cm when administered at ages 1, 5, and 10 years, respectively. [734] A larger contribution to decreased stature stems from impaired GH secretion. After irradiation that includes the hypothalamic-pituitary axis, GH deficiency can be detected as early as 3 months after treatment and may become an almost universal finding in long-term survivors. [735] Abnormal responses to provocative GH testing and diminished growth velocity may become apparent after application of 29 Gy or less to the hypothalamic-pituitary region or 18 Gy to the craniospinal axis. [345,736] The use of concomitant chemotherapy may increase further the severity of growth retardation. [737] The effect of precocious puberty prematurely fusing bony epiphyses also can contribute to short stature.

Hormone replacement therapy should be considered in patients whose growth velocity has declined and who do not respond to provocative GH testing. The decision regarding whether and when to initiate replacement remains emotional and controversial for parents and physicians. Although the hormone is mitogenic, it does not appear to produce any increased risk for tumor recurrence. [738,739] Regardless, even when used, GH does not appear to correct fully the loss of stature caused by radiotherapy.

Other neuroendocrine deficits may also be seen. Primary, or less commonly secondary or tertiary, hypothyroidism may occur in more than half of patients as a result of irradiation to the thyroid gland or the hypothalamic-pituitary axis, respectively. [719,740] Puberty may occur prematurely or at normal onset but only seldom is delayed. Abnormalities of gonadotropin or corticotropin secretion may be less common, although this has not been examined rigorously in brain tumor survivors. [740] Male patients appear to be less at risk than female patients for gonadal dysfunction secondary to spinal irradiation, but the synergistic effect from commonly used drugs such as cyclophosphamide and nitrosoureas, known to affect oogenesis and spermatogenesis, has not been estimated. [719] Diabetes insipidus or panhypopituitarism follows radiotherapy rarely but seldom improves when present at diagnosis of a craniopharyngioma or germ cell tumor.

High-frequency, sensorineural hearing loss is another complication that is frequent among brain tumor survivors, most commonly caused by repeated administration of cisplatin. The contribution of radiotherapy to hearing loss appears to be less severe but less well studied. [741] In a recent CCG trial for medulloblastoma with 23.4 Gy craniospinal irradiation and a boost to the posterior fossa totaling 55.8 Gy, followed by adjuvant lomustine, vincristine, and cisplatin, the cisplatin dosage was halved or suspended because of ototoxicity in nearly one-third of patients. [364] Highly conformal radiotherapy may reduce the risk of ototoxicity.

Management of all these sequelae often is suboptimal. Due to the evident acute and long-term needs of these patients, a multidisciplinary team best manages them. This team should include not only physicians and nurses but also an occupational therapist, physical therapist, child life worker, educational psychologist, and social worker. The team and family must remember that effects may not occur or become fully manifest for 1 or several years after completion of therapy. Consequently, yearly psychological evaluations should be performed for at least the first 5 years after therapy. Children who demonstrate intellectual impairment require further evaluation so that proper educational intervention can begin. Even years after cranial irradiation, educational intervention has been associated with improvements in spelling and reading, particularly when written feedback was provided to parents and schools. [722] An evaluation by an occupational therapist may also be indicated to assess fine motor and visual skills. For at least 5 or more years, annual thyroid function studies should be performed to monitor for the often subclinical manifestations of hypothyroidism. Remediation is important to growth, learning, and prevention of thyroid tumors from persistently elevated thyroid-stimulating hormone. Other endocrinologic evaluations should be obtained as appropriate. Longitudinal audiometry should be considered for at least several years.

Long-term management of the child with a brain tumor also includes surveillance for disease relapse. Surveillance of brain tumor patients, unlike patients with other childhood cancers, is indeed a chronic issue. Progression or recurrence of tumors such as ependymoma or the LGAs frequently does not occur until 3 to 5 or more years from diagnosis. For medulloblastoma, with a median time to relapse of 18 to 24 months, recurrence may occur 8 or more years after diagnosis. [742] The ideal surveillance modalities and schedule for all the diverse tumor pathologies is unclear. Despite fair agreement that serial clinical examination is important not only to detect signs suggestive of relapse but also to monitor for the already mentioned sequelae of treatment, controversy surrounds the timing and need for surveillance MRI. For malignant brain tumors, the CCG has recommended surveillance MRI every 3 months during the first year after diagnosis, every 4 months during the second year, biannually during years 3 and 4 from diagnosis and, finally, annual to biennial scanning until 12 years after diagnosis. [743] Other investigators have questioned whether neuroimaging surveillance affects outcome, as the salvage rate for relapsed tumors such as medulloblastoma is low. [744,745] Further data are forthcoming from the POG experience to help answer this question. Even less clear is the decision regarding when to stop routine MRI scanning, as secondary brain tumors, particularly meningiomas, gliomas, and sarcomas, have been reported 5 to 25 years after treatment of the original tumor. [719] Most recommendations today are based on retrospective analyses. Prospective evaluation of neuroimaging surveillance schedules appropriate to the heterogeneous CNS tumor pathologies is needed.

Although prevention of these deleterious sequelae is beginning to receive attention, judging the efficacy of current interventions is difficult. Attempts to decrease, delay, or avoid radiotherapy have been made with the use of adjuvant or pre-irradiation chemotherapeutic regimens, particularly among very young children. However, several factors other than radiotherapy can influence neuro-cognitive and neuroendocrine function, and chemotherapy itself may have deleterious effects on the developing nervous system. [717,718,728,733] Furthermore, prolonged chemotherapy with alkylators and etoposide among infants with brain tumors has been associated with an excess risk of second malignancies. [439] Other new strategies to mitigate damage have yet to be tested. Conformal techniques can better focus the radiation delivered, such as in the posterior fossa where, in the past, local field treatment still exposed the hypothalamus and hippocampus just beyond the posterior clinoid processes. The chemoprotectant amifostine has yet to be widely studied with cisplatin administration.

Because most patients with neuro-cognitive deficits do not have observable histopathologic changes, the location and pathogenesis of their problems are not well

established. Thus, understanding the ways in which radiation and chemotherapy alter axonal growth, dendritic arborization and pruning, synaptogenesis, and myelination, all of which occur in childhood and adolescence, is presumably critical to understanding the development of these problems and remains largely unknown. Evidence suggests that MRI is capable of demonstrating areas of treatment-related white-matter abnormalities not visible on CT that may correlate with the degree of clinical neurologic compromise, particularly in IQ, factual knowledge, and verbal and nonverbal thinking. [339] Prospective evaluation with new MRI techniques and other novel neuroimaging modalities may improve understanding of the location and dynamics of damage associated with various therapies.

Imprecise methods, small patient numbers, and limited funding for studying patients with CNS tumors have been barriers to our knowledge of late effects. Closer collaboration with schools for assessment and intervention might help. In the future, comprehensive batteries that take the entire child into account are needed. Given that executive function, memory, pragmatic language, and other cognitive functions change over time, such evaluations should steer assessment away from IQ and toward developmental neuropsychological models. More precise definitions of disability and quality of life are needed. Newly validated instruments that measure quality of life should be implemented. Assessments will also have to consider practical outcomes, such as the ability to hold a job, drive a car, manage finances, or live independently.[741] Interventional trials of medications that improve arousal, attention, and memory, such as modafinil, methylphenidate, or donepezil, are needed also.

## INFORMATION ON CLINICAL TRIALS

For individuals wanting more information about clinical trials for children with brain tumors, the following resources are suggested:

## INTRODUCTION

Retinoblastoma is a malignant tumor of the embryonic neural retina and is the most common intraocular malignancy in children. Although usually not recognized at birth, retinoblastoma is congenital and affects predominantly young children. The tumor has a variable growth rate, can originate from single or multiple foci in one or both eyes, and in bilateral cases, may be manifest in one eye many months before it is evident in the other. Retinoblastoma is caused by a mutation in a gene that expresses a protein central to the control of the cell cycle and may occur sporadically or be inherited. Children with the hereditary type of retinoblastoma have a particular susceptibility to developing other malignant tumors. This disease serves as a model for understanding the genetics and heredity of childhood cancer.

The term *retinoblastoma* was first adopted by the American Ophthalmological Society in 1926.[1] The cellular origin of retinoblastoma had been a topic of debate since 1809 when the Scottish surgeon Wardrop first recognized, based only on gross pathological findings, that retinoblastoma is a discrete tumor arising from the retina.[2,3] After this publication, other pathologists including Robin and Langenbeck confirmed the observations at a microscopic level. Virchow, however, thought that the cell of origin was glial and named it *glioma of the retina*. In the late 1800s, the term *neuroepithelioma* was proposed by Flexner, and supported later by Wintersteiner, because they believed that the tumor originated from the neuroepithelium and that the typical rosettes that now bear their names were attempts to form photoreceptors. In the early 1900s, Verhoeff concluded that the tumor was derived from undifferentiated embryonic retinal cells called *retinoblasts* and proposed the term *retinoblastoma*.[1] Margo and colleagues proposed the term *retinocytoma* for the well-differentiated tumor that displays benign features.[4] For this same tumor Gallie and colleagues described the clinical features and proposed the term *retinoma*.[5] The histopathological, ultrastructural, immunohistochemical, and molecular characteristics of retinoblastoma support the concept that this tumor originates from a multipotent precursor cell. This cell could develop into almost any type of inner or outer retinal cell, including photoreceptors.[6,7,8,9,10,11,12,13,14,15,16,17,18,19,20] and [21]

## EPIDEMIOLOGY

The Third National Cancer Survey indicates an average incidence of 11 new cases of retinoblastoma per million population younger than 5 years, or 1 in 18,000 live births in the United States.[22] Although data from developing countries are less complete, oncologists in Central and South America, the Middle East, and India generally feel that the incidence may be greater in these regions. The estimated frequency of bilateral retinoblastoma ranges from 20% to 30%. Thus, in the United States, an estimated 200 children per year develop retinoblastoma; of these 200, at least 40 to 60 cases are bilateral. There are no racial or gender predilections.

Retinoblastoma is often present at birth and is almost entirely restricted to early childhood. Approximately 80% of cases are diagnosed before children reach the age of 3 to 4 years, with a median age at diagnosis of 2 years.[23] The discovery of retinoblastoma beyond age 6 years is rare. Bilateral disease is diagnosed earlier than unilateral disease. Sporadic bilateral retinoblastoma has been associated with advanced parental age.[24]

Multiple congenital anomalies associated with retinoblastoma have been reported in approximately 0.05% of U.S. patients with retinoblastoma.[25] The reported anomalies include congenital cardiovascular defects, cleft palate, infantile cortical hyperostosis, dentinogenesis imperfecta, familial congenital cataracts, and incontinentia pigmenti, or Bloch-Sulzberger syndrome (an X-linked inherited disease that is lethal in males but affects females with pigmentary retinopathy, corneal opacities, cataracts, nystagmus, blue sclerae, myopia, pseudoglioma, dental abnormalities, abnormal skin pigmentation, and mental deficiency).[23] An association with mental retardation has been suggested in children with the D-deletion syndrome; however, most patients with retinoblastoma have no intellectual impairment.

## GENETICS

The majority of retinoblastomas appear sporadically; however, an inherited form of the disease has been documented[26,27] and is transmitted with few exceptions as a typical mendelian autosomal dominant trait with high but incomplete penetrance. Of all cases, approximately 60% are nonhereditary and unilateral, 15% are hereditary and unilateral, and 25% are hereditary and bilateral.[28,29]

A “two-hit” model has been proposed to explain the observations that familial cases are generally multifocal and bilateral, whereas sporadic cases typically present with unilateral unifocal disease at a later age.[28,30] According to the model, as few as two stochastic mutational events are required for tumor initiation, the first of which

can be inherited through the germ line (in heritable cases) or can occur somatically in individual retinal cells (in nonheritable cases). The second event occurs somatically in either case and leads to tumor formation from each doubly defective retinal cell.

The presence of a microscopically visible deletion in one chromosome 13 homologue in constitutional cells of a small number of retinoblastoma patients was the first evidence that supported an inherited mechanism for retinoblastoma development. [31,32,33 and 34] Although the deletions varied between families, each deletion minimally encompassed chromosome 13q14.[35,36] This chromosomal locus contains the RB1 retinoblastoma gene. In the two-hit model, such deletions in the germline could act as the first hit and confer the risk of tumor formation as an autosomal dominant trait. The increasing resolution of cytogenetic technology and the development of DNA probes for loci in the immediate vicinity of the RB1 gene locus has allowed the detection of more subtle genomic rearrangements. These techniques can be used to identify people who carry nonpenetrant mutations in the retinoblastoma susceptibility locus. [37]

Patients without a gross chromosome 13 deletion but who have bilateral or familial retinoblastoma have submicroscopic mutations at the RB1 locus similar to mutations that have been found in the tumor cells of patients with nonhereditary retinoblastoma. The second step in tumorigenesis in both heritable and nonhereditary retinoblastoma involves somatic alteration of the normal allele at the RB1 locus in such a way that the mutant allele is unmasked. Thus, the first mutation in this process, although it may be inherited as an autosomal dominant trait in the child, is in fact a recessive defect in the individual retinal cell. Elimination of the chromosome containing the wild-type allele followed by reduplication of the remaining mutant chromosome may be one mechanism by which the affected RB1 locus becomes homozygous within the cell.[38,39,40 and 41] The potential tumor cell becomes recessive for the mutant allele.

Although the unmasking of predisposing mutations at the RB1 locus occurs in mechanistically similar ways in sporadic and heritable retinoblastoma, only the latter carries the initial mutation in each cell. Patients with heritable disease also seem to be at greatly increased risk for the development of second primary tumors, particularly osteogenic sarcoma.[42] This high propensity is genetically determined by the predisposing RB1 mutation. The notion of a pathogenetic association between these two rare tumor types was tested by determining the constitutional and osteosarcoma genotypes at restriction fragment length polymorphism loci on chromosome 13. The data indicated that osteosarcomas arising in patients with retinoblastoma had become homozygous specifically around the chromosomal region carrying the RB1 locus.[43] Furthermore, these same chromosomal mechanisms eliciting losses of constitutional heterozygosity were observed in sporadic osteosarcomas, suggesting a genetic similarity in pathogenetic causality.

These studies provided data useful for the molecular isolation of the RB1 gene. [44] The genomic organization of the approximately 200-kb locus was determined, and the expression of its 4.7-kb messenger RNA transcript in tumor and normal tissues was documented. Introduction of the wild-type gene into retinoblastoma and osteosarcoma cell lines using recombinant retroviral vector transfer resulted in a partial reversal of the tumorigenic phenotype. [45,46] Further characterization of the complete RB1 genomic sequence[47] allowed a rigorous cataloging of the different mutations affecting the gene in retinoblastoma tumors. Over 200 disease-causing mutations have been identified in the retinoblastoma genes of patients. [37,48,49,50,51,52,53,54,55,56 and 57]

The examination of sporadic cases of bilateral retinoblastoma showed that disease frequently arises subsequent to a new germline mutation in the paternal allele, followed by somatic alteration or loss of the maternally derived wild-type allele. [58,59] This finding suggests either that mutations in the RB1 locus occur more commonly during spermatogenesis or that the paternal chromosome in the early embryo is at a higher risk of mutation. Analyses of sporadic osteosarcomas also showed preferential mutation of the paternal allele. [60]

Investigations of RB1 gene alterations at both the DNA and the RNA level cumulatively reveal a strong correlative relationship between the lack of RB1 gene product and the appearance of retinoblastoma tumors. In addition to osteosarcomas, other tumor types contain mutations involving the retinoblastoma ene. Molecular analyses of small cell lung carcinomas have revealed RB1 structural abnormalities in approximately 15% of cases. [61] Loss of heterozygosity for chromosome 13 has been detected in approximately 25% of breast cancers and related breast cancer–derived cell lines. [62,63] However, a more detailed analysis of the effects of chromosome 13 mutations in tumors has been compiled and clearly shows that not all tumors are either a direct or an indirect result of loss of heterozygosity of the RB1 locus.[64] The cumulative data suggest that only subsets of tumors may share a common pathogenetic mechanism that results from unmasking mutations affecting the tumor-suppressing function of RB1.

RB1 messenger RNA is a 4.7-kb transcript in normal human and rat tissues including brain, kidney, ovary, spleen, liver, placenta, and retina. [65] The expressed protein contains 928 amino acids and has an estimated molecular mass of 110 kd. Although the number of different types of tumors that occur as a result of inherited mutations of the RB1 locus is small, the broad tissue expression and species conservation of this gene suggest a common and potentially important role in the growth or differentiation of many cell types.

The protein has been shown to be primarily localized in the cell nucleus. [66] Posttranslational phosphorylation of the RB protein in quiescent cells overrides growth suppression and allows cell division to take place. [67] The RB protein also has a role in the regulation of the cell cycle of actively dividing cells. The unphosphorylated RB protein (p110RB) has been shown to bind E2F1, a transcription factor and a cell cycle regulator during the $G_1$ stage of the cell cycle. The RB/E2F1 complex masks the E2F1 transactivation domain and inhibits surrounding enhancer elements, thereby causing transcription of E2F1-regulated genes to cease. The RB protein accomplishes this by physically associating with histone deacetylase 1. This recruitment of the deacetylase to the E2F1 regulating domain by Rb allows for deacetylation of histone, thereby modulating the local structure of the chromatin. [68,69] Phosphorylation of the RB protein at the $G_1$/S boundary results in the release of these transcriptional factors, allowing them to become positive transcriptional elements. Additional cell cycle–specific kinases become activated and facilitate the progression of the cells through $G_2$ and M. At the completion of the cell cycle, phosphatases dephosphorylate the RB protein, allowing the protein to again sequester E2F1 and form an inactive complex. Thus, positive and negative regulation of transcription and, therefore, cell proliferation are linked to the phosphorylation cycle of the RB protein. In tumors in which RB protein is mutated or absent, these intracellular transcriptional elements are dissociated and free to promote consistent and uncontrolled progression through the cell cycle. Such behavior results in unchecked cell proliferation consistent with a malignant phenotype.

The viral oncoproteins of polyomaviruses (SV40), adenoviruses (Ad-2 and Ad-5), and papillomaviruses (HPV-16) have also been shown to complex with the RB protein.[70,71 and 72] Because one function of these viral oncoproteins appears to be the creation of a cellular environment that is permissive for DNA synthesis, one of their modes of action may involve sequestration of the antiproliferative unphosphorylated RB protein. Releasing the cell from its negative regulation by RB might allow the cell to enter S phase and synthesize DNA. Taken together, the data support a model in which the unphosphorylated form of RB is the species active in growth suppression.

### Genetic Counseling

Approximately 40% of patients with retinoblastoma have the inherited form of the disease. Because the inherited form of retinoblastoma is transmitted as an autosomal dominant trait with high but incomplete penetrance, there is a 45% chance that a child of the patient will inherit the disease. In addition, although there is high penetrance of the retinoblastoma phenotype, the possibility exists that one of the patient's siblings could also develop retinoblastoma even if neither of the parents was affected by the disease due to germline mosaicism and low penetrant alleles (see Chapter 3).[73,74 and 75] All children with a family history of retinoblastoma should be screened shortly after birth by a qualified ophthalmologist to permit early detection of the disease and increase the chance of ocular and vision salvage. These increased familial risks support the need for expert genetic counseling.

To effectively counsel patients and families of retinoblastoma patients, the underlying cause of the disease must be determined. Patients who present with bilateral disease can be assumed to have a germline mutation in the RB1 gene. Patients with unilateral disease at presentation may also have an underlying germline mutation. If a mutation in the RB1 gene is detected in the tumor, somatic cells should also be screened. A mutation initially detected in the somatic cells is presumptive evidence of a mutation in the germline. Genetic testing for the presence of this specific mutation in siblings or offspring should be pursued. These children can then be aggressively surveyed for the presence of emerging tumors. If genetic testing is not pursued, then tumor surveillance is recommended for all siblings of the affected patient. Current recommendations suggest examination at birth and every 4 months until age 4 years. For children with unilateral disease, genetic screening for RB mutations can now be offered to families at the time of enucleation. The testing requires a sample of tumor and peripheral blood from the patient[37] or, for patients with bilateral disease, a blood sample can be analyzed directly.

## CLINICAL PRESENTATION

Most cases of retinoblastoma in the United States are diagnosed while the tumor remains intraocular without local invasion or distant metastases. In developing countries, however, the diagnosis is frequently made only after an enlarged eye or gross orbital extension is apparent. These patients more commonly present with

local invasion.

The signs and symptoms of an intraocular tumor depend on its size and position. The most common presenting sign is leukocoria of one or both eyes ( Fig. 28-1). Leukocoria, a lack of the normal red reflex of the eye, is manifest when the tumor is large or has caused a total retinal detachment leading to a retrolental mass that is visible through the pupil. If vitreous hemorrhage occurs due to bleeding of the retinoblastoma vessels, the pupil may appear to have a dark reflex instead of the white reflex typically seen in retinoblastoma ( Fig. 28-2).[18,76,77] The second most common presenting sign is strabismus. Loss of central vision from a tumor in the macula may result in a disruption of the fusional reflex and cause the affected eye to drift.

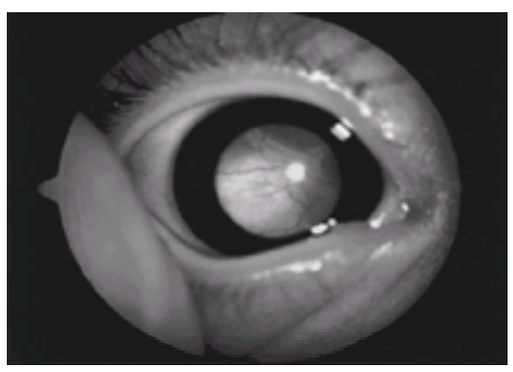

**FIGURE 28-1.** Photograph of the eye of a patient with retinoblastoma who presented with leukocoria.

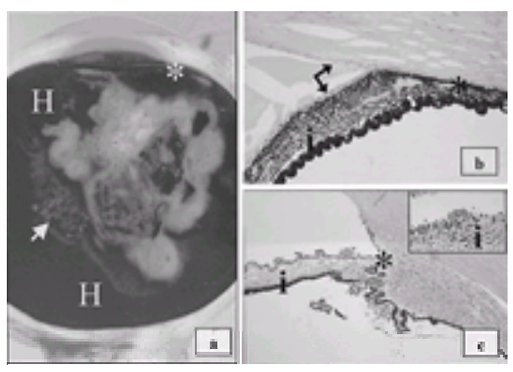

**FIGURE 28-2. A:** Gross photograph of an eye with retinoblastoma (white membranous tissue at center of the eye) with subretinal tumor seeds ( *arrow*) and vitreous and subretinal hemorrhages (H). Neovascularization of the anterior chamber and partial closure of the anterior angle ( *asterisk*) are also present. **B:** Histologic picture of rubeosis iridis showing neovascularization ( *arrows*) of the anterior portion of the iris (i) and focally on the endothelial surface of the cornea ( *arrows*). Contraction of the neovascular membrane produces closure of the anterior chamber angle ( *asterisk*). (Hematoxylin and eosin; original magnification 20×.) **C:** Histologic picture of the anterior segment of an eye with retinoblastoma seeds on the surface of the iris (i) with focal rosette formation ( *inset*). The anterior chamber angle (*asterisk*) is opened. (Hematoxylin and eosin; original magnification 20×.)

Other ophthalmic features accompany some cases of retinoblastoma and may indicate the necessity for immediate enucleation. Heterochromia (different color for each iris) may present as an initial sign of retinoblastoma secondary to iris neovascularization. The diagnosis of retinoblastoma should be excluded in children that present with this condition.[20] Rubeosis iridis (neovascularization of the surface of the iris) occurs in approximately 17% of patients with retinoblastoma and in more than 50% of patients with advanced retinoblastoma requiring enucleation ( Fig. 28-2).[20,76,79,80 and 81] Extensive necrosis of the tumor and liberated angiogenic factors may be responsible for this neovascularization of the iris.

Spontaneous bleeding from rubeosis iridis may also cause hyphema (blood in the anterior chamber), and the potential diagnosis of retinoblastoma should be investigated in a child presenting with spontaneous hyphema without history of trauma.[18,20,76,77] Glaucoma may be secondary to neovascularization of the anterior chamber angle or anterior synechia as a result of rubeosis iridis. Closed-angle glaucoma can also be secondary to mechanical obstruction of the anterior chamber angle by the iris and lens that has been pushed forward by a large intravitreal tumor. Most children with these presentations undergo enucleation.[18,76,77] Anterior chamber seedings from endophytic tumors or diffuse infiltrating tumors may produce pseudohypopyon (cells in the anterior chamber) ( Fig. 28-2). Intraocular tumors are not associated with pain unless secondary glaucoma or inflammation is present.

## DIAGNOSIS

Most commonly, a parent or relative of an affected child notes an abnormality of the eye that prompts physician evaluation. Current detection strategies involve a pediatrician looking for leukocoria using an ophthalmoscope. The gross appearance of a creamy pink to snow white mass projecting into the vitreous during the ophthalmoscopic examination (Fig. 28-1) may suggest retinoblastoma; however, associated findings of retinal detachment, vitreous hemorrhage, or opaque media often make inspection difficult. Pupillary dilation and examination with the patient under anesthesia are essential to evaluate the retina fully. Characteristically, the diagnosis is made by the ophthalmoscopic, radiographic, and ultrasonographic appearance, and pathologic confirmation is unnecessary. When the tumor is in an advanced stage, distinguishing vitreal seeding from multifocal tumors may be difficult; however, this distinction has important ramifications for the prognosis for the patient and for genetic counseling for the family. Earlier detection of the tumor would benefit the patient both by decreasing the chance of a child presenting with metastatic disease and by increasing the chance of being able to salvage the affected eye. A suggestion has been made to include dilation of the pupil before examination at the first well-child visit. An additional benefit of screening would be the earlier detection and treatment of congenital and infantile cataracts. Whether routine screening would be practical is controversial because diseases such as retinoblastoma and congenital cataracts are rare (congenital cataracts affect approximately 1 in 2,000 live births) and because pediatricians may not be adequately trained to recognize these conditions.

Ultrasonography and computed tomography (CT) (Fig. 28-3) of the orbit are the imaging studies most frequently used to confirm the diagnosis of retinoblastoma and to detect ectopic disease in the pineal gland.[82] Magnetic resonance imaging (MRI) of the orbit (Fig. 28-3) may be a more useful technique to detect tumor extension into the optic nerve and orbital coats.[83]

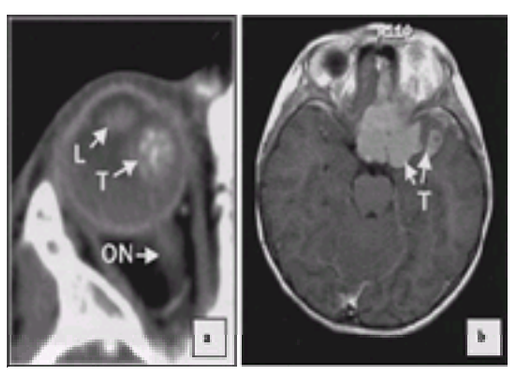

**FIGURE 28-3.** Diagnostic imaging of children with retinoblastoma. **A:** Computed tomography scan of the orbit. Axial view showing a partially calcified mass (T)

consistent with retinoblastoma, a normal lens (L), and normal optic nerve (ON). The globe is intact and shows no evidence of extraocular invasion by tumor. **B:** Magnetic resonance imaging of the orbits and brain. Contrast-enhanced coronal T1-weighted image showing parasellar and left middle fossa spread of retinoblastoma (T) with extension along the sylvian fissure. The eye on the left is normal. The orbit on the right contains a prosthesis.

The pretreatment evaluation must be individualized for each patient. In patients who present with small tumors, ultrasonography or CT scan of the orbits and careful examination under anesthesia may be all that is necessary to make the diagnosis. A more extensive metastatic workup is unnecessary in these patients unless there is a question of optic nerve extension or extensive choroidal invasion. A lumbar puncture to obtain cerebral spinal fluid cytology and CT or MRI of the brain to rule out brain metastases can be performed in those patients. Because of the rarity of distant metastases in patients with retinoblastoma, a bone marrow examination or bone scan is usually unwarranted unless the physician has suspicions of systemic involvement.

**Differential Diagnosis**

A number of benign conditions can clinically simulate retinoblastoma (pseudoretinoblastomas) and sometimes create considerable diagnostic difficulty for the ophthalmologist. Clinical definition is mandatory because the management of these entities differs considerably from the radical treatment of retinoblastoma.

Early reports of the frequency of enucleations performed for suspected retinoblastomas when an alternative final pathologic diagnosis is made varied from 30% to 16% according to the degree of oncologic experience of and the type of referrals received by the group reporting the series. [18,77,84,85] Most clinicians are now more familiar with pseudoretinoblastomas, and the frequency of erroneous enucleation is currently much lower. [20]

Other conditions that might be confused clinically also produce or simulate a mass in the vitreous or the retina. With the exception of medulloepithelioma, these lesions have in common a variety of histopathologic features distinct from retinoblastoma that create a difficult differential diagnosis for the pathologist.[79,86,87,88,89,90,91,92,93,94,95,96,97] and [98]

Approximately 60% of pseudoretinoblastomas include the differential diagnosis of three non-neoplastic entities: *Toxocara canis* endophthalmitis, persistent hyperplastic primary vitreous (PHPV), and Coats' disease.[18] All of these entities might present with retinal detachment and may have retrolenticular fibrosis. *T. canis* endophthalmitis is caused by the larvae of the nematode *T. canis* and presents almost always in children, although never at birth. Clinical history and serology are important for the diagnosis. Usually there are no signs of ocular inflammation, as the live larvae do not elicit an inflammatory response. Dead larvae elicit the formation of a localized eosinophilic abscess surrounding the microorganism. Condensed vitreous with gliosis and fibrosis may be present at the site of infection. Because these organisms are very small and degenerate, histological confirmation is very difficult.

PHPV is a congenital anomaly of the primary vitreous in which embryonal vessels do not regress and may pull the retina resulting in an anterior detachment. If the posterior capsule of the lens is ruptured by the traction of the vessels and fibrous membrane, a posterior subcapsular cataract forms. Some cases of PHPV are associated with a wide band to the optic nerve and with retinal dysplasia. There are rare cases reported in which PHPV has been associated with retinoblastoma.[99,100,101,102] and [103]

In contrast to toxocariasis and PHPV, Coats' disease lacks the fibrosis and vascularization of vitreous. Coats' disease is characterized by peripheral retinal vascular telangiectasis. These abnormal vessels leak and create an exudative retinal detachment rich in lipids with subretinal foamy macrophages and cholesterol clefts. Toxocariasis and PHPV simulate endophytic retinoblastoma, and Coats' disease mimics the exophytic type (see Pathology: Gross Features).[84,88,104,105,106,107] and [108] Ancillary imaging technology that includes ultrasound, CT scans, and MRI have greatly helped in the differential diagnosis of these lesions. [99,108,109,110,111,112] and [113]

**Use of Cytology in the Diagnosis of Retinoblastoma**

Retinoblastoma is the most frequent intraocular tumor of childhood in the United States, and in some other countries retinoblastoma is the most frequent intraocular tumor overall. However, retinoblastoma is one of the only human tumors that is radically treated without tissue biopsy confirmation. The clinical presentation and the ancillary radiologic and ultrasonic findings are typical for retinoblastoma in the majority of patients. Usually the correct diagnosis does not represent a diagnostic dilemma for the experienced pediatric/oncologic ophthalmologist. The resistance to biopsy confirmation of the tumor arises from the dramatic difference between survival for patients with contained intraocular tumors versus those with extraocular seeding of the tumor. The bias against biopsy is also aggravated by the reports of cases in which the tumor was misdiagnosed as “uveitis” or obscured by cataract, and patients developed orbital extensions of retinoblastoma after vitrectomy. [114]

The development of more refined techniques of fine-needle aspiration biopsy (FNAB) and the increased knowledge of the biological behavior of retinoblastoma has allowed some patients to benefit from pretreatment biopsy. [104,115,116,117,118,119,120,121] and [122] The FNAB technique is more difficult to perform; however, FNAB is safer for the patient because it prevents tumor seedings by avoiding the subconjunctival and scleral/orbital routes of entry. The 30-gauge needle passes through the peripheral cornea, anterior chamber, peripheral iris, lens zonules (avoiding puncture of the lens), and vitreous and penetrates the tumor ( Fig. 28-4). There have been no reports of extraocular tumor spread through the needle tract when FNAB has been used. FNAB is recommended only in selected cases in which the diagnosis is ambiguous and when adequate steps are taken to prevent extraocular seeding of tumor cells.

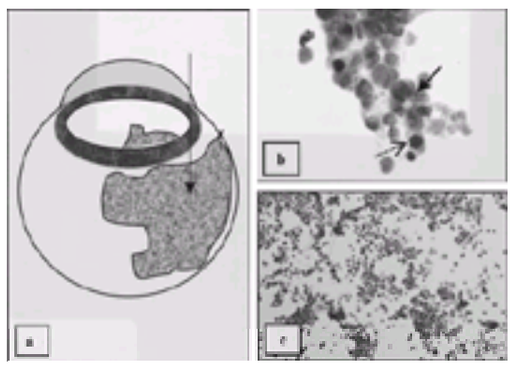

**FIGURE 28-4. A:** Drawing of an eye with retinoblastoma indicating the entrance of the needle ( *arrow*) through the peripheral cornea and peripheral iris, then between the ciliary body and the lens into the tumor. The technique avoids vascularized conjunctiva of the limbus and the orbit, sclera, and pars plana, preventing possible spreading of tumor cells via the needle tract. **B:** Cytologic preparation of a retinoblastoma showing cohesive groups of neoplastic cells with high nuclear to cytoplasmic ratio, increased mitotic activity (*dotted arrow*), and focal rosette formation (*solid arrow*). (Papanicolaou; original magnification 100×.) **C:** Cytologic preparation of cerebrospinal fluid in a patient with retinoblastoma metastatic to the brain. Notice the cohesive groups of neoplastic cells with high nuclear to cytoplasmic ratio. (Hematoxylin and eosin; original magnification 20×.)

The cytological findings are those of small- to medium-sized basophilic cells with scanty cytoplasm that tend to group together (rosettelike). Mitoses may be easy to find, and necrosis is frequently encountered ( Fig. 28-4). Similar features can be seen in cytologic cerebrospinal fluid specimens in children with intracranial metastases (Fig. 28-4). In one series of FNAB of pediatric intraocular tumors, the overall accuracy of FNAB was 95%, and the accuracy of cytologic interpretation was 100%. Therefore FNAB is a reliable and accurate diagnostic tool for the assessment of selected pediatric ophthalmic diseases in which the diagnosis is in question.[123,124]

## PATHOLOGY

## Gross Features

Primary retinoblastomas originate in the sensory retina and occupy the retina and vitreal cavity. Retinoblastoma is usually white-gray with a chalky appearance and a soft, friable consistency. Bright white speckles corresponding to calcifications present throughout the tumor. The gross features of retinoblastoma depend on the growth pattern of the tumor.[18,21,76] Some of these patterns correlate with clinical presentations and differences in biological behavior, especially as they relate to intraocular and extraocular types of tumor spread.

The endophytic growth pattern is represented by tumors arising from the retina and growing into the vitreal cavity ( Fig. 28-5). These tumors tend to entirely fill the cavity and produce floating tumor spheres called *vitreal seeds*. Tumor left untreated eventually invades the anterior portion of the eye, reaching the aqueous venous channels and the conjunctiva. From there, the tumor can permeate the lymphatic vessels and metastasize to regional lymph nodes. [18,21,125,126] and [127]

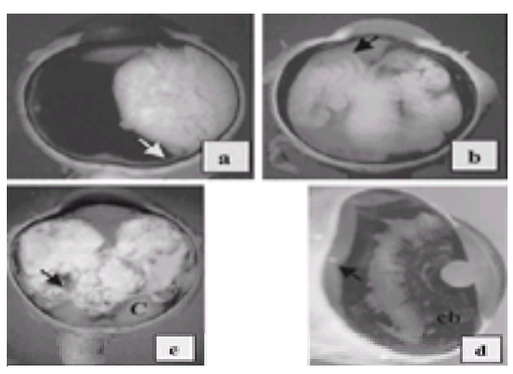

**FIGURE 28-5. A:** Gross photograph of an eye with a retinoblastoma showing an endophytic growth pattern. Notice that the tumor mass is growing from the retina (*arrow*) into the vitreal cavity. **B:** Gross photograph of an eye with a retinoblastoma showing an exophytic growth pattern. Notice that the tumor is growing from the retina (*arrow*) into the subretinal space with associated retinal detachment. **C:** Gross photograph of an eye with a retinoblastoma showing a mixed growth pattern, the most frequent type. Notice that the tumor grows both into the vitreous cavity and into the subretinal space with the retina ( *arrow*) entrapped in the middle. The tumor has massively invaded the choroid (C). **D:** Gross photograph of an eye with a diffuse retinoblastoma. Notice the absence of a well-formed mass; instead there are white seeds of tumor cells along the retina (*arrow*) and ciliary body (cb).

Exophytic tumors grow from the retina into the subretinal space and often cause serous detachments of the retina ( Fig. 28-5). These tumors may invade the choroid through Bruch's membrane.[18,21,128,129] and [130] Mixed endophytic and exophytic tumor growth is the most common pattern encountered (Fig. 28-5).[18,20,21]

Diffuse infiltrating retinoblastoma is the least common tumor growth pattern but is the most diagnostically challenging type because there is no predominant mass (Fig. 28-5). This presentation of retinoblastoma is seen in children with an average age of 6 years. The tumor cells grow throughout the retina while single cells and vitreal seeds invade the anterior portions of the retina, the ciliary body, and eventually the anterior chamber. Clinically this type of tumor resembles an inflammatory process with pseudohypopyon mimicking inflammatory cell accumulation (hypopyon) and vitreal seeds simulating the inflammatory cellular reaction seen in uveitis. Because this type of retinoblastoma resembles an inflammatory process, the diagnosis is often delayed until cytological examination of the aqueous humor or, in rare cases, of the vitreous. Almost all reported cases have a unilateral, sporadic presentation without family history. Although the diagnosis is difficult, children with diffuse infiltrating retinoblastoma have a good prognosis after enucleation. [101,127,131,132,133,134,135,136,137,138,139] and [140] Any child, regardless of age, who presents with signs of endophthalmitis should be considered to have diffuse infiltrating retinoblastoma until proved otherwise. [138]

Complete spontaneous tumor regression through unknown mechanisms occurs more commonly in retinoblastoma than in any other malignant tumor. In most of these cases complete occlusion of the central retinal artery is found; however, it is unknown whether this is a primary event or the result of tumor necrosis. [141,142] Severe inflammatory reaction with massive necrosis of the tumor followed by phthisis bulbi (complete atrophy of the eye) is the usual presentation.[141,142,143,144,145,146,147,148,149,150,151,152] and [153] If the eye is enucleated at the time of acute necrosis, the gross findings are those of massive tumor necrosis with edema of the conjunctiva.[141,154] If the eye is examined after complete atrophy has occurred, the findings are those of a small shrunken eye with mostly necrotic calcified tumor and a disorganized retina.

## Histologic Features

Microscopic examination of the affected eye displays one or more tumors with large areas of necrosis and multifocal calcifications replacing portions of the retina ( Fig. 28-6). The majority of the tumor is formed by small hyperchromatic cells with a high nuclear to cytoplasmic ratio. The tumor cells are mitotically active but frequently exhibit apoptosis (Fig. 28-6).[18,20,21,76,95,155,156,157,158] and [159] The viable cells surround blood vessels in a range of 90 to 110 mm forming a collarette (pseudorosettes) ( Fig. 28-6). Viability of the tumor cells depends on the intrinsic tumor blood supply. Areas of coagulative necrosis contain multiple foci of dystrophic calcification. Tumor cell necrosis liberates DNA from the nuclei of the cells. The released DNA forms deposits on the basement membranes of the vessels, the lens (capsule), the retina (internal limiting membrane), and the choroid (Bruch's membrane) ( Fig. 28-6).[160]

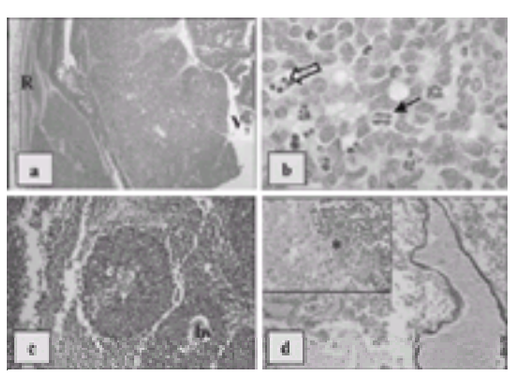

**FIGURE 28-6. A:** Histologic picture of a retinoblastoma growing from the retina (R) into the vitreous cavity (V). (Hematoxylin and eosin; original magnification 4×.) **B:** Histologic photograph showing poorly differentiated retinoblastoma cells with high nuclear to cytoplasmic ratio, increased mitotic activity ( *solid arrow*), and increased apoptosis (*open arrow*). (Hematoxylin and eosin; original magnification 100×.) **C:** Microphotograph showing viable tumor cells surrounding blood vessels (bv) with necrotic cells beyond a rim of approximately 110 µm. (Hematoxylin and eosin stain; original magnification 20×.) **D:** Microphotograph of retinoblastoma with extensive necrosis (*inset*) with foci of calcification (*asterisk*). Notice the large vessel darkly stained with hematoxylin (basophilic) secondary to DNA deposits in the vascular basement membrane as a result of extensive tumor cell necrosis that liberates nuclear DNA. (Hematoxylin and eosin; original magnification 10×.)

Some retinoblastomas show large areas of undifferentiated or poorly differentiated tumor ( Fig. 28-7); other retinoblastomas show a certain degree of differentiation represented by the formation of rosettes. Flexner-Wintersteiner rosettes are highly characteristic of retinoblastoma although they are also seen in pinealoblastomas and medulloepitheliomas. Flexner-Wintersteiner rosettes are lined by tall cuboidal cells that circumscribe an apical lumen. The apical ends attach to each other by terminal bars, and the cells may have apical cytoplasmic projections into the lumen of the rosette ( Fig. 28-7). Electron microscopy has demonstrated that these projections represent inner and outer segments of photoreceptors.[93,161,162] This and several other observations support the idea that retinoblastomas arise from

undifferentiated retinal cells that may differentiate into photoreceptors, [8,93,161,162,163,164,165,166 and 167] usually of the cone cell lineage.[6,7] Homer Wright rosettes are less common than Flexner-Wintersteiner rosettes, and they are found in a variety of neuroblastic tumors in addition to retinoblastoma. These rosettes do not surround a lumen but rather extend cytoplasmic processes that fill the center of the rosette. Homer Wright rosettes may be incomplete and admixed with well-formed Flexner-Wintersteiner rosettes (Fig. 28-7).

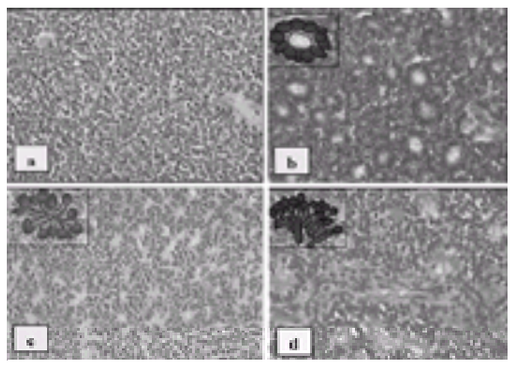

**FIGURE 28-7. A:** Microphotograph of a poorly differentiated retinoblastoma showing sheets of neoplastic cells without rosette formation. (Hematoxylin and eosin; original magnification 40×.) **B:** Microphotograph of a retinoblastoma showing Flexner-Wintersteiner rosette formation ( *inset*). Notice that these rosettes have a center partially filled by cytoplasmic prolongations with apical terminal bars. (Hematoxylin and eosin; original magnification 40×.) **C:** Microphotograph of a retinoblastoma showing Homer Wright rosette formation (*inset*). The lumen of the rosette is filled by cytoplasmic prolongations. (Hematoxylin and eosin; original magnification 40×.) **D:** Microphotograph of a well-differentiated retinoblastoma showing fleurettes ( *inset*). Fleurettes are groups of well-differentiated cells similar to photoreceptors, joined by cytoplasmic junctions and forming a figure similar to a bouquet of flowers. (Hematoxylin and eosin; original magnification 40×.)

Approximately 6% of tumors show benign photoreceptor differentiation into groups of cells with short cytoplasmic processes, abundant cytoplasm, and small round nuclei similar to photoreceptors. These groups of cells, which resemble a bouquet of flowers, are called *fleurettes*.[16,168,169] Neither significant mitotic activity nor necrosis is observed within the fleurettes (Fig. 28-7).[170,171 and 172]

### Retinocytoma

A benign counterpart of retinoblastoma called *retinocytoma* (also *retinoma*) that solely contains well-differentiated glial cells and fleurettes has recently been described. These benign tumors contain areas of abrupt calcification associated with retinal pigment epithelium proliferation ( Fig. 28-8). They exhibit specific features that allow experienced clinicians to follow the behavior of the tumor without radical treatment. [4,9,76,173,174] Singh and colleagues[173] reported on the ophthalmoscopic features of 24 tumors considered to be characteristic of retinocytoma, including the presence of a translucent retinal mass in 21 (88%), calcification in 15 (63%), and retinal pigment epithelial alteration in 13 (54%) of the tumors. A combination of all three features was observed in 8 (33%) of the 24 tumors. In 13 (54%) of the tumors, a zone of chorioretinal atrophy could be observed. Although the majority of these tumors behave as benign lesions, close follow-up is suggested because a few tumors have been reported to have undergone malignant transformation into retinoblastomas that eventually required enucleation. [168,173]

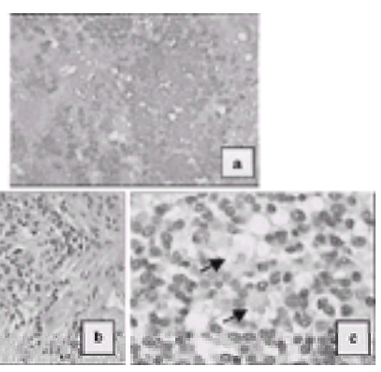

**FIGURE 28-8. A:** Histologic picture of abrupt cell calcification in a retinocytoma. (Hematoxylin and eosin; original magnification 40×.) **B:** Histologic picture of a well-differentiated area of a retinocytoma showing glial and neural differentiation ( *asterisk*). (Hematoxylin and eosin; original magnification 40×.) **C:** Histologic picture of a well-differentiated area of a retinocytoma showing fleurettes ( *arrows*). (Hematoxylin and eosin; original magnification 40×.)

In retinocytoma tumors that have undergone complete regression, either spontaneously or secondary to treatment, mummified calcified tumor cells and large areas of dystrophic calcification are observed. Exuberant reactive retinal pigment epithelial proliferation, ciliary epithelial cells, and glial cells with occasional ossification accompany this process.[76]

## METASTASIS AND RECURRENCE

If left untreated, retinoblastoma usually fills the eye and completely destroys the internal architecture of the globe. The most common route of spread is by invasion through the optic nerve. Once in the nerve, tumor spreads directly along the nerve fiber bundles toward the optic chiasm or infiltrates through the pia into the subarachnoid space. From the subarachnoid space, the retinoblastoma can involve the cerebrospinal fluid, the brain, and the spine. The second major route of spread is through massive involvement of the choroid into the orbit via either scleral canals (areas within the sclera in which ciliary vessels, nerves, and vortex veins enter or exit the eye) or by direct extension through the sclera.[175] Extraocular extension generally occurs within 6 months if intraocular tumors are left untreated.

Extraocular extension dramatically increases the chances of hematogenous and lymphatic spread. There are four routes for metastatic spread of retinoblastoma. [18,76]

1. Metastatic spread can occur by direct infiltration either through the optic nerve into the brain or through the choroid into the orbit soft tissues and bones.
2. Dispersion of the tumor cells through the subarachnoid space of the optic nerve into the opposite optic nerve or through the cerebrospinal fluid into the brain and spine can cause metastatic spread of the tumor. This can occur without detectable presence of retinoblastoma at the surgical margin of the optic nerve.
3. Metastasis can occur by hematogenous dissemination secondary to orbital and bone invasion or when lymphatic invasion reaches the lymph nodes. Widespread metastasis can present in lung, bone, and brain, among other sites.
4. Metastasis via lymphatic dissemination occurs in tumors that spread anteriorly into the conjunctiva and eyelids or extend into extraocular tissues. Lymphatic vessels and lymphoid tissue are absent in the orbit and intraocular tissues. In the ocular region, only conjunctiva and skin have lymphatic channels. Tumors must first reach these areas to permeate the lymphatic vessels and then spread into regional lymph nodes.

Histologically, retinoblastoma metastases appear less differentiated than intraocular tumors. Rosettes are rarely encountered, and fleurettes have never been described. When very well-differentiated extraocular tumors appear outside of the orbit, a differential diagnosis of a primary primitive neuroectodermal tumor must be considered.

## TRILATERAL RETINOBLASTOMA AND OTHER TUMORS

Primary retinoblastomas of the pineal and parasellar sites have been called *trilateral retinoblastoma* and usually present as single tumors. Trilateral retinoblastoma is

a well-recognized, although rare, syndrome.[176] The majority of the reported cases have involved patients with a family history of retinoblastoma, and the disease is usually fatal. These tumors may appear several years after successful treatment of intraocular retinoblastoma. They may be far more differentiated than the primary tumor and may contain numerous rosettes, fleurettes, and individual cells showing photoreceptor differentiation. The presentation of trilateral retinoblastoma contrasts with metastatic retinoblastoma because metastatic retinoblastoma presents as multiple, undifferentiated tumors within the first 2 years of initial treatment.

## STAGING

Different classifications have been introduced as guidelines for predicting prognosis for vision, globe salvage, and life. The Reese-Ellsworth classification ( Table 28-1)[177] relates to eyes treated by methods other than enucleation—specifically, radiotherapy. This classification, devised before the development of current ophthalmologic methodologies for diagnosis and treatment, has often been used to imply prognosis for life rather than for vision. Although the Reese-Ellsworth classification is not necessarily prognostic for outcomes using modern treatment modalities, it is still the classification used most often to compare therapeutic results. Other staging systems have been published which classify disease within or beyond the globe. [178] The American Joint Committee on Cancer has proposed a clinical and pathologic staging classification for retinoblastoma in which complete spontaneous regression of the tumor has not occurred. Using these criteria for cases of bilateral retinoblastoma, each eye is staged separately. Histologic verification of the disease in an enucleated eye is required, and any unconfirmed cases must be reported separately. The extent of retinal involvement is indicated as a percentage of the total retinal area. For the pathologic staging, all of the clinical and pathologic data from the resected specimen are to be used. A revised staging classification that would better predict clinical outcome using current therapeutic modalities is necessary.

| | | |
|---|---|---|
| Group I | | Very favorable |
| | a | Solitary tumor, <4 disk diameters in size, at or behind the equator |
| | b | Multiple tumors, none >4 disk diameters in size, all at or behind the equator |
| Group II | | Favorable |
| | a | Solitary tumor, 4–10 disk diameters in size, at or behind the equator |
| | b | Multiple tumors, 4–10 disk diameters in size, behind the equator |
| Group III | | Doubtful |
| | a | Any lesion anterior to the equator |
| | b | Solitary tumors >10 disk diameters behind the equator |
| Group IV | | Unfavorable |
| | a | Multiple tumors, some >10 disk diameters |
| | b | Any lesion extending anteriorly to the ora serrata |
| Group V | | Very unfavorable |
| | a | Massive tumors involving more than half the retina |
| | b | Vitreous seeding |

*Refers to chances of salvaging the affected eye and not systemic prognosis.

**TABLE 28-1. REESE-ELLSWORTH CLASSIFICATION FOR CONSERVATIVE TREATMENT OF RETINOBLASTOMA[a]**

## PROGNOSTIC FACTORS

Prognosis for vision in children with unilateral retinoblastoma is excellent for the uninvolved eye. The development of tumors in the contralateral eye after 3 years is very rare. A primary tumor with vitreous, subretinal, and retinal seeds can be mistaken as a multifocal primary tumor. Primary tumors arise from the sensory retina, whereas retinal seedings sit on top of the retina ( Fig. 28-9) or on the inner subretinal surface of the photoreceptors. The presence of multiple primary tumors or the emergence of tumors in both eyes (bilateral retinoblastoma) supports a diagnosis of inherited retinoblastoma. The prognosis for vision in bilateral retinoblastoma depends on the extent of tumor involvement and the effectiveness of treatment modalities. If the tumors are small and away from the fovea (central portion of the retina with best visual acuity), one may anticipate a good prognosis for vision after successful treatment. [18,21,76]

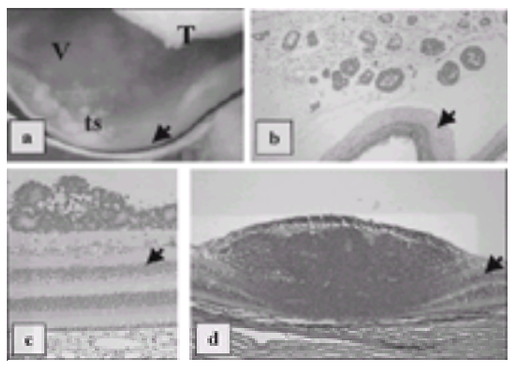

**FIGURE 28-9. A:** Gross photograph showing a primary retinoblastoma tumor (T) with tumor seeds (ts) on the inner retina ( *arrow*) and in the vitreous (Y). **B**: Microphotograph of an area of vitreous tumor seeds. Notice the hollow center of the retinoblastoma seeds. The retina ( *arrow*) is without tumor. (Hematoxylin and eosin; original magnification 10×.) **C:** Microphotograph of a retinoblastoma seed on the inner surface of the retina. Notice the rosette formation of the tumor and the intact architecture of the retina (*arrow*). (Hematoxylin and eosin; original magnification 40×.) **D:** Microphotograph of a retinoblastoma arising from the retina ( *arrow*). Notice the tumor replacing the normal architecture of the retina. (Hematoxylin and eosin; original magnification 20×.)

The survival rate from retinoblastoma has improved dramatically over the last century. One of the first retinoblastoma survival studies was reported in 1897 by Wintersteiner.[179] That 13% survival rate is in sharp contrast to the 90% overall 5-year survival reported by many centers today. [180,181,182 and 183] The main reasons for this improvement are the improved ability to detect retinoblastoma before the onset of metastatic disease and the development of alternative treatment strategies (see Therapeutic Options).

Metastatic disease is still associated with a poor prognosis. Most clinical findings are not useful in predicting the occurrence of metastasis in children with retinoblastoma, although histopathologic data provide a fair estimate of its risk. Multivariate statistical analysis has suggested the correlation of certain histopathologic findings and prognostic risk factors.[182,184,185,186,187 and 188] The most important prognostic indicators for the development of metastasis are the presence of tumor in the optic nerve posterior to the lamina cribrosa at the site of surgical transection and extrascleral extension of tumor into the orbit. [104,125,126,129,175,182,184,188,189,190,191,192,193,194 and 195] The extent of tumor invasion in the optic nerve correlates with prognosis ( Fig. 28-10). Superficial invasion of the optic disk is associated with a mortality rate of 10%, a rate similar to that seen when the optic nerve is not involved. The presence of tumor up to the lamina cribrosa is associated with a mortality rate of 29%. Invasion of tumor posterior to the lamina cribrosa is associated with a mortality rate of 42%, whereas the presence of tumor at the transected surgical margin is associated with a mortality of 80%.[125,175,182,184,188,196] The importance of obtaining a large portion of optic nerve at the time of enucleation is underscored by these results. Specific studies related to the length of the optic nerve stump alone show that patients with the optic nerve measuring less than 5 mm in the enucleated eye have a worse prognosis than those having stumps longer than 5 mm.[182,188,192,197,198]

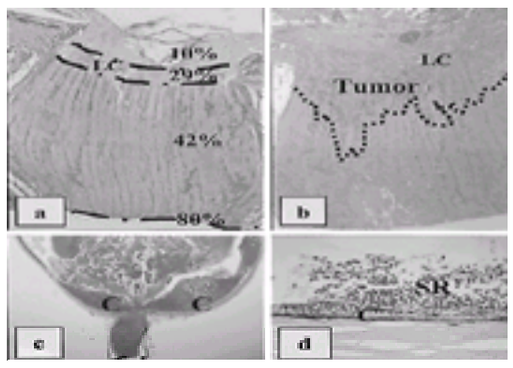

**FIGURE 28-10. A:** Microphotograph of a normal optic nerve showing the prognostic percentages of survival of patients with invasion of the optic nerve by anatomic portions of the nerve. Patients with tumors invading the pre–lamina cribrosa have a 10% mortality rate similar to that seen without invasion of the nerve. Invasion into the lamina cribrosa (LC; *between the two dotted lines*) carries a 29% mortality rate, and invasion beyond the lamina cribrosa carries a 42% mortality rate. Patients with tumors that are present at the surgical margin of resection (*single dotted line*) have an 80% mortality rate. (Myelin stain; original magnification 10×.) **B:** Microphotograph of an optic nerve showing tumor invasion beyond the lamina cribrosa (LC) but not at the surgical margin of resection. (Hematoxylin and eosin; original magnification 10×.) **C:** Microphotograph of the posterior pole and optic nerve of an eye with massive involvement of the choroid (C) and optic nerve by tumor. Notice that retinoblastoma tumor is present at the surgical margin of resection of the optic nerve ( *single dotted line*). (Hematoxylin and eosin; original magnification 4×.) **D:** Microphotograph of the subretinal space (SR) and choroid (C) of an eye with retinoblastoma with focal involvement of the subretinal space and minimal involvement of the choroid. (Hematoxylin and eosin; original magnification 20×.)

Massive, but not focal, invasion of the choroid by tumor increases the possibility for hematogenous spread, either through vascular permeation of choroidal vessels or, more frequently, by extension through the sclera into the orbital tissues ( Fig. 28-10).[125,182,187,189] MRI studies are helpful in evaluating the extent of involvement of choroid or optic nerve by tumor.[113]

Retinoblastomas that are poorly differentiated tend to behave more aggressively and are associated with a worse prognosis. Other factors associated with some risk for metastatic behavior, especially in conjunction with the major factors cited above, are tumor invasion into the anterior chamber and large tumor size with vitreous seeding, rubeosis iridis, and glaucoma.

## THERAPEUTIC OPTIONS

The management of retinoblastoma is complex. The diagnosis and treatment of patients with retinoblastoma involve a team approach requiring pediatric oncologists, ophthalmologists, and radiologists skilled in the treatment of patients with retinoblastoma. An important team role is also filled by child psychologists, social workers, nurses, and genetic counselors who can support families dealing with the difficulties of caring for a child who not only has cancer but also may lose an eye and vision. The goals of treatment are, most important, to save the child's life and, secondly, to salvage the eye or vision. Therapy is tailored to each individual case and is based on the overall situation, including threat of metastatic disease, risks for second cancers, systemic status, laterality of the disease, size and location of the tumor(s), and visual prognosis. There are several medical and surgical options for treatment of retinoblastoma, and the ocular oncologist should be thoroughly familiar with the indications, techniques, and expected results, as well as the associated systemic and visual problems of all treatment methods. [199] The currently available treatment methods for retinoblastoma include enucleation, external beam radiotherapy, plaque radiotherapy, laser photocoagulation, cryotherapy, thermotherapy, chemothermotherapy, intravenous chemoreduction, subconjunctival chemoreduction, systemic chemotherapy for possible metastatic disease, and orbital exenteration.

### Enucleation

Enucleation is still the treatment of choice for advanced retinoblastoma with concern of tumor invasion into the optic nerve, choroid, or orbit and no hope for salvage of useful vision in the affected eye. Those eyes with secondary glaucoma, pars plana seeding, or anterior chamber invasion are also generally best managed with enucleation.

In the past, most children with unilateral retinoblastoma were managed with enucleation. Those patients with bilateral retinoblastoma usually had the most advanced eye treated with enucleation and the less advanced eye treated with external beam radiotherapy. [200] This management philosophy has been gradually modified with the advent of newer, more conservative but effective methods.[201,202] and [203] There has been a substantial decrease in the frequency of enucleation over recent decades.[204] In a review of 324 consecutive cases of retinoblastoma managed on the Oncology Service at Wills Eye Hospital from 1974 to 1988, Shields and coworkers[204] found that unilateral retinoblastoma was managed with enucleation in 96% of cases from 1974 to 1978, in 86% of cases from 1979 to 1983, and in 75% of cases from 1984 to 1988. A similar decreasing trend was found with bilateral retinoblastoma. [204] The frequency of enucleation is even lower today.

Enucleation involves the gentle removal of the intact eye without seeding the malignancy into the orbit. Special care must be taken to perform all steps in a controlled fashion to avoid globe perforation or compression. Shields and Shields [200] and Shields and colleagues[205,206] have described the surgical technique for enucleation of an eye with retinoblastoma. Because the underlying sclera is thin at the site of muscle insertions, the rectus muscles are handled delicately when the hook is placed flat along the sclera. At the time of optic nerve cutting, scleral or muscle insertion traction sutures are avoided to prevent inadvertent globe perforation. Mild traction with a hemostat on the medial rectus muscle stump is used to lift the globe cautiously to avoid inadvertent lamellar rip of the sclera and cornea, which could threaten the integrity of the eye. Optic nerve snares or clamps should be avoided because they induce more vigorous trauma to the eye and can produce crush artifact in the optic nerve. This artifact can cause difficulty for the pathologist assessing the possibility of retinoblastoma invasion of the optic nerve. The use of minimally curved enucleation scissors is preferred to achieve a long optic nerve section ( Fig. 28-11).

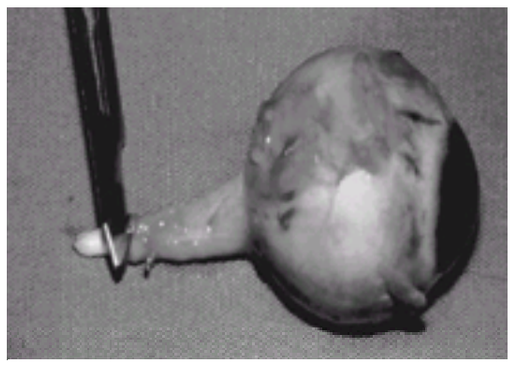

**FIGURE 28-11.** Enucleation and fresh tissue harvesting. A long section of optic nerve is obtained with the globe at enucleation of an eye with retinoblastoma. The posterior aspect of the optic nerve is cut and submitted to pathology separately for analysis of optic nerve invasion.

Historically, an orbital implant was not usually placed after enucleation for retinoblastoma because of potential interference with palpation of the socket and clinical detection of orbital tumor recurrence. More recently, with improved knowledge of the behavior of retinoblastoma and the risks of local orbital recurrence, there is less hesitation for placing an orbital implant. Available orbital imaging modalities, including CT and MRI, allow detailed orbital analysis despite the presence of an implant. The orbital implant provides a more natural cosmetic appearance of the patient's artificial eye, minimizes sinking of the prosthesis, and enables motility of the prosthesis. Orbital implants made of polymethylmethacrylate sphere, coralline hydroxyapatite, bovine hydroxyapatite, or polyethylene are commonly used. [205,207] A tissue wrap is usually provided to these implants so that the four rectus muscles can be anatomically reattached to the implant and provide implant motility with little

resistance in the orbit. Available tissue wraps are many and include povidone iodine-treated human sclera, irradiated human sclera, bovine pericardium, fascia lata, and polyglactin 910 (Vicryl) mesh, among others. The motility implant, when properly placed surgically, has been shown to be well tolerated by children and adults.[205,206,208]

### External Beam Radiotherapy

Retinoblastoma is generally a radiosensitive tumor. External beam radiotherapy is a method of delivering whole-eye irradiation to treat advanced retinoblastoma, particularly when there is diffuse vitreous seeding. The whole-eye and lens-sparing techniques used currently have been shown to improve the eye preservation rate as compared to reported older techniques. The rate of ocular salvage depends on the Reese-Ellsworth stage of the disease at the time of treatment as well as on the availability of focal therapy for limited recurrences. [209,210] Recurrence of retinoblastoma after external beam radiotherapy continues to be a problem and can develop within the first 1 to 4 years after treatment.[211] Tumor recurrence in other studies has also been found to be related to the stage of the disease and to the largest tumor size at the time of treatment.[211,212,213] and [214] Prophylactic radiotherapy to a normal contralateral eye is almost never indicated today. [215]

Little has been written on the visual outcome after external beam radiotherapy for retinoblastoma. Radiation damage to the retina, optic nerve, and lens can be challenging to manage.[216] Patients with macular retinoblastoma have visual outcomes that are dependent on the size of the tumor and the degree of involvement of the fovea.[217] Superimposed amblyopia can pose a problem, and patching therapy should be used if hope for vision remains.

External beam radiotherapy may induce a second cancer in the field of irradiation. The 30-year cumulative incidence for second cancers in bilateral retinoblastoma has been reported to be 35% for patients who received radiation therapy, compared to 6% for those who did not receive radiation. [218] Overall, the cumulative probability of death from second primary neoplasms was reported at 26% at 40 years after bilateral retinoblastoma diagnosis. External beam radiotherapy has been reported to further increase the risk of mortality from second neoplasms. [42] Abramson and Frank[219] found that external beam radiotherapy increased the incidence of second cancers in the field of radiation but did not stimulate second cancers outside the field of irradiation. In their series, patients younger than 12 months were more likely to develop second malignancies after external beam radiotherapy than patients older than 12 months. [219]

### Plaque Radiotherapy

Plaque radiotherapy is a form of brachytherapy in which a radioactive implant is placed on the sclera over the base of a retinoblastoma with the intent of irradiating the tumor transsclerally. The use of plaque radiotherapy is limited to tumors less than 16 mm in base and 8 mm in thickness. Effective treatment requires an average of 2 to 4 days of treatment time to deliver the total dose of 4,000 cGy to the apex of the tumor. Plaque radiotherapy can be used as either a primary treatment or a secondary treatment (Fig. 28-12).[220,221,222] and [223] In 70% of cases, plaque radiotherapy is used as a secondary treatment to salvage a globe after failure of prior treatment, usually failed external beam radiotherapy or chemotherapy. [200,201,202,203,204,205,206,207,208,209,210,211,212,213,214,215,216,217,218,219,220,221,222] and [223] In one series, solitary plaque radiotherapy was used in 91 cases of recurrent or residual retinoblastoma in which the only other option was enucleation. [223] Tumor control and globe salvage were achieved in nearly 90% of these eyes.[223]

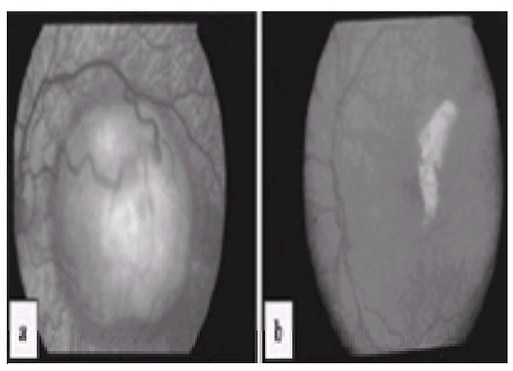

**FIGURE 28-12.** Plaque radiotherapy. **A:** Macular retinoblastoma before plaque radiotherapy. **B:** Regressed retinoblastoma after plaque radiotherapy.

Overall there is nearly a 90% tumor control rate with one application of plaque radiotherapy. [224] Carefully selected retinoblastomas, even juxtapapillary and macular tumors, can be successfully treated with plaque radiotherapy. The visual outcome for the patient varies with tumor size and location as well as associated radiation toxicity, which can include retinopathy or papillopathy. Positive visual outcomes have been reported in 62% of patients; the measured vision was 20/20 to 20/30 in more than one-half of the cases.[220] Radiation retinopathy and papillopathy become clinically manifest at approximately 18 months after irradiation, and these complications are more prominent in children who have been exposed to systemic chemotherapy. In an effort to avoid these problems with chemotherapy-treated patients, the tumor apex dose has been decreased to 3,500 cGy, and radiation plaque therapy is delayed for at least 1 month after the child has discontinued chemotherapy. Innovations with custom design of plaques, especially those for small tumor recurrences, have also assisted in avoiding radiation retinopathy. Because of the use of focal, shielded radiation fields, plaque radiotherapy has not yet been found to be associated with induction of second cancers.

### Laser Photocoagulation

Laser photocoagulation can be used to treat small posterior retinoblastomas using argon laser, diode laser, or xenon arc photocoagulation. Because the tumor size is important to the successful use of this treatment, tumors 4.5 mm or less in base and 2.5 mm or less in thickness with no evidence of vitreous seeds are usually selected.[225,226] The treatment is directed to delimit the tumor and specifically coagulate all blood supply to the tumor. Two or three sessions at 1-month intervals are usually adequate to control most tumors. Use of the indirect ophthalmoscope laser photocoagulation system has greatly improved the facility of laser delivery. [227] With laser treatment of properly selected cases of retinoblastoma, a 70% tumor control rate can be achieved. Recurrences are often treated with plaque radiotherapy. Complications of treatment include transient serous retinal detachment, visually significant retinal vascular occlusion, retinal traction, retinal hole, and preretinal fibrosis.

### Cryotherapy

Cryotherapy is useful for managing equatorial and peripheral small retinoblastomas and is most successful if limited to tumors measuring 3.5 mm or less in diameter and 2.0 mm or less in thickness.[228] Tumor destruction is usually achieved with one or two sessions of triple freeze-thaw cryotherapy at 1-month intervals. Cryotherapy will usually fail if there are overlying vitreous seeds. In these failed cases, plaque radiotherapy is usually used. Complications of cryotherapy include transient serous retinal detachment, retinal tear, localized preretinal fibrosis, and rhegmatogenous retinal detachment. [229]

### Thermotherapy and Chemothermotherapy

Thermotherapy uses ultrasound, microwaves, or infrared radiation to deliver heat to the eye. The heat can be delivered to the whole eye with an attempt to spare the anterior segment,[230] or the heat can be focused on one portion of the eye. The goal is to achieve a temperature of 42 $^{o}$ to 60$^{o}$C, a temperature that is below the coagulative threshold and therefore spares the retinal vessels of photocoagulation. The combination of heat and chemotherapy is termed *chemothermotherapy*, and the combination of heat and radiation is termed *thermoradiotherapy*. Heat has been found to have a synergistic effect with both chemotherapy and radiation therapy for the treatment of systemic and ocular cancers.[231,232]

The selection of the modality of thermotherapy or chemothermotherapy depends on many factors, including tumor size, location, laterality, status of the opposite eye, presence of subretinal fluid and seeds, presence of vitreous seeds, and prior or ongoing chemoreduction. Thermotherapy alone can often be used to effectively treat small retinoblastomas, outside the retinal vascular arcades, measuring 3 mm or less in size without vitreous or subretinal seeds. Thermotherapy alone without chemotherapy may be appropriate. The addition of other factors, such as larger tumors or seeds, often necessitates chemotherapy combined with thermotherapy for

best tumor control.

When using thermotherapy alone, the goal is to heat the tumor to 45 $^{o}$ to 60$^{o}$C, which would leave a gray-white scar at the site. In general, small tumors require approximately 300 MW power for 10 minutes or less, repeated for three times at 1-month intervals ( Fig. 28-13). Tractional and vasoocclusive complications can occur within the retina due to the prolonged heating. When employing chemothermotherapy, the goal is to heat the tumor to 42 $^{o}$ to 45$^{o}$C for 5 to 20 minutes depending on the tumor size and location. Tumors up to 15 mm in base can be adequately treated with chemothermotherapy, especially if the patient is receiving three-agent chemoreduction. The result from chemothermotherapy is a light gray scar with less risk for tractional and retinal vascular problems than is found with thermotherapy alone.[231]

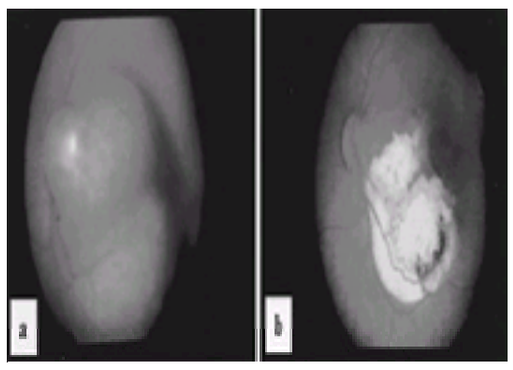

**FIGURE 28-13.** Chemoreduction and chemothermotherapy. **A:** Large macular retinoblastoma overhanging the optic disk. **B:** After chemoreduction and chemothermotherapy, the tumor has regressed to a calcified regressed scar.

There are several different chemothermotherapy protocols, each of which varies in chemotherapeutic agents and methods of delivery. Kaneko and coworkers [276] reported preliminary results using systemic and superselective ophthalmic artery injection of chemotherapy combined with thermotherapy. Murphree and Munier [233] have used a specific protocol of intravenous carboplatin tightly coupled with thermotherapy. Shields and associates [231,234,235 and 236] coupled thermotherapy within 4 hours of a chemoreduction regimen, thereby achieving the benefit of chemotherapy for both tumor reduction and consolidation. This method was more practical for those children with large or multiple tumors simultaneously on a chemoreduction protocol ( Fig. 28-13). If a child is receiving chemoreduction, thermotherapy for tumor consolidation is generally initiated at cycle two or three of the chemoreduction protocol. Thermotherapy is repeated as necessary at each of the remaining chemoreduction cycles until six cycles are completed. Using this method for 188 retinoblastomas, complete tumor control in 86% of the tumors has been achieved. [231] Success of this combined therapy is dependent on careful identification of suitable tumors. Smaller tumors without subretinal fluid or tumor seeds show the best response. In a recent study on the use of thermotherapy and chemothermotherapy for retinoblastoma, tumors less than 3 mm in base responded best with complete control and few complications.[231] Tumors greater than 6 mm in base are at increased risk for recurrence of the main tumor or associated seeds and often require plaque radiotherapy.

The main complication of thermotherapy is focal iris atrophy related to heat effects on the pigmented iris tissue. [231] In some instances, the lens develops a focal paraxial opacity. Chemothermotherapy is especially suited for small tumors adjacent to the fovea and optic nerve in which radiation or laser photocoagulation would possibly induce more profound visual loss. This treatment modality is a time-consuming, tedious process that requires careful observations, recordings, judgments, and treatment adjustments in response to subtle tumor changes.

### Intravenous Chemoreduction for Intraocular Retinoblastoma

Until recently, chemotherapy played only a minor role in the treatment of retinoblastoma. Chemotherapy was only used for patients in whom the disease had spread into the choroid, optic nerve or orbit, or to distant extraocular sites. In the past few years, considerable experience has been gained in the use of chemotherapy for patients with intraocular retinoblastoma involving only the retina. The main objective of the ongoing clinical trials using chemotherapy in localized intraocular retinoblastoma has been to reduce the size of the tumors to an extent that would allow a variety of local surgical modalities such as laser photocoagulation, cryotherapy, or thermotherapy to control the residual disease. Successful management using chemotherapy in combination with local surgical methods can eliminate the use of external beam radiotherapy and, therefore, reduce significantly the risk of development of secondary malignancies and abnormalities of growth of orbital and facial bones associated with radiotherapy.[219,237,238 and 239]

The indications for chemoreduction in intraocular retinoblastoma are not clearly established. The goal of preserving vision in at least one eye while curing children with retinoblastoma makes patients with bilateral retinoblastoma the initial focal point for this form of therapy. A pilot study involving 40 eyes in 31 patients with bilateral disease who were treated with vincristine, teniposide, and carboplatin combined with cyclosporine resulted in a relapse-free rate of 89% in patients who were not previously treated.[240] Relapse in this study was defined as tumor progression requiring either radiotherapy or enucleation. The median follow-up at the time of this report was 2.7 years. In another study of 20 patients who had 54 tumors in 31 eyes, a 2-month chemoreduction program with vincristine, carboplatin, and etoposide was followed by local treatment methods.[241] Enucleation was avoided in all and external beam radiation therapy was necessary in only nine eyes because of diffuse vitreous seeds. Before therapy, the mean tumor base was 12 mm and the thickness 7 mm. Vitreous seeds were present in 14 eyes. After the 2-month chemotherapy regimen, there was no evidence of residual viable tumor in 25 of 54 tumors. There was a mean decrease of 35% in tumor base and nearly 50% decrease in tumor thickness, with resolution of subretinal fluid in 76% of cases. In the 14 eyes that had vitreal seeds, however, only 5 showed 90% to 100% calcification, indicating that different therapeutic modalities must be developed for the treatment of vitreous seeds.

### Chemotherapy for Possible Metastatic Disease

The treatment strategy for patients with intraocular retinoblastoma and extraretinal spread has not been conclusively studied. This includes patients with pathologic evidence of disease with extensive choroidal involvement, evidence of disease extending to the sclera, or disease extending beyond the lamina cribrosa but not yet involving the cut end of the optic nerve. There are conflicting reports about the significance of choroidal invasion. Kopelman and colleagues [242] reported that choroidal invasion was not significantly associated with a fatal outcome. Messmer and colleagues [243] reported that choroidal invasion was a low-risk factor and was not clinically significant when it was the only risk factor. The clinical significance increased considerably when choroidal invasion occurred in combination with other risk factors, such as postlaminar optic nerve involvement, involvement of the optic nerve to the transection line, and late enucleation. Shields and coworkers [244] reported that patients with choroidal invasion with any optic nerve invasion were at high risk for the development of metastases. However, in those patients with choroidal invasion alone the risk for metastases was insignificant. In this study choroidal invasion was not classified as to extent of invasion, although others have reported that the degree of choroidal invasion assessed subjectively was an accurate predictor of survival. [245] In the above studies, some of the patients with choroid invasion with or without optic nerve invasion received radiotherapy, chemotherapy, or both, further clouding the interpretation of true metastatic potential of these risk factors. If significant choroidal invasion is present in the absence of optic nerve invasion, prophylactic adjuvant therapy may be considered. When extensive choroidal invasion is present in combination with optic nerve invasion beyond the lamina cribrosa, prophylactic adjuvant therapy is indicated.

Various chemotherapy regimens have been used for significant deep choroidal, optic nerve, ciliary body, or iris involvement. The combination of cyclophosphamide and doxorubicin has been used.[246] Carboplatin, vincristine, and etoposide for 6 to 18 months has also been recommended. [247,248] Recent retrospective studies suggest that prophylactic chemotherapy in patients with retinoblastoma with some of the above high-risk features can minimize the risk of metastases. [249] There are no randomized studies to recommend a particular regimen, just as there are no randomized studies to identify specific criteria in patients with intraocular retinoblastoma with extraretinal extension who would benefit from chemotherapy.

### Combined Radiotherapy and Chemotherapy

In three separate studies, patients presenting with Reese-Ellsworth eye group V retinoblastoma treated with radiotherapy alone have had 10%, 29%, and 66% of their eyes salvaged.[209,214,250] In patients with bilateral retinoblastoma Reese-Ellsworth eye group V, Kingston and colleagues [251] have shown that two cycles of

chemotherapy in addition to external beam radiation therapy can preserve 70% of the eyes treated (14 of 20 eyes) with a median follow-up of 60 months. The study reporting a 66% salvage rate with radiotherapy alone and the study using chemotherapy in addition to radiotherapy were performed at the same institution; however, the patients in the latter study were reportedly more severely affected. Taken together these data suggest that, for patients with retinoblastoma group V disease, the combination of chemotherapy with external beam radiotherapy may result in a salvage rate superior to that with radiotherapy alone. In a recent study with a median follow-up of 13 months, chemotherapy alone consisting of six cycles of carboplatin, vincristine, and etoposide resulted in the salvage of only 50% of the eyes with groups IV and V disease without requiring external beam radiotherapy or enucleation. [248] In the same study, chemotherapy eliminated the need for external beam radiotherapy or enucleation in all 39 eyes with groups I, II, and III disease ( Table 28-2).

| Reese-Ellsworth Group | EBRT alone (%) Ellsworth[204] (1963–1972) | EBRT + salvage treatment (%) Hungerford[209] (1970–1985) | Chemoreduction[a] + adjuvant treatment[b] (%) Shields[203] (1994–1998) |
|---|---|---|---|
| I | 91 | 100 | 100 |
| II | 83 | 64 | 100 |
| III | 82 | 82 | 100 |
| IV | 62 | 43 | 100 |
| V | 29 | 66 | 78 |

[b]Laser photocoagulation, cryotherapy, thermotherapy, chemothermotherapy, plaque radiotherapy, EBRT.
[c]Vincristine, 1.5 mg/m² (0.05 mg/kg for children aged ≤36 mo and maximum dose ≤2 mg).
[d]Etoposide, 150 mg/m² (5 mg/kg for children aged ≤36 mo).
[e]Carboplatin, 560 mg/m² (18.6 mg/kg for children aged ≤36 mo).

**TABLE 28-2. PERCENTAGE OF GLOBES SALVAGED USING EXTERNAL BEAM RADIOTHERAPY ALONE, EXTERNAL BEAM RADIOTHERAPY AND SALVAGE TREATMENT, AND CHEMOREDUCTION AND FOCAL ADJUVANT TREATMENT**

From the above data it is clear that chemoreduction is an effective initial measure for selected children with intraocular retinoblastoma. Retinal tumor and seed recurrence remain a worrisome problem with chemoreduction, however.[203] Seeds in the vitreous or subretinal space can recur in approximately 30% of eyes and enlarge to a visual and life threatening state. Chemotherapy regimens used have included carboplatin, etoposide, and vincristine. Cyclosporine has been used with the above regimen in an attempt to improve results by reversing multidrug resistance. [252,253] Use of chemotherapy is not without concern, especially in patients with bilateral retinoblastoma who have a higher incidence of second malignancies. The use of etoposide, an epipodophyllotoxin, has been associated with second malignancies in patients with leukemia and non-Hodgkin's lymphoma. However, the schedule and the cumulative dose of etoposide used in most of the treatment regimens for retinoblastoma are different from those implicated in the incidence of second malignancies. [254] Other side effects of concern are transient bone marrow suppression with a risk for infection.

### Treatment of Systemic Retinoblastoma

Treatment of extraocular retinoblastoma requires a combined therapeutic approach using both chemotherapy and radiotherapy. Scleral involvement, orbital or bony involvement, involvement beyond the cut end of the optic nerve, metastatic disease involving brain or other sites, and trilateral retinoblastoma all require such an aggressive combined therapeutic approach. Central nervous system involvement generally carries a poor prognosis.

Many different agents have been used to treat systemic retinoblastoma. One regimen used is the three-drug regimen including vincristine, carboplatin, and etoposide, similar to the chemoreduction regimen mentioned above but with a much longer course of 6 to 18 months, depending on the clinical response. [203,241] Others have found favorable results with similar chemotherapy regimens for extraocular retinoblastoma. [255,256,257,258] and [259] White[260] has reported on chemotherapy for retinoblastoma and recently advocated cyclophosphamide, etoposide, and vincristine as well as the support of peripheral stem cell rescue in multiple sequential courses for metastatic retinoblastoma.

### Orbital Exenteration

Orbital exenteration is rarely used for retinoblastoma management in the United States, as most retinoblastoma patients present with no evidence of extraocular invasion.[261] Exenteration is most often used for orbital recurrence after the child has received a maximum acceptable dose of irradiation and chemotherapy. In other countries, patients may present with more advanced retinoblastoma, including orbital involvement. For these patients, exenteration, chemotherapy, and external beam radiotherapy are crucial for survival. Use of more advanced exenteration techniques, such as the eyelid-sparing exenteration, allows for rapid healing of the wound. [262]

### Trilateral Retinoblastoma

*Trilateral retinoblastoma* is a term to describe the association of bilateral retinoblastoma and neuroblastic tumor in the pineal gland or other midline structures. A report from de Potter and coworkers[263] revealed that this tumor occurs in children aged 4 years of age or younger. MRI or CT is essential to the diagnosis. The disease is highly fatal despite aggressive treatment with chemotherapy, radiation therapy, and gamma knife therapy. Longer survival has been correlated with earlier tumor diagnosis in asymptomatic patients. Trilateral retinoblastoma is a major cause of mortality in children within the first 5 years after diagnosis of bilateral retinoblastoma.[264] No case of pinealoblastoma was observed in 147 children treated with initial chemoreduction who were followed for 1 to 4 years. Although follow-up is limited, it is tempting to speculate that chemoreduction may reduce the risk for development of pinealoblastoma. [265]

## HISTOPATHOLOGIC CHANGES ASSOCIATED WITH TREATMENT

Enucleation of eyes from patients with retinoblastoma treated with different modalities that either do not eradicate the tumor or result in major treatment complications allows the study of effects of therapy on the tumor and the ocular structures. Clinically, three types of regression patterns have been described in tumors that have undergone treatment: type 1 (cottage cheese), type 2 (fish flesh) or type 3 (combined).

In one study, five patients with sporadic bilateral retinoblastoma underwent planned enucleation of their functionally blind eye after two, three (in two patients), four, and six courses of primary chemotherapy with carboplatin, etoposide, cyclophosphamide, and vincristine. The eyes were examined histopathologically, using light microscopy and immunohistochemical analysis with proliferation markers. One patient had a type 1 (cottage cheese) regression and four patients had either a type 2 (fish flesh) or a type 3 (combined) regression pattern. Histopathologic examination revealed complete tumor necrosis with calcification ( Fig. 28-14) in one patient with type 1 regression after three courses of chemotherapy and in one patient with type 3 regression after four courses of chemotherapy. The remaining three patients with type 2 or type 3 regression had histological evidence of actively proliferating tumor cells after two, three, and six courses of chemotherapy. This report confirms histopathologically the clinically described efficacy of primary chemotherapy in the treatment of retinoblastoma. The necessity of careful observation and the use of ancillary treatment whenever there is not complete tumor regression (type 2 and 3 regression patterns) is, however, underscored. [266] In another study, photoreceptor differentiation was observed in 17 of 42 enucleated eyes containing viable tumor following radiotherapy. Complications of external beam radiation include massive necrosis of the retina with associated hemorrhage (Fig. 28-14). Patients with retinoblastoma that have undergone chemotherapy and radiotherapy sometimes are left with tumors with large areas of fossilized cells and calcification with areas of photoreceptor differentiation similar to retinocytoma. Whether these cases represent chemotherapy or radiotherapy resistance of a focus of retinocytoma or differentiation induced by treatment has not been elucidated. [267]

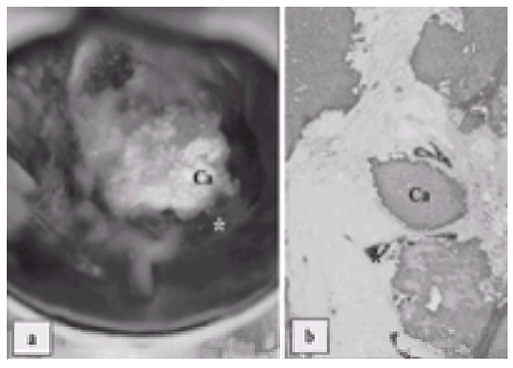

**FIGURE 28-14. A:** Gross photograph of an autopsy eye in a patient with regressed retinoblastoma for more than 6 years after chemotherapy and radiotherapy. The patient died of complications of chemotherapy (cardiomyopathy). Notice the cottage cheese appearance (type 1 regression pattern) of the calcified (Ca) tumor associated with proliferation of retinal pigment epithelium ( *asterisk*). **B:** Microscopic photograph of the same eye as **(A)** showing the calcified tumor (Ca), proliferation of retinal pigment epithelium (*asterisk*), and admixed glial tissue. (Hematoxylin and eosin; original magnification 20×.)

## FUTURE DIRECTIONS

### Subconjunctival Chemoreduction for Intraocular Retinoblastoma

To avoid the toxicity of systemic administration of chemotherapy, there is increasing interest in local delivery of these drugs to achieve chemoreduction for intraocular retinoblastoma. Studies in animal models show that carboplatin penetrates the sclera into the vitreous cavity, allowing for effective dosages within the eye with minimal toxicity.[268,269 and 270] Local subconjunctival injection of carboplatin under protocol in humans as both a secondary and a primary treatment have been used [271] (C.L. Shields and J.A. Shields, *unpublished data*). Within 3 to 4 weeks, tumor regression is usually noted, but the response may not be long term. Further investigations are necessary to determine the efficacy of local application of chemotherapy.

### Chemotherapy to Prevent and Treat Metastases

The development of innovative modalities in the treatment of retinoblastoma has been hampered by the lack of suitable animal models of this uniquely human disease. Recently murine models of retinoblastoma using human xenografts in the vitreal space that mimic both metastatic and nonmetastatic disease [272] as well as transgenic mouse models of retinoblastoma[273] have been developed. These newer animal models will aid in the testing of new therapeutic approaches to retinoblastoma.

### Gene Therapy

An alternative approach to local chemoreduction without the side effects of systemic chemotherapy is gene therapy. One form of gene therapy, *suicide gene therapy*, uses the delivery of the herpes simplex thymidine kinase gene by a replication-defective adenoviral vector injected directly into the tumor. Ganciclovir, a nucleoside analog, is then administered intravenously to the patients. The expressed thymidine kinase phosphorylates the ganciclovir within the tumor cells. The resulting nucleotide analog is a potent inhibitor of DNA synthesis and causes the death of the dividing tumor cells. Nondividing cells are unaffected. The safety of this form of suicide gene therapy has been demonstrated in patients with brain tumors.[274] Effective reduction of retinoblastoma tumors in a mouse model of the disease has also recently been demonstrated.[275] A phase I clinical trial has been approved and is currently testing the safety of this approach in children with retinoblastoma.

### International Cooperative Studies

Because retinoblastoma is a very rare disease, clinical trials addressing basic diagnostic and therapeutic questions are very difficult to perform. Recently, the American College of Surgeons Oncology Group and the Children's Oncology Goup have formed Retinoblastoma Study Groups to address therapeutic questions concerning the treatment of retinoblastoma.

## ACKNOWLEDGMENTS

The authors thank Janice Gant for her assistance in preparing the manuscript. Support for this chapter was obtained from the National Eye Institute, the Foundation for Research, the Retina Research Foundation, the Moran Foundation, and Knights Templar, Inc.

# TUMORS OF THE LIVER

GAIL E. TOMLINSON
MILTON J. FINEGOLD

## EPIDEMIOLOGY

Of all liver masses in children, approximately two-thirds are malignant. Malignant liver tumors account for approximately 1.1% of all childhood tumors according to the Surveillance, Epidemiology, and End Results (SEER) program cancer registries, with an annual incidence rate of 1.5 cases per million children younger than 15 years.[1] From these data, it has been calculated that approximately 100 to 150 new cases of liver cancer in children develop in the United States each year. Of the malignant liver tumors of childhood, hepatoblastoma accounts for approximately two-thirds. A listing of the various types of hepatic tumors, both benign and malignant, along with the typical ages of presentation is shown in Table 29-1. Eleven separate series totaling 1,256 primary benign and malignant liver tumors in children were reviewed in Weinberg and Finegold,[2] and of these, 43% were hepatoblastoma, 23% hepatocellular carcinoma (HCC), 13% benign vascular tumors, 6% mesenchymal hamartomas, 6% sarcomas, 2% adenomas, 2% focal nodular hyperplasia, and 5% other tumors. Although the salient features of the less common forms of liver cancer in children are discussed briefly, this chapter focuses primarily on hepatoblastoma and HCC, which together account for the majority of malignant liver tumors in children.

| Age | Benign | Malignant |
|---|---|---|
| Infancy (0–1 yr) | Hemangioendothelioma<br>Mesenchymal hamartoma<br>Teratoma | Hepatoblastoma, especially small cell undifferentiated<br>Rhabdoid tumor<br>Yolk sac tumor<br>Langerhans' cell histiocytosis<br>Megakaryoblastic leukemia<br>Disseminated neuroblastoma |
| Early childhood (1–3 yr) | Hemangioendothelioma<br>Mesenchymal hamartoma<br>Inflammatory myofibroblastic tumor | Hepatoblastoma<br>Rhabdomyosarcoma |
| Later childhood (3–10 yr) | Angiomyolipoma | HCC<br>Embryonal sarcoma (undifferentiated)<br>Angiosarcoma |
| Adolescence (10–15 yr) | Adenoma<br>Biliary cystadenoma | Fibrolamellar HCC<br>Hodgkin's disease/lymphoma<br>Leiomyosarcoma |

HCC, hepatocellular carcinoma.

**TABLE 29-1. NEOPLASIA OF THE LIVER IN CHILDREN ACCORDING TO USUAL AGE OF PRESENTATION**

Most cases of hepatoblastoma occur in infants or very young children. The observed incidence rate of malignant liver tumors in infancy is 11.2 per million and decreases throughout childhood.[1] In a recent Pediatric Oncology Group (POG) series of 106 hepatoblastomas accrued on biologic studies, the mean age of diagnosis was 19 months and the median age was 16 months, consistent with that of previous reports.[3,4] Only 5% of cases occurred in children older than 4 years of age. Hepatoblastoma has been reported in adults, although this is rare. [5,6] Hepatoblastoma is more common in males with a reported male to female ratio of 1.4:1.0 to 2.0:1.0.[2,3 and 4]

HCC occurs primarily after age 10 years and is the most common hepatic malignancy of adolescence. The clearest pathogenetic factor is hepatitis B virus. When hepatitis B infection is acquired after the prenatal period, it may take 20 years to demonstrate its carcinogenic effect; however, perinatally acquired hepatitis B virus has been associated with hepatocarcinoma in very young. [7] Similar to hepatoblastoma, HCC demonstrates a male predominance, except for the fibrolamellar variant, which is seen in equal frequency in males and females.[8,9 and 10] Occasionally, malignant tumors are seen that have features of both hepatoblastoma and HCC ( Fig. 29-1). There are several suggestions that the incidence of liver tumors in children is increasing in the United States; this is discussed in more detail below.

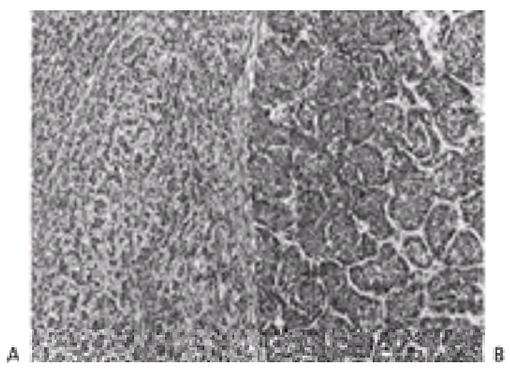

**FIGURE 29-1.** Composite tumor from a 15-year-old with perinatally acquired hepatitis B infection. Well-differentiated fetal hepatoblastoma is present in **(A)** and a macrotrabecular hepatocarcinoma in **(B)**. Hepatitis B core antigen was abundant in the hepatoblastoma and in the nontumoral hepatocytes affected by chronic hepatitis. Only the carcinoma was positive for a-fetoprotein.

In the Far Eastern regions of the world, the incidence of liver cancer has historically been higher than that in the United States. The International Agency for Research on Cancer reported that during the 1970s the incidence of liver cancer in Hong Kong, Shanghai, Taiwan, and Fiji was 4.0 per million children younger than 15 years; this was tenfold higher than in western countries, primarily due to the high carrier rate for hepatitis B in these countries. [11] In Taiwan in 1988, 80% of primary liver tumors in children were reported to be HCC.[12]

During the past two decades, data from several sources have suggested an increase in the number of cases of hepatoblastoma. The SEER data reveal an average 5% annual percent increase in the incidence of hepatoblastoma from 1972 to 1992. [13] In the period from 1979 to 1981, liver cancers represented 2% of all cancers in

infants younger than 1 year, whereas a decade later, liver cancers represented 4% of all cancers in infants. [14] The Manchester, England, Tumor Registry observed an increased incidence of hepatoblastoma from 0.4 to 1.0 per million.[11] The SEER data have also revealed a significant increase in the incidence of HCC in the overall population, including both children and adults, from the period 1991 to 1995 compared to 1976 to 1990. [15] This is in contrast to a marked decrease in the incidence due to the introduction of universal hepatitis B vaccination in Taiwan, in which hepatitis B historically has played a major role in the development of HCC. [16]

Mounting evidence suggests an association of hepatoblastoma with prematurity, which may account for part of the observed increase in hepatoblastoma overall as survival rates have increased among premature infants. Ikeda and colleagues [17,18] observed that in Japan, hepatoblastomas account for 58% of all malignancies occurring in surviving premature infants weighing less than 1,000 g at birth. Further analysis of the Japanese Children's Cancer Registry data revealed that 15 of 303 (5%) hepatoblastomas between 1985 and 1995 occurred in postpremature infants weighing less than 1,500 g. The relative risk for hepatoblastoma increased inversely with birth weight. The relative risk of infants weighing less than 1,000 g at birth was 15.64 compared to 2.53 for infants weighing 1,000 to 1,499 g and 1.21 for infants weighing 2,000 to 2,499 g.[19] These data have implications for the need to determine the specific factors related to prematurity which contribute to hepatic tumorigenesis as well as the need for surveillance of the survivors or extreme prematurity.

## ETIOLOGY

The causes of most liver tumors, similar to other types of childhood cancer, are unknown. Hepatoblastoma occurs in association with several well-described cancer genetic syndromes. HCC often occurs after the development of cirrhosis, which may have both genetic and environmental contributions.

A number of associations have been observed of liver tumors in children with genetic syndromes. These are summarized in Table 29-2. In the absence of a recognizable familial cancer syndrome, hepatoblastoma has been observed in siblings. [20,21 and 22]

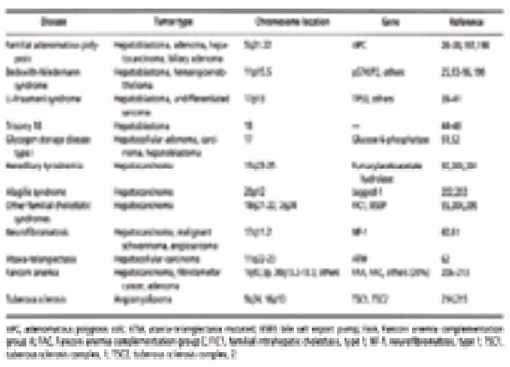

**TABLE 29-2. CONSTITUTIONAL GENETIC SYNDROMES LEADING TO LIVER TUMORS**

Beckwith-Wiedemann syndrome is associated with a risk of embryonal tumors.[23,24] Data recently reported from the National Cancer Institute's Beckwith-Wiedemann support group indicate a relative risk of hepatoblastoma as 2,280, higher than that for other embryonal tumors, including Wilms' tumor. [25] The recognition of physical stigmata of Beckwith-Wiedemann syndrome in an infant should prompt surveillance efforts for detection for embryonal tumors by means of serial abdominal sonography and serum a-fetoprotein (AFP) measurements.

The association of hepatoblastoma with familial adenomatous polyposis (FAP) was first reported by Kingston. [26,27] Several additional reports of case studies and small series have further documented the association of hepatoblastoma and adenomatous polyposis. [28,29,30,31,32 and 33] This syndrome is caused by germline mutation of the adenomatous polyposis coli (APC) gene.[34] Giardiello and colleagues [35] have estimated a relative risk of 800 of hepatoblastoma in children in FAP families compared to the general population risk. There are no definitive differences in age range, histologic type, or outcome in hepatoblastomas associated with FAP. FAP has also been implicated in the pathogenesis of some cases of hepatocellular adenoma, HCC, and fibrolamellar carcinoma, and it has been hypothesized that mutation of the APC may confer a general low-level predisposition to tumorigenesis in the liver dependent on other environmental or developmental factors. [36,37 and 38]

Although liver tumors are not among the tumor types frequently associated with Li-Fraumeni syndrome, two Li-Fraumeni kindreds reported from Japanese series having underlying mutations of the *TP53* gene have a family member with hepatoblastoma.[39,40] In addition, Lack and colleagues [41] reported a case of undifferentiated (embryonal) sarcoma of the liver in a Li-Fraumeni syndrome kindred. Mutation of the *TP53* gene is not, however, thought to be a major contributing factor in sporadic hepatoblastoma.[42,43]

Trisomy 18 has been observed in several patients with hepatoblastoma, one of whom developed multiple primary tumors. [44,45,46,47 and 48] Hepatoblastoma has also been reported in Prader-Willi syndrome.[49]

Almost all cases of hepatoblastoma, even those that occur in association with predisposition syndromes, occur in the setting of normal hepatic function and histology. HCC, except for the fibrolamellar variant, occurs in various syndromes that produce cirrhosis or other chronic damage to the liver parenchyma.

Children with hereditary tyrosinemia type 1 (fumarylacetoacetate hydrolase deficiency) have a very high incidence of HCC. [50] Glycogen storage disease type I is associated with the development of adenomas and occasionally HCC.[51] Two adolescents aged 12 and 19 with glycogen storage disease type 1A have also been reported to have developed hepatoblastoma.[52] Hepatic adenomas have been observed in type IV glycogen storage disease, [53] and carcinomas have been reported in type III.[54] Alagille syndrome and other familial cholestatic syndromes are also associated with the development of HCC. [55,56 and 57] Many but not all of the latter are also associated with liver dysfunction and cirrhosis of the liver.

$Alpha_1$-antitrypsin deficiency has been associated with an increased incidence of HCC and cholangiocellular carcinomas, although tumors do not occur until late adulthood.[58,59]

Liver tumors of various types are also reported in association with neurofibromatosis, tuberous sclerosis, and ataxia-telangiectasia. [60,61 and 62] In Fanconi's anemia, prolonged use of anabolic steroids such as oxymetholone methyltestosterone is associated with development of hepatic tumors, both benign and malignant. [63] In some cases, tumor regression has been observed with the withdrawal of steroids. The several cases of hepatic tumors in patients with Fanconi's anemia who are treated with anabolic steroids demonstrate how a genetic defect in DNA repair coupled with an exogenous agent may contribute to the development of neoplasia.

Environmental factors have been implicated in hepatoblastoma. Buckley and colleagues [64] reported an association with certain occupational exposures in fathers of children with hepatoblastoma. These include excess exposures to metals such as in welding and soldering fumes (odds ratio, 8.0), petroleum products, and paints (odds ratio, 3.7). A prenatal exposure to acetaminophen in combination with petroleum products has also been noted in association with hepatoblastoma. [65]

Hepatitis B virus has historically played a major role in the development of HCC worldwide. In areas in which hepatitis B virus is endemic, HCC is a common malignancy, and a high rate of hepatitis B surface antigenemia has been observed. Perinatally acquired hepatitis B has also been demonstrated to have integrated into the genome in tumors from children with no clinical signs of present or past hepatitis B infection. [66] Hepatitis C has been implicated to a lesser extent than hepatitis B in the development of HCC in adults, but not in children.

With the intriguing observation in the past decade of increasing incidence of hepatoblastoma in premature infants, we may speculate about possible environmental factors acting in conjunction with prematurity to stimulate tumor development. Prenatal, neonatal, and perinatal factors may play a role, although it is unclear whether this relates to exposures in the neonatal period or other medical complications of either mother or neonate, or perhaps an altered pathway of normal hepatic development that is disrupted by premature birth. Anecdotal reports of hepatoblastoma with oral contraceptives or other use of hormones as well as the development

of hepatoblastoma in infants with fetal alcohol syndrome argue for events early in organogenesis that may be contributory. [67,68 and 69]

Parenteral nutrition in infancy has been associated with the development of HCC in childhood. [70,71] How much of role parenteral nutrition, which is clearly lifesaving for many premature infants, plays in the observed increase in the subsequent development of liver cancer in premature infants will await additional epidemiologic studies.

HCC has also been reported as a second malignancy in patients with Wilms' tumor treated with hepatic irradiation, presumably due to radiation-induced hepatic changes.[72] HCC has also been seen after treatment for acute lymphoblastic leukemia treated with prolonged use of methotrexate associated with hepatic inflammation and damage.[73,74]

## ACQUIRED GENETIC CHANGES IN TUMORS

Karyotyping of hepatoblastomas has revealed a recurrent pattern of chromosomal abnormalities. The most common karyotypic changes are extra copies of entire chromosomes (trisomies), sometimes in conjunction with other complex structural changes and often in association with double-minute chromosomes.[75,76,77,78 and 79] In a single tumor, several clones may be observed, with differing numbers of trisomies suggesting clonal evolution with the addition of extra chromosomes. Trisomies of chromosomes 2 and 20 have each been reported most commonly, and each of these trisomies has been reported as a sole karyotypic event, suggesting that they may represent an early stage of tumor evolution.[75,76 and 77] Trisomy of chromosome 20 and duplication of the long arm of chromosome 20 have been also observed in rhabdomyosarcoma, suggesting a link between these two embryonal tumors, both of which are associated also with losses at the Beckwith-Wiedemann syndrome locus.[80,81 and 82] Trisomy of chromosome 8 is also common, and other trisomies are seen with lesser frequency. Occasional losses of entire chromosomes are seen and these, too, are not random. Figure 29-2 displays the frequency of both chromosomal gains and losses in a series of 42 hepatoblastomas with abnormal karyotypes. [83] The clinical significance of these trisomies is at present unknown, although one recent study using comparative genomic hybridization has suggested that chromosomal gains at chromosome 8 and 20 may be associated with an adverse prognosis.[84] A unique translocation has been reported in undifferentiated small cell hepatoblastoma,[85] a variant associated with a poor prognosis, although this cytogenetic variant has not been reported in repeated cases. Interestingly, cytogenetically visible chromosomal aberrations of chromosome 5q, the locus for the APC gene, or 11p15, the locus for Beckwith-Wiedemann syndrome, have not been reported in sporadic cases of hepatoblastoma. Likewise, trisomy 18, despite its association with hepatoblastoma when present constitutionally, is not a feature of sporadic tumors.

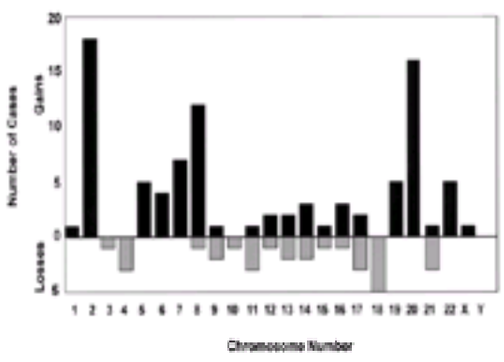

**FIGURE 29-2.** Distribution of numerical abnormalities in a series of 42 hepatoblastoma karyotypes. The most common abnormalities included trisomy of chromosomes 2, 20, and 8. Chromosomal losses occur less commonly. Loss of chromosome 18 has been observed in five cases. (From Schneider N, Tomlinson G. Cytogenetics in a series of hepatoblastoma. In preparation, 2001.)

In 1998 Schneider and colleagues[86] described a translocation, t(1;4)(q12;q34), occurring in four cases of hepatoblastoma, all male and high-stage tumors. Since then others have also reported this translocation. [78,79,87] In all reported cases, this translocation has been associated with other chromosomal changes including trisomies of 2, 8, 20. The breakpoint of this translocation has not yet been characterized. The region involved on chromosome 1 is a region of heterochromatin with few structural genes; the region on chromosome 4 contains multiple genes involved in cellular growth and is also one of several genomic sites at which the hepatitis B virus is known to integrate.[88] The distal region of chromosome 4 is also rearranged in 10% of HCCs. [89,90 and 91]

Several acquired genetic changes are known to occur in hepatoblastoma, which may be shared by other embryonal tumors. [80,81,92] Loss of heterozygosity at chromosome 11p15 is well described as a common feature in embryonal tumors, including Wilms', hepatoblastoma, and rhabdomyosarcoma. [82] It is thought that an important tumor suppressor gene or growth factor gene located at 11p15.5 is a factor in the development of embryonal tumors. It has been generally assumed but not proven that the critical gene lost is the same gene that is responsible for Beckwith-Wiedemann syndrome. Several genes of interest in the study of embryonal tumors and Beckwith-Wiedemann syndrome are located at this chromosomal locus. The p57KIP2 gene at 11p15.5 is a regulator of cellular proliferation and has been shown to be mutated in some families with Beckwith-Wiedemann syndrome.[93,94,95 and 96] Although not mutated in hepatoblastoma, the p57K1P2 gene may be aberrantly expressed in hepatoblastoma.[97] The insulin-like growth factor 2 gene is preferentially expressed from the father in normal tissue. In tumor tissue the parental allele specific expression is variable, however, suggesting that disruption of normal expression pattern may be involved in tumorigenesis. The H19 gene, also at 11p15.5, shows the opposite pattern of expression of parental alleles, although the role of this gene in tumorigenesis is unclear. [98] An intriguing phenomenon observed is that when losses of genetic material at 11p15.5 occur, the losses are always of maternal origin. This suggests that the imprinting of genes, or differential function depending on parental origin, may have a role in the pathogenesis of hepatoblastoma. [99] In hepatoblastomas that do not demonstrate loss of heterozygosity at 11p15.5, the differential expression of genes is lost with subsequent expression from both parental alleles. [100]

Acquired mutations of the APC gene have been reported in a few cases of hepatoblastoma and have not been reported in other embryonal tumors. [101] Several recent studies, however, have focused on abnormalities of b-catenin, whose degradation is regulated by APC. b-Catenin is more commonly altered in hepatoblastoma than is the APC gene itself. A study from Germany has shown that 48% of hepatoblastomas are associated with mutation of the b-catenin gene. [102] The importance of mutation of this gene was confirmed in a second series from Taiwan.[103] Nuclear localization of b-catenin in hepatoblastomas, especially more aggressive tumors, is different from that of normal hepatocytes, which have only plasma membrane localization. [104] These observations suggest that alterations of the wnt signaling pathway play a crucial role in the malignant transformation in immature hepatic cells.

Among the other liver tumors, various cytogenetic changes have been reported. Multiple reports of mesenchymal hamartoma have demonstrated a recurring translocation with a breakpoint at chromosome band 19q13.4. [105,106 and 107] None of the sarcomas observed in association with or following a mesenchymal hamartoma has been shown to have the 19q13.4 breakpoint. A unique karyotype that is near triploid and near hexaploid has been reported in undifferentiated sarcoma, although this has not been observed in additional cases. [108]

A specific *TP53* mutation has been reported in HCC in association with aflatoxin exposure. [109] One study reported a hot-spot mutation of *TP53* in a series of hepatoblastomas.[110] However, other studies of *TP53* in hepatoblastoma have failed to demonstrate that mutations occur frequently. [42,111] In HCC, the presence of a *TP53* mutation or the presence of serum antibody to TP53 is associated with a shorter survival. [112,113]

## PRESENTATION AND INITIAL DIAGNOSTIC ASSESSMENT

Most liver tumors present with an asymptomatic abdominal mass palpated either by a parent or pediatrician. Abdominal pain, weight loss, anorexia, nausea, and vomiting may be present, particularly in advanced disease. Jaundice is rare; however, it is seen in some cases of rhabdomyosarcoma. A presenting feature occasionally seen in males is pseudoprecocious puberty. [4] Infants with hemangioendothelioma may present with signs and symptoms of congestive heart failure.

Presurgical assessment often initially begins with a plain film or ultrasonography, which reveals a right upper quadrant mass. Calcifications on x-ray are seen only in a minority of cases and are nonspecific so that plain films are of very limited value in characterizing hepatic masses. Sonography is useful for the initial detection of

masses, as increased echogenicity is suggestive of malignant disease. The value of sonography is increased when accompanied by Doppler flow studies to assess tumor vascularity. However, sonography is limited in defining tumor margins to definitively establish resectability. To accurately define the extent of disease, computerized tomographic (CT) scanning[114] or enhanced magnetic resonance imaging[115] is needed. Figure 29-3 demonstrates the delineation of a small resectable hepatoblastoma by CT. Magnetic resonance imaging of an unresectable HCC is shown in Figure 29-4.

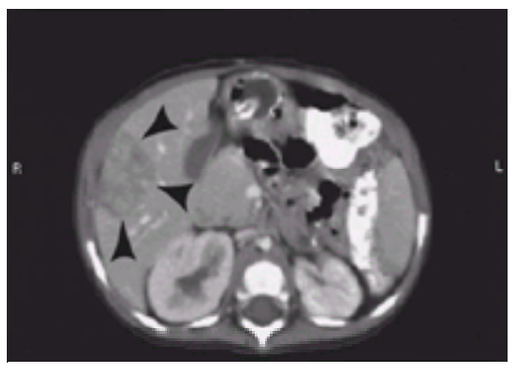

**FIGURE 29-3.** Computed tomography scan of a low-stage hepatoblastoma, demonstrating clear tumor margins (*arrowheads*). This tumor was picked up initially by periodic screening with sonography in a patient with Beckwith-Wiedemann syndrome. (Courtesy of Children's Medical Center, Dallas.)

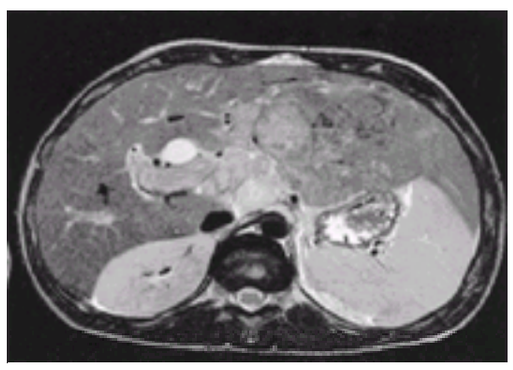

**FIGURE 29-4.** Magnetic resonance imaging study of a hepatocellular carcinoma with extensive involvement of both lobes as well as bulky lymphadenopathy. In this T2-weighted image, tumor involvement of both right and left lobes is visualized as lighter areas compared to normal liver parenchyma. (Courtesy of Dr. Jeanne Dillenbeck, Children's Medical Center, Dallas.)

By far, the vast majority of metastases present at diagnosis occur in the lungs. Therefore, CT imaging of the chest is essential. Bone lesions have been reported but it is unclear whether these represent true metastases or areas of demineralization.[116] Metastasis to the brain has been reported but is extremely rare.[117,118] Bone marrow involvement has only very rarely been observed, and current therapeutic protocols do not call for bone marrow evaluation.

Presurgical laboratory assessment should include a complete blood count. Anemia may be seen and is usual mild and normochromic normocytic. Thrombocytosis is seen in approximately one-fifth of cases[4] and is related to thrombopoietin production by tumor in some, but not all, cases.[119,120 and 121] It has also been suggested that thrombocytosis is mediated by interleukin 6.[122] Liver enzymes and bilirubin are usually normal or only mildly elevated. Human chorionic gonadotropin b is produced by some hepatoblastomas, and substantial elevations result in physical signs of precocious puberty.[123,124] Hypertension secondary to a renin-secreting mixed hepatoblastoma has been reported.[125]

Measurement of AFP is essential and is markedly elevated in more than 90% of hepatoblastomas and in many cases of HCC. The AFP is usually normal, however, in the fibrolamellar variant of HCC as well as in most benign liver tumors. However, we have seen examples of significantly elevated AFP in cases of infantile hemangioendothelioma and mesenchymal hamartoma, which have misled clinicians into treating for hepatoblastoma without confirmatory diagnostic biopsy. AFP is the major protein produced by the fetal liver and is thus produced in high amounts in the newborn. In the normal-term infant the AFP level can be as high as 100,000 ng per mL or greater. The half-life of AFP is 5 to 7 days and levels fall throughout the first several months of life. By age 1 year the AFP level is less than 10 ng per mL.[126] In infants younger than 1 year with hepatoblastoma it may be initially difficult to distinguish the components of elevated AFP from normal liver versus malignant tumor, however, the AFP is a useful tumor marker to both assess response to therapy as well as to monitor for disease recurrence.[127,128] After a complete resection, AFP levels should decline substantially and approach normal ranges within several weeks. Failure to do so may indicate residual disease. It is possible to fractionate the malignant and nonmalignant forms of AFP by immunoelectrophoresis; however, this is not a generally available clinical laboratory procedure.[129,130] Although of potential diagnostic interest, this is not important in the monitoring of AFP levels after the diagnosis in a young infant, because levels should only trend downward if treatment is effective, with a rise in AFP raising concern of recurrent or progressive disease.

As part of the workup of any child with a liver tumor, care should be taken to review neonatalhistory for the presence of features such as high birth weight, hemihypertrophy, macroglossia, umbilical hernia, or ear pits, which would suggest Beckwith-Wiedemann syndrome. In addition, inquiry as to family history of tumors is essential, particularly to ascertain a family history of early-onset colon cancer or colonic polyps or other manifestation of Gardner's syndrome.[131,132] Although recognition of these syndromes would not change the clinical management of the primary tumor, their recognition would have implications for following patients long-term. Patients with Beckwith-Wiedemann syndrome are at potential risk for second embryonal malignancies. Children with hepatoblastoma from polyposis kindreds would be at risk for colon cancer as young adults as well as desmoid tumors and other extracolonic manifestations throughout childhood.

## STAGING

The conventional POG/CCG staging system is shown in Table 29-3.[133,134] As with other solid tumors, *stage I* is defined as a tumor completely resected at diagnosis. *Stage II* refers to resection with microscopic residual disease. *Stage III* indicates gross residual disease, including involvement of local lymph nodes and inability to resect the primary tumor. *Stage IV* tumors are those with distant metastases.

Stage I (favorable histology) tumors are those that are completely resected and have a typical histology of a purely fetal histologic pattern with a low mitotic index (<2 per 10 high-power fields).
Stage I (other histology) tumors are completely resected tumors with a histologic picture other than purely fetal with low mitotic index.
Stage II tumors are grossly resected tumors with evidence of microscopic residual. Such tumors are rare, and patients with this stage have not fared differently from those with stage I tumors in previous protocols. Resected tumors with preoperative (intraoperative) rupture are classified as stage II.
Stage III (unresectable) tumors are those that are considered by the attending surgeon to be not resectable without undue risk to the patient. This includes partially resected tumors with measurable tumor left behind. It does not include grossly resected tumors with microscopic disease at the margins or resected tumors with preoperative/intraoperative rupture. Lymph node involvement is considered to constitute stage III disease and may require evaluation with a second laparotomy after the initial four courses of chemotherapy.
Stage IV tumors are those which present with measurable metastatic disease to lungs or other organs.

**TABLE 29-3. PEDIATRIC ONCOLOGY GROUP STAGING OF HEPATOBLASTOMA**

An alternative staging system is that developed by the International Society of Pediatric Oncology based on the number of liver segments involved as determined by preoperative imaging studies.[135] This pretreatment classification scheme (PRETEXT) is shown in Figure 29-5 and is useful in determining resectability preoperatively.[136] In this system, the liver is divided into four sectors—namely, an anterior and a posterior sector on the right, and a medial and a lateral sector on the left. Staging groups are assigned according to tumor extension within the liver as well as the presence or absence of involvement of the hepatic vein, portal vein, regional lymph nodes, or distant metastases. The classification overlaps considerably but is not synonymous with the more conventional POG staging system, which is based on postsurgical tumor status. This classification scheme has been shown to correlate well with resectability and ultimate survival in a large European study.[136] The current U.S. Intergroup Study stratifies patients according the postsurgical staging system but will also attempt to validate the PRETEXT staging system with respect to tumor resectability and outcome.[137]

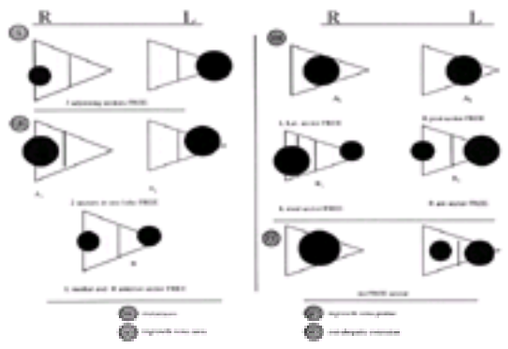

**FIGURE 29-5.** International Society of Pediatric Oncology PRETEXT staging scheme according to surgical anatomy. The liver is divided into four sectors. The number of sectors free is related to stage as follows: PRETEXT I, three adjoining sectors free (tumor only in one sector); PRETEXT II, two adjoining sectors free (tumor involving two sectors); PRETEX III, one sector or two nonadjoining sectors free (tumor involves two or three sectors); PRETEXT IV, no free tumor (tumor in all four sectors). E, extrahepatic direct spread to hilar lymph nodes; M, distant metastases; P, portal vein involvement; V, hepatic vein involvement.

## PATHOLOGY

The usual gross presentation of a primary hepatic neoplasm, whether benign or malignant, is an expansile solitary mass ( Fig. 29-6, Fig. 29-7A, and Fig. 29-8A). The exceptions are some hemangiomas and hemangioendotheliomas, rare hepatoblastomas, adenomas, and hepatocarcinomas with multiple nodules, and in a few infants, diffuse hepatomegaly secondary to systemic dissemination of megakaryoblastic leukemia or neuroblastoma. Encapsulation is limited to some adenomas, although pseudocapsules secondary to compressive atrophy of the adjacent parenchyma can be deceptive with respect to an operative margin. Spontaneous focal necrosis of the rapidly growing hepatoblastoma is common (Fig. 29-6), and many of them have large telangiectatic vessels, both of which account for highly diverse images and Doppler patterns and may lead to erroneous diagnosis, especially in infants when the serum AFP level does not reflect the expected values (i.e., poorly differentiated small cell hepatoblastomas may not have elevations, whereas benign hemangioendotheliomas and mesenchymal hamartomas sometimes can be associated with significant excesses).

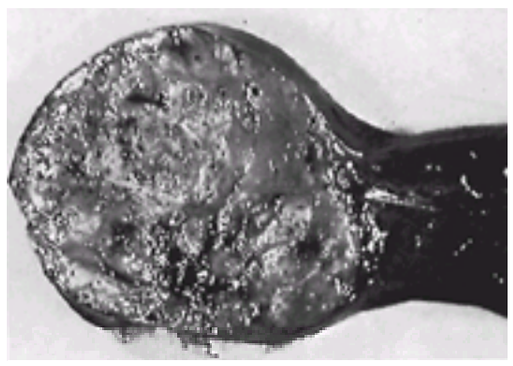

**FIGURE 29-6.** Gross specimen showing hepatoblastoma. The large tumor mass expands the liver. The cut surface is slightly variegated in appearance; one area is hemorrhagic.

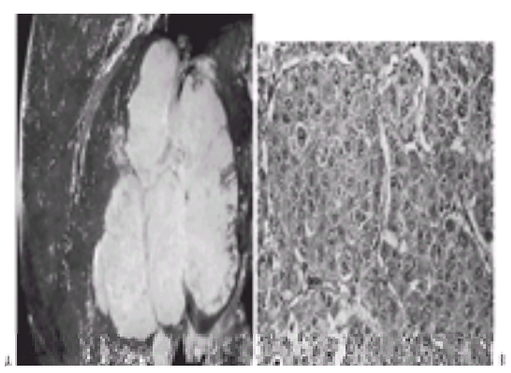

**FIGURE 29-7. A:** Large primary liver cell carcinoma in a noncirrhotic liver. **B:** A well-differentiated hepatocellular carcinoma. Note large polygonal hepatic cells with central nuclei. Mitoses are plentiful.

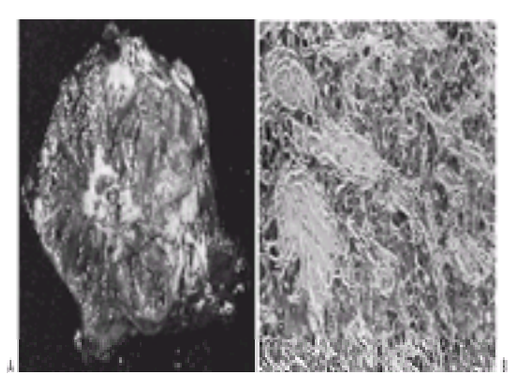

**FIGURE 29-8. A:** Gross specimen showing fibrolamellar carcinoma. Large tumor mass is multilobulated and centrally scarred. **B:** The large polygonal hepatic cells

that make up this tumor are separated by almost acellular collagen. This is the classic appearance of the fibrolamellar variant of hepatocellular carcinoma.

Hepatoblastomas arise from a precursor to the mature hepatocyte and therefore display many histologic patterns, ranging from undifferentiated small cells that coexpress cytokeratin and vimentin reflecting neither epithelial nor stromal differentiation ( Fig. 29-9)[138] to embryonal epithelial cells resembling the histology of the liver at 6 to 8 weeks of gestation (Fig. 29-10) to well-differentiated fetal hepatocytes virtually indistinguishable in cytologic and architectural growth pattern from the normal fetal liver (Fig. 29-11). Rarely, the entire tumor is composed of only one cell type; 5% of the 189 cases reviewed for the POG from 1986 to 1995 were small cell undifferentiated, whereas 7% were pure well-differentiated fetal with minimal mitotic activity ( Fig. 29-11A). The remainder were mixtures of diverse epithelial cells in varying proportions and of cells intermediate among the broad categories, with either discrete nodules of a single cell type or intimate intermingling of diverse cytologies (Fig. 29-9 and Fig. 29-12). Well-differentiated fetal cells having significant mitotic activity (greater than 2 in 10 high-power microscopic fields) ( Fig. 29-11B) very rarely occurred in “pure” form except in small biopsies of stages III and IV cases. Twenty-one percent were classified as “mixed” hepatoblastoma because of stromal derivatives, particularly osteoid-like protein deposits, occasional rhabdomyoblasts, and even more rarely, chondroid elements ( Fig. 29-12).

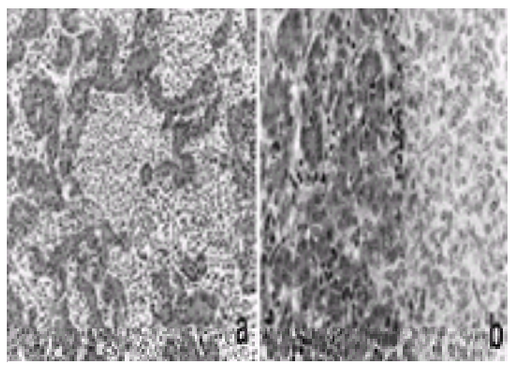

**FIGURE 29-9.** The small undifferentiated type of hepatoblastoma can be thoroughly intermingled with epithelial tubules, as in **(A)**, or form discrete nodules, as in **(B)**. These are the cells that have sometimes failed to respond to conventional chemotherapy and recurred to produce fatalities. Such foci may be readily missed in a small biopsy or fine needle aspirate.

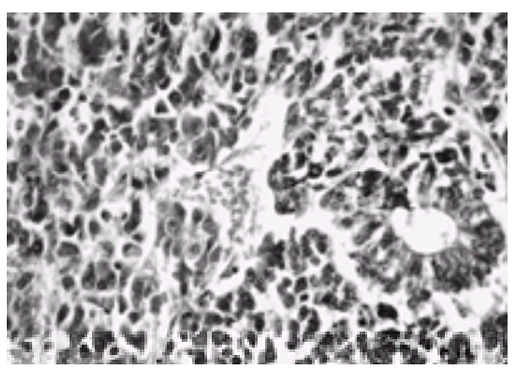

**FIGURE 29-10.** Embryonal hepatoblastoma. Primitive tubules formed by small epithelial cells with minimal cytoplasm are very similar to the liver of 6- to 8-week embryos. Less cohesive cells of the same type are also present. Such foci are mitotically active and often aneuploid.

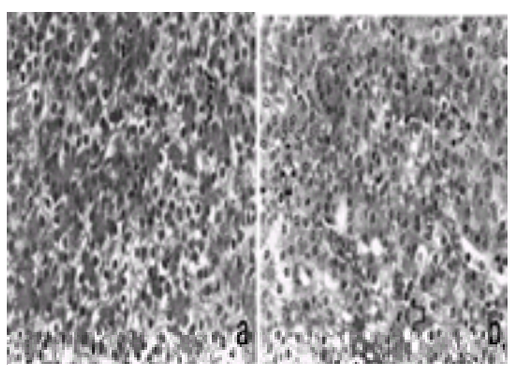

**FIGURE 29-11.** Well-differentiated fetal hepatoblastoma. Both images demonstrate cords of uniform neoplastic hepatocytes smaller than normal cells of the fetal liver with a higher nuclear to cytoplasmic ratio. In **(B)**, arrows point to two mitotic figures in part of 1 high-power field. Only patients with completely resected tumors, as in **(A)**, with few or no mitoses, are classified as having “favorable” histology and spared chemotherapy in current protocols.

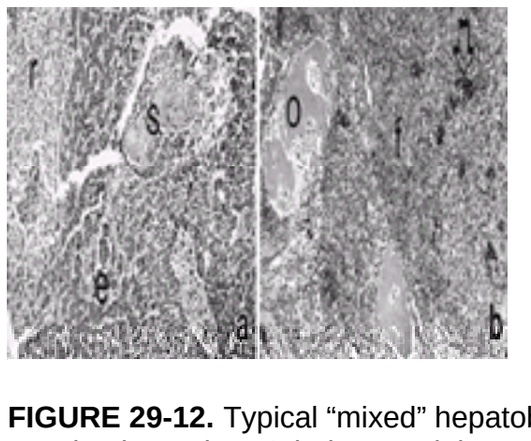

**FIGURE 29-12.** Typical “mixed” hepatoblastoma with diverse histologic features. In **(A)**, the epithelium is relatively primitive, with small cells having minimal cytoplasm growing in cords or tubules, reminiscent of the embryonic liver (e). A nest of keratinizing squamous epithelium is present (s), as well as a zone of elongated spindle cells having the cross-striations of rhabdomyoblasts (r). In **(B)**, the epithelium is more mature “fetal” in type (f) and contains several clusters of hematopoietic cells (*arrow*) as in the normal fetal liver. The mesenchymal component resembles osteoid (o).

Five percent of the hepatoblastomas were designated “teratoid” because a few cells reflecting neural or neural crest origin were present. [139] These included glial cells, neurons, and melanocytes. True teratomas arising in the liver of infants have a full range of tissues, including brain-like and extraembryonal derivatives such as

yolk-sac and trophoblastic cells.[140]

Rarely, enteroendocrine derivatives containing chromogranin and diverse hormones, such as gastrin, serotonin, or somatostatin, are found in mixed hepatoblastomas and even more rarely as pure primary hepatic tumors.[141] Small squamous pearls are frequent in mixed and teratoid tumors (Fig. 29-12A). Very rarely, glandular or ductal forms resembling the embryonal intestine or fetal bile ducts, respectively, were found. The rare rhabdoid tumor arising in the liver shares with small undifferentiated cells the coexpression of epithelial and mesenchymal intermediate filaments. Such cells may occur rarely as a small part of an otherwise typical hepatoblastoma[140] in which their influence on prognosis is unknown, but when they occur in young infants and comprise the entire tumor they suggest a very poor prognosis.[142,143] Although the name *rhabdoid* suggests a relationship to skeletal muscle, these tumors do not contain muscle proteins. True rhabdomyoblasts may be components of hepatoblastomas (Fig. 29-12A), and there are full-fledged primary embryonal rhabdomyosarcomas of the liver that arise in close association to biliary epithelium, often having a polypoid growth pattern and causing obstructive jaundice. [144,145]

When hepatoblastoma cells with either fetal or embryonal cytology grow in trabeculae of 20 to 100 or more cells rather than in the 2- to 4-cell thick cords of the fetal liver, the pattern is called *macrotrabecular,* as suggested by Gonzalez-Crussi and colleagues.[146] Eighteen percent of our series contained macrotrabecular foci and one-third of them were stage IV at presentation. This aggressivity may reflect the fact that such histology can be indistinguishable from hepatocarcinoma when it occurs in pure form (Fig. 29-1 and Fig. 29-13).

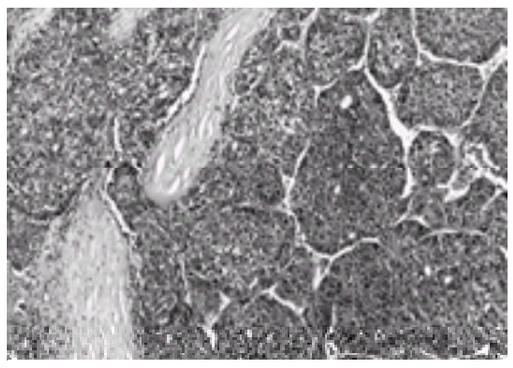

**FIGURE 29-13.** Macrotrabecular hepatoblastoma. Such foci may be indistinguishable from hepatocarcinoma (compare to Fig. 29-1B).

Hepatocarcinomas in children do not differ histologically from those in adults ( Fig. 29-7B), although the fibrolamellar variant (Fig. 29-8B) is more common in adolescents and younger adults. Fibrolamellar carcinomas arise in otherwise normal livers, unlike most hepatocarcinomas, and for that reason are more readily resected and in most series have a higher rate of cure.

A few biliary tract carcinomas have occurred in older children with antecedent cystic or inflammatory disease. [147] They are very resistant to treatment. Solitary benign bile duct cysts are amenable to surgical excision. They may be mature forms of infantile mesenchymal hamartoma.[2]

Angiosarcomas rarely arise de novo and have been reported in children as young as 4 and 5 years following removal of benign hemangiomatous hamartomas in infancy[2] or simultaneously in livers containing hemangiomas. [148] These highly infiltrative lesions disseminate widely within the liver and metastasize to lungs and lymph nodes. The benign hemangioendotheliomas may be solitary masses or multiple in the liver or part of a syndrome of angiomas in many organs and even the placenta of an infant. High-output congestive heart failure is more common in the latter circumstance than with solitary lesions. [149]

Undifferentiated, or embryonal sarcomas, may also present in middle-aged children subsequent to or contemporaneous with a benign infantile mass lesion, a mesenchymal hamartoma.[150,151 and 152] Most arise de novo. These sarcomas generally present as large expansile masses but infiltrate the adjacent parenchyma widely and spread via veins through the liver and to the lungs. Despite the name *undifferentiated*, many of them contain diverse elements displaying maturation of mesenchymal derivatives, including vessels, pericytes, smooth muscle, lipomatous, and fibrohistiocytic features in addition to large bizarre cells with irregular processes and multiple cytoplasmic globular inclusions containing secretory proteins such as alpha $_1$-antitrypsin. The putative pathogenetic relationship between infantile mesenchymal hamartomas, which are typically single expansile masses composed of cystic spaces lined by either biliary epithelium or endothelial cells in a loose myxoid stroma, and the sarcomas is inexplicable by cytogenetic analyses, which thus far have not shown related abnormalities (see the section Acquired Genetic Changes in Tumors).

One other hamartoma of the liver is the angiomyolipoma, a feature of tuberous sclerosis. Although this is most often a tumor of adult females in whom the differential diagnosis from hepatocarcinoma on imaging and in fine-needle aspirates has been the subject of most reports, there have been a few examples in children, not all of whom have had confirmed tuberous sclerosis. The antibody to homatropine methylbromide, which stains the adipocytes and myoblasts of the hamartoma but not hepatocytes, has proved useful in the examination of fine-needle aspirates. One case of malignant transformation has been reported recently. [153]

Another benign tumor occurring in older children and adolescents that may prove problematic on imaging and in fine-needle aspiration cytology is the hepatocellular adenoma. It may be difficult to distinguish from well-differentiated carcinoma. A few cases of carcinoma arising in young adults with glycogen storage disease 1a have been especially confusing because even when these patients have multiple tumors, most are benign. [154] The benign tumors are well reviewed in Patterson.[155]

The relative infrequency of liver tumors in children means that few centers care for more than one or two malignant examples each year. Therefore, it is not surprising that 10.6% of 123 biopsy cases submitted for pathology review in a recent U.S. Intergroup study were incorrectly interpreted. Among the errors were neuroblastoma, Wilms' tumor, and choriocarcinoma.[140]

## TREATMENT

Despite the small number of new cases of hepatoblastoma yearly, cooperative group trials have enabled the development of treatment protocols for hepatoblastomas, resulting in a dramatic increase in survival, particularly for initially unresectable tumors. These trials are discussed in more detail below. HCCs in childhood are sufficiently rare that it has not been feasible to develop separate protocols. Therefore, HCCs have been treated either according to standards in adult centers or similarly to hepatoblastomas, albeit with less success. The approach to the less common malignant tumors of the liver such as rhabdomyosarcoma, other sarcoma variants, and malignant rhabdoid tumors has in general paralleled the approach to tumors of similar histology at other sites, and the rarity of these tumors has precluded the development of treatment protocols. As orthotopic liver transplantation has become a more commonly available and successful option for hepatoblastoma and HCC, allowing definitive surgical resection, it may be that patients with unresectable liver tumors of the less common histologic types may also benefit from transplantation (discussed in the section Liver Transplantation).[156]

### Surgery

Surgical resection is the most important therapeutic modality in treatment of liver tumors. Features that limit surgical resection are involvement of both lobes, involvement of the porta hepatis, or bulky lymphadenopathy. Assessment is usually made by review of CT or magnetic resonance imaging, sometimes with the aid of hepatic arteriogram. The PRETEXT staging system based on the number of liver sectors involved is helpful in determining resectability, together with the extent of extrahepatic extension, involvement of vena cava or portal vein, and the presence of metastatic lesions. Resectability is ultimately determined at the discretion of the surgeon. Surgical resection usually involves hepatic lobectomy or trisegmentectomy. Lymph nodes at the porta hepatis should be sampled, as they represent the primary site of lymphatic drainage. Nodes in the celiac or paraaortic regions should be examined and sampled if suspiciously enlarged. If possible, pulmonary lesions should be surgically resected, as this is thought to improve survival. [157,158 and 159] Although as described below, chemotherapy regimens have facilitated the conversion of unresectable to resectable tumors, in all studies done to date, highest survival rates are observed in tumors in which disease is resected initially. Therefore an

attempt should be made to resect primary as well as metastatic disease.

Resection is curative for most of the benign liver tumors, including the hepatic adenoma, the mesenchymal hamartoma, and hemangioendothelioma. Treatment of hemangioendothelioma is controversial, as surgical resection of large lesions has substantial risks such that alternative strategies are often used, including shrinkage with arterial embolization, corticosteroids, interferon, or cyclophosphamide with variable degrees of success. [149,160] In a review of 30 cases of mesenchymal hamartoma, surgical excision was the only treatment used, with no recurrences observed,[161] although occasionally these tumors show late recurrence or malignant transformation.[162]

**Chemotherapy**

In the 1960s and 1970s, it became evident that hepatoblastoma was a chemosensitive tumor, but early survival rates were low, in the range of 20% to 30%. Agents shown to be effective included vincristine, 5-fluorouracil, and doxorubicin. [163,164 and 165]

Early studies from the Children's Cancer Study Group and the POG documented beneficial effects of adjuvant chemotherapy, consisting of sequential doses of vincristine, doxorubicin, cyclophosphamide, and 5-fluorouracil in completely resected malignant liver tumors. For surgically resected patients, only 1 in 16 (6%) recurred when given this adjuvant regimen compared to 7 of 11 (64%) recurrences in a previous group not given adjuvant chemotherapy. In patients with unresectable hepatic tumors, survival was very poor in those given vincristine, act, and cyclophosphamide. However, when 5-fluorouracil was given in addition to those three agents, the response rate was 44% (12 of 27), although only 7 of 27 (26%) had a sustained response of 20 months or more. [166]

The introduction of cisplatin into chemotherapy regimens for hepatoblastoma markedly improved survival in unresectable tumors. When given as a single agent, a response was shown in four of five patients in a series from St. Jude Children's Hospital. [167] In a subsequent POG pilot study, when cisplatin was added to a regimen with vincristine and 5-fluorouracil, 9 of 11 patients with initially unresectable hepatoblastoma had a complete or partial remission. Five of these patients had measurable pulmonary disease and four achieved a complete disappearance of pulmonary lesions. The average interval of disease control following cisplatin was three times that of doxorubicin.[168]

The survival rate was further improved in a subsequent trial of continuous infusion cisplatin and doxorubicin given over 4 days. [169] The 2-year survival on this regimen was reported as 66%. Douglass and coworkers[170] reported in a POG study that children with resectable hepatoblastoma treated with cisplatin, vincristine, and 5-fluorouracil had a survival rate of 90%. This high survival rate excluded patients with completely resected tumors that were of pure fetal histology, who were cured without adjuvant therapy. Of patients with initially unresected tumors treated with the same regimen for four courses, 24 of 31 patients (77%) became completely resectable. The survival rate at 4 years of 67% was comparable to that observed with cisplatin and doxorubicin given as continuous infusion. Only one of eight patients with metastatic disease survived on this regimen. Two of the 33 patients developed doxorubicin cardiomyopathy, and because of this, subsequent protocols have favored cisplatin in combination with vincristine and 5-fluorouracil rather than in combination with doxorubicin. Doxorubicin, however, remains to be considered an effective agent for refractory or recurrent tumors. The Children's Cancer Group observed similar outcomes for initially unresectable tumors using continuous-infusion doxorubicin and cisplatinum.[169]

In Europe, several multiinstitutional studies have contributed to the treatment of hepatoblastoma. The International Society of Pediatric Oncology Epithelial Liver Group (SIOPEL) reported presurgical treatment of all hepatoblastoma patients, resectable and unresectable, with cisplatin and doxorubicin given by continuous infusion. The overall survival of all patients at 5 years was 75%. [171] The German Cooperative Pediatric Liver Tumor Study HB-89 treated initially unresectable tumors with ifosfamide, cisplatinum, and doxorubicin with response allowing subsequent resection in 76% of patients. [172] A summary of the most recent published chemotherapy regimens from the United States and Europe is shown in Table 29-4.

| Study Group | Scheme[a] | Overall survival (length of follow-up) | N | Reference |
|---|---|---|---|---|
| Children's Cancer Group | Cisplatin, 100 mg/m² / Doxorubicin, 20 mg/m², day 1-4 } 4 courses | 67%/ (2 yr) | 35 | 169 |
| Pediatric Oncology Group | Cisplatin, 90 mg/m² (course 1), followed by Cisplatin, 90 mg/m² / Vincristine, 1.5 mg/m² / 5-fluorouracil, 600 mg/m² } courses 2-5 | 67%/ (4 yr) | 60 | 170 |
| International Society of Pediatric Oncology | Cisplatin, 80 mg/m² over 24 h / Doxorubicin, 60 mg/m² over 48 h } 4 courses → surgery → 2 courses | 75%/ (5 yr) | 154 | 171 |
| German Society of Pediatric Oncology and Hematology | Ifosfamide, 3.5 g/m² / Cisplatin, 100 mg/m² / Doxorubicin, 60 mg/m² } 2 or 4 courses → resection → 2 courses | 35%/ (median 64 mo) | 72 | 172 |

[a]Reader should consult references for full schema.
[b]Includes only patients with unresectable disease at presentation.
[c]Includes patients with all stages at presentation.

**TABLE 29-4. RECENT CHEMOTHERAPY REGIMENS FOR HEPATOBLASTOMA**

A present intergroup study in the United States is examining the possibility of using amifostine to reduce the toxicity of cisplatin-based regimens. Because of the historically high survival rates in children with completely resected hepatoblastomas of well-differentiated pure fetal histology with minimal mitotic activity, this subgroup is being observed without use of adjuvant chemotherapy. The poor responsiveness to current protocols of hepatoblastomas in infants having pure or predominantly small undifferentiated histology indicates the need for additional agents. The Children's Oncology Group is exploring the use of irinotecan and liposomal doxorubicin in recurrent hepatoblastoma. Despite aggressive chemotherapy, 25% to 30% of initially unresectable tumors remain resistant to treatment.

In the cases in which surgical resection is impossible, other approaches have been tried with only moderate success. The introduction of chemotherapy via the hepatic artery has been tried with some success in children. [173,174 and 175] Embolization with an absorbable gelatin sponge (Gelfoam) has also been tried, as has ligation of the hepatic artery.[176,177,178,179 and 180] Targeting with specific antibodies against AFP has also been tried on an experimental basis. [177]

Chemotherapy for HCC has been much less successful than that for hepatoblastoma. Complete resection is the basis for survival, but unfortunately only 10% to 20% of HCCs are resectable. When children with HCC were treated with cisplatinum and doxorubicin in a Children's Cancer Study Group regimen identical to that used successfully in hepatoblastoma, only 2 of 14 patients survived. European studies with different regimens have not demonstrated significantly different overall survival. In the German Cooperative Study HB-89, only 3 of 10 patients with unresectable HCC treated with ifosfamide, cisplatinum, and doxorubicin had a favorable outcome.[172]

The fibrolamellar variant of HCC tends to have a more favorable outcome, presumably because it is more often resectable at diagnosis, and the remainder of the liver is normal.[8,10] Lack and colleagues[8] report an average survival of 28.5 months in patients with the fibrolamellar variant of HCC compared to 4.2 months in other HCCs. The fibrolamellar variants tend to present at a lower stage. However, there was no significant difference from other types of HCC in combined studies of POG and Children's Cancer Study Group in which 28 patients with HCC (14 with fibrolamellar and 14 nonfibrolamellar HCC) were compared stage for stage. [181]

Among the rarer histologic types of liver cancers it is more difficult to reach a definitive treatment recommendation. A response to ifosfamide, carboplatin, and etoposide has been reported in an undifferentiated sarcoma of the liver. [156] Angiosarcoma of the liver has been successfully treated with multi-agent chemotherapy in some but not all cases.[181,183]

**Radiation**

Radiation therapy historically has not played a major role in the treatment of hepatoblastoma. A survey of European institutions indicated that in some cases radiation was helpful in controlling gross or microscopic residual disease. In two of eight inoperable tumors, control was achieved by use of radiation. However, toxicity reported included radiation hepatitis, scoliosis, and bowel obstruction. [184] Radiation has not been extensively used in cooperative group trials in the United States except as an

adjunct in unresectable tumors that remain unresectable even after chemotherapy.[185]

### Liver Transplantation

Whereas tumor resection historically has implied conventional techniques of subtotal hepatic resection, strides have been made over the last two decades in introducing total hepatectomy and orthotopic liver transplantation as a treatment modality in childhood liver tumors, particularly hepatoblastoma and HCC. Liver cancers now account for approximately 2% of all liver transplants in children.[186] An early series of liver transplantation for malignant disease in the 1960s, 1970s, and early 1980s showed promise for this technique, although tumor recurrences posttransplant were common.[187] Survival has shown to be best in tumors that are unifocal and intrahepatic compared to the multifocal tumors and tumors with extrahepatic spread.[188] In most centers, however, extrahepatic spread limits the possibility of liver transplant.

In a recent series of 31 children with initially unresected liver tumors treated initially with chemotherapy followed by total hepatectomy and liver transplant, the 5-year posttransplantation survival was 83% for hepatoblastoma and 68% for HCC.[189] As newer agents have resulted in less toxicity related to control of graft rejection, the quality of life posttransplantation has improved.[190] Remaining challenges in liver transplantation for liver cancer in children include better defining the role of posttransplant adjuvant chemotherapy and prioritization of candidates as recipients for a limited number of donor livers.

### Prognostic Factors

The most important prognostic factor in malignant liver tumors is complete tumor resection. Unfortunately most hepatoblastomas are not amenable to primary surgical total disease resection. The past ten years of POG accessions revealed 67% high-stage tumors with 41% of new cases of hepatoblastomas presenting as stage III and 26% as stage IV. Similarly, in a previous intergroup study, high-stage tumors represented 70% of new cases.[181] Fortunately, most hepatoblastomas that are initially deemed unresectable can be rendered resectable by initial treatment with combination chemotherapy consisting of cisplatin-, carboplatin-, or doxorubicin-containing regimens.

A feature of liver tumors also known to have important prognostic value is the degree of mitotic activity, which may be measured by routine histologic sections, flow cytometry, or by immunohistochemical stains for DNA synthesis. These observations have been made on hepatoblastoma and HCC but also apply to sarcomas, which tend to be aneuploid and inflammatory myofibroblastoma.

Among hepatoblastomas, the presence of pure fetal histology, which is seen in a small percentage of cases, has prognostic significance in that patients with these tumors have an exceptionally good outcome. Kasai and Watanabe[191] observed early that fetal histology was associated with a favorable outcome. In the series reported by Weinberg and Finegold,[2] six of six patients with surgically excised tumors of pure fetal histology and low mitotic activity were cured without the need for additional chemotherapy in contrast to survival of only 2 of 19 patients with resected tumors of other histologies, suggesting that the fetal histology is a key factor influencing cure rate. To date, every known patient with a pure fetal hepatoblastoma and minimal mitotic count has been cured by primary resection with the only three reported exceptions found on review to have contained small undifferentiated cells that constituted the recurrence.[192]

Among patients with unresected tumors who undergo chemotherapy initially because of unresectability, the reduction in AFP level is a good predictor of outcome. A report from the Children's Cancer Group demonstrated that a decline in serum AFP levels early in the course of chemotherapy is a reliable measure of response and indicates a favorable outcome.[128] Patients whose initial AFP levels decreased by 2 logs in the initial four courses of chemotherapy had a 75% survival, whereas patients whose AFP did not decrease 2 logs before second surgery had a very poor survival.

Studies of DNA content have shown that diploid tumors and tumors with low-proliferation index may have a better prognosis than do aneuploid tumors or tumors with a high proliferative index.[193,194] Recent reports of comparative genomic hybridization suggested that addition of material on chromosome 8q or chromosome 20 conferred a poorer prognosis in a small series.[84] Prospective studies examining the role of chromosomal trisomies of 2, 8, or 20 in predicting outcome are in progress.

## FUTURE DIRECTIONS

As toxicity from antirejection therapy improves for liver transplantation, this may become more of a treatment of choice to be considered in patients with otherwise unresectable tumors. In addition, as the need for cadaveric livers for transplantation exceeds the supply, the use of living-related donors who undergo partial hepatectomy with transplantation of a lobe into young infants is becoming recognized as a feasible and sometime more desirable option than cadaveric donors.[195]

Hepatoblastoma is a tumor in which identification of the high-risk individual may facilitate early detection and enhance the ability to cure with limited therapy. A recent series of infants with fumarylacetoacetate hydrolase deficiency (tyrosinemia type 1) known to be at very high risk for HCC underwent treatment with NTBC [2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione], an inhibitor of an enzyme upstream in the catabolic pathway. Both the liver failure and incidence of carcinoma diminished, although some children developed carcinomas despite early and continuous treatment.[196] Efforts to control this and other metabolic conditions associated with cirrhosis will contribute to possibly decreasing the development of hepatic tumors associated with antecedent liver damage.

The recognition of individuals predisposed to hepatic malignancies, whether because of known genetic syndromes such as Beckwith-Wiedemann syndrome or FAP, or because of a history of prematurity and perhaps other pertinent exposures, viral hepatitis, or chronic cholestatic conditions known to be associated with cirrhosis or other factors, sets the stage for development of surveillance strategies. Efforts toward early detection should be made in the high-risk individual to increase the probability of initial surgical resection, which will increase the likelihood of cure while lessening treatment-associated morbidity.

An additional challenge is the need for introduction of novel therapies for both hepatic carcinomas and the rarer hepatic tumors such as the undifferentiated small cell variant or tumors with rhabdoid histology, which have been refractory to conventional chemotherapy.

## INTRODUCTION

Wilms' tumor is the most common primary malignant renal tumor of childhood and is the paradigm for multimodal treatment of a pediatric malignant solid tumor. Developments in surgical techniques and postoperative care, recognition of the sensitivity of Wilms' tumor to irradiation and several active chemotherapeutic agents have led to a dramatic change in the prognosis for most patients with this once uniformly lethal malignancy. This chapter reviews the epidemiology, molecular biology, pathology, treatment, and prognosis of children with Wilms' tumor, emphasizing the central role of randomized clinical trials in the progress that has been achieved.

## EPIDEMIOLOGY

From 1975 to 1995, the annual incidence of Wilms' tumor in the United States was 7.6 cases per million children younger than 15 years. [1] Wilms' tumor represented 6% of childhood cancers and the total incidence in the United States was estimated at 500 cases per year. The incidence rate is slightly higher for black populations but substantially lower in Asians, both nationally and internationally. [2] Wilms' tumor in the United States is slightly less frequent in boys than in girls. The male to female ratio is 0.92:1.00 for those with unilateral disease and 0.60:1.00 for those with bilateral disease. [3] The tumor presents at an earlier age among boys, with the mean age at diagnosis for those with unilateral disease being 41.5 months compared to 46.9 months among girls. The mean age at diagnosis for those who present with bilateral disease is 29.5 months for boys and 32.6 months for girls. [3]

In a few children, Wilms' tumor occurs as part of a recognized congenital malformation syndrome ( Table 30-1). The *W*ilms' tumor, *a*niridia, *g*enitourinary malformation, mental *r*etardation (WAGR) syndrome results from a germline deletion at chromosome arm 11p. [4,5] Children with pseudohermaphroditism, degenerative renal disease (glomerulonephritis or nephrotic syndrome) and Wilms' tumor have Denys-Drash syndrome, [6,7] which is associated with mutations within the same 11p chromosomal segment. [8] Hemihypertrophy may occur as an isolated abnormality or as a component of the Beckwith-Wiedemann syndrome (BWS), which includes macroglossia, omphalocele, and visceromegaly. [9,10] Wilms' tumor has been reported in patients with other overgrowth syndromes, including the Perlman [11,12] and Simpson-Golabi-Behmel syndromes. [13] Although cases of Wilms' tumor have also been reported in patients with neurofibromatosis, [14] Sotos' syndrome, [15] and Klippel-Trénauny-Weber syndrome, [16] these associations are weaker and not clearly causal. [17] Wilms' tumor has been described in patients with genetic instability syndromes, including the Bloom syndrome [18] and incontinentia pigmenti [19] and has been observed in families affected by Li-Fraumeni syndrome. [20] The causal significance of these latter observations is also unclear.

| Anomaly or syndrome | Number of patients | Prevalence rate (per 1,000) |
|---|---|---|
| Wilms' tumor, aniridia, genitourinary malformation, mental retardation syndrome | 52 | 7.5 |
| Denys-Drash syndrome | 28 | 4.0 |
| Beckwith-Wiedemann syndrome | 74 | 10.7 |
| Sporadic hemihypertrophy | 171 | 25.1 |
| Cryptorchidism (boys only) | 49 | 46.6 |
| Hypospadias (boys only) | 64 | 20.0 |

**TABLE 30-1. CONGENITAL ANOMALIES AND SYNDROMES IN 6,890 PATIENTS REGISTERED BY THE NATIONAL WILMS' TUMOR STUDY GROUP FROM 1980 TO 1999**

Stimulated by an early report of an excess of Wilms' tumor among children whose fathers worked in occupations having the potential for contact with hydrocarbons or lead,[21] a series of epidemiologic studies has investigated the potential role of parental occupational and environmental exposures as risk factors for Wilms' tumor.[22,23,24,25,26,27,28 and 29] These were mostly small case-control studies that had serious methodological weaknesses, including inaccurate exposure assessment and unavoidable bias in the selection of the control series. Although several studies noted an excess of fathers who worked as machinists or vehicle mechanics, no consistent positive findings have emerged. Previously reported associations between maternal smoking, tea consumption, and hypertension during pregnancy likewise have not been confirmed. On balance, the fact that incidence patterns vary more with ethnicity than geography combined with the inconsistent findings from case-control studies suggest that genetic risk factors are likely to be of greater consequence for Wilms' tumor than are environmental risk factors.

## GENETICS AND MOLECULAR BIOLOGY

Wilms' tumor appears to result primarily from the loss of function of certain tumor suppressor genes as opposed to the activation of oncogenes. Based on a statistical analysis of the age of onset of unilateral and bilateral tumors, Knudson [30] and Knudson and Strong[31] proposed in the early 1970s that Wilms' tumors develop as a consequence of two rate-limiting mutational events. The first event can be prezygotic (i.e., a constitutional or germline event) or postzygotic. If the first event is prezygotic, the tumor is potentially hereditary, and affected individuals are at risk of developing multiple tumors because all their cells are affected by the first event. Consequently, only one new event in any one cell is required for tumor development. By contrast, the nonhereditary or sporadic form results from two relatively rare independent, somatic mutations in a single cell. Because it is unlikely for these two events to occur independently in more than one cell, patients with nonhereditary Wilms' tumor are unlikely to develop more than one tumor. The clearest example of the two-event theory is the inactivation of both copies of *RB1* in the development of retinoblastoma. In the 1990s, however, it became clear that the genetic pathways leading to the development of Wilms' tumor are more complicated. [32] Several chromosomal regions have been associated with Wilms' tumor, including band 11p13, which harbors the Wilms' tumor suppressor gene *WT1*; band 11p15, the location of the putative Wilms' tumor gene *WT2*; chromosome arm 17q, which harbors the familial locus *FWT1*; chromosome arm 19q, the location of *FWT2*; and chromosome arms 16q, 1p, 7p, and 17p, the location of *p53*. The first four of these loci have been implicated in the actual development of Wilms' tumor. The remaining four may not predispose to Wilms' tumor but may be associated with aspects of the phenotype, including outcome of treatment.

### *WT1*

The first genetic region involved in the development of Wilms' tumor was revealed by the study of patients with the WAGR syndrome. Children with the WAGR syndrome were shown to have heterozygous germline deletions at band 11p13.[5] This constitutional deletion was thought to represent the first hit and provided the initial clue to the location of a gene involved in the development of Wilms' tumor. Molecular analysis of this specific region led to the identification of *WT1*.[33,34 and 35] It is now known that the WAGR deletion encompasses a number of contiguous genes, including the aniridia gene *PAX6*[36] and the Wilms' tumor suppressor gene *WT1*, so the syndrome constitutes a contiguous gene syndrome.

Characterization of *WT1* revealed ten exons encoding a protein with a predicted molecular weight of 45 to 49 kd, depending on the presence or absence of two alternative splicing events. Cells expressing *WT1* produce four distinct messenger RNAs (mRNAs), reflecting the presence of the two alternative splice sites. The most prevalent *WT1* mRNA species is the one with both alternative splices present.[37] The carboxyl terminus of the WT1 protein contains four zinc finger domains of the histidine-cysteine type, a motif that in other proteins is associated with sequence-specific binding to DNA. The WT1 amino terminus contains a domain rich in proline and glutamine, a motif characteristic of transcriptional factors.[33,34] This suggests that WT1 functions as a regulator of the transcription of other genes.[38] The identity of one of the genes targeted by the WT1 protein during normal kidney development, amphiregulin,[39] suggests a role of WT1 as a transcriptional regulator during kidney differentiation. Although several genes appear to be regulated by *WT1* in different *in vitro* models, the WT1-regulated pathway involved in tumorigenesis remains unclear.

*WT1* was established as a Wilms' tumor suppressor gene by several criteria. First, tumor-specific homozygous deletions of all or part of *WT1* were described in several Wilms' tumor cases.[34,40] Second, certain patients with bilateral Wilms' tumor were found to have constitutional *WT1* mutations.[41] Third, investigators reported homozygous somatic mutations in patients with nonhereditary unilateral Wilms' tumor.[42,43 and 44] Thus it is clear that *WT1* is a tumor suppressor gene involved in the development of certain Wilms' tumors. Because approximately 30% to 40% of Wilms' tumors manifest loss of heterozygosity (LOH) for the region encompassing *WT1*, a similar incidence of tumors with underlying *WT1* mutations was expected. Surprisingly, though, the incidence of *WT1* mutations remains at less than 10%,[45] despite the identification of a potential mutational hot spot involving the first exon of the gene.[46]

*WT1* was initially thought to be a classic tumor suppressor gene, requiring the loss of both alleles for tumor development. It has now become clear that specific alterations to only one allele may also contribute to abnormal cell growth. Patients with Denys-Drash syndrome harbor constitutional point mutations in only one *WT1* allele,[8,42] resulting in a dominant negative oncogene.[47] The abnormal protein product is thought to disrupt the function of the normal gene product (from the remaining normal allele) through the formation of protein complexes or through abnormal interactions with DNA targets. Thus, loss of *WT1* function may result from a dysfunctional mutation in only one allele (a dominant effect). The phenotypic effects of the constitutional *WT1* mutations found in Denys-Drash syndrome are in fact far more severe than those resulting from complete deletion of *WT1*, seen in patients with the WAGR syndrome. This supports the concept that the altered WT1 protein in Denys-Drash syndrome is dysfunctional rather than nonfunctional. Most Denys-Drash mutations are single–base-pair mutations, with a mutational hot spot in exon 9.[8] Potential dominant negative *WT1* mutations have also been seen in sporadic Wilms' tumor specimens containing only one mutated *WT1* allele.[48,49 and 50]

The characterization of *WT1* has provided insight not only into the mechanisms underlying the development of Wilms' tumor but also into those involved in genitourinary development.[51,52 and 53] Study of the embryonic-lethal homozygous *WT1*-knockout mouse reveals failure of kidney development and that WT1 expression is necessary for the survival and differentiation of the metanephric blastema.[52] These mice also exhibit lack of gonadal development, which may reflect lack of interaction between *WT1* and sex-determining genes such as *SRY*, Müllerian-inhibiting substance, and the androgen receptor.[53]

The unexpectedly low frequency of *WT1* mutations suggests that other genetic alterations account for the majority of Wilms' tumors. Given the complex pattern of *WT1* transcription, DNA-binding specificity, and transcriptional regulating capacity, however, it remains possible that *WT1* may be involved in more cases than are immediately obvious or that a further Wilms' tumor suppressor locus may reside in the 11p13 region.

### *WT2*

The existence of a second Wilms' tumor gene on chromosome arm 11p was first appreciated by the fact that a subset of Wilms' tumors undergoes LOH for markers telomeric to 11p13, not including *WT1*. This second locus, designated *WT2*, may explain the association of Wilms' tumor with BWS,[54,55] a congenital overgrowth syndrome characterized by overgrowth—ranging from gigantism to regional hypertrophy (hemihypertrophy) or visceromegaly and macroglossia, hyperinsulinemic hypoglycemia and a predisposition to several embryonal neoplasms. Although most BWS cases are sporadic, approximately 15% are familial or associated with chromosomal abnormalities.[56] Linkage analysis has suggested that the locus for the familial form of BWS maps to band 11p15.[54,55] Whether the *BWS* gene and *WT2*

are one and the same gene is unclear. Interestingly, in tumors with LOH, it is invariably the maternal copy of band 11p15 that is lost, [57,58 and 59] suggesting that the two copies of *WT2* are not functionally equivalent. This phenomenon is thought to be due to genomic imprinting, a process whereby one allele is marked, or imprinted, in a parental-specific manner to be functionally inactive. The imprint is not coded for by the DNA sequence because it must be reversible during gametogenesis.

Thus far at least three candidate imprinted genes have been proposed for *WT2*, including the insulin-like growth factor II gene (*IGFII*),[60,61 and 62] *H19* (an untranslated RNA),[63,64] and *p57*$^{kip2}$.[65,66 and 67] *IGFII* encodes an embryonal growth factor that is highly expressed in fetal kidney and Wilms' tumors. [60] In humans only the paternal *IGFII* allele is expressed,[61,62] and increased expression of this imprinted gene could conceivably contribute to the development of Wilms' tumor and BWS. Because LOH for 11p15 markers in Wilms' tumors represents loss of the inactive maternal allele with duplication of the active paternal allele, the LOH may cause up-regulation of the “oncogene” *IGFII* rather than loss of a tumor suppressor gene. Consistent with this hypothesis is the observation that some Wilms' tumors that have not lost heterozygosity at 11p15 have instead a relaxation (or loss) of the imprint at the *IGFII* locus.[61,62] This results in biallelic and presumably increased expression of the *IGFII* gene. Similarly, constitutional loss of the imprint has been associated with some cases of BWS. [68]

There is also evidence for the involvement of an adjacent locus *H19*. *H19* is imprinted in a reciprocal manner to *IGFII*, with expression restricted to the maternal allele.[63] Introduction of *H19* into Wilms' tumor and rhabdomyosarcoma cell lines suppresses both growth and tumorigenicity, suggesting that loss of *H19* may contribute to the development of Wilms' tumor. [64] Transfection of a subchromosomal 11p15 fragment not including *IGFII* or *H19* into a rhabdomyosarcoma cell line, however, also results in growth suppression, [69] suggesting additional or alternate tumor suppressor genes at 11p15. Notably, loss of the maternal *H19* allele and loss of the imprint both result in inactivation of *H19*.[62,63] Finally, *p57*$^{kip2}$, a paternally imprinted gene encoding a cell cycle regulator and located 500 kb centromeric to *IGFII*, might also be involved in Wilms' tumorigenesis. Although expression of the *p57*$^{kip2}$ gene is reduced in some Wilms' tumors,[66,67,70] the relationship between decreased expression and Wilms' tumor development remains to be determined.

In summary, there is strong evidence that alterations at one or more imprinted loci on band 11p15 underlie the development of BWS and may predispose to the development of Wilms' tumor. Whether BWS and Wilms' tumor result from alterations to the same gene or whether multiple loci are affected by a single genetic mechanism remains uncertain.

### Other Possible Wilms' Tumor Loci

LOH for markers on the distal long arm of chromosome 16 has been found in approximately 20% of Wilms' tumors, [59,71] and loss of the short arm of chromosome 1 has been found in approximately 10% of cases.[72] Both events may be associated with adverse outcome,[72] so the putative underlying tumor suppressor loci are likely involved in tumor progression rather than initiation. One of the major objectives of the ongoing fifth National Wilms' Tumor Study (NWTS-5) is to confirm the prognostic significance of 1p and 16q LOH and to ascertain their clinical significance within each tumor stage.

Analyses of karyotypes from Wilms' tumors and from patients with Wilms' tumor have identified recurrent deletions and translocations involving the short arm of chromosome 7.[73,74,75 and 76] In addition, tumor-specific LOH for 7p markers has been detected in 14% of 35 Wilms' tumors analyzed, [77] together suggesting the presence of a genetic locus involved in the genesis of Wilms' tumor at chromosome arm 7p. Clinical correlates of 7p LOH have not been published, so the exact role of this possible Wilms' locus, if any, has yet to be determined.

Alterations of the *p53* tumor suppressor gene and its encoded protein are the most frequently encountered genetic events in human cancer, having been reported in almost every type of sporadic neoplasm.[78] Moreover, constitutional *p53* mutations are associated with the multi-cancer predisposition syndrome named after Li and Fraumeni.[79] Based on a study of the family histories of 176 children with Wilms' tumor, [20] the suggestion was made that Wilms' tumor might be a rare component of the Li-Fraumeni syndrome. Given the rarity of the Li-Fraumeni syndrome and the relatively higher frequency of Wilms' tumor, however, this observation may represent a sampling bias rather than a true association. Meanwhile, the incidence of *p53* mutations in sporadic Wilms' tumors, unlike that observed in many other malignancies, is relatively low, probably less than 10%.[80,81 and 82] Results of one study suggest that *p53* alterations in Wilms' tumor are associated with anaplastic histology, [80] a histopathologic variant of Wilms' tumor with poor prognosis. A second study, [81] however, identified a *p53* mutation in a favorable histology Wilms' tumor that carries an excellent prognosis. Further studies are required to ascertain the exact biologic significance of *p53* mutations in Wilms' tumor.

### Familial Wilms' Tumor

Familial Wilms' tumor accounts for 1% to 2% of all cases.[83,84 and 85] In view of the absence of parental consanguinity in such families, the mode of inheritance is generally thought to be autosomal dominant, with variable penetrance and expressivity. [86] Only one-tenth of the kindreds reported involve affected parents. [85] More often, the disease occurs in siblings, cousins, or other relatives. The fraction of Wilms' tumor cases that are of hereditary origin was originally estimated to be 38%, but this has since been revised downward to between 15% and 20%. [87] If the two-stage model is correct, one would expect to see increasing numbers of Wilms' tumors in the offspring of survivors of the disease, especially if they had the familial, bilateral, or other “hereditary” form. However, a survey of 191 children of 99 patients with unilateral Wilms' tumor did not identify a single case of cancer. [88,89] True estimates of the risks in offspring of Wilms' tumor patients will await follow-up of offspring from survivors of the National Wilms' Tumor Study Group (NWTSG) and other large patient populations.

Linkage analyses in several pedigrees have excluded both *WT1* and *WT2* on chromosome arm 11p from conferring susceptibility to Wilms' tumor.[90,91] Similarly, chromosome arm 16q has been excluded as the site for the familial Wilms' tumor locus. [92] Several pedigrees have now demonstrated linkage to band 17q12-21 and the locus termed *FWT1*. Neither familial nor sporadic Wilms' tumors have undergone LOH for this region, as would be expected if *FWT1* were a tumor suppressor locus.[93] A second locus, *FWT2*, has been mapped to chromosome region 19q13.3-q13.4.[94] As some families exhibit evidence against linkage to WT1, FWT1, and FWT2,[94,95 and 96] however, the existence of yet additional Wilms' tumor loci must be assumed. Comparative genomic hybridization analysis of familial tumors has implicated chromosome arms 4q, 9p, 20p, and 3q as areas of potential interest. [97] These regions have not previously been implicated in the biology of Wilms' tumor and may potentially harbor genes predisposing to familial Wilms' tumor or involved in sporadic Wilms' tumor.

In summary, the development and progression of Wilms' tumor involves a number of genetic loci. Ongoing research will undoubtedly help uncover which genetic and epigenetic (imprinting) alterations are truly important in the biology of this tumor. This knowledge in turn will facilitate a better understanding of the disease as well as provide new prognostic factors useful for determining the intensity of therapy.

To this same end, measures of telomerase levels and function have been studied in a relapsed case:cohort series of Wilms' tumors. Virtually all tumors demonstrated evidence of telomerase expression or function, consistent with other malignant neoplasms. One measure, mRNA expression of *hTERT*, the RNA component that encodes the catalytic component of telomerase, was found to be associated with risk of recurrence in univariate analyses. [98] Further studies are necessary to confirm this finding and to discern its clinical utility.

## PATHOLOGY

The earliest known specimen of Wilms' tumor is on display in the Hunterian Museum of the Royal College of Surgeons in London, England. [99] This specimen of bilateral renal tumors from a young infant was prepared by John Hunter, who died in 1793, and is in an excellent state of preservation. Subsequently, Rance, Eberth, and others recorded examples of this tumor. A detailed analysis of 145 cases was published in 1897 by Walker, but the monograph by Max Wilms is regarded as the classic description.[100]

Since its classic description by Wilms, nephroblastoma has been noted for its tremendous histologic diversity and ability to display a wide variety of cell and tissue types.[101] Much of the past success of the NWTSG has relied on the accurate subclassification of tumors into high- and low-risk types, allowing the intensity of therapy to be modified appropriately. Pathologic review of these tumors centrally at the NWTSG Pathology Center from 1969 onward has ensured the consistency of pathologic assessments and allowed for this progress. Further subclassification will likely depend on categorization of Wilms' tumors on the basis of molecular features.

### Gross Appearances and Patterns of Extension

Most Wilms' tumors are solitary lesions; however, a substantial number are multifocal, with 7% involving both kidneys either at presentation or subsequently, and an

additional 12% arising multifocally within a single kidney. [102] There is no predilection for either side, and the tumor may arise anywhere within the kidney. Extrarenal Wilms' tumors are rare and generally occur in the retroperitoneum adjacent to but unconnected with the kidney. [103] Others have been found in the pelvis, inguinal region, and thorax and are thought to arise in displaced metanephric elements, mesonephric remnants, or teratomas.

Wilms' tumors commonly have a uniform pale gray or tan color on section, although hemorrhage and necrosis frequently impart a variegated appearance. Cysts are commonly encountered and may be a dominant feature. Not uncommonly, especially in infants, a polypoid extension into the pyelocalyceal lumen may resemble the growth pattern seen in botryoid rhabdomyosarcoma.[104] Tumors with a predominance of differentiating stromal elements may have a firm texture, but most specimens are notably soft and friable. This may contribute to the local spread of tumor cells when a tumor is ruptured either before or during operation. Wilms' tumors are usually sharply demarcated, relatively spherical masses with a “pushing” border relative to the adjacent renal parenchyma. A distinct intrarenal pseudocapsule composed of compressed, atrophic renal tissues commonly surrounds Wilms' tumors. This feature may help to distinguish Wilms' tumor from mesoblastic nephroma, clear cell sarcoma, rhabdoid tumor, and renal lymphoma, all of which demonstrate infiltrative borders. Wilms' tumors not infrequently involve the renal vein and may extend up the inferior vena cava to reach the right atrium.

**Histology**

The most distinctive microscopic feature of Wilms' tumor is its diversity. The classic nephroblastoma is made up of varying proportions of three cell types—blastemal, stromal, and epithelial—often recapitulating various stages of normal renal development ( Fig. 30-1). Blastemal cells are undifferentiated small blue cells that may be arranged in diffuse or organoid patterns. [105] Epithelial structures such as glomeruli and tubules simulating the normal nephrogenic zone are commonly seen. Less commonly, papillary formations or heterologous squamous or mucinous epithelium unlike any in the normal developing kidney are identified. Stromal differentiation is usually manifest as immature spindled cells, heterologous skeletal muscle, cartilage, osteoid, or fat. [101,106] Not all specimens are triphasic, and biphasic as well as monophasic patterns are frequently encountered. The monophasic patterns often present diagnostic difficulties. Monophasic blastemal Wilms' tumor are often highly invasive and may raise the differential diagnosis of other small round blue cell tumors, such as primitive neuroepithelial tumor, neuroblastoma, and lymphoma. Similarly, monophasic undifferentiated stromal Wilms' tumor may simulate primary sarcomas such as clear cell sarcoma of the kidney, congenital mesoblastic nephroma, or synovial sarcoma. Other stromal Wilms' tumors show a predominance of skeletal muscle differentiation varying from well differentiated (rhabdomyomatous) to poorly differentiated skeletal muscle (rhabdomyoblastic). The distinction of a pure rhabdomyoblastic Wilms' tumor (which is quite rare) from a primary renal rhabdomyosarcoma is often impossible on morphologic grounds. Such lesions should be treated on the basis of their line of differentiation rather than their putative cell of origin. Finally, purely tubular and papillary Wilms' tumor may at times be difficult to distinguish from papillary renal cell carcinoma. [105] In fact, it has been suggested that there may be a biologic link between nephroblastic lesions and some renal cell carcinomas. [105]

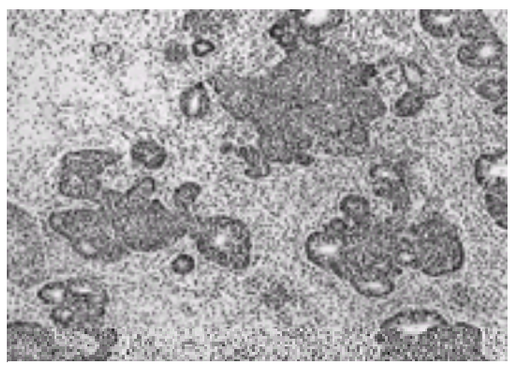

**FIGURE 30-1.** Triphasic Wilms' tumor, with well-defined tubules surrounded by dense clusters of blastemal cells and zones of pale-staining stromal differentiation (hematoxylin and eosin, 100×).

Wilms' tumors often contain scattered cysts; however, not uncommonly tumors present that are predominantly or purely cystic. Those that have grossly identifiable solid nodules of tumor are best classified as cystic Wilms' tumors. Tumors that are devoid of any solid nodular growth but which contain immature nephrogenic elements within their septa are designated *cystic partially differentiated nephroblastoma* (CPDN). Others contain only mature cell types and are classified as cystic nephroma (CN). CPDN and CN are both curable by surgery alone and are thought to represent the most favorable end of the Wilms' spectrum in children. Either lesion can recur if ruptured or incompletely excised, so distinction of CN from CPDN is of little clinical significance. [107] A familial association between CN and the often cystic pleuropulmonary blastoma has been reported.[108,109]

A correlation between the histologic pattern and the clinical behavior of Wilms' tumor has long been sought. The most significant correlation that has been reported is the distinction of “favorable” from “unfavorable” histology Wilms' tumor. When anaplastic nuclear changes, as described below, are not present, the histology is termed *favorable* because of the generally good outcome for these patients. [101] Other more limited correlations between behavior and histology have been reported. Blastemal-rich tumors tend to be extremely invasive and present at a high stage, but often respond well to chemotherapy. In contrast, predominantly epithelial and rhabdomyomatous Wilms' tumors more frequently present at a low stage, reflecting less aggressiveness, yet are often resistant to chemotherapy. Although these prognostic trends are intriguing, they have not been statistically significant possibly due to the small number of stage IV predominantly epithelial Wilms' tumor available for analysis.[110]

***Anaplastic Wilms' Tumor***

*Anaplasia* is defined by the presence of markedly enlarged polyploid nuclei within the tumor sample ( Fig. 30-2). The criteria for the diagnosis of anaplasia include the following: (a) the identification of nuclei with a diameter at least three times those of adjacent cells; (b) hyperchromasia of the enlarged cells, providing evidence for increased chromatin content; and (c) the presence of multipolar or otherwise recognizably polyploid mitotic figures. [111] All of these features must be identified for the diagnosis of anaplasia, although occasionally, when only a small biopsy is available, the presence of a single multipolar mitotic figure or an unequivocally gigantic tumor cell nucleus will suffice to establish the diagnosis. The frequency of anaplasia is approximately 5% and correlates with patient age. It is rare in the first 2 years of life (2% of NWTS-3 patients) and then increases to a relatively stable rate of approximately 13% in patients older than 5 years. It is significantly more frequent in African-American than in white patients.[111]

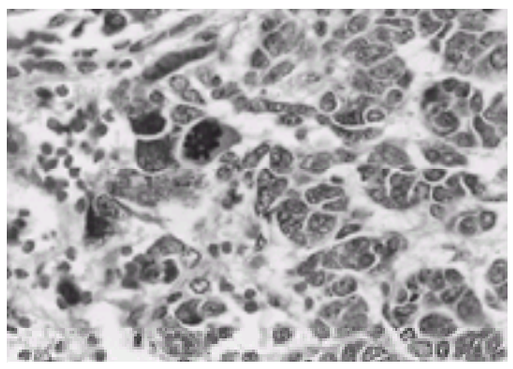

**FIGURE 30-2.** Anaplastic Wilms' tumor with a large, darkly stained multipolar mitotic figure near the center and a markedly enlarged interphase nucleus to its left. Nuclei throughout this field exhibit increased variation in size and shape (hematoxylin and eosin, 600×).

Stage I anaplastic Wilms' tumor has the same excellent prognosis as stage I favorable histology Wilms' tumor, whereas stages II through IV anaplastic Wilms' tumor have a markedly diminished prognosis, suggesting that anaplasia is a marker of resistance to chemotherapy but not of increased aggressiveness or tendency to disseminate.[112] This recognition has resulted in a distinction between tumors showing anaplastic changes that are focal and those that are diffuse. [113] The diagnosis of focal anaplasia requires that cells with anaplastic nuclear changes be confined to sharply circumscribed regions within the primary tumor, and that these cells are not present in any site outside the kidney parenchyma. The diagnostic criteria for diffuse anaplasia includes any one of the following: (a) presence of anaplasia in any extrarenal site, including vessels of the renal sinus, extracapsular infiltrates, or nodal or distant metastases; (b) presence of anaplasia in a random biopsy specimen; (c) unequivocal anaplasia in one region of the tumor, coupled with extreme nuclear pleomorphism approaching the criteria of anaplasia (extreme nuclear unrest) elsewhere in the lesion; (d) presence of anaplasia in more than one tumor slide, unless (i) it is known that every slide showing anaplasia came from the same region of the tumor, or (ii) anaplastic foci on the various slides are minute and surrounded on all sides by nonanaplastic tumor. The distinction between focal and diffuse anaplasia has been demonstrated to be prognostically significant. [113]

### *Nephrogenic Rests*

The existence of precursor lesions to Wilms' tumor has been recognized for many years. [114,115] These nephrogenic rests are found in almost 1% of unselected pediatric autopsies, in 35% of kidneys with unilateral Wilms' tumor, and in nearly 100% of kidneys with bilateral Wilms' tumor. [116] They are composed of abnormally persistent embryonal nephroblastic tissue with small clusters of blastemal cells, tubules, or stromal cells ( Fig. 30-3). Nephrogenic rests are classified by their position within the kidney. Intralobar nephrogenic rests are randomly distributed but tend to be situated deep within the renal lobe, likely reflecting an earlier developmental insult to the kidney. These lesions are commonly stroma rich and intermingle with the adjacent renal parenchyma. Perilobar nephrogenic rests are located at the periphery, are usually subcortical and sharply demarcated, and contain predominantly blastema and tubules. These presumably reflect later developmental disturbances in nephrogenesis. Morphologic distinction of the two types of rests is of interest because they have different clinical and pathologic associations ( Table 30-2).[117] The term *nephroblastomatosis* is used to refer to the presence of multiple nephrogenic rests. Diffuse overgrowth of perilobar nephrogenic rests may produce a thick “rind” of blastemal or tubular cells that enlarge the kidney but preserve its original shape. There are several possible fates for nephrogenic rests. Only a small number develop a clonal transformation into Wilms' tumor. When this happens, the Wilms' tumor is typically spherical and develops a pseudocapsule separating it from the nephrogenic rest. Some nephrogenic rests may become hyperplastic, with dramatic enlargement that preserves the shape of the preceding rest. Such lesions may be histologically indistinguishable from Wilms' tumor unless the interface between the rest and the adjacent normal kidney is present within the sample. Hyperplastic nephrogenic rests may completely regress or differentiate after the administration of chemotherapy. The majority of nephrogenic rests becomes dormant or involutes spontaneously. The presence of nephrogenic rests within a kidney resected for a Wilms' tumor indicates the need for monitoring the contralateral kidney for tumor development, particularly in infants.[118]

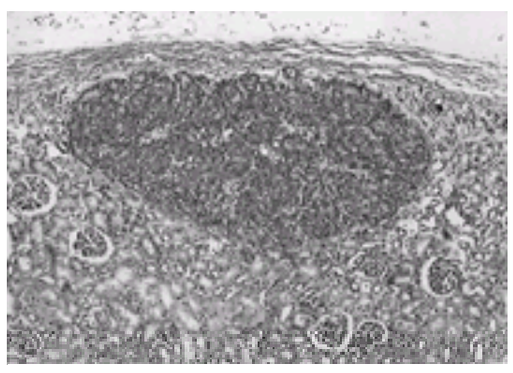

**FIGURE 30-3.** Perilobar nephrogenic rest. An ovoid subcapsular mass of embryonal blastemal and tubular cells is sharply demarcated from the adjacent renal cortex. This was found in the grossly normal portion of the kidney in a 3-year-old child with unicentric Wilms' tumor (hematoxylin and eosin, 125×).

| | Intralobar | Perilobar |
|---|---|---|
| Associated syndromes | Wilms' tumor, aniridia, genitourinary malformation, mental retardation, Denys-Drash | Beckwith-Wiedemann |
| Location within renal lobe | Random, often central | Peripheral |
| Interface with kidney | Intermingling | Distinct |
| Dominant histologic component | Stroma | Blastema or tubules |
| Number | Usually single | Often multiple |

**TABLE 30-2. NEPHROGENIC RESTS: PERILOBAR VERSUS INTRALOBAR**

### Clear Cell Sarcoma of the Kidney

Clear cell sarcoma of the kidney is the second most common pediatric renal neoplasm and is a tumor associated with a significantly higher rate of relapse and death than favorable histology Wilms' tumor. This variant was described in detail in 1978 by three independent groups. [101,119,120] The descriptive term *clear cell sarcoma of the kidney* is based on the staining characteristics of the predominant cell type; others have referred to *bone-metastasizing renal tumor of childhood* because bone is a common metastatic site. Clear cell sarcoma of the kidney has a far wider distribution of metastases than favorable histology Wilms' tumor, both by age and by site. Both spread to the lungs most frequently, but clear cell sarcoma of the kidney has a strikingly increased number of brain, bone, and soft tissue metastases, as well as an extended time period during which metastases may present. [121,122 and 123]

Most clear cell sarcoma of the kidney specimens have a distinct histologic appearance, but a number of variant patterns, such as epithelioid, spindling, myxoid, and cystic, invite confusion with Wilms' tumor or other tumor types. [123,124,125 and 126] As a result, clear cell sarcoma of the kidney remains the pediatric renal tumor most frequently misdiagnosed. The classic morphologic pattern of clear cell sarcoma is biphasic, composed of nests of plump cord cells containing abundant extracellular matrix separated by a network of capillary vascular arcades that are often surrounded by more spindled septal cells ( Fig. 30-4). Finally, clear cell sarcoma can show anaplastic nuclear features identical to those of anaplastic Wilms' tumor. Immunohistochemical studies are useful in the exclusion of other tumors, but no positive diagnostically useful immunohistochemical or genetic markers have been identified to date. [123]

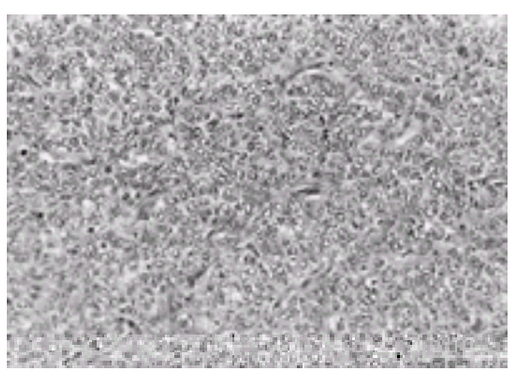

**FIGURE 30-4.** Clear cell sarcoma of the kidney, classic pattern. Cords and nests of pale-stained tumor cells are separated by a delicate but distinct network of fine vascular septa. Nuclei are vesicular, with poorly stained chromatin and inconspicuous nucleoli (hematoxylin and eosin, 200×).

### Rhabdoid Tumor of the Kidney

A distinctive and highly malignant tumor, rhabdoid tumor of the kidney was identified in 1978 by NWTSG pathologists. [101] Rhabdoid tumor of the kidney occurs more frequently in infants, with 85% of cases occurring within the first 2 years of life and a sharp decline thereafter. The diagnosis should be considered highly suspect over the age of 5 years.[127] The tumor is commonly widely metastatic at presentation, and in both NWTSG and Societe Internationale d'Oncology Pediatrique (SIOP) studies, more than 80% of children died within 1 year of diagnosis. [127,128]

Rhabdoid tumors are usually bulky masses centered in the renal hilum, with a grossly indistinct tumor border reflecting aggressive invasion. Prominent intrarenal vascular invasion leads to frequent satellite nodules that may be seen grossly. The tumor characteristically grows as sheets of monotonous discohesive cells characterized by vesicular nuclei, prominent macronucleoli, and hyaline cytoplasmic inclusions ( Fig. 30-5). However, these cytologic features may be variably present and diligent search may be required before diagnostic foci are encountered. In addition, a large number of variant patterns have been described, including sclerosing, epithelioid, spindled, vascular, and lymphomatoid, all of which can simulate other neoplasms. [129] Rhabdoid tumor received its name because of the prominent acidophilic cytoplasm, resembling rhabdomyoblasts. However, it has been amply demonstrated that rhabdoid tumors are not related to myogenic cells and are negative for ultrastructural or other markers of skeletal muscle. The cell of origin for this distinctive tumor remains unknown. [129,130] and [131] It is not a variant of Wilms' tumor and has not been encountered as a focal change in a conventional Wilms' tumor.

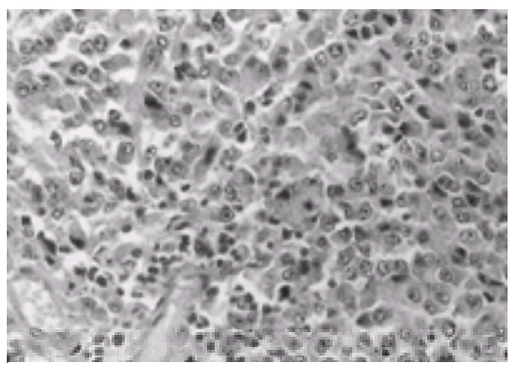

**FIGURE 30-5.** Rhabdoid tumor. Most nuclei have a large, single nucleolus, imparting an “owl's eye” appearance to the nucleus. Several cells, including one near the center, have hyaline globular cytoplasmic inclusions. Ultrastructurally, the latter inclusions consist of whorled masses of intermediate filaments, usually composed of vimentin (hematoxylin and eosin, 600×).

Rhabdoid tumors characteristically show a polyphenotypic immunohistochemical staining pattern, with focal strong positivity for a variety of markers, including cytokeratin, epithelial membrane antigen, desmin, and neurofilament. The presence of scattered clusters of intensely epithelial membrane antigen or cytokeratin positive cells in a background of negative staining is a characteristic of rhabdoid tumors that is unique among the pediatric tumors in the differential diagnosis.

The pathologic diagnosis of renal rhabdoid tumors is complicated by two features. The first is that a variety of renal and nonrenal tumors can show rhabdoid features.[132,133] The majority of such tumors in patients older than 5 years represent other neoplasms. Many of these “pseudorhabdoid” lesions have been identified by immunohistochemistry or other techniques to be carcinomas, melanomas, histiocytic tumors, or sarcomas. The recent establishment of consistent deletion of 22q11-12 in both renal and extrarenal rhabdoid tumors in infants supports the existence of a biologically distinct primary rhabdoid tumor of early childhood. [134,135,136] and [137] The common area of deletion has been recently been mapped to the *hSNF5/INI1* gene.[138] Tumor-specific genetic abnormalities that have been reported include deletions and truncating mutations. Germline mutations have been demonstrated in some children. [139]

A second complicating feature of renal rhabdoid tumors is the association with brain tumors, most of which are located in the midline cerebellum. [140] Many of these tumors have been classified as medulloblastoma or primitive neuroectodermal tumors, although tumors classified as gliomas and ependymomas have been reported. More recently, it has been recognized that infantile rhabdoid tumors of the brain, also known as atypical teratoid tumors, often have the same histologic appearance as undifferentiated medulloblastomas or primitive neuroectodermal tumors yet show the chromosome 22 abnormalities seen in renal rhabdoid tumors. [141] It may be difficult, if not impossible, in individual cases to determine if synchronous or metachronous renal and central nervous system lesions represents metastases or two primary sites in a patient with a predisposition of tumor development.

### Congenital Mesoblastic Nephroma

The term *congenital mesoblastic nephroma* was applied by Bolande and colleagues [142] in 1967 to a distinctive renal neoplasm of infancy. Congenital mesoblastic nephroma occurs predominantly in infants, with a median age of 2 months.[143] Three histologic subtypes have been defined: the classic type (24% of cases), the more frequent cellular type (66% of cases), and mixed type (10% of cases) showing both classic and cellular patterns. [144] The classic subtype of congenital mesoblastic nephroma grows as intersecting fascicles of bland spindle cells with tapered nuclei and pink cytoplasm and is histologically similar to infantile fibromatosis. Mitoses are usually infrequent and necrosis is absent. The cellular subtype of congenital mesoblastic nephroma has a solid, cellular, sheetlike growth pattern of oval or round cells with little cytoplasm and frequent mitoses and necrosis. The mixed type of congenital mesoblastic nephroma features areas resembling both classic and cellular morphologies. Although classic congenital mesoblastic nephromas histologically resemble infantile fibromatosis, the cellular congenital mesoblastic nephroma resembles infantile fibrosarcoma. Recently, a genetic linkage between infantile fibrosarcoma and cellular congenital mesoblastic nephroma was established when the chromosome translocation t(12;15)(p13;q25), initially discovered in infantile fibrosarcoma, [145] was also identified in cellular congenital mesoblastic nephroma. [146,147] and [148] The cloning of the resulting gene fusion has allowed the development of molecular detection assays for this subtype of congenital mesoblastic nephroma. [149] The absence of the fusion product in classic congenital mesoblastic nephroma correlates with its demonstrated absence in infantile fibromatosis.

The most significant clinical and pathologic feature of congenital mesoblastic nephromas is their tendency to grow into the hilar and perirenal soft tissue, often in a subtle fashion. As a result, recurrence or metastasis is seen in up to 20% of patients. [150,151,152] and [153] Because of this tendency, congenital mesoblastic nephroma deserves a radical surgical approach, with efforts to secure a wide margin of uninvolved tissue on all aspects of the specimen, but particularly the medial aspect. After surgery, any residual tumor may recur with astonishing rapidity; therefore, close radiographic follow-up is indicated for the first year. The poor response shown by congenital mesoblastic nephromas to chemotherapy and radiation therapy highlights the importance of surgical excision.

### Renal Cell Carcinoma

The classic forms of renal cell carcinoma of adulthood are quite rare in children in the absence of a genetic predisposition. [154,155] However, there is a growing appreciation that a distinctive, but rare, subtype of renal cell carcinoma presents in adolescence and young adulthood. These tumors are genetically unique in that they have chromosome translocations involving a common breakpoint at Xp11.2.[156,157,158] and [159] These tumors show a distinct male predominance. Histologically, these may show a great resemblance to clear cell renal cell carcinoma, with copious clear cytoplasm. However, one clue to their diagnosis is that they often have a papillary architecture. The genetic alterations commonly associated with papillary renal cell (trisomy 7,17) and clear cell renal cell (3p deletion) carcinomas in adults have not been found in the tumors containing Xp11 alterations. The NWTSG pathology center has encountered other translocations as the sole genetic abnormality in tumors classified as renal cell carcinomas ( *unpublished data*). The clinical significance of these translocations, including the Xp11 translocation, is currently unknown.

Because these tumors are genetically distinct from those found in adults, however, the utility of nuclear grading is questioned.

Another unique and rare renal carcinoma that predominantly involves children is the recently described renal medullary carcinoma. [160] This highly lethal tumor is virtually restricted to patients with sickle cell hemoglobinopathy, most commonly sickle cell trait. This tumor may present in children as young as 3 years and has been reported into middle age; however, the median age at presentation is 13 years. Renal medullary carcinomas are histologically characterized by a rhabdoid phenotype, abundant acute inflammation, a highly invasive growth pattern, and early metastasis. Sickled cells are usually present in the tissue sections and should make the diagnosis evident.

## CLINICAL PRESENTATION

Osler[161] provided the first North American description of the signs and symptoms of the tumor that Wilms described 20 years later. Most children with Wilms' tumor are brought to medical attention because of abdominal swelling or the presence of an abdominal mass. [100] Often this is noticed by a parent while bathing or dressing the child. Abdominal pain, gross hematuria, and fever are other frequent findings at diagnosis. [100] Hypertension, present in approximately 25% of cases, has been attributed to an increase in renin activity. [162]

A characteristic presentation for a subset of Wilms' tumor patients includes rapid abdominal enlargement, anemia, hypertension, and, sometimes, fever. These symptoms may be associated with egg-shell–type calcification visible on plain radiographs of the abdomen. The syndrome appears to be related to sudden subcapsular hemorrhage.[162]

During the physical examination, it is important to note the location and size of the abdominal mass. A Wilms' tumor is usually a large flank mass that does not particularly move with respiration. These findings help differentiate Wilms' tumor from splenomegaly and neuroblastoma, the latter often arising in the celiac axis or extending across the midline because of lymph node involvement. A varicocele secondary to obstruction of the spermatic vein may be associated with the presence of a tumor thrombus in the renal vein or inferior vena cava. Persistence of the varicocele when the child is supine is highly suggestive of venous obstruction. It is also important to specifically note any signs of the Wilms' tumor–associated syndromes marked by the presence of aniridia, BWS-associated facial dysmorphisms, partial or complete hemihypertrophy, and genitourinary abnormalities including hypospadias, cryptorchidism, and pseudohermaphrodism.

### Differential Diagnosis

The chief differential diagnosis for Wilms' tumor is another embryonal tumor, neuroblastoma. The distinction is usually relatively easy, because most neuroblastomas arise from the adrenal gland or the paravertebral sympathetic ganglia, whereas Wilms' tumors are almost always intrarenal. Benign processes and other malignant intrarenal neoplasms can produce clinical and radiographic findings similar to those of Wilms' tumor, however, and as many as 9% of tumors are misdiagnosed without the benefit of biopsy (Table 30-3).[163,164]

| Diagnosis | National Wilms' Tumor Study Group | Société Internationale d'Oncologie Pédiatrique | Total |
|---|---|---|---|
| Neuroblastoma | 9 | 19 | 28 |

**TABLE 30-3. DIAGNOSES IN 1,028 CHILDREN WITH SUSPECTED WILMS' TUMOR**

### Workup

Laboratory evaluation should include a complete peripheral blood count, liver function tests, renal function tests, serum calcium, and urinalysis. Elevation of the serum calcium may occur in children with rhabdoid tumor of the kidney or congenital mesoblastic nephroma. [165,166] Acquired von Willebrand's disease may occur in approximately 8% of patients at diagnosis, and consideration should be given to coagulation assays. [167]

## IMAGING STUDIES

Imaging studies preoperatively and in follow-up should be designed to assist the clinicians managing the child. They must therefore consider the known characteristics of the tumors at presentation and of metastatic patterns based on the tumor type, including favorable and anaplastic histology Wilms' tumor, clear cell sarcoma of the kidney, rhabdoid tumor of the kidney, and congenital mesoblastic nephroma.

Initial imaging studies should be restricted to those necessary to establish the presence of an intrarenal space-occupying lesion, to guide the surgeon, and to assist the radiation therapist should postoperative radiation therapy be indicated. Data of importance to the surgeon include the presence and function of the opposite kidney, whether the opposite kidney is involved with tumor, and the presence and extent of an intravascular tumor thrombus.

The initial radiographic study often selected is an abdominal ultrasound examination ( Fig. 30-6). This will demonstrate whether the abdominal mass is solid or cystic and establish the renal origin of the mass as well as the measurement of the maximum diameter of the mass. Contrast-enhanced computed tomography (CT) of the abdomen (Fig. 30-7) is also recommended to further evaluate the nature and extent of the mass. Although this study may suggest apparent extension of the tumor into adjacent structures such as the liver, spleen, or colon, most children identified as having possible invasion of the liver on CT are found at the time of surgical exploration to have hepatic compression rather than hepatic invasion. [168] In addition the examination may demonstrate small lesions in the opposite kidney that may be nephrogenic rests or Wilms' tumor, although small superficial or intrarenal lesions are frequently not identified even when CT is used. [169] It is important, when CT is used, that the radiologist obtain a supine x-ray film of the abdomen after contrast injection, because this view is necessary for planning and review of radiation therapy.

**FIGURE 30-6.** Wilms' tumor sonogram. A prone sagittal scan of right renal fossa demonstrates a large, complex, mainly solid intrarenal mass.

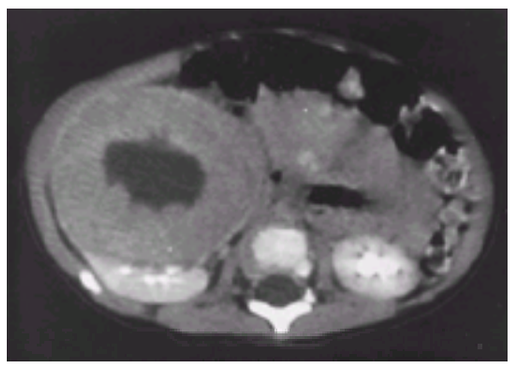

**FIGURE 30-7.** Computed tomography scan of the abdomen showing a right renal tumor and a normal appearing left kidney.

The patency of the inferior vena cava may be demonstrated relatively inexpensively using real-time ultrasonography. When a tumor is identified within that vessel, the proximal extent of the thrombus must be established before operation because extension of the thrombus to the right atrium may result in few if any clinical signs. [170,171] Exceptionally, sudden death has been reported following dislodgement and mobilization of the tumor lying within the draining vessels at laparotomy. [172]

The results of the radiographic studies and real-time ultrasonography provide sufficient information on which to make a decision for laparotomy in most children, although no imaging study unequivocally establishes the histologic diagnosis of Wilms' tumor.

Plain chest radiographs or CT of the chest should be obtained to determine whether pulmonary metastases are present. CT has been compared to conventional radiographic studies in Wilms' tumor patients in two studies. In the first, 9.4% (11 of 117) of the CT scans demonstrated densities not identified on a plain chest radiograph, although none of these patients underwent open lung biopsy for confirmation of the histology of the pulmonary lesions. [173] In the other, only 2.4% (2 of 83) of the CT scans demonstrated densities not identified using *four-view* chest radiography, and one of the lesions was shown pathologically to be a granuloma, not a metastasis.[174] Conversely, another study reported that four of five biopsied solitary lesions from the lungs of children with Wilms' tumor identified only by CT were, in fact, pulmonary metastases.[175] These data suggest that when pulmonary nodules are small enough to be identified by CT only, consideration should be given to biopsying at least one of them.

A radionuclide bone scan and x-ray skeletal survey should be obtained postoperatively in children with clear cell sarcoma of the kidney and other children with pulmonary or hepatic metastases who have suggestive symptomatology. Both studies are necessary because plain radiographs of the bones involved with clear cell sarcoma of the kidney can demonstrate lytic lesions that may not be seen on bone scan.[176,177]

Brain imaging using magnetic resonance imaging or computerized tomography should be obtained on all children with clear cell sarcoma of the kidney or with rhabdoid tumor of the kidney, because both are associated with intracranial metastases. [121,129] Second primary malignant brain tumors of varying histologic type, often arising in the posterior fossa, are also found in patients with rhabdoid tumor of the kidney. [127,129,140]

## STAGING

A single set of criteria is used by the NWTSG to stage all pediatric renal tumors. These criteria have evolved over the years, and the current definitions are listed in Table 30-4. The most significant recent change has been in the criteria for distinguishing between stages I and II. [178] Before NWTS-5, the criteria for stage II included either renal capsular penetration or extension of the tumor past the hilar plane, an imaginary boundary marked by the medial border of the renal sinus. The hilar region, also referred to as the renal sinus, is biologically quite important because it contains the major renal vessels, an important mode of hematogenous and lymphatic spread. The hilar plane lacks a defining anatomic border, however, is often distorted by bulky tumors and can be assessed only on initial gross pathologic examination of the nephrectomy specimen. The hilar plane criterion for staging was removed from NWTS-5 and replaced by the criterion of renal sinus vascular invasion. This definition includes involvement of vessels located in the radial extensions of the sinus into the renal parenchyma but excludes other intrarenal vascular invasion. Applying the new criteria, the difference in survival between stage I and II Wilms' tumors continues to be statistically significant.

| Stage | Description |
|---|---|
| I | Tumor confined to the kidney and completely resected. No penetration of the renal capsule or involvement of renal sinus vessels. |
| II | Tumor extends beyond the kidney but is completely resected (negative margins and lymph nodes). At least one of the following has occurred: (a) penetration of the renal capsule, (b) invasion of the renal sinus vessels, (c) biopsy of tumor before removal, (d) spillage of tumor locally during removal. |
| III | Gross or microscopic residual tumor remains postoperatively, including inoperable tumor, positive surgical margins, tumor spillage involving peritoneal surfaces, regional lymph node metastases, or transected tumor thrombus. |
| IV | Hematogenous metastases or lymph node metastases outside the abdomen (e.g., lung, liver, bone, brain). |
| V | Bilateral renal Wilms' tumors at onset. |

**TABLE 30-4. NATIONAL WILMS' TUMOR STUDY GROUP STAGING SYSTEM FOR RENAL TUMORS**

The most common sites of metastases of Wilms' tumor are the lungs, the regional nodes, and the liver. Of NWTSG patients presenting with hematogenous metastases at diagnosis (stage IV), the lungs were the only site in approximately 80% of cases. The liver, with or without lung involvement, was involved in 15%. [179] Other metastatic sites are distinctly uncommon in Wilms' tumor.

## PROGNOSTIC CONSIDERATIONS

Tumor size, the age of the patient, histology, lymph node metastases, and local features of the tumor, such as capsular or vascular invasion, have in the past been predictive of risk for tumor recurrence or progression. Because prognostic factors are identified retrospectively, however, the significance of previously determined prognostic factors may change when more effective treatment regimens are developed. This in fact has occurred with the sequential evaluation of prognostic factors among children treated on the NWTSG studies.

The histologic finding of anaplasia has been identified as the most important determinant of prognosis. [111,180] More recent analyses have confirmed the importance of histopathology.[113] Likewise, lymph node involvement, as originally suggested by Jereb and colleagues, [181,182] remains an important predictor of treatment failure.

Children entered on NWTS-1 who were younger than 24 months had a significantly better prognosis than did those who were older. The relapse rate was 14.8% for those younger than 2 years compared to 34.7% for those aged between 2 and 4 years and 27.6% for those older than 4 years. [183] The prognostic significance of age and tumor size, however, have lessened as treatment efficacy improved.[183,184] and [185]

Recent research has focused on identification of additional prognostic factors, ideally ones that are independent of stage and histology, that could be used for further

stratification of therapy according to the risk of recurrence.

Possible molecular genetic prognostic factors have been identified in a study of 232 children with Wilms' tumor registered on NWTS-3 and -4. LOH for markers on chromosome arm 16q, which was present in tumor tissue from 17% of those with favorable or anaplastic histology Wilms' tumor, was associated with significantly poorer 2-year relapse-free and overall survival percentages. [72] The difference remained when the analysis was adjusted for stage or histology. LOH for chromosome arm 1p markers, present in tumor tissue from 11% of children with Wilms' tumor, was also associated with poorer relapse-free and overall survival, differences that were not statistically significant however ($p$ = .08 and .12, respectively). By contrast, LOH for 11p markers or duplication of 1q, present in 33% and 25% of cases, respectively, was not associated with any difference in outcome. [72] The possible associations between LOH for chromosome arms 16q and 1p are being tested in NWTS-5.

Several authors have evaluated the relationship between tumor cell DNA content and prognosis in Wilms' tumor. Aneuploidy occurs more frequently in anaplastic histology tumors.[186,187 and 188] Tetraploidy is associated with a worse prognosis in some series, [186,189] and aneuploidy was associated with a worse prognosis among patients with favorable histology Wilms' tumor in one series [190] but not in two others.[188,191] One of the objectives of NWTS-5 study is to define the relationship between cellular DNA content, as determined using flow cytometry, and prognosis.

Based on retrospective studies, measures of nuclear morphometry were proposed to discriminate outcome in Wilms' tumor patients. [192] Further study, however, did not reveal any association between the proposed measures and outcome.[193]

## GENERAL SURGICAL PRINCIPLES

Surgical excision is the initial treatment for most children with Wilms' tumor. The surgeon has an important responsibility to perform safe and complete removal of the Wilms' tumor. Intraoperative events that can have an adverse impact on patient survival include tumor spill, incomplete removal, and surgical complications. Careful removal of the tumor without rupture or spill is mandatory, as these patients have an increased risk of local abdominal relapse. [194] Complete tumor resection improves patient survival. The surgeon's responsibility is not only to remove the primary tumor intact but also to assess the tumor spread precisely. Accurate staging is essential for the subsequent determination of the need for radiation therapy and the administration of the appropriate chemotherapy regimen.

### Technique

The transperitoneal approach to the tumor has been the standard procedure since the work of Ladd and colleagues. [195] The flank approach should never be used, because adequate staging cannot be performed, and the contralateral kidney cannot be examined. [196] Once the peritoneal cavity is entered, thorough exploration of the abdominal cavity is carried out.[181,197] One should assess the liver and regional periaortic lymph nodes and look for other evidence of tumor spread. The presence or absence of lymph node metastases is of major importance in determining treatment and relapse-free survival. [183,184 and 185] Thus, selective sampling of nodes is necessary for accurate staging. There is no evidence that extensive lymph node removal alters the outcome in patients with Wilms' tumor, and thus formal retroperitoneal lymph node dissection is not recommended.

Exploration of the contralateral kidney should be performed before nephrectomy. The colon is reflected and Gerota's fascia opened so that the kidney can be palpated and inspected on all surfaces for evidence of a synchronous bilateral tumor or evidence of nephrogenic rests. These may not be identified on preoperative imaging studies, especially if they are small or flat. Any abnormalities of the opposite kidney should be biopsied. The presence of bilateral Wilms' tumor alters the surgical approach significantly (see below); thus the status of the contralateral kidney must be determined *before* nephrectomy.

After the contralateral exploration is completed, radical nephrectomy is performed. The colon is mobilized off the tumor and reflected medially, preserving the colonic blood supply.[198] Gentle handling of the tumor throughout the procedure is mandatory to avoid tumor spillage, because this complication results in a sixfold increase in local abdominal relapse.[199] Although early ligation of the renal vein does not appear to have an appreciable effect on survival, separate ligation is performed before mobilization of the tumor but only if exposure is adequate. More important, the surgeon should be certain that the contralateral renal vessels, aorta, iliac, or superior mesenteric arteries have not been mistakenly ligated.[198]

Palpation of the renal vein and inferior vena cava should be performed to exclude intravascular tumor extension before vessel ligation. Wilms' tumor extends into the inferior vena cava in approximately 6% of cases and may be clinically asymptomatic in more than 50% of these. [200,201] Involvement of the renal vein or inferior vena cava by tumor does not adversely affect the prognosis if appropriate treatment is given. Identification of intracaval extension on the preoperative imaging studies allows the surgical team to adequately prepare for the operative procedure.

Surgery should not be overlooked as a cause of morbidity in children with Wilms' tumor. A recent review of NWTS-4 patients undergoing primary nephrectomy found an 11% incidence of surgical complications.The most common complications were hemorrhage and small bowel obstruction. Risk factors associated with increased surgical complications are higher local tumor stage, incorrect preoperative diagnosis, intravascular extension, and en bloc resection of other visceral organs. [202] Heroic attempts to excise en bloc all or parts of adjacent organs to which the tumor appears to be adherent are not warranted because such procedures are associated with an increased risk of surgical complications. Wilms' tumors are generally very large, and the gross appearance of the tumor at the time of surgery can be misleading in interpreting tumor extent. These tumors often compress and adhere to adjacent structures without frank invasion, and in the majority of cases, pathological evidence of organ invasion is not present.[202]

### Preoperative Therapy

Prevailing North American practice is to proceed with primary surgery after appropriate workup. This is because treatments can best be modulated in their intensity according to accurate histopathologic and staging criteria, which are obscured when preoperative treatments are given. However, there are occasional patients in whom primary nephrectomy may pose too great a risk.[202] The NWTSG has recommended preoperative chemotherapy for a few select groups of patients, including those with tumor extension into the inferior vena cava above the hepatic veins, [171] those found to be unresectable at surgical exploration, [203] and children with bilateral renal tumors.[196,204] Studies conducted by the SIOP[205,206] and the NWTSG experience have shown that pretreatment with chemotherapy almost always reduces the bulk of the tumor. This makes tumor removal easier and may reduce the frequency of surgical complications. [171] Preoperative chemotherapy does not result in improved survival rates, however, and does result in the loss of important staging information. [207]

All patients with tumors considered to be unresectable after imaging studies should undergo initial exploration to assess operability and to obtain a biopsy of the tumor. It is important to keep in mind that the error rate in the preoperative diagnosis of renal masses after roentgenographic assessment is 5% to 10% ( Table 30-3).[163,164] Percutaneous needle biopsy of lesions presumed to be inoperable is also to be avoided because the histologic diagnosis based on material obtained from a needle biopsy has an error rate of up to 7.4%.[208,209] Patients who are staged by imaging studies alone are at risk for either understaging or overstaging. Thorough exploration of the abdomen is necessary to detect evidence of extrarenal extension of tumor. If suspicious lymph nodes or other metastatic deposits are found, these should be biopsied to document tumor involvement. If the tumor is found to be unresectable, biopsy of the tumor can be followed by chemotherapy or radiation therapy. This will generally produce tumor shrinkage to allow resection. Unresectable tumors should be outlined with titanium clips for possible postoperative radiation therapy. These clips are radiopaque but scatter the beam less than other metal clips during postoperative CT scanning.

Inoperable tumors must be treated as stage III, using vincristine, dactinomycin, and doxorubicin (regimen DD-4A; see Fig. 30-10). If preoperative therapy for inoperable tumors is given based on imaging alone, with or without a needle biopsy, the local tumor should also be considered as stage III. Once there has been an adequate reduction in the size of the tumor to facilitate nephrectomy, definitive resection should be completed. In general, radiographic reevaluation should be performed at week 5 after initiating chemotherapy. The operative procedure can be performed shortly thereafter. Serial imaging evaluation is helpful to assess response, but radiographic evidence of persistent tumor mass can occasionally be misleading. Failure of the tumor to shrink can be due to predominance of skeletal muscle or differentiated elements, and a second look procedure to confirm persistent tumor may be necessary. [203,210]

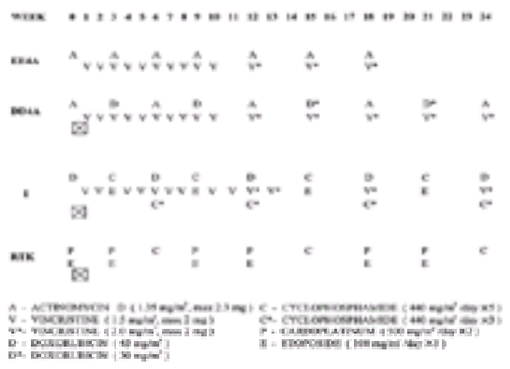

**FIGURE 30-10.** Treatment regimens used on National Wilms' Tumor Study 5.

Patients who do not respond adequately can be considered for preoperative irradiation, which may produce enough shrinkage to permit nephrectomy. The suggested dose is 1,200 to 1,260 cGy, administered using daily fractions of 150 to 180 cGy. Vincristine should be administered weekly during the period of radiation therapy. Postoperative radiation therapy is given to all patients who did not receive it preoperatively. This recommendation is based on the results of the SIOP-6 nephroblastoma trial, in which a significantly higher infradiaphragmatic relapse rate was reported in nonirradiated children given only postoperative chemotherapy.  The radiation therapy field is enlarged beyond the flank if the surgical findings warrant. After radiation therapy, patients should continue on chemotherapy until they have completed the regimen for stage III disease.

Primary surgical excision of the tumor with caval extension is associated with increased surgical morbidity. [201] For vena caval involvement below the level of the hepatic veins, the caval thrombus can be removed via cavotomy after proximal and distal vascular control is obtained. Generally the thrombus will be free floating, but if there is adherence of the thrombus to the caval wall, the thrombus can often be delivered with the passage of a Fogarty or Foley balloon catheter. Patients with extension of intracaval tumor thrombus above the level of the hepatic veins should receive preoperative chemotherapy to shrink the tumor and thrombus. [171,211] This facilitates complete removal of the tumor with decreased morbidity.

In patients with intracardiac extension of tumor that has not responded to preoperative combination chemotherapy, a median sternotomy and midline abdominal incision provide excellent exposure of the right atrium and the intrapericardial portion of the inferior vena cava. [171,212] Extracorporeal circulation is necessary in these situations. This finding does not necessarily adversely affect life expectancy, however, because all 16 NWTSG children reported with intracardiac tumors of favorable histology survived.[171]

**Bilateral Disease**

Various reports record the incidence of synchronous bilateral Wilms' tumor as ranging from 4.4% to 7.0% and that of metachronous bilateral Wilms' tumor from 1.0% to 1.9% of Wilms' tumor patients.[196,213,214] As imaging techniques have improved, a greater percentage of bilateral lesions have been diagnosed preoperatively. In a review of NWTS-2 and -3 patients with bilateral Wilms' tumor, CT of the abdomen was accurate in diagnosing synchronous bilateral Wilms' tumor in 83%. [169] However, a review of 122 patients with synchronous bilateral Wilms' tumor enrolled in NWTS-4 noted that 7% of bilateral lesions were not identified by the preoperative imaging studies.[118] These data emphasize the importance of contralateral renal exploration at the time of laparotomy for apparent unilateral disease.

The historical approach to the surgical management of children with bilateral Wilms' tumors included nephrectomy of the more involved side combined with excisional biopsy or partial nephrectomy of the presumably smaller lesion in the remaining kidney. Consequently, many patients with synchronous bilateral Wilms' tumor developed significant renal insufficiency, some to the extent of requiring renal transplantation. [215] An NWTSG review found that 9.1% of patients with synchronous bilateral Wilms' tumors and 18.8% of those with metachronous bilateral tumors developed renal failure. [216] The most common etiology for renal failure was the need for bilateral nephrectomy for persistent or recurrent tumor in the remaining kidney after initial nephrectomy. Treatment-related injury (radiation-induced damage, surgical complications) to the remaining kidney was the second leading cause of renal insufficiency. Renal insufficiency secondary to hyperfiltration-induced injury (focal glomerulosclerosis) was less common.[216]

In 1977, NWTSG investigators reported 30 children with bilateral Wilms' tumor. [204] Nineteen of the patients had been managed with unilateral nephrectomy with or without contralateral heminephrectomy or biopsy, whereas 11 children had undergone a renal biopsy alone followed by chemotherapy or radiation therapy. Overall survival was excellent (87% 2-year survival) with no obvious difference between the two groups. A subsequent larger series of 145 bilateral Wilms' tumor patients enrolled in NWTS-2 and -3 confirmed the observation that patients undergoing initial biopsy followed by postoperative chemotherapy had an equivalent survival to patients undergoing initial surgical resection (83%). [196,217] Most important, it was noted that nephrectomy could be avoided entirely in almost 50% of the group of patients undergoing initial biopsy.

The management presently recommended, therefore, is initial bilateral renal biopsy with staging of each kidney. Abnormal lymph nodes or other lesions suggestive of extrarenal spread should be biopsied and a surgical (local) stage assigned to both kidneys. Primary excision of the tumor masses should not be attempted, but rather patients should be given preoperative chemotherapy appropriate to the stage and histology of the tumors. Initial treatment is with the combination of vincristine and dactinomycin if the renal tumors are favorable histology and not more extensive than stage II (see Fig. 30-9 and Fig. 30-10). Those with more extensive, favorable histology disease would receive the combination of dactinomycin, vincristine, and doxorubicin, and those with anaplastic histology would receive vincristine, doxorubicin, cyclophosphamide, and etoposide (see Fig. 30-9 and Fig. 30-10).

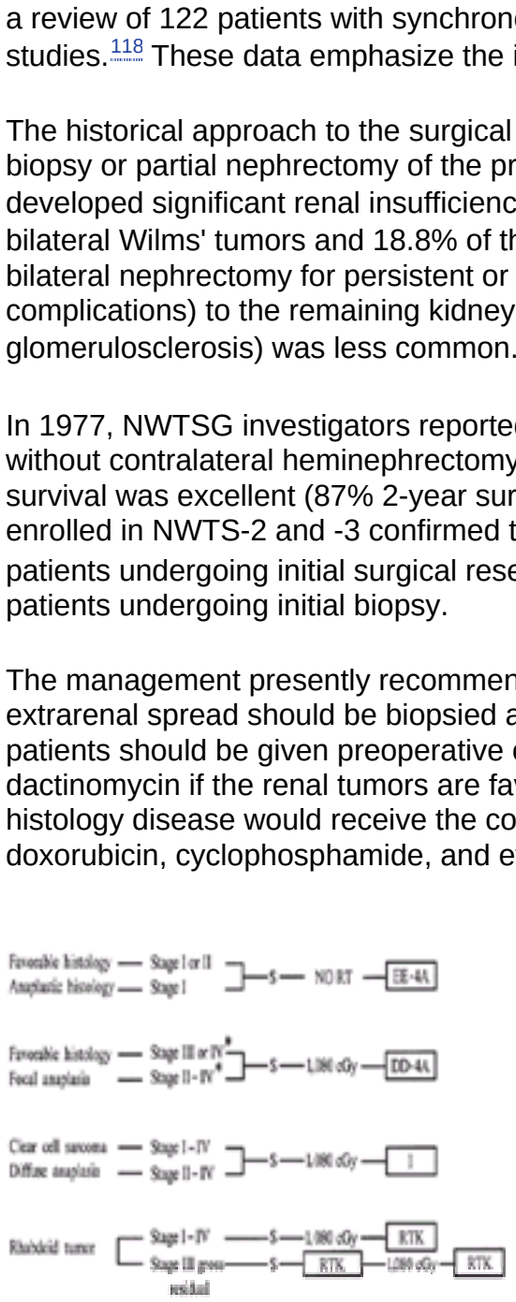

**FIGURE 30-9.** Treatment algorithms by tumor histology and stage used on National Wilms' Tumor Study 5. Stage IV patients (*) receive abdominal radiation therapy (RT) depending on the local stage of the abdominal primary. S, surgery.

A reevaluation is performed at approximately week 5 to determine if there has been sufficient response of the tumors to allow tumor resection, with preservation of a substantial amount of normal renal tissue. Experience in SIOP has shown that maximal shrinkage occurs after 4 to 6 weeks of chemotherapy. Although a longer course of preoperative chemotherapy may not benefit a patient with a unilateral tumor, that is not always the case with a bilateral Wilms' tumor wherein even a modest further reduction in tumor size may be helpful. This is particularly true for centrally located tumors for which a 1-cm reduction in size may allow partial nephrectomy with sparing of the renal hilum. Additional chemotherapeutic agents, such as doxorubicin, with or without radiation therapy, may be necessary for the management of children whose tumors respond poorly to the combination of vincristine and dactinomycin.

In any event, a second look procedure is recommended when serial imaging studies show no further reduction in the tumor. Failure of the mass to shrink is not always

due to persistent viable tumor. There may be necrosis, fibrosis, or persistence of skeletal muscle or differentiated elements within the original lesion. [218] A biopsy of the kidney may be necessary to confirm persistent viable tumor. At the time of the second look procedure, partial nephrectomy or wedge excision of the tumor should be considered, but only if complete tumor resection with negative margins can be obtained and part of either or both of the kidneys can be salvaged. Radical nephrectomy is performed when the extent of the tumor precludes salvage.

### Partial Nephrectomy

The occurrence of renal failure, presumably due to hyperfiltration injury, in occasional patients following treatment for unilateral Wilms' tumor [219,220] has led some investigators to evaluate the potential for renal parenchymal-sparing surgery. The data regarding renal damage from hyperfiltration following unilateral nephrectomy is conflicting. After treatment for unilateral Wilms' tumor, some patients may develop proteinuria and a reduced creatinine clearance. [221,222]However, other investigators have not confirmed these findings.[223,224]A recent review of NWTSG patients with unilateral Wilms' tumor identified the incidence of renal failure as 0.25% with a median follow-up of 6 years.[216] Most of these patients had the Denys-Drash syndrome with intrinsic renal disease, and generally presented with renal failure or progressed to end-stage renal disease. Another risk factor for the development of renal failure was irradiation of the remaining kidney, which is now given to few children and at a markedly reduced dose. Therefore, the risk of developing renal failure after current treatment for unilateral Wilms' tumor appears to be quite low, although continued long-term follow-up of this cohort of children is necessary.

The majority of Wilms' tumors are too large to consider partial nephrectomy at initial presentation. Using stringent diagnostic imaging criteria—including (a) tumor limited to one pole and occupying less than one-third of the kidney; (b) preserved renal function in the involved kidney; (c) no tumor invasion of the collecting system or the renal vein; and (d) clear margins between the tumor, kidney, and surrounding structures—investigators from St. Jude Children's Research Hospital determined that only 4.6% (2 of 43) of patients would be eligible for partial nephrectomy at the time of diagnosis. [225]

Therefore, pretreatment with chemotherapy is usually required if renal-sparing surgery is to be considered, [226,227 and 228] remembering that postchemotherapy staging is inaccurate. After preoperative chemotherapy, as many as 10% to 15% of patients may be amenable to partial nephrectomy. [226,227 and 228] Some advocate enucleation of the tumor to allow parenchymal-sparing procedures for even centrally located tumors in which partial nephrectomy with a rim of renal tissue would be inadvisable. [227] The efficacy of this approach remains unclear, however.[229]

The possible benefits of renal parenchymal-conserving surgery must be evaluated against the potential risks of such procedures. There are surgical complications unique to partial nephrectomy, including urine leak and ischemic injury if cross clamping of the vessels is required. The failure to include nephrogenic rests in the surgical resection, identified in 28% of unilateral Wilms' tumor specimens, might increase the risk of intra-abdominal tumor recurrence or metachronous tumor in patients who have an excellent prognosis with current treatment approaches.

In summary, parenchymal-sparing renal surgery for patients with unilateral Wilms' tumor is controversial. The current recommendation of the NWTSG is to consider partial nephrectomy only for patients with a solitary kidney, renal insufficiency, bilateral Wilms' tumor, and possibly for those with Wilms' tumor–predisposing syndromes.

## GENERAL RADIOTHERAPEUTIC CONSIDERATIONS

Pioneering radiation oncologists noted that Wilms' tumors were responsive to radiation therapy, and this modality then became routine postoperative treatment at the Boston Children's Hospital, at which many of the initial observations concerning the management of these children were made. [230] Two methods were used at that institution to define the treatment volume. First, the portal was extended across the midline to include the entire circumference of the implicated vertebral bodies. [231] This was done to equalize the growth suppression; irradiation of only one side of a vertebra had been shown to lead to an obligatory scoliosis convex away from the irradiated side. Concern for late treatment complications obviously was much in the minds of the early workers, notably M. H. Wittenborg. Second, a preoperative excretory urogram was used to define the location and size of the kidney and its associated mass, considered to be the tissues of the original tumor bed. The upper, lateral, and lower limits of the field were thus defined. The dosage was age-adjusted, with infants receiving lower doses than 3- or 4-year-olds, because radiation effects on their normal tissues would result in more serious damage.

These radiation therapy concepts have been modified as the result of the clinical trials conducted by the NWTSG. For example, the age-adjusted dosages were shown to be unnecessary in tumors of favorable histology. The advent of effective drugs had a profound impact not only on the general management of these children but also on the indications for the administration of postnephrectomy abdominal irradiation. The first NWTSG randomized clinical trial indicated that presumed microscopic residual disease in the tumor bed of children with stage I/favorable histology Wilms' tumor can be successfully treated with combination chemotherapy rather than flank irradiation. Retrospective analyses of the data accumulated in NWTS-1 and NWTS-2 were conducted to determine the patterns of relapse and to evaluate the relationship between abdominal radiation therapy dose and intra-abdominal tumor recurrence. [232,233 and 234] In NWTS-3 the nonirradiated and irradiated (2,000 cGy) stage II/favorable histology patients had similar relapse-free survival percentages, as did those with stage III/favorable histology who received nominal doses of 1,000 versus 2,000 cGy. Meanwhile, excellent results continued to be recorded for stage I/favorable histology patients, none of whom received radiation therapy.[199]

In summary, NWTS-1, -2, and -3 demonstrated that stage I and II patients with favorable histology tumors who receive vincristine and dactinomycin do not require postoperative irradiation, and that a dose of 1,000 cGy is sufficient for local control in stage III/favorable histology patients if they also received chemotherapy with vincristine, dactinomycin, and doxorubicin. [235]

Whole lung irradiation (1,200 cGy) has been recommended for patients who present with pulmonary metastases visible on plain chest radiographs. A pilot study conducted by investigators from the SIOP produced similar outcomes to those of the NWTSG [179] in stage IV/favorable histology patients following treatment with nephrectomy and chemotherapy only.[236] Only patients with persistent or recurrent lung nodules received whole lung radiation therapy or surgical removal of the metastatic lesion(s). However, the United Kingdom Children's Cancer Study Group, using a similar approach, reported results that were inferior to those of the NWTSG in this group of patients.[237] The adverse effects of whole lung irradiation and chemotherapy as used in the NWTSG treatment regimens included radiation pneumonitis or *Pneumocystis carinii* pneumonitis. These complications are important causes of morbidity and mortality in patients with stage IV Wilms' tumor, [238] although *P. carinii* pneumonitis can be prevented with administration of prophylactic trimethoprim/sulfamethoxazole. It is recommended that chemotherapy doses given immediately after the completion of whole lung irradiation be decreased by 50% to reduce the incidence of radiation pneumonitis. Additional studies are needed to evaluate the need for whole lung radiation therapy in this group of patients.

Patients with pulmonary lesions identified on CT of the chest, but not on the chest radiograph, should undergo biopsy of one or more lesions to confirm that they are due to metastatic Wilms' tumor if treatment with whole lung irradiation and doxorubicin is planned. A report from St. Jude Children's Research Hospital suggested that patients with pulmonary metastases detectable only by CT have an increased risk of pulmonary recurrence after treatment with chemotherapy only, [173] but a retrospective review of the experience with similar patients treated on NWTS-3 did not demonstrate a clear benefit of whole lung irradiation. The 4-year relapse-free survival rate was 88.1% among 18 irradiated patients and 88.9% among nine nonirradiated patients. [175] Only a meticulously conducted randomized trial in which histologic confirmation of metastatic disease was mandatory could settle this issue.

## GENERAL CHEMOTHERAPY PRINCIPLES

Wilms' tumor was the first pediatric malignant solid tumor found to be responsive to the systemic chemotherapeutic agent dactinomycin. The use of dactinomycin for the adjuvant treatment of children with Wilms' tumor was pioneered by Farber. [239] Other active agents were identified subsequently, including vincristine, with a complete and partial response rate of 63% (17 of 27 patients); doxorubicin (Adriamycin), with a response rate of 60% (31 of 52 patients); and cyclophosphamide, with a complete and partial response rate of 27% (10 of 37 patients). [100]

The initial apparent success with dactinomycin led to other single-institution studies and cooperative group randomized trials to evaluate the use of adjuvant single-agent chemotherapy (Table 30-5).[100]

| | Chemotherapy | Radiation therapy |
|---|---|---|
| NWTS-1 | Vincristine and dactinomycin combination better for group I, II | Unnecessary for group I <2 years (if received chemotherapy) |
| NWTS-2 | Only 6 months vincristine and dactinomycin necessary for group I | Unnecessary for all group I |
| | Additional doxorubicin beneficial for groups II–IV | – |
| NWTS-3 | Only 11 weeks therapy necessary for stage I | – |
| | Doxorubicin unnecessary for stage II | Abdominal irradiation unnecessary for stage I |
| | Doxorubicin necessary for stage III | If use 1,000 cGy abdominal irradiation |
| | Doxorubicin unnecessary for stage III | If use 2,000 cGy abdominal irradiation |
| | Cyclophosphamide (as used) did not benefit stage IV | |
| NWTS-4 | "Pulse-intensive" chemotherapy as effective, less toxic and expensive | |
| | Only 6 months chemotherapy necessary for stages II–III | |

**TABLE 30-5. SUMMARY OF CONCLUSIONS FROM NATIONAL WILMS' TUMOR STUDY (NWTS) STUDIES 1 THROUGH 4 FOR PATIENTS WITH FAVORABLE HISTOLOGY TUMORS**

### National Wilms' Tumor Studies 1 and 2

In NWTS-1 (1969 to 1973), postoperative abdominal radiation therapy was shown to be unnecessary for the therapy of children younger than 2 years with group I Wilms' tumor who were treated with dactinomycin. The combination of vincristine and dactinomycin was shown to be more effective for the treatment of those with group II or III Wilms' tumor than either drug alone. [163]

The results of NWTS-2 (1974 to 1978) demonstrated that for children with group I disease, none of whom received abdominal irradiation, reducing the duration of chemotherapy with the combination of vincristine and dactinomycin to 6 months did not effect their prognosis adversely. The addition of doxorubicin to the combination of vincristine and dactinomycin, however, improved the relapse-free survival percentage of irradiated children with stages II to IV Wilms' tumor. [240]

### National Wilms' Tumor Study 3

The results of NWTS-3 confirmed that patients with stage I favorable histology Wilms' tumor can be treated successfully using an 11-week regimen composed of vincristine and dactinomycin without abdominal irradiation. The 4-year relapse-free survival percentage with this regimen was 89%, and the 4-year survival percentage was 95.6%.[199]

Patients with stage II favorable histology Wilms' tumor were randomized to receive vincristine and dactinomycin or these two drugs and doxorubicin. They were also randomized to receive tumor bed irradiation (2,000 cGy) or no radiation therapy. There was no statistically significant difference between the outcome for patients who were treated with vincristine and dactinomycin without abdominal irradiation compared with the results for patients on the remaining three treatment regimens. [199] Thus, both doxorubicin and abdominal irradiation were shown to be unnecessary for children with stage II favorable histology tumors.

Patients with stage III favorable histology Wilms' tumor were similarly randomized to treatment with vincristine and dactinomycin or these two drugs and doxorubicin. They were also randomized to receive 1,000 cGy or 2,000 cGy of abdominal irradiation. This study demonstrated that these patients benefitted from the addition of doxorubicin to the two-drug combination of vincristine and dactinomycin. Overall there was no statistically significant difference in the frequency of intra-abdominal relapse among those treated with 1,000 cGy compared to 2,000 cGy. However, there appeared to be a higher frequency of relapse among those treated with vincristine and dactinomycin with 1,000 cGy of irradiation (7 of 61) compared with those receiving vincristine and dactinomycin with 2,000 cGy of irradiation (3 of 68) or those receiving vincristine, dactinomycin, and doxorubicin with 1,000 cGy of irradiation (3 of 70). [235] This suggested the necessity of either doxorubicin or 2,000 cGy (rather than 1,000 cGy) of irradiation for treatment of stage III favorable histology patients.

Patients with stage IV Wilms' tumor were randomized to receive vincristine, dactinomycin, and doxorubicin, or these three drugs and cyclophosphamide. All underwent immediate nephrectomy, and all received abdominal irradiation and whole lung irradiation (1,200 cGy). There was no statistically significant improvement in relapse-free or overall survival percentage with the addition of cyclophosphamide to the three-drug regimen. [199]

### National Wilms' Tumor Study 4

Previous success in treatment strategies allowed the design of a unique study, NWTS-4, with the primary aims of continuing to improve treatment results while decreasing the cost of therapy through modification of the schedule of drug administration. This study was based on experimental [241] and clinical [242,243,244] and [245] data demonstrating the safety and efficacy of dactinomycin when administered in a single, moderately high dose.

The design of NWTS-4 (Fig. 30-8) allowed the results of “pulse-intensive” chemotherapy regimens (EE-4A, K-4A, DD-4A) using single doses of dactinomycin and doxorubicin to be compared with treatment regimens (EE, K, and DD) using traditionally divided-dose regimens of each drug. In addition, a reduction in treatment duration from approximately 15 months to 6 months was studied in patients with stages II to IV/favorable histology tumors.

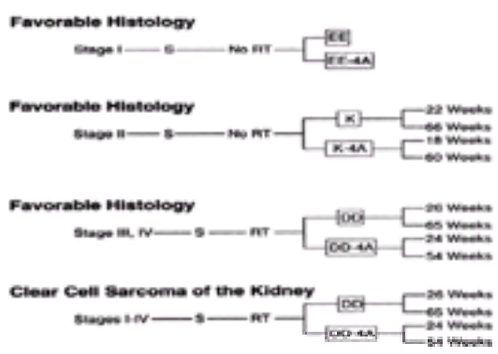

**FIGURE 30-8.** Treatment randomization for patients entered on National Wilms' Tumor Study 4. Doxorubicin and radiation therapy (RT) are included in the treatment regimen only for patients with stages III and IV Wilms' tumor. S, surgery.

Toxicity analyses confirmed that the pulse-intensive regimens actually produced less hematologic toxicity than the standard regimens, and that the administered drug dose intensity is greater on the pulse-intensive regimens. [246] In addition, an analysis of the cost of chemotherapy treatment suggested that at least $790,000 per year is saved if all U.S. children with stages I to IV/favorable histology Wilms' tumor are treated using the pulse-intensive regimens. [247]

Analysis of the results of the comparison between the standard (divided-dose) and pulse-intensive (single-dose) modes of chemotherapy administration demonstrated that there was no significant difference between the 2-year relapse-free percentages for patients treated with the pulse-intensive regimens (89.4%) and those treated with the standard regimens (90.5%).[248] Similarly, comparisons between the short and long treatment regimens suggest that they are equivalent for patients with stages II to IV favorable histology disease. [247] The results of the first four NWTS studies are summarized in Table 30-5.

## COMBINED-MODALITY THERAPY

These recommendations are based on the NWTSG experience and advocate early surgery without preoperative therapy for patients with apparently resectable unilateral disease with subsequent therapy according to stage and histology.

**Chemotherapy**

Many chemotherapy regimens appear to produce good results.[206,237,249] Those used by the NWTSG are detailed here because they have been tested in the largest numbers of patients. The treatments are modulated in intensity according to risk, based on stage and histology. An algorithm of treatments by stage and histology is shown in Figure 30-9 and the protocol details in Figure 30-10.

***Favorable Histology Wilms' Tumor***

For stage I and II disease, regimen EE-4A (Fig. 30-10) involves dactinomycin beginning within 5 days postnephrectomy (during week 0), and then at three weekly intervals, and vincristine beginning day 7 postnephrectomy once peristalsis has been established, then weekly for a total of 10 doses, then an increased dose with dactinomycin at weeks 12, 15, and 18. No radiation therapy is given.

For stage III and IV disease, regimen DD-4A (Fig. 30-10) includes four doses of doxorubicin in addition to dactinomycin and vincristine for 24 weeks. Postoperative irradiation is added for stage III primary tumors and for metastatic disease according to the relevant guidelines ( Table 30-6).

| Disease extent | Radiation volume | Dose[a] |
|---|---|---|
| Hilar lymph nodes<br>Gross or microscopic residual confined to flank | Tumor bed, crossing midline to include entire vertebral bodies | 1,080 cGy in six fractions |
| Para-aortic lymph nodes | Include entire length of bilateral paraaortic chains | 1,080 cGy in six fractions |
| Peritoneal seeding<br>Gross residual abdominal disease<br>Preoperative intraperitoneal rupture<br>Diffuse operative spill | Whole abdomen | 1,080 cGy in six fractions or 1,050 cGy in seven fractions |

[a]Local supplements of 1,080 cGy should be given to volumes greater than 3 cm in maximum diameter. A cone down field should encompass residual disease with a 1-cm margin. Greater than one-third of the contralateral kidney or the residual normal kidney in patients with bilateral Wilms' tumor should not receive doses higher than 1,440 cGy. Doses to more than one-half of the liver should not exceed 1,980 cGy.

**TABLE 30-6. DOSE AND VOLUME OF ABDOMINAL RADIATION FOR LOCAL STAGE III TUMORS**

***Anaplastic Wilms' Tumor***

Stage I tumors with focal or diffuse anaplasia are treated using regimen EE-4A as in stage I favorable histology tumors ( Fig. 30-10). It is currently recommended that stage II–IV tumors with focal anaplasia be treated the same as stage III favorable histology with regimen DD-4A and abdominal irradiation ( Fig. 30-10 and Table 30-6).

Patients with tumors having diffuse anaplasia that are greater than stage I have fared relatively poorly with the traditional Wilms' tumor agents dactinomycin, vincristine, and even doxorubicin. A newer regimen is under study in the NWTS-5, the details of which are shown in Figure 30-10, although no outcome data is yet available for this regimen. Previous studies demonstrated a benefit from the addition of cyclophosphamide to the standard three-drug regimen.[250] Cyclophosphamide has previously been used in relatively low doses for Wilms' tumor. Regimen I uses cyclophosphamide in high dose in conjunction with etoposide and continues the use of doxorubicin but in combination with cyclophosphamide. Whether this regimen improves the outcome for stages III and IV diffusely anaplastic disease, which have been particularly poor, remains to be demonstrated.

***Clear Cell Sarcoma of the Kidney***

The use of doxorubicin appears to be particularly effective in the treatment of clear cell sarcoma of the kidney.[123] Because the outcome for patients with clear cell sarcoma has remained inferior to those with favorable histology Wilms' tumor, patients on NWTS-5 are currently being treated with regimen I, as for anaplastic tumors, which uses increased doses of doxorubicin with the vincristine backbone but also introduces higher-dose cyclophosphamide and etoposide. As for children with anaplastic tumors, outcome results for children with clear cell sarcoma of the kidney treated with regimen I are not yet available.

***Rhabdoid Tumor of the Kidney***

No satisfactory treatment for this disease has been reported. A recent analysis of patients with rhabdoid tumor, however, suggests that although the outcome has been particularly poor for children younger than 1 year; older children with the disease may be more readily curable with traditional approaches (G. Tomlinson, *personal communication*, 2000). Patients with rhabdoid tumor of the kidney of all stages are being treated on the NWTS-5 with a new regimen, RTK ( Fig. 30-10), which includes carboplatin and etoposide as well as high-dose cyclophosphamide in a single-arm, phase II study. This study has not yet completed accrual.

**Radiation Therapy**

Megavoltage teletherapy apparatus or the equivalent is used, and daily doses of 180 cGy are delivered. The daily dose is reduced to 150 cGy when large volumes, such as the whole abdomen or the whole thorax, are included in the fields. Doses are specified as midplane values without correction for air transmission or bone absorption. The use of simulation and portal films is essential to ensure accurate beam direction.

Radiation therapy, when indicated, is initiated when the patient is stable postoperatively, free of ileus or diarrhea, and has a hemoglobin level of at least 10 g per dL. Retrospective analysis of the results from each of the first three completed NWTSG trials showed the prognostic importance of starting radiation therapy within 10 days of surgery.[233,234 and 235] Thus, arrangements should be made for treatment simulation while the pathology examination is pending so that irradiation can be started promptly if indicated, because it is usually easier to cancel such arrangements than to initiate them at the last minute.

***Favorable Histology Wilms' Tumor***

**Stages I and II**

No postoperative radiation therapy is recommended in children receiving dactinomycin plus vincristine according to regimens similar to those reported by the NWTSG.

**Stage III**

Doses and volume of radiation for abdominal tumors that are classified as stage III are shown in Table 30-6. The tumor bed is defined as the kidney and its associated lesion as they are visualized on preoperative imaging studies. The portal is always extended medially to include the entire vertebral column at the implicated levels (i.e., across the midline medially). The field is extended as needed to include the para-aortic chains when para-aortic nodes are found to be involved. The portal for whole abdominal irradiation includes all the peritoneal surfaces and extends from the domes of the diaphragm to the inferior margins of the obturator foramina. External beam blocks are introduced to shield the femoral heads.

### Stage IV

Postoperative abdominal irradiation is given only to patients whose primary tumor is classified as Stage III ( Table 30-6).

Recommendations for irradiation of metastatic sites are shown in Table 30-7 and discussed below. For bilateral lung irradiation, the entire thoracic cavity is irradiated without shields, except those protecting the humeral heads. The field extends from the apex of the lung to the posterior inferior recesses of the costophrenic sulci. The latter come to the bottom of T12 or lower in most children. Shielding of mediastinal structures is not recommended because marginal recurrences in mediastinal lymph nodes have developed in patients managed in this way. Infants are managed differently, as discussed in the section on special considerations.

| Disease site | RT field | RT dose |
|---|---|---|
| Liver | Involved portion plus 2-cm margin | 1,980 cGy* in 11 fractions |
| Lung | | |
| Age ≥18 mo | Bilateral lung | 1,200 cGy in eight fractions |
| Age <18 mo | Bilateral lung if no response to chemotherapy | 900 cGy in six fractions with 150-cGy supplements to specific nodules |
| Lymph nodes | Involved lymph nodes | 1,980 cGy in 11 fractions |
| Brain | Whole brain | 3,060 cGy in 17 fractions |
| Bone | Lesion plus 3-cm margin | 3,060 cGy in 17 fractions |

RT, radiation therapy.
*Local supplements of 540 to 1,080 cGy can be given to small portions of the liver containing residual gross tumor at the completion of the recommended 1,980 cGy.

**TABLE 30-7. TREATMENT OF METASTATIC DISEASE**

For liver metastases, only those that are unresectable at diagnosis are irradiated. The treatment portal includes that portion of the liver known to be involved, as visualized on CT or magnetic resonance imaging studies. The whole liver is treated in children with diffuse metastases. It is recognized that liver tolerance is approached by the doses recommended, especially in view of the radiation-enhancing and radiation-reactivating drugs (dactinomycin and doxorubicin) used in the management of these children. Extreme caution is therefore recommended, with careful monitoring of liver function tests and blood counts during treatment. A selective thrombocytopenia can appear in these patients, who nonetheless have a surprisingly good outlook after aggressive therapy. Breslow and coworkers [179] reported 72% survival at 4 years in NWTS-1 and -2 children with favorable histology tumors and liver lesions at diagnosis, with or without lung metastases. These findings were confirmed in an analysis of liver involvement at diagnosis in NWTS-3 patients. [251]

Metastases to bulky lymph nodes, brain, bone, or other areas are treated similarly to the liver, although with higher doses for the brain and bone ( Table 30-7). The whole brain is treated in daily doses of 180 cGy, but the entire bone need not be irradiated for skeletal metastases.

#### *Anaplastic Wilms' Tumor*

Patients with tumors classified as stage I with focal anaplasia are treated exactly as those with favorable histology. NWTSG analyses have also shown that children with stage I diffusely anaplastic tumors have the same outlook as those with stage I/favorable histology lesions when treated similarly. [252] Therefore these children should also receive combination chemotherapy only, with vincristine and dactinomycin, and no postoperative radiation therapy. Tumors with focal or diffuse anaplasia that are stage II or III, however, require more aggressive therapy and postoperative irradiation as is given for stage III favorable histology ( Table 30-6).[250]

Metastatic sites in patients with tumors with diffuse anaplasia should be treated the same as for stage IV/favorable histology disease ( Table 30-7), except those in the liver, for which doses of 3,060 cGy in 18 fractions are given, with 540 to 1,080 cGy supplements permissible to small residual volumes.

#### *Clear Cell Sarcoma of the Kidney*

All patients, regardless of stage, are recommended to receive postoperative irradiation. The abdomen should be treated as outlined in Table 30-6, even with stage I disease, and metastatic sites should be treated as outlined in Table 30-7.

#### *Rhabdoid Tumor*

All patients with rhabdoid tumor of the kidney are also currently recommended to receive irradiation according to Table 30-5 and Table 30-6, although in the current NWTS-5 studies this irradiation is delayed until week 6 to allow determination of initial response to chemotherapy.

## SPECIAL CONSIDERATIONS

### Neonates and Infants

Wilms' tumor is rarely found in neonates.[253,254] Newborns and infants younger than 11 months require reduction of chemotherapy doses to 50% of those used in older children, even after conversion of amounts calculated on the basis of surface area to the dose per kilogram. Infants with pulmonary metastases pose particular problems. The NWTSG committee recommends that thoracic irradiation be given only to those children younger than 18 months who do not have complete resolution of metastases within 4 weeks of initiating chemotherapy. Children with residual nodules should receive 900 cGy in 150-cGy daily doses with a single 150-cGy supplement to nodules that do not disappear after 900 cGy ( Table 30-7). Irradiation is recommended, because evidence from relapsed NWTS-3 patients suggests that the best relapse-free survival is obtained in children who had thoracic irradiation added to chemotherapy. [255] An alternative to irradiation is surgical excision of lesion(s) that remain after the first cycle of dactinomycin, vincristine, and doxorubicin (all such children should be on three-agent chemotherapy). Another alternative is to reserve surgical excision for children who have residual masses after the delivery of 900 cGy to the whole chest. The efficacy of these operative approaches has not been tested systematically, however. The NWTSG reported no difference in survival for relapsed patients with a solitary metastasis who did or did not have the lesion removed surgically.[256]

### Extrarenal Wilms' Tumor

Though rare, extrarenal Wilms' tumors can be found in the pelvis and even the thorax as well as the retroperitoneal space. [103,257] The same general therapy precepts can be followed as when the kidney is affected, although it may be prudent to use the guidelines for chemotherapy and radiotherapy for stage III tumors under these unusual circumstances.

### Horseshoe Kidneys

Thirteen cases of Wilms' tumor arising in a horseshoe kidney were found among 2,961 (0.4%) patients reviewed by the NWTSG. [258] Seven of the thirteen had stage I or II disease. Treatment was according to the guidelines for comparable-stage unilateral disease, with an overall survival of 85% (mean follow-up, 32 years). These findings indicate that the tumors are no more aggressive than unilateral tumors. By extension, patients with tumors in discoid kidneys can be managed successfully using preservative approaches.

### Recurrent Disease

Children with relapsed, favorable histology Wilms' tumor have a variable prognosis, depending on their initial stage, the site of relapse, the time from initial diagnosis

to relapse, and their previous therapy. Favorable prognostic factors include no prior treatment with doxorubicin, relapse more than 12 months after diagnosis, and subdiaphragmatic relapse in patients not previously given abdominal irradiation. [255] Children in this more favorable group should be treated aggressively, because they generally have a good response to retrieval therapy. Although surgical excision of pulmonary metastases does not improve outcome, [256] surgical biopsy or excision of recurrence should nonetheless be performed to histologically confirm the presence of recurrent disease, particularly in the case of intra-abdominal recurrence, to reduce the tumor burden before the initiation of radiation therapy and combination chemotherapy.

The optimal chemotherapy regimen has not been defined but should include doxorubicin, if not used previously. The combination of etoposide and carboplatin [259] is active against recurrent Wilms' tumor with favorable histology and, although studied in few cases, probably with diffuse anaplasia and in clear cell sarcoma of the kidney. There are insufficient studies of this combination in patients with rhabdoid tumor.

The combination of etoposide and ifosfamide is also highly active in favorable histology Wilms' tumor and clear cell sarcoma, [260,261] although the nephrotoxicity of ifosfamide in children with Wilms' tumor discourages its use in previously untreated children. [261,262] The substitution of cyclophosphamide, using a dose intensity similar to that used in the phase II trial of ifosfamide and etoposide, may also be effective [263] and is currently under study in NWTS-5.

Patients who relapse after prior treatment with a regimen that included doxorubicin or who develop a recurrence in the abdomen (including liver) after previous irradiation have a poor prognosis. It has been suggested that high-dose chemotherapy with stem cell rescue should be used in the management of patients with adverse prognostic factors at the time of relapse,[264,265] although the relative efficacy of this approach remains unproved. In general, these children should be referred to centers that are conducting research in the treatment of children with recurrent solid tumors.

## FOLLOW-UP DURING AND AFTER THERAPY

Children treated for Wilms' tumor should be examined regularly by a physician who is familiar with the natural history of this tumor and the complications of therapy. Careful palpation of the abdomen will help detect local tumor recurrence, tumor growth in the liver, or contralateral tumor development. Suspicious findings on physical examination should be confirmed or clarified using abdominal ultrasound or CT. Lung irradiation may affect the thyroid gland, which should therefore be palpated yearly for life because of the known association between irradiation and thyroid neoplasms. In addition, these patients should have thyroid function tests performed at yearly intervals for 5 years to detect possible hypothyroidism.

A routine schedule for diagnostic imaging follow-up is shown in Table 30-8. Although no studies have been carried out to evaluate the most effective schedule of follow-up, these proposed intervals are based on the fact that most recurrences (approximately 90%) occur in the first 2 years after diagnosis, and virtually the remainder occur in the next 2 years.[199,247] Subsequent imaging studies should be obtained as clinically indicated.

| Imaging study | Patient | Schedule |
|---|---|---|
| Chest x-ray or computed tomography scan of thorax | All patients | Every 6 wk until complete remission is documented; every 3 mo × 8, followed by every 6 mo × 4 |
| Abdominal ultrasound | Patients with nephrogenic rests | Postoperatively after 6 wk and 3 mo then every 3 mo until age 8 yr |
| | Patients without nephrogenic rests | Postoperatively after 6 wk and 3 mo; then every 3 mo × 7, followed by every 6 mo × 4 |

**TABLE 30-8. IMAGING STUDIES RECOMMENDED FOR FOLLOW-UP OF CHILDREN WITH FAVORABLE OR ANAPLASTIC HISTOLOGY WILMS' TUMOR**

The first site of disease recurrence with all stages is most frequently the lung. Lung metastases are best seen on CT, although not every lesion detected by CT represents metastatic disease. Abdominal ultrasonography is obtained for the early detection of infradiaphragmatic relapses, which is a greater issue for stage II and III tumors. Patients who at diagnosis present with hematogenous metastasis (brain, lung, liver, and bone) require evaluation of the affected sites at similar intervals to those recommended for the chest and abdomen.[266] The brain is most easily evaluated using magnetic resonance imaging. Although plain radiographs may be suitable to follow the progress of a specific bone lesion, a radionuclide bone scan should be obtained in patients whose presentation suggests bony involvement and in all patients with clear cell sarcoma. Consideration should be given to longer follow-up for clear cell sarcoma patients because relapses are known to occur for as long as 5 years postdiagnosis.

In children with any of the Wilms' tumor–predisposing syndromes or with nephrogenic rests in one or both kidneys, ultrasonography of the remaining kidney is performed for a longer period because the opposite kidney continues to be at risk for several years ( Table 30-8). This is particularly true for children younger than 12 months at diagnosis.[118]

Patients with mesoblastic nephroma require fewer studies, however, because distant metastases are rare. [267,268 and 269] Infradiaphragmatic recurrence may occur, however, particularly in the setting of intraoperative tumor rupture, and ultrasonographic studies should be obtained every 3 months for 18 months postnephrectomy.

Irradiated bony structures are monitored for life for possible radiation-associated neoplasms. Radiographs of irradiated bony structures (e.g., lumbar spine, pelvis, and ribs) are taken annually until full growth is attained. Thereafter they are obtained every 5 years indefinitely. This regimen is advised for the early detection of second neoplasms.[266] Patients receiving pulmonary or even abdominal radiotherapy for Wilms' tumor may have abnormalities of pulmonary function, and therefore pulmonary function tests should be considered as part of their long-term follow-up.

## LONG-TERM COMPLICATIONS AND FOLLOW-UP OF THERAPY

Because Wilms' tumor is usually a curable malignancy, it is essential to limit iatrogenic sequelae. Although the damage from the primary treatment, nephrectomy, may be limited to the kidney, additional treatment modalities may cause acute and chronic damage to several organs, such as the heart, lungs, liver, bones, and gonads. In addition, both chemotherapeutic agents and radiation therapy can induce second malignant neoplasms (SMNs).

### Renal Function

Nephrectomy, the use of nephrotoxic agents (primarily chemotherapy and certain antibiotics), and radiation therapy to the remaining kidney can potentially affect renal function in children treated for Wilms' tumor. However, the NWTSG experience suggests that serious renal dysfunction is not common in this patient population. [216] Of 5,823 children evaluated, of whom 451 had bilateral disease, a total of 55 patients (approximately 1%) were identified with renal failure. Thirty-nine of the fifty-five (71%) children had bilateral disease in which the most common cause of renal failure was surgery (bilateral nephrectomy) followed by radiation-induced damage and postsurgical complications in the remaining kidney. For patients with unilateral Wilms' tumor and an apparently normal contralateral kidney, the risk of renal failure was very low (0.25%) and the most common cause was unrecognized renal disease (Denys-Drash syndrome) followed by radiation nephritis. [216] It is noteworthy, however, that many of these children with unilateral Wilms' tumor are still young. They therefore remain at risk for renal deterioration as time goes on. Indeed, patients have been described with proteinuria and hypertension developing 10 to 20 years after nephrectomy, local irradiation, and chemotherapy for unilateral Wilms' tumor.[220]

### Cardiac Function

Up to 25% of Wilms' tumor patients treated with doxorubicin can be expected to develop some cardiac abnormality, most frequently signs of increased left ventricular

afterload.[270] Risk factors include both the cumulative dose and dose intensity of anthracycline. [270] The cumulative percentage of children treated with doxorubicin on NWTS-2 and -3 who actually developed congestive heart failure was 1.7% at 15 years postdiagnosis. [271] The onset of heart failure occurred 1.3 to 11.7 years after diagnosis, with 50% occurring after 8 years. [271] Whole lung irradiation is an additional risk factor. The percentage of children who developed congestive heart failure after treatment in NWTS-2 and -3 increased from 1.0% among those whose treatment did not include whole lung irradiation to 5.4% among those whose treatment did.[271] There have also been reports of congestive heart failure in patients who received left ventricular irradiation from the abdominal radiation therapy for a left sided tumor.[272]

### Pulmonary Function

Radiation therapy, as well as certain chemotherapeutic agents, can cause serious changes in pulmonary function. [273] Review of patients with metastatic pulmonary disease entered on NWTS-3, revealed “pneumonitis of unknown etiology” (likely radiation pneumonitis) in approximately 12% of patients after pulmonary irradiation.[238] The mortality associated with pneumonitis of unknown etiology was high; only 25% of patients survived. [238] By contrast, all children with pneumonitis due to *P. carinii* survived the episode. The incidence of pneumonitis has been reduced by the reduction in doxorubicin and actinomycin dosage when given concurrently with irradiation.

### Hepatic Function

The liver may be damaged by several cytotoxic agents, including dactinomycin and irradiation. [274] Although most early reports suggested that hepatic irradiation was the most important factor, recent publications have documented hepatic toxicity after the use of vincristine and dactinomycin in nonirradiated children with Wilms' tumor.[275,276] In NWTS-4, the incidence of significant hepatotoxicity ranged from 2.8% to 14.3% in groups that received different doses and schedules of dactinomycin, suggesting a dose-related toxicity.[275] Investigators in Europe have reported a similar incidence of hepatotoxicity (12.5%) on SIOP-9. [276]

Hepatic veno-occlusive disease (VOD) is primarily a clinical diagnosis with the following features: hepatomegaly, right upper-quadrant pain, jaundice, ascites, and unexplained weight gain. VOD, which occurs within the first 10 weeks of therapy, has been diagnosed in children with Wilms' tumor that undergo initial nephrectomy, as well as in those receiving chemotherapy before surgery. [276] In the latter group, hepatotoxicity occurred during preoperative chemotherapy as well as during postnephrectomy therapy. Although treatment for VOD is primarily supportive, chemotherapy does not need to be withheld once the signs of VOD have disappeared. Long-term or permanent hepatic dysfunction has not been a problem for Wilms' tumor survivors.

### Bone Marrow

The frequency of severe hematologic toxicity was evaluated in patients treated with the divided-dose or the single-dose regimens in NWTS-4. The single-dose regimens produced less hematologic toxicity, despite the fact that the myelosuppressive drugs were administered at a higher dose intensity. [246]

Morgan and colleagues[277] reported severe hematologic toxicity among 47% of infants younger than 12 months after treatment with full doses of chemotherapeutic agents, compared with 13% of similar patients treated with 50% of the protocol drug doses. The use of lower drug doses did not increase the frequency of relapse among patients younger than 12 months.[277] These data confirmed the results of other investigators[278,279] and led to the recommendation that all infants receive only 50% of the usual dose of any chemotherapeutic agent. [280]

### Gonadal Function

Infertility is one of the main late sequelae of cytotoxic chemotherapy. Because dividing cells are most sensitive to the cytotoxic effects of alkylating agents, the impairment of gonadal function is more frequent in boys than in girls. [281,282] Because most patients with Wilms' tumor are not treated with alkylating agents, gonadal dysfunction is primarily of concern for those that receive these drugs after relapse.

Women who received whole abdominal irradiation in childhood may develop ovarian failure, [283] but this may be prevented by moving both ovaries out of the irradiation field.[284] Several investigators have reported that pregnancy outcomes are adversely affected by abdominal irradiation for Wilms' tumor. [87,88,285] In the largest study thus far, women irradiated for Wilms' tumor had an increased perinatal mortality rate (relative risk of 7.9) and an excess of low-birth-weight infants (relative risk of 4.0) when compared with white women in the United States.[88] By contrast, an adverse outcome was found in only 2 (3%) of the 77 pregnancies in nonirradiated girls with Wilms' tumor or in wives of boys with Wilms' tumor. [88] The high-risk nature of pregnancy should be considered in the counseling and prenatal care of women who have received abdominal radiotherapy for Wilms' tumor.

### Musculoskeletal Function

The late effects of trunk irradiation—scoliosis and soft tissue underdevelopment—are still being seen despite the advent of megavoltage irradiation. [286,287,288 and 289] One would expect the least deformity, of course, when radiation is omitted entirely. That expectation has been documented by the NWTSG, which recorded 66 instances of “musculoskeletal” difficulties (not otherwise defined) among 88 irradiated stage I children followed for 5 or more years, versus 7 in 93 unirradiated cohorts. [290] A radiation dose greater than 20 Gy is associated with a greater risk of major morbidity in the spine or any irradiated bone. [291]

### Second Malignant Neoplasms

Wilms' tumor survivors are at risk for SMNs, possibly due both to inherited predisposition and to treatment such as chemotherapy and radiotherapy. The NWTSG experience reveals a cumulative incidence of SMN of 1.6% 15 years after the initial diagnosis of Wilms' tumor. [292] The most important risk factor for the occurrence of an SMN in this cohort was treatment with radiation therapy. Initial treatment that included doxorubicin further increased this risk. Significantly, though, even those whose therapy included only dactinomycin and vincristine, without radiation therapy, had an increased risk of cancer when adjusted for age, sex, and race, compared to the U.S. population.[292] Treatment for relapse further increased the risk for a SMN by a factor of four to five. [292] The experience in Europe has been similar.[293] Compared to the general population, survivors of Wilms' tumor had a fivefold increased risk of developing an SMN in the first 10 years from diagnosis. [293]

### Long-Term Follow-Up

These data demonstrate the importance of the continued efforts to limit the use of intensive therapy in the treatment of patients thought to be at low risk for recurrence. Intensive therapy is now applied only to patients with advanced-stage disease or those with tumors displaying unfavorable histologic features.

Ongoing care for Wilms' tumor survivors should include screening for complications that can be expected based on the therapeutic regimen used. Many of these possible long-term sequelae can be detected by a simple protocol that includes history, physical examination, assessment of renal function, urinalysis, and echocardiogram as indicated. The most important factor is knowledge of the possible adverse outcome. This will allow for the implementation of early intervention if needed.

## FUTURE CONSIDERATIONS

Major progress has been made in the management of children with Wilms' tumor. More than 85% can be cured by current therapies. Future treatment research must address several important issues. The most important of these is the need to identify new prognostic markers to distinguish those patients who require more effective therapy for cure from those who could potentially be cured without agents that are associated with adverse sequelae, such as radiation or doxorubicin. Such factors may be biological, genetic, or traditional histologic factors to better predict for local recurrence—distinguishing current stage II patients who relapse without irradiation from stage III patients that are irradiated unnecessarily, for example.

The role of whole lung irradiation in the management of patients with stage IV/favorable histology tumors requires further clarification. Although not all such patients require whole lung irradiation, it is not yet possible to clearly distinguish those that do. It may even be possible with emerging technical advances, such as

intensity-modulated radiotherapy, to restrict whole lung fields to small, highly conformal fields, minimizing the amount of lung tissue irradiated.

The efficacy of chemotherapeutic agents other than anthracyclines in combination with vincristine and dactinomycin for the treatment of patients with stage III or IV/favorable histology tumors with a high risk of relapse must be studied. Combinations currently being studied in relapsed patients such as cyclophosphamide/etoposide and carboplatinum/etoposide show promise in this regard.

Other problems that need to be carefully evaluated include the use of renal-sparing surgical procedures in the management of patients with bilateral Wilms' tumor and those with conditions known to predispose to the development of metachronous Wilms' tumor. It is still hoped that characteristics can be identified that define those with a negligible risk of recurrence for whom nephrectomy only might be an appropriate treatment approach.

Evolving understanding of the genesis of Wilms' tumor at the genetic level may allow an increased ability to identify individuals at highest risk for development of the disease: the predisposed members of a family segregating the tumor or the subset of children with a Wilms' tumor–predisposing condition who will actually develop a tumor.

Finally, the best treatment for Wilms' tumor will not likely always be chemotherapy as we know it. Emerging treatments such as the antiangiogenic factors will likely be actively explored in the near future.

## ACKNOWLEDGMENTS

The authors thank the investigators of the Pediatric Oncology Group and the Children's Cancer Group and the many pathologists, surgeons, pediatricians, radiation therapists, and other health professionals who managed the children entered on the National Wilms' Tumor Studies, and Gina Kennedy for preparation of the manuscript. Supported in part by USPHS Grant CA-42326.

# NEUROBLASTOMA

GARRETT M. BRODEUR
JOHN M. MARIS

## INTRODUCTION

The neuroblastic tumors (including neuroblastoma, ganglioneuroblastoma, and ganglioneuroma) are derived from primordial neural crest cells, that ultimately populate the sympathetic ganglia, adrenal medulla, and other sites. The variations in tumor locations and degrees of histopathologic differentiation result in an array of diverse clinical and biologic characteristics and behavior. [1,2] and [3] In addition to demonstrating spontaneous regression as well as differentiation to benign neoplasms, these tumors also exhibit extremely malignant behavior when observed in older children with regional or disseminated disease.

In the last 30 years, there has been substantial improvement in the outcome of infants as well as older children with local or regional neuroblastoma. Indeed, improvement has also occurred in the outlook for older children with metastatic disease at diagnosis. The ever-increasing ability to distinguish prognostic subsets of patients based on clinical and biologic features has allowed a better understanding of relative risk for recurrent disease and, therefore, the development of risk-related therapy that is not based solely on age and stage. In the face of these advances, age still remains an important indicator of outcome. With current treatment, the risk distinction seems most clear between infants, defined hereafter as 1 year or younger, and older children.

This chapter reviews the current understanding of the prognostic implications of various clinical and biologic features of neuroblastoma and relates these characteristics to current trends as well as future strategies for treatment.

## EPIDEMIOLOGY

### Incidence

Neuroblastoma is the most common extracranial solid tumor in children, accounting for 8% to 10% of all childhood cancers. The prevalence is approximately 1 case per 7,000 live births, and there are approximately 600 new cases of neuroblastoma per year in the United States. [3,4] and [5] This corresponds to an incidence of 10.4 per million per year in white children and 8.3 per million per year in black children younger than 15 years. Evidence indicates that this incidence is fairly uniform throughout the world, at least for industrialized nations. The tumor is slightly more common in boys than in girls, with a male to female sex ratio of 1.1:1.0 in most large studies.

Neuroblastoma is almost exclusively a pediatric neoplasm and is the most common cancer diagnosed during infancy. [4] Review of 3,059 neuroblastoma patients registered on cooperative group studies at POG institutions from February 1990 to February 2000 (n = 2,148) and at CCG institutions from August 1991 to August 1995 (n = 911) showed a median age at diagnosis of 17.3 months. In this cohort, 40.1% of patients were diagnosed as infants, 89.4% at ages younger than 5 years, and 97.8% by 10 years of age (Fig. 31-1). Of note, past estimates of the median age at diagnosis for neuroblastoma patients were approximately 22 months and suggested a bimodal distribution. [5] The earlier median and exponential decrease of age at diagnosis noted here may be due to either (a) earlier diagnosis as a result of better awareness or improved diagnostic imaging, or (b) patients with high-risk disease, who are generally older at diagnosis, not being consistently registered on

POG and CCG cooperative group trials during the years reviewed.

### Environmental Studies

The etiology of neuroblastoma is unknown in most cases, but it seems unlikely that environmental exposures play a major role. There have been a few reports that have implicated the following intrauterine exposures: alcohol (fetal alcohol syndrome), seizure medications, diuretics, neurally active drugs (such as tranquilizers and prescription pain medications), fertility drugs or hormones, and maternal use of hair coloring products. [6,7,8,9,10,11 and 12] However, none of these have been seen consistently or confirmed by larger studies. There have also been reports of an association with a variety of parental occupations, including certain electrical, farming, gardening, and painting jobs, suggesting parental environmental exposures may have contributed to neuroblastoma in their offspring, but none has been seen consistently.[13,14,15 and 16] Finally, there has been a recent report that BK virus infection may play a role in the pathogenesis of neuroblastoma, [17] but this has not yet been confirmed. At present, therefore, although limited studies have implicated a variety of prenatal exposures and parental occupations in neuroblastoma causation, in general the associations are weak. Thus, no prenatal or postnatal exposure to drugs, chemicals, viruses, or radiation has been associated strongly, consistently, or unequivocally with an increased incidence of neuroblastoma. This does not preclude a possible role of environment in the pathogenesis of neuroblastomas, but to date no strong environmental exposure or factor has been identified.

## GENETICS

### Constitutional Chromosomal Abnormalities and Associated Conditions

Germline chromosomal abnormalities have been seen rarely in children with neuroblastoma, but such abnormalities can facilitate the identification of a predisposing gene. Chromosome band 1p36 is a frequent site of somatic deletion in neuroblastoma cells, and three neuroblastoma patients have been described with germline interstitial deletions of 1p36. [18,19 and 20] Each patient was diagnosed with neuroblastoma during infancy and had profound neurocognitive deficits. The constitutional deletions overlap the location of a putative 1p36 tumor suppressor gene (see below), suggesting that germline absence of a gene within this region may predispose to the development of neuroblastoma. Constitutional balanced translocations involving 1p have also been identified in two additional infants with neuroblastoma. [21,22] These translocations involved the long arm of chromosome 17 [t(1;17)(p36;q12-21)] in a patient with localized disease and the long arm of chromosome 10 [t(1;10)(p22;q21)] in a patient with stage 4S disease. A gene located at chromosome band 1p22 ( *NB4S*) was disrupted by the latter translocation, suggesting that inactivation of this gene may play a causal role in neuroblastoma tumorigenesis. [23] At least 14 other cases of constitutional chromosomal rearrangements in neuroblastoma patients have been identified, [24] but the lack of a consistent pattern indicates that many of these rearrangements may be coincidental rather than causal.

Neuroblastoma occurring coincident with congenital anomalies is uncommon. One study showed a higher incidence of neurodevelopmental abnormalities in the brains of children dying of neuroblastoma, but the significance of these findings is unclear. [25] One recent review suggested a higher incidence of neuroblastoma in girls with Turner's syndrome,[26] although this has not yet been independently confirmed. Interestingly, another study suggested a lower incidence of neuroblastoma among patients with Down syndrome.[27] Hirschsprung's disease, central hypoventilation (Ondine's curse), and NF1 have all been described in both sporadic and familial neuroblastoma patients, suggesting the existence of a global disorder of neural crest–derived cells (neurocristopathy). [28,29,30,31,32,33,34,35 and 36] Indeed, two studies have documented *NF1* gene mutations in a subset of neuroblastoma cell lines,[37,38] and a patient has been reported with NF1 and neuroblastoma whose tumor had a homozygous deletion of the *NF1* gene.[39] Epidemiological evidence suggests that the association of neuroblastoma with NF1 is merely coincidental, [36] however, and familial neuroblastoma is not linked to the *NF1* locus, even in a family in which the proband had both conditions. [35] Thus, germline inactivation of *NF1* does not appear to predispose to neuroblastoma, but somatically acquired inactivation may occur as a later event in tumor evolution in some cases.

### Hereditary Neuroblastoma

Although neuroblastoma usually occurs sporadically, 1% to 2% of patients report a family history of the disease. [40,41,42,43 and 44] This is similar to the other embryonal cancers of childhood, in which a subset of patients develop their cancers as a result of hereditary predisposition. Familial neuroblastoma is inherited in an autosomal dominant Mendelian fashion with incomplete penetrance. Affected children from these families differ from those with sporadic disease in that they are often diagnosed at an earlier age (usually infancy) and they frequently have multiple primary tumors. [41,43,44] These clinical characteristics are hallmarks of the “two-mutation” model for cancer predisposition first proposed for retinoblastoma. [45] Therefore, it appears likely that familial neuroblastoma occurs due to a germline mutation in one allele of a tumor suppressor gene (or genes). In addition, Knudson and Strong [43] proposed that germline mutations may account for initiation of tumorigenesis in up to 22% of sporadic neuroblastomas.

There is remarkable heterogeneity among patients with familial neuroblastoma. Within individual families, the disease can vary from asymptomatic ganglioneuroma or spontaneously regressing neuroblastoma to rapidly progressive and fatal disease. [46] Thus, the timing of inactivation of the second tumor suppressor gene allele and additional mutations are postulated to confer the ultimate clinical phenotype. The clinical heterogeneity of familial neuroblastoma may partially explain its rarity, because some tumors remain occult or regress and thus are never detected. In addition, others result in death before reproductive age, so the germline mutations are never passed on.

Many candidates for the hereditary neuroblastoma gene or locus have been proposed, including several regions of deletion containing putative tumor suppressor loci. Linkage analysis has excluded each of these candidate regions, including the distal short arm of chromosome 1. [40,41,47] However, a recent genome-wide search for linkage has identified the short arm of chromosome 16 as a likely site of a hereditary neuroblastoma predisposition gene. [48]

## CELLULAR AND MOLECULAR PATHOGENESIS

Considerable progress has been made in the past decade in understanding human neuroblastoma at a cellular and molecular level. [49,50,51,52,53 and 54] These studies have contributed to better methods of tumor diagnosis and subclassification, and they provide information that is useful in predicting clinical behavior. In addition to providing insights into mechanisms of malignant transformation and progression, these studies may identify critical genes, proteins, and pathways that may serve as targets for future therapy. In turn, these novel approaches to treatment may prove to be more effective and less toxic than current therapeutic modalities.

### Embryology

Several studies have demonstrated that microscopic neuroblastic nodules occur uniformly in the adrenal glands of all fetuses studied. [55,56] These nodules peaked between 17 and 20 weeks of gestation and gradually regressed by the time of birth or shortly after. Previously, Beckwith and Perrin [57] reported that microscopic

neuroblastic nodules, resembling “neuroblastoma *in situ*,” were found frequently in infants younger than 3 months who died of other causes. This finding was interpreted initially to indicate that neuroblastomas develop much more often than they are detected clinically and that the tumor regresses spontaneously in the majority of cases. However, these neuroblastic nodules most likely represent the remnants of normal fetal adrenal development. [55,56] Nevertheless, these neuroblastic cell rests likely represent the cells from which adrenal neuroblastomas develop.

It is unlikely that the microscopic neuroblastic nodules described above would be detected clinically, nor would they be detected by screening infants for neuroblastoma by measuring urinary catecholamine metabolites (see below). The concept of *in situ* neuroblastoma has been used to support the argument that the number of neuroblastomas that arise and regress spontaneously is many times the number detected clinically. Indeed, there are a number of well-documented cases in infants with neuroblastoma that have had complete regression of their tumor. [58,59 and 60] Mass screening studies in Japan, Quebec, and elsewhere, however, give a more realistic estimate of the number of neuroblastomas that regress without treatment. [61,62 and 63] It appears that approximately half of all neuroblastomas that reach a size that would be detectable by screening actually regress without specific therapy, whereas an equivalent number are detected clinically in unscreened populations.

**Neuronal Differentiation**

Neuroblastoma cells are derived from postganglionic sympathetic neuroblasts, and they frequently exhibit features of neuronal differentiation. Indeed, neuroblastomas may show spontaneous or induced differentiation to ganglioneuroblastoma or ganglioneuroma, so the malignant transformation of these cells may result in part from a failure to respond fully to the normal signals to undergo morphologic differentiation. The factors responsible for regulating normal differentiation are not understood completely at present, but they probably involve one or several neurotrophin receptor pathways that signal the cell to differentiate. One of the important pathways appears to be NGF and its receptor. Indeed, this pathway is representative of a family of homologous neurotrophins and receptors that may play important roles in regulating the survival, growth, and differentiation of sympathetic neuroblasts. Additional neurotrophic factors and receptors have been described recently, [64,65 and 66] so there is reason for optimism that the differentiation process may become understood better. This in turn may lead to better means of tumor classification or of treatment aimed at inducing differentiation or regression.

**Neurotrophin Receptors**

Neurotrophic factors and their receptors have been implicated in the pathogenesis of neuroblastoma, but their *precise* role has been unclear. Indeed, most neuroblastoma cell lines are neither dependent on nor responsive to the presence of NGF *in vitro*. Previous studies have demonstrated defects of expression and function of the NGF receptor in neuroblastoma cell lines, [67,68] but the role of the NGF receptor pathway in the pathogenesis of neuroblastomas has been uncertain.

NGF is a member of a family of homologous neurotrophins that includes BDNF, neurotrophin-3, and neurotrophin-4/5. [69] Recently, three TRK genes encoding receptors for the neurotrophic factors of the NGF family have been cloned. The genes *TRKA*, *TRKB*, and *TRKC* encode the primary receptors for NGF, BDNF and neurotropin-3, respectively. [69] The primary receptor for neurotropin-4/5 is unknown, but it appears to function through *TRKB*.

Nakagawara and colleagues [70,71] demonstrated that *TRKA* expression was inversely correlated with *MYCN* amplification. Indeed, high *TRKA* expression was associated with a biologically and clinically favorable group of patients (age younger than 1 year; stage 1, 2, and 4S) and with a very good outcome. [71,72,73,74,75 and 76] The combined assessment of *MYCN* copy number and *TRKA* expression provided additional prognostic information over either variable alone. Furthermore, studies have demonstrated that primary neuroblastoma cells with high *TRKA* expression differentiate in the presence of NGF *in vitro*, whereas the same cells die in the absence of NGF. [71] Thus, the NGF/*TRKA* pathway may explain the propensity for some neuroblastomas to differentiate or to regress spontaneously.

The studies of *TRKB* and *TRKC* expression in neuroblastomas are more limited. *TRKB* was expressed in about one-third of the neuroblastomas tested, and its cognate ligand BDNF was expressed in two-thirds of the tumors. [77] The truncated form of *TRKB*, lacking the tyrosine kinase domain, was expressed predominantly in more differentiated tumors (ganglioneuroblastomas and ganglioneuromas), whereas the full-length *TRKB* transcript was expressed in tumors with *MYCN* amplification. [77] Thus, the *TRKB*/BDNF pathway may serve as an autocrine or paracrine pathway to promote survival in *MYCN*-amplified tumors. In contrast, *TRKC* expression was found in approximately 25% of neuroblastomas tested, and its pattern of expression resembles that of *TRKA*. [78,79] Because all tumors with *TRKC* expression also had high *TRKA* expression, it did not add additional prognostic significance. However, it may represent an alternate or additional pathway for neuronal differentiation in these tumors.

**Neuropeptides**

Two other markers of neuronal differentiation sometimes associated with neuroblastomas are chromogranin A and neuropeptide Y. Chromogranin A is an acidic protein that is a component of neurosecretory granules of neuroendocrine cells, tissues, and tumors, and it is developmentally regulated. [80,81 and 82] It is present in the serum of patients with neuroblastoma, so it may serve as a sensitive and specific serum marker for disease activity and response to treatment. [83,84] Neuropeptide Y is another neurosecretory protein whose expression is developmentally regulated and restricted to the nervous system. [85,86] These two proteins may be useful in characterizing neuroblastomas in terms of their developmental state of differentiation or patient monitoring. [87,88 and 89] SS and VIP represent additional peptide hormones that are associated with neuroblastoma. Expression of SS receptors on neuroblastoma cells is associated with more differentiated histology, lower stages of disease, and a favorable outcome. [90,91,92 and 93] Furthermore, SS analogs can be used for neuroblastoma imaging *in vivo* (see below). Although VIP is associated with a paraneoplastic syndrome that includes watery diarrhea and abdominal distension (see below), VIP expression is also associated with differentiated tumors, and it can also induce neuronal differentiation in neuroblastoma cells in culture. [94,95] The role that these two proteins play in regulating growth or differentiation of sympathetic neurons during normal development is unclear.

**DNA Index**

Flow cytometric analysis of DNA content is a simple and semiautomated way of measuring total cell DNA content, which correlates well with modal chromosome number. Studies by Look and colleagues [96,97] and others have demonstrated that determination of the DI of neuroblastomas from infants provides important information that can be predictive of response to *therapy* as well as outcome. Interestingly, infants with tumors that have a “hyperdiploid” DNA content (DI greater than 1) are more likely to have lower stages of disease and to respond to initial therapy, whereas those with a “diploid” DNA content (DI = 1) more likely have advanced stages of disease and do not respond to this combination. [96,97] Although this analysis cannot detect specific chromosome rearrangements, such as deletions, translocations, or even gene amplification, it is a relatively simple test that correlates with biologic behavior, at least in this age group. The favorable prognostic association of hyperdiploidy appears restricted to infants, however, particularly those with advanced stages of disease. This is likely because whole chromosome gains account for the hyperdiploidy in this age group. [97] Hyperdiploid tumors in older children are more likely to have structural changes, and this karyotypic pattern is not associated with a favorable outcome. [97,98]

**Cytogenetic Characterization**

Neuroblastomas are characterized cytogenetically by recurrent deletions of 1p, 11q, and other sites, as well as unbalanced gain of 17q. The former abnormalities are thought to represent loss of tumor suppressor genes at these sites, whereas unbalanced 17q gain may represent a gain of function of a gene or genes on this chromosomal region. In addition, cytogenetic manifestations of gene amplification, such as dmins or HSRs are found in a subset of neuroblastomas. [99,100,101,102 and 103] Although the majority of tumors that have been karyotyped are in the diploid range, a substantial number from patients with lower stages of disease are hyperdiploid or near triploid. The modal karyotype number has been shown to have prognostic value, but the distinction between patterns of genetic change (whole chromosome gains versus structural changes) may be particularly important. [104,105 and 106]

***MYCN* Amplification and Expression**

Extrachromosomal dmins and chromosomally integrated HSRs are cytogenetic manifestations of gene amplification, but the presence of these findings per se does not indicate which gene is amplified. For neuroblastomas, the region amplified is virtually always derived from the distal short arm of chromosome 2, and it contains the proto-oncogene *MYCN* (also known as N-*myc*). Brodeur, Seeger and colleagues [107,108] have demonstrated that *MYCN* amplification occurs in approximately 25% of primary neuroblastomas from untreated patients (Fig. 31-2A); and amplification is associated predominantly with advanced stages of disease, rapid tumor progression, and a poor prognosis. Amplification is found in 5% to 10% of patients with low stages of disease and stage 4S and 30% to 40% of advanced disease

patients (Table 31-1).[24,101,102 and 103,109] *MYCN* amplification is almost always present at the time of diagnosis if it is going to occur, [107] so it appears to be an intrinsic biologic property of a subset of very aggressive tumors that frequently have a poor outcome.

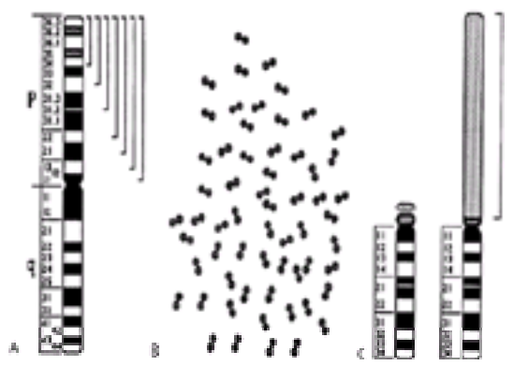

**FIGURE 31-2.** Common cytogenetic abnormalities in human neuroblastomas. Shown are diagrammatic representations of the three most common cytogenetic abnormalities seen in human neuroblastomas. **A:** Deletions of the short arm of chromosome 1. The brackets indicate that the region deleted in different tumors is variable in terms of its proximal breakpoint, but the distal short arm appears to be deleted in all cases, resulting in partial 1p monosomy. **B:** Extrachromosomal double minutes (dmins). Dmins are seen in approximately 30% of primary neuroblastomas and are a cytogenetic manifestation of gene amplification. **C:** A representative homogeneously staining region (HSR) on the short arm of chromosome 13 is shown in this example. HSRs are a cytogenetic manifestation of gene amplification in which the amplified sequences are chromosomally integrated. (From Brodeur GM. Neuroblastoma—clinical applications of molecular parameters. Brain Pathol 1990;1:45, with permission.)

| Stage at diagnosis | *MYCN* amplification (%) | 3-yr survival (%) |
|---|---|---|
| Benign ganglioneuromas | 0/64 (0) | 100 |
| Low stages (1, 2) | 31/772 (4) | 90 |
| Stage 4S | 15/190 (8) | 80 |
| Advanced stages | 612/1,974 (31) | 40 |
| Total | 658/3,000 (22) | 55 |

**TABLE 31-1. CORRELATION OF MYCN AMPLIFICATION WITH ADVANCED STAGE**

The genomic region amplified with *MYCN* is quite large, usually on the order of 500 to 1,000 kb. Therefore, it has been postulated that additional genes located near *MYCN* may contribute to the ultimate tumor phenotype when co-amplified. High-resolution restriction mapping of the *MYCN* locus has shown that a 130-kb core domain is the consistent target of amplification.[111] To date, no other gene besides *MYCN* has been identified in this core domain.[112] However, the RNA helicase gene *DDX1* maps within 300 kb 5' of *MYCN* and is co-amplified in approximately 40% to 50% of neuroblastomas with *MYCN* amplification.[113] *DDX1* can transform NIH-3T3 cells and allow for establishment of sarcomatous primary tumors in immunodeficient mice.[114] Nevertheless, *DDX1* amplification has not been identified in the absence of *MYCN* amplification. Thus, *MYCN* is primarily responsible for the aggressive nature of the neuroblastomas with amplification at the 2p24.1 locus, but *DDX1* may contribute to the highly malignant nature of some *MYCN*-amplified tumors.

In general, there is a correlation between *MYCN* copy number and expression, and tumors with amplification usually express *MYCN* at much higher levels than those seen in tumors without amplification.[70] Thus, *MYCN* overexpression in the context of amplification consistently identifies a subset of neuroblastomas with highly malignant behavior. However, it is controversial whether overexpression of *MYCN* messenger RNA or MycN protein has prognostic significance in nonamplified tumors.[115,116 and 117] Some neuroblastoma cell lines express high levels of *MYCN* messenger RNA or MycN protein without gene amplification.[116,118] This may be due to alterations in normal protein degradative pathways[119] rather than loss of *MYCN* transcriptional autoregulation.[120] Some studies have suggested that MycN expression correlates inversely with survival probability,[121] whereas others have found no such correlation.[122] Further studies in a larger cohort of consistently treated patients with standardized methods will be necessary to determine whether quantitative assessment of MycN expression in tumors lacking *MYCN* amplification provides additional prognostic information.

### Amplification and Expression of Other Oncogenes

No other human oncogene has been shown to be consistently amplified, mutated, or overexpressed in neuroblastoma. Mutations of members of the *RAS* gene family are common in many other types of cancer, but the role of *RAS* genes in neuroblastomas is unclear. *NRAS* was originally identified as a transforming gene in a neuroblastoma cell line, and *RAS* can cooperate with *MYCN* to transform embryonic fibroblasts.[123,124] In addition, targeting of *HRAS* overexpression to the neuroectoderm of mice causes ganglioneuromas and occasional neuroblastomas,[125] but *HRAS* overexpression has been associated with a favorable outcome in neuroblastomas.[76,126] In any case, activating mutations of any members of the *RAS* gene family are rarely observed in primary neuroblastomas.[127,128 and 129] Co-amplification of *MYCL* or *MDM2* has been observed with *MYCN* in a few neuroblastoma cell lines,[130,131 and 132] and recent CGH studies have identified other novel regions of amplification at 2p13-15, 2p23, 3q24-26, 4q33-35, and 6p11-22 in occasional tumors.[133,134] However, the biologic significance of these observations has not yet been defined.

### Unbalanced Gain of 17q

Recurrent abnormalities of the long arm of chromosome 17 were originally identified by analysis of Giemsa-banded karyotypes derived from neuroblastoma primary tumors and cell lines.[135] It has recently become apparent that unbalanced gain of distal 17q material is perhaps the most common genetic abnormality in primary neuroblastomas (Fig. 31-3). Unbalanced 1;17 translocations occur frequently in primary neuroblastomas [136,137] and often result in loss of distal 1p with concomitant gain of distal 17q material.[138] However, the 17q translocation breakpoints are heterogeneous and often involve other partner chromosomes, most notably 11q.[139] Bown and colleagues[140] demonstrated that 54% of 313 neuroblastomas analyzed at diagnosis had unbalanced 17q21qter gain. Unbalanced 17q gain is associated with adverse prognostic features and is present in the vast majority of neuroblastomas with *MYCN* amplification.[140,141,142 and 143] Thus, this genomic region is likely to harbor a gene that contributes to neuroblastoma tumorigenesis when present in increased copy number or overexpressed.

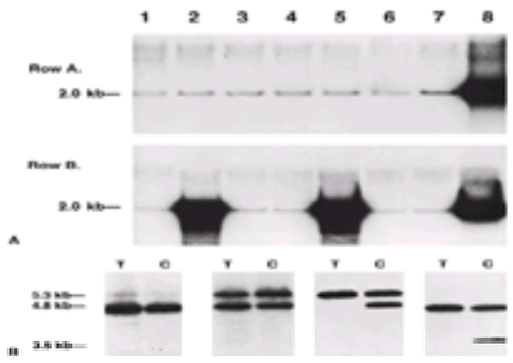

**FIGURE 31-3. A:** Southern blots showing *MYCN* amplification and 1p allelic loss. Lane 1 represents DNA from a normal lymphoblastoid cell line as a single-copy control, and lane 8 represents DNA from the NGP cell line, with 150 copies of *MYCN* per haploid genome. (*Row A*): Lanes 2 through 7 represent six neuroblastomas with a single copy of *MYCN* per haploid genome. (*Row B*): Lanes 2 and 5 show examples of tumors with *MYCN* amplification, whereas the other tumors have the normal single-copy signal. (From Brodeur GM. Neuroblastoma—clinical applications of molecular parameters. Brain Pathol 1990;1:45, with permission.) **B:** 1p allelic loss. Southern hybridization with a polymorphic probe (D1S57) to normal and tumor DNA after restriction enzyme digestion. The first panel shows a case in which polymorphism was not seen in the constitutional DNA (C), so the case is uninformative with respect to allelic loss or LOH in the tumor DNA (T). The second panel shows a case in which polymorphism was seen in the constitutional DNA, so it was informative, but no LOH was seen in the tumor. The last two panels show cases in which the constitutional DNA was informative, and LOH was detected in the tumor, as demonstrated by the absence of the lower band in both cases. (From Brodeur GM, Fong CT. Molecular biology and genetics of human neuroblastoma. Cancer Genetics Cytogenet 1980;41:153–174, with permission.)

## Chromosome Deletion or Allelic Loss

### *Chromosome 1*

Deletions of 1p are found in 70% to 80% of the near-diploid tumors that have been karyotyped. [99,104,106,135,144,145,146 and 147] Molecular genetic studies have confirmed these observations by documenting LOH in approximately 35% of primary tumors (Fig. 31-2B; Fig. 31-3) and in the vast majority of neuroblastomas with *MYCN* amplification.[148,149,150,151,152,153 and 154] Addition of an intact human chromosome 1p to a 1p-deleted neuroblastoma cell line induced cellular differentiation or death. [155] It therefore appears likely that a neuroblastoma suppressor gene is located on the short arm of chromosome 1 and that this gene is inactivated in at least one-third of primary neuroblastomas. However, the majority of 1p deletions are large and the proximal breakpoints heterogeneous, [149,154,156,157,158 and 159] suggesting that distal 1p may contain more than one suppressor gene critical for malignant transformation or progression.

### *Chromosome 11*

Several lines of evidence suggest that a neuroblastoma suppressor gene is located on the long arm of chromosome 11. Chromosome 11q deletions have been noted in approximately 20% of reported neuroblastoma karyotypes (Fig. 31-3),[147] and transfer of an intact chromosome 11 into a neuroblastoma cell line induced differentiation.[155] Constitutional rearrangements of chromosome 11q have also been observed in four neuroblastoma patients. [160] Molecular genetic studies have demonstrated loss of 11q in more than one-third of primary tumors[133,134,143,151,161,162] Guo and colleagues[162] mapped a common region of deletion to 11q23, indicating that this is the most likely location of an 11q neuroblastoma suppressor gene. In contrast to 1p LOH, there was a striking *inverse* correlation of 11q LOH with *MYCN* amplification.

### *Chromosome 14*

Deletion of the long arm of chromosome 14 is also a common abnormality in neuroblastomas (Fig. 31-3).[151,161,163,164] Unlike for chromosomes 1 and 11, there are only a few reports of cytogenetically visible deletions or rearrangements involving 14q. [145,165] This may indicate that deletions of chromosome 14 are too small to be identified easily by conventional cytogenetic analysis or that the mechanism of LOH involves homologous mitotic recombination. A recent study of 372 primary neuroblastomas with markers evenly spaced along 14q showed LOH in 22%, with a common region of deletion within 14q23qter. [166] LOH for 14q was highly correlated with 11q LOH and *inversely* related to 1p36 LOH and *MYCN* amplification. Furthermore, data from another group have suggested that there may be two distinct regions of allelic loss on 14q, [167] so there may be more than one suppressor gene on this chromosome arm.

### *Deletions of Other Chromosomal Regions*

There are other regions of the genome that are frequently deleted in neuroblastoma DNAs, suggesting the existence of additional tumor suppressor genes. There have been reports of LOH or allelic imbalance by CGH at chromosome arms 3p,[168] 4p,[169] 9p,[170,171] and 18q,[172] but these appear less common than 1p or 11q LOH. The genes that are targets for these apparent nonrandom deletions are unknown.

### *Alterations of Known Tumor Suppressor Genes*

No novel tumor suppressor genes have been isolated to date, and there is currently no evidence for consistent mutation in any known tumor suppressor genes. *TP53* is the most frequently mutated gene in human cancer, but it is rarely inactivated by deletion or mutation in neuroblastomas obtained at diagnosis. [173,174,175 and 176] Moll and colleagues[177] have reported aberrant cytoplasmic localization of the p53 protein in neuroblastoma and found evidence for dysregulated $G_1$/S checkpoint control. However, others have shown that DNA damage to neuroblastoma cells causes normal translocation of wild-type p53 to the nucleus and induction of p21. [178] *CDKN2* encodes p16, another cell cycle control protein commonly inactivated in human cancers, but mutations and deletions have rarely been found in neuroblastomas. [179,180] The *DCC* and *DPC4* genes are located at 18q, a region that is frequently deleted in primary neuroblastomas. Although expression of *DCC* may be altered in some cell lines and tumors, no inactivating mutations of *DCC* or *DPC4* have been identified.[172,173,174,175,176,177,178,179,180 and 181]

## Genetic Model of Neuroblastoma Development

In summary, there is increasing evidence for two or three genetic subsets of neuroblastomas that are highly predictive of clinical behavior. One recently proposed classification takes into account abnormalities of 1p, *MYCN* copy number, and assessment of DNA content, and distinct genetic subsets of neuroblastomas can be identified (Fig. 31-4, Table 31-2).[24,103,109] The first group (type 1) is characterized by mitotic dysfunction leading to a hyperdiploid or near-triploid modal karyotype, with few if any cytogenetic rearrangements. These tumors lack specific genetic changes such as *MYCN* amplification or 1p LOH, and they have high *TRKA* expression. These patients are generally younger than 1 year, with localized disease and a very good prognosis. Most of the infants detected by the neuroblastoma screening studies fall into this category. The second group is characterized by gross chromosomal aberrations, and they generally have a near-diploid karyotype. No consistent abnormality has been identified to date, but 17q gain is common. Within this type, two subsets can be distinguished. One subset (type 2) is characterized by 11q deletion, 14q deletion, or other changes, but it lacks *MYCN* amplification and generally lacks 1p LOH. Patients with these tumors are generally older, with more advanced stages of disease that is slowly progressive but often fatal. The other subset (type 3) is characterized by amplification of *MYCN*, usually with 1p36 LOH and high *TRKB* expression. These patients are generally between 1 and 5 years of age, with advanced stages of disease that is rapidly progressive and frequently fatal. It is unknown if a tumor from one type ever converts to a less favorable type, but current evidence suggests that they are genetically distinct.

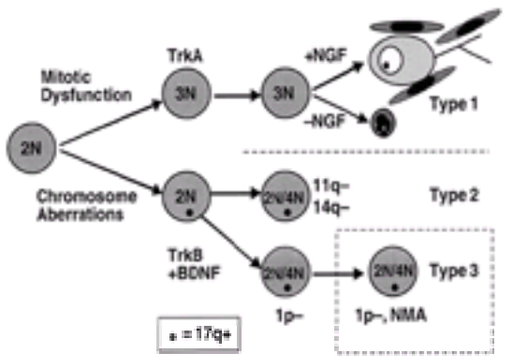

**FIGURE 31-4.** Genetic model of neuroblastoma development. According to this model, all neuroblastomas have a common precursor (NB) and may have a common mutation (the one responsible for familial neuroblastoma). However, a commitment is made to develop into one of three major types. The first type is characterized by mitotic dysfunction, leading to a hyperdiploid or near-triploid modal karyotype (3N) with whole chromosome gains but few if any structural cytogenetic rearrangements. These tumors usually express high levels of NGF receptor *TRKA*, so they are prone to either differentiation or apoptosis, depending on the presence or absence of NGF in their microenvironment. The second type generally has a near-diploid (2N) or near-tetraploid karyotype but is characterized by gross chromosomal aberrations. No consistent abnormality has been identified to date, but 17q gain is common, and allelic loss of 1p, 11q, or 14q is seen frequently. The third type is related to the second but is characterized by *MYCN* amplification. These tumors frequently have allelic loss of 1p. The latter tumors frequently express *TRKB* plus BDNF, probably representing an autocrine survival pathway. Thus, neuroblastoma represents fundamentally two major types and three subtypes, but they may all arise from a common precursor cell. NMA, *MYCN* ampification.

| Feature | Type 1 | Type 2 | Type 3 |
|---|---|---|---|
| *MYCN* | Normal | Normal | Amplified |
| DNA ploidy | Hyperdiploid<br>Near triploid | Near diploid<br>Near tetraploid | Near diploid<br>Near tetraploid |
| 11q gain | Rare | Common | Common |
| 11q, 14q LOH | Rare | Common | Rare |
| 1p LOH | Rare | Uncommon | Common |
| *TRKA* expression | High | Low or absent | Low or absent |
| *TRKB* expression | Truncated | Low or absent | High (full length) |
| *TRKC* expression | High | Low or absent | Low or absent |
| Age | Usually <1 yr | Usually >1 yr | Usually 1–5 yr |
| Stage | Usually 1, 2, 4S | Usually 3, 4 | Usually 3, 4 |
| Three-year survival (%) | 95 | Approximately 50 | Approximately 25 |

## PATHOLOGY

Neuroblastoma is one of the “small, round blue cell” neoplasms of childhood; also included are Ewing's sarcoma, non-Hodgkin lymphoma, primitive neuroectodermal tumors (or neuroepitheliomas), and undifferentiated soft tissue sarcomas (including rhabdomyosarcoma). Neuroblastomas presumably arise from primitive, pluripotential sympathetic cells (sympathogonia), which are derived from the neural crest. The degree and type of differentiation, and the location of the sympathogonia after migrating from the neural crest, generate the different normal tissues of the sympathetic nervous system, including spinal sympathetic ganglia and adrenal chromaffin cells. The histologic subtypes of the neuroblastic tumors appear to correlate with the normal differentiation patterns of the sympathetic nervous system.

The three classic histopathologic patterns of neuroblastoma, ganglioneuroblastoma, and ganglioneuroma reflect a spectrum of maturation and differentiation ( Fig. 31-5). The typical neuroblastoma is composed of small but uniformly sized cells containing dense, hyperchromatic nuclei and scant cytoplasm. The presence of neuritic processes, or neuropil, is a pathognomonic feature of all but the most primitive neuroblastomas. The Homer-Wright pseudorosette ( Fig. 31-6), another diagnostic feature of neuroblastoma seen in 15% to 50% of cases,[182] is composed of neuroblasts surrounding areas of eosinophilic neuropil.

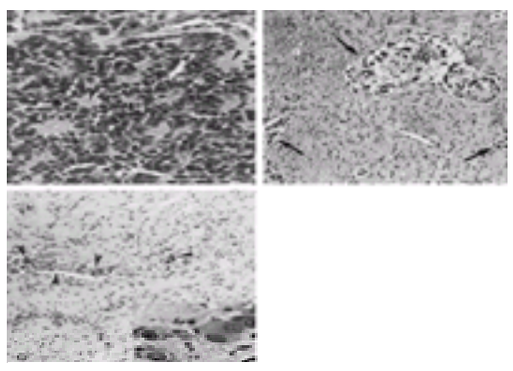

**FIGURE 31-5.** The principal histopathologic subtypes of neuroblastoma. **A:** Neuroblastoma, with monotonous arrays of hyperchromatic cells with scant cytoplasm, rosettes, and minimal neuropil (*arrowheads*). (Hematoxylin and eosin, ×132.) **B:** Ganglioneuroblastoma with rests of neuroblasts (*arrows*) within Schwannian stroma. (Hematoxylin and eosin, ×33.) **C:** Ganglioneuroma demonstrating mature ganglion cells (*arrowheads and inset*) with Schwannian stroma. (Hematoxylin and eosin, ×33, inset ×198.) (Courtesy David Kelly, University of Alabama at Birmingham and Vijay Joshi, East Carolina University.)

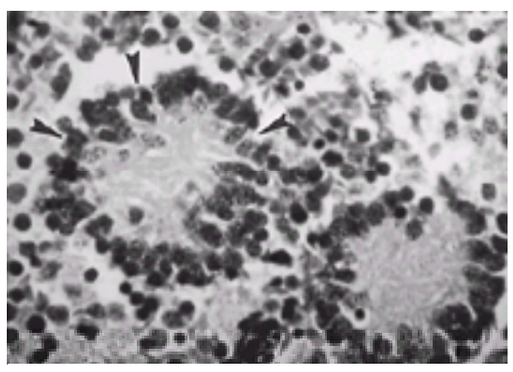

**FIGURE 31-6.** Homer-Wright pseudorosettes are typically rings of neuroblasts ( *arrowheads*) surrounding a central core of eosinophilic neuropil. (Hematoxylin and eosin, ×198). (Courtesy David Kelly, University of Alabama at Birmingham.)

The fully differentiated and benign counterpart of neuroblastoma is a *ganglioneuroma.* It is composed of mature ganglion cells, neuropil, and Schwannian cells. *Ganglioneuroblastoma* defines a heterogeneous group of tumors with histopathologic features spanning the extremes of maturation represented by neuroblastoma and ganglioneuroma. Histopathologic characteristics range from a predominance of neuroblastic elements with rare maturing cells to those neoplasms comprised almost exclusively of ganglioneuroma containing occasional rests of neuroblasts. Some use the term *maturing neuroblastoma* for tumors that contain less than 50% maturing or mature ganglion cells, and *ganglioneuroblastoma* for tumors with more extensive maturation. Ganglioneuroblastomas may be focal or diffuse, depending on the gross pattern seen, but diffuse ganglioneuroblastoma is associated with less aggressive behavior. Because tumor viability and histopathologic features may vary within a single tumor, multiple sections, particularly from regions with different gross appearance, should be examined to categorize these tumors accurately.

Distinguishing neuroblastoma from other small, round blue cell tumors of childhood often requires techniques beyond hematoxylin and eosin staining and light microscopy. Immunohistochemistry (e.g., immunoperoxidase techniques) is a helpful adjunct to light microscopy. Neuroblastomas will stain with monoclonal antibodies recognizing neurofilament proteins, synaptophysin, and NSE.[183,184] Electron microscopy typically demonstrates dense core, membrane-bound neurosecretory granules as well as microfilaments and parallel arrays of microtubules within the neuropil ( Fig. 31-7)[185,186] but is seldom used for diagnostic purposes.

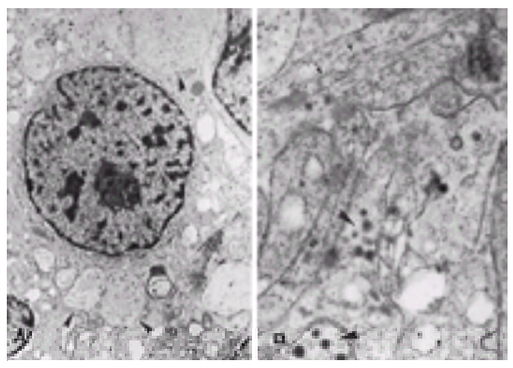

**FIGURE 31-7.** Electron micrograph of a neuroblast. **A:** In transverse cross section are numerous primitive dendritic processes of neuroblasts ( *arrowheads*) surrounding the cell body of a neuroblast. The neuroblast has a high nuclear to cytoplasmic ratio and relatively few organelles. (Uranyl acetate and lead citrate, ×9,500.) **B:** Dendritic processes (neurites) of varying sizes lie in close juxtaposition. Some processes contain many microtubules ( *small arrowheads*), whereas others display small clusters of dense core neurosecretory granules ( *large arrowheads*). (Uranyl acetate and lead citrate, ×40,000.) (Courtesy David Kelly, University of Alabama at Birmingham.)

The prognostic classification of neuroblastoma based on histopathologic features has been attempted by several investigators. [187,188,189] and [190] The most widely used histopathologic classification system was developed by Shimada and colleagues [189] and is formulated around patient age and the following histologic features: the presence or absence of Schwannian stroma, the degree of differentiation, and the MKI. A retrospective evaluation of the Shimada method in 295 CCG patients identified favorable and unfavorable patient subsets. When compared to other clinical features, these histologic patterns were independently predictive of outcome, and stage was prognostically less important than histologic grade.[189,191,192]

In an attempt to simplify the Shimada system yet maintain the predictive power of histopathologic features, Joshi and colleagues [193,194] conducted a retrospective analysis of pathologic data collected in the POG from 211 patients with neuroblastoma. The presence of calcification and a low mitotic rate (less than or equal to ten mitoses per ten high-power fields) predicted a favorable outlook, independent of stage or age. The Joshi method provided greater simplicity in determining the histologic features and prognostic categories but did not demonstrate the same prognostic power as the Shimada system. Therefore, Shimada, Joshi and other noted pediatric pathologists have developed an International Neuroblastoma Pathology Classification that combines the best features of these two systems (see below).[195,196] This classification is based primarily on the Shimada system but incorporates other features that should permit improved concordance among pathologists using this system around the world.

## CLINICAL PRESENTATION AND PATTERN OF SPREAD

Because neuroblastoma can arise from any site along the sympathetic nervous system chain, the locations of primary tumors at the time of diagnosis are varied and change with age. Most primary tumors occur within the abdomen (65%), although the frequency of adrenal tumors is slightly higher in children (40%) compared to infants (25%). Infants also have more thoracic and cervical primary tumors. In approximately 1% of patients, a primary tumor cannot be found. The majority of children with neuroblastoma is diagnosed by age 5 years, and it is rare after age 10 years ( Fig. 31-1).

Metastatic extension of neuroblastoma occurs in lymphatic and hematogenous patterns. Regional lymph node metastases are noted in 35% of patients with apparently localized tumors. Spread of tumor to lymph nodes outside the cavity of origin is considered to be disseminated disease. However, these children may have a better outlook if there is no other metastatic disease noted.[197] Hematogenous spread occurs most frequently to bone marrow, bone, liver, and skin. Rarely, disease may spread to lung and brain parenchyma, usually as a manifestation of relapsing or end-stage disease. The proportion of patients presenting with localized, regional, or metastatic disease is age dependent. In 910 consecutive CCG patients, the prevalence of INSS stage 3 and 4 disease was 41% in infants compared to 80% in older children (Table 31-3).

| | Age at diagnosis | | |
|---|---|---|---|
| INSS stage | <1 yr (%) | ≥1 yr (%) | Total (%) |
| 1 | 95 (27)[a] | 72 (13) | 167 (18) |
| 2A | 19 (5) | 13 (2) | 32 (4) |
| 2B | 33 (9) | 29 (5) | 62 (7) |
| 3 | 61 (17) | 113 (20) | 174 (19) |
| 4 | 82 (24) | 334 (60) | 416 (46) |
| 4S | 59 (17) | 0 (0) | 59 (6) |
| Total | 349 | 561 | 910 |

**TABLE 31-3. EXTENT OF DISEASE AT DIAGNOSIS ACCORDING TO AGE**

The signs and symptoms of neuroblastoma reflect the location of primary, regional, and metastatic disease. Abdominal disease results in complaints of fullness, discomfort, and, rarely, obstruction. Physical examination commonly reveals a fixed, hard abdominal mass. When primary tumors arise from the organ of Zuckerkandl, bladder and bowel symptoms may occur due to compression. Massive involvement of the liver in metastatic disease is particularly frequent in infants (e.g., stage 4S) and may result in respiratory compromise. Occasionally, the size of primary or metastatic abdominal tumors can result in compression of venous and lymphatic drainage from the lower extremities leading to scrotal and lower extremity edema ( Fig. 31-8A). Rarely, patients will experience renin-mediated hypertension due to compromise of renal vasculature.[198,199] Because epinephrine is rarely released from most neuroblastomas, hypertension, tachycardia, flushing, and sweating are uncommon symptoms.

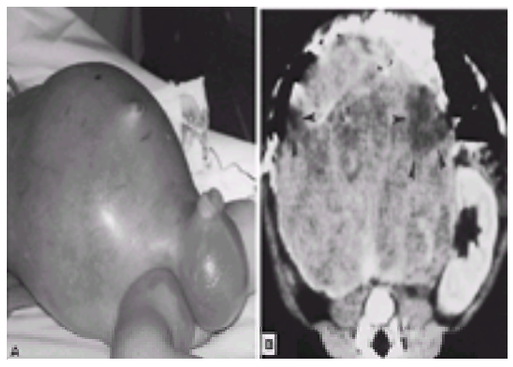

**FIGURE 31-8.** Clinical findings in abdominal neuroblastoma. **A:** Dramatic abdominal distention and scrotal edema in a 2-month-old patient. **B:** Computed tomography of abdomen of patient in **(A)** reveals a large suprarenal mass on the right with hemorrhage (*large arrowheads*) and calcification (*small arrowheads*). (Courtesy Walter Cain and Gregory Odrezin, University of Alabama at Birmingham.)

Sudden and dramatic enlargement of abdominal tumors with resultant increased abdominal distention and discomfort can result from spontaneous hemorrhage into the tumor (Fig. 31-8B). Primary thoracic tumors often are diagnosed coincidentally when chest radiographs are obtained to evaluate patients for trauma or infectious disease. High thoracic and cervical masses can be associated with Horner's syndrome, which consists of unilateral ptosis, myosis, and anhydrosis ( Fig. 31-9). Occasionally, large thoracic tumors are associated with mechanical obstruction and resultant superior vena cava syndrome. Cervical masses from primary or metastatic neuroblastoma may be confused with infection and are correctly diagnosed only at the time of attempted incision and drainage. Paraspinal tumors in the thoracic, abdominal, and pelvic regions may extend into the neural foramina of the vertebral bodies and result in symptoms related to compression of nerve roots and spinal cord. The range of symptomatology includes radicular pain and subacute or acute paraplegia as well as bladder or bowel dysfunction.

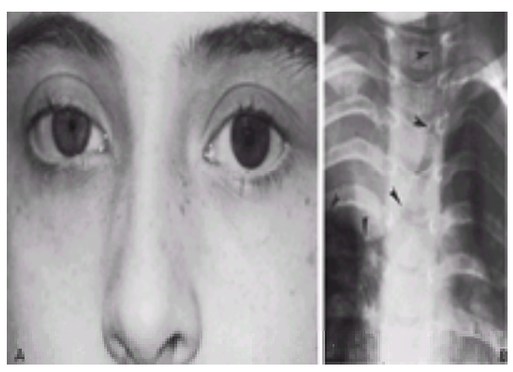

**FIGURE 31-9.** Horner's syndrome **(A)** with anisocoria secondary to a large, superior mediastinal mass and **(B)** causing tracheal deviation (*arrowheads*).

Several classical signs and symptoms have been associated with metastatic neuroblastoma. Proptosis and periorbital ecchymoses are frequent and result from tumor infiltration of periorbital bones ( Fig. 31-10). Widespread bone and bone marrow disease causes bone pain, which can lead to limping and irritability in a younger child. In addition, there may be bone marrow replacement and symptoms of bone marrow failure, such as anemia, bleeding, or increased risk of infection. Hematologic manifestations leading to bleeding or thrombosis have also been reported. [200,201 and 202] Skin involvement is seen almost exclusively in infants with INSS stage 4S tumors[203] and is characterized by variable numbers of nontender, bluish subcutaneous nodules. Constitutional symptoms associated with disseminated disease may include failure to thrive and fever, the latter observed most often in the presence of extensive bone metastases.

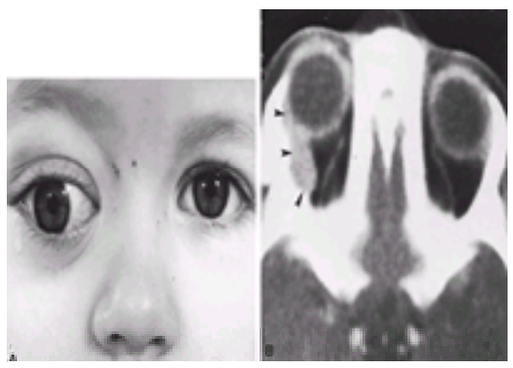

**FIGURE 31-10.** Proptosis on the right **(A)** in a 14-month-old patient who demonstrated on computed tomography scan **(B)** metastatic neuroblastoma in the retrobulbar space (*arrowheads*). (Courtesy Laura Bowman, St. Jude Children's Research Hospital, Memphis, TN.)

Although a minority of the overall patient population, adolescents and adults with neuroblastoma have been reported. [204,205,206 and 207] In general, the distribution of primary sites is similar to that seen in children, but the course of the disease is somewhat more indolent. [206,207] Also, neuroblastomas in these patients may be less sensitive to chemotherapy. Biologically, neuroblastomas from adolescents and adults fit genetic type 2 ( Table 31-2),[101,102,208] as they lack *MYCN* amplification but usually have near-diploid karyotypes with structural changes. [97] Tumors in older patients represent a special challenge, because even localized tumors can be recurrent and fatal over long periods.

**Paraneoplastic Syndromes**

Several unique paraneoplastic syndromes have been associated with both localized and disseminated neuroblastoma. Opsomyoclonus (myoclonic jerking and random eye movement) or cerebellar ataxia has been observed in up to 4% of patients. [209,210 and 211] Most children with this syndrome have a favorable outcome with respect to their tumor, although the outcome seems to correlate with the presence or absence of *MYCN* amplification.[212,213] The majority of these children appears to have long-term neurologic deficits, however, including cognitive and motor delays, language deficits, and behavioral abnormalities. [214,215] These are presumably due to antineural antibodies directed against the tumor that cross-react with neural cells in the cerebellum or elsewhere in the brain. [211,216,217 and 218] There is the suggestion that patients who received chemotherapy as part of their initial tumor management had fewer long-term side effects, suggesting that immunosuppression at a diagnosis may be beneficial.[216] In addition, most have improvement with adrenocorticotropic hormone or steroid therapy as well as tumor removal, although the majority has persistent or recurrent neurologic sequellae. [219,220 and 221] This indicates that one should anticipate long-term neurologic abnormalities, and early intervention may minimize these deficits.

Intractable secretory diarrhea associated with hypokalemia and dehydration is a manifestation of tumor secretion of VIP. [222,223 and 224] Most tumors secreting VIP are mature histologically (ganglioneuroblastomas or ganglioneuroma), and these patients almost always have a favorable outcome. [90] Surgical removal of the tumor

usually results in complete resolution of symptoms. Hypercalcemia has been reported also, [225] but it is uncommon and its origin is unknown.

### Neurologic Manifestations

In addition to the opsomyoclonus syndrome, there are other neurologic manifestations of neuroblastoma. Because of its origin next to the spinal column, neuroblastomas have a tendency to invade through neural foramina into the spinal canal and cause spinal cord compression. This situation can be a medical emergency (see Chapter 39), and there is controversy as to the optimum approach to managing spinal cord compression (see below). In addition to cord compression, neuroblastoma can disseminate to the central nervous system. This occurs most commonly by inward compression on the brain from cranial metastases, but it can occur also as meningeal involvement or as intracranial disease without adjacent parameningeal metastases [226,227,228,229,230 and 231] The route of spread may be hematogenous or via the cerebrospinal fluid. Although dissemination in the central nervous system is rarely seen at diagnosis, it may occur with progression or relapse and is regarded as a very ominous sign.

## METHODS OF DIAGNOSIS

Neuroblastomas generally arise in the adrenal medulla or along the sympathetic chain. To confirm this diagnosis, generally some histologic evidence is required that demonstrates neural origin or differentiation by light microscopy or immunohistology. Alternatively, because the bone marrow is frequently involved, some patients can be diagnosed with neuroblastoma based on the presence of "compatible" tumor cells involving the bone marrow accompanied by increased urinary catecholamine metabolites. In the past, some have used a compatible radiographic or scintigraphic appearance with increased urinary catecholamine metabolites. However, using this approach precludes the availability of tissue for critical diagnostic, prognostic, and research studies. Indeed, differences in diagnostic criteria for neuroblastoma have led to some difficulties in comparing studies from different institutions, but an international consensus on diagnostic criteria for neuroblastoma should avoid this problem (see Diagnostic Criteria).

### Catecholamine Metabolism

If sensitive techniques are used, increased urinary metabolites can be detected in 90% to 95% of neuroblastoma patients. [232,233 and 234] This provides a great advantage in confirming the diagnosis of neuroblastoma, as well as in following disease activity in those patients whose tumors are secretors. A diagrammatic representation of catecholamine synthesis and metabolism is depicted in Figure 31-11. Although the major pathways and products of catecholamine catabolism are shown, the actual pathways of intracellular and extracellular catecholamine breakdown are more complex.

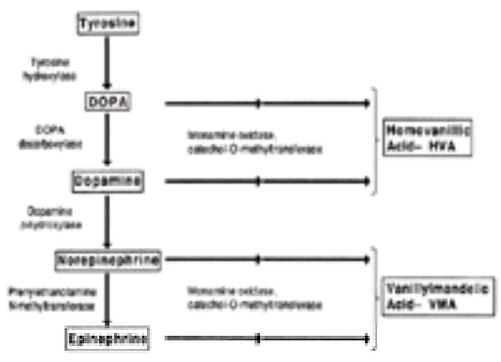

**FIGURE 31-11.** Pathway of catecholamine metabolism. Shown is a simplified diagram of catecholamine synthesis and metabolism. Homovanillic acid and vanillylmandelic acid are the urinary catecholamine metabolites usually measured. (From Brodeur GM. Neuroblastoma and other peripheral neuroectodermal tumors. In: Fernbach DJ, Vietti TJ, eds. Clinical pediatric oncology, 4th ed. St. Louis: Mosby, 1991;337, with permission.)

The precursor amino acids for catecholamine synthesis are phenylalanine and tyrosine. Phenylalanine is converted by phenylalanine hydroxylase to tyrosine. Tyrosine is then converted by tyrosine hydroxylase to DOPA, which is a catecholamine precursor. DOPA is converted by DOPA decarboxylase to the first catecholamine in the pathway, dopamine. Dopamine is converted by dopamine-b-hydroxylase to norepinephrine, which is then converted by phenylethanolamine-N-methyltransferase to epinephrine. Neuroblastoma cells lack this last enzyme, which is present in adrenal chromaffin cells and pheochromocytomas. The two enzymes primarily responsible for catecholamine catabolism are catechol-O-methyl transferase and monamine oxidase. DOPA and dopamine are converted primarily to HVA, whereas norepinephrine and epinephrine are converted primarily to VMA. Most laboratories involved in neuroblastoma diagnosis measure both urinary VMA and HVA.

### Diagnostic Criteria

An agreement on minimum criteria for establishing a diagnosis of neuroblastoma has been reached by an international group of conferees and corresponding participants, representing most of the major pediatric oncology groups throughout the world. [235,236] A diagnosis of neuroblastoma is established if

- An unequivocal pathological diagnosis is made from tumor tissue by light microscopy, with or without immunohistology, electron microscopy, or increased urine (or serum) catecholamines or metabolites; or
- Bone marrow aspirate or trephine biopsy contains unequivocal tumor cells (e.g., syncytia or immunocytologically positive clumps of cells), *and* increased urine or serum catecholamines or metabolites.

If histology is equivocal, and karyotypic abnormalities in tumor cells are characteristic of other tumors [e.g., t(11;22)], a diagnosis of neuroblastoma is excluded, whereas genetic features characteristic of neuroblastoma (e.g., *MYCN* amplification) would support this diagnosis.

At least two catecholamines and metabolites such as urine HVA and VMA (at a minimum) or serum dopamine or norepinephrine (assuming appropriate controls and standardization) must be measured. Levels must be greater than 3.0 SD above the mean for age to be considered increased. Normalizing urinary VMA and HVA excretion to the mg creatinine in the sample makes a timed collection unnecessary, and it avoids most false-negatives due to dilute urine on spot testing. Also, measurement of catecholamines and metabolites by sensitive techniques like high-pressure liquid chromatography, gas chromatography with mass spectroscopy, or specific enzyme-linked immunosorbent assays avoids the false-positives sometimes encountered with concentrated urine or with certain dietary components.

These criteria exclude the combination of a compatible radiographic or scintigraphic appearance and increased urinary catecholamine metabolites. Although allowing this definition may spare some patients an initial surgical procedure to confirm the diagnosis, patients with ganglioneuromas, pheochromocytomas, or other neural tumors potentially could receive inappropriate treatment. [237,238 and 239] In addition, biologic characterization of neuroblastoma cells is critically important for diagnosis or prognostication—for example, histopathology, *MYCN* gene copy number, tumor cell DI, or expression of *TRKA*. To perform the necessary biologic studies, it is critical to obtain tumor tissue as part of the initial diagnostic workup.

### Differential Diagnosis

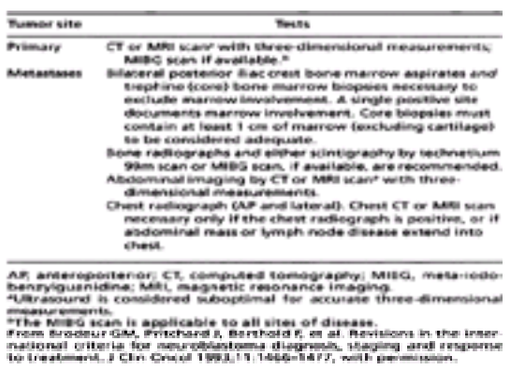
Due to the many potential clinical presentations, neuroblastoma may be confused with a variety of other neoplasms as well as non-neoplastic conditions. This is a problem particularly in the 5% to 10% of tumors that do not produce catecholamines [61,240,241] as well as the 1% of patients who do not have an obvious primary tumor. Alternatively, neuroblastoma should be considered in the differential diagnosis of a variety of non-neoplastic conditions or presenting symptoms. Clinically, patients with disseminated bone disease may resemble those with systemic infections or inflammatory diseases, such as osteomyelitis or rheumatoid arthritis. The VIP syndrome can be confused with infectious or inflammatory bowel disease, [222,224] and the opsoclonus-myoclonus and ataxia syndromes can resemble primary neurologic disease. [210,211,242] Neuroblastoma may be confused with calcified adrenal gland(s) following adrenal hemorrhage. [243,244] Patients with hepatomegaly must

have polycystic or storage diseases considered.

Histologically, neuroblastoma tissue from primary or metastatic sites may be quite undifferentiated and may be confused with other small, round blue cell tumors (see the section on pathology). Differential diagnosis of metastatic disease involving the marrow must include rhabdomyosarcoma, Ewing's sarcoma/neuroepithelioma/primitive neuroectodermal tumor, lymphoma, or leukemia (especially megakaryoblastic leukemia). However, a battery of monoclonal antibodies have been developed that allow reliable histopathologic diagnosis of these various disease entities. [186,245,246,247 and 248]

## CLINICAL AND LABORATORY EVALUATION

The recommended minimum testing to define the clinical stages is presented in Table 31-4. Certainly, the more tests that are performed, the greater the likelihood of finding disseminated disease. Uniformity with respect to minimum testing should improve the comparability of studies, and the tests recommended can be done in most medical centers. The conventional diagnostic imaging modalities include plain radiographs, bone scintigraphy, [249,250 and 251] ultrasound,[252] CT,[253,254] and MRI.[255,256] Plain radiographs can be useful to detect a calcified abdominal mass or posterior mediastinal mass. Both bone scintigraphy and skeletal survey should be used to detect cortical bone metastases.[250,257] Ultrasound and CT provide more information about abdominal disease, including lymph node enlargement and liver metastases, whereas thoracic CT or MRI are useful in evaluating the extent of disease above the diaphragm. However, only CT and MRI provide accurate three-dimensional measurements of tumor volume. These modalities may permit identification of intraspinal extension through neural foramina, although myelography may be helpful in some cases. Finally, CT or MRI of the head can further define metastases to the skull, orbits, mandible, or brain.



| Tumor site | Tests |
|---|---|
| Primary | CT or MRI scan[a] with three-dimensional measurements; MIBG scan if available.[b] |
| Metastases | Bilateral posterior iliac crest bone marrow aspirates and trephine (core) bone marrow biopses necessary to exclude marrow involvement. A single positive site documents marrow involvement. Core biopsies must contain at least 1 cm of marrow (excluding cartilage) to be considered adequate.<br>Bone radiographs and either scintigraphy by technetium 99m scan or MIBG scan, if available, are recommended.<br>Abdominal imaging by CT or MRI scan[a] with three-dimensional measurements.<br>Chest radiograph (AP and lateral). Chest CT or MRI scan necessary only if the chest radiograph is positive, or if abdominal mass or lymph node disease extend into chest. |

AP, anteroposterior; CT, computed tomography; MIBG, meta-iodobenzylguanidine; MRI, magnetic resonance imaging.
[a]Ultrasound is considered suboptimal for accurate three-dimensional measurements.
[b]The MIBG scan is applicable to all sites of disease.

**TABLE 31-4. MINIMUM RECOMMENDED TESTS FOR DETERMINING EXTENT OF DISEASE**

The potential specificity and sensitivity of MIBG scintigraphy for evaluation of bone and soft tissue involvement by neuroblastoma is attractive. [258,259] MIBG is taken up by catecholaminergic cells, including most neuroblastomas. Thus, radiolabeled MIBG scintigraphy is a specific and potentially sensitive method of assessing the primary tumor and focal metastatic disease. Another modality that shows promise in terms of detection of neuroblastomas is the use of radiolabeled SS analogs.[260,261,262 and 263] Although these analogs provide considerable specificity for neuroblastomas, not all tumors express sufficient receptors to be detectable by this modality. MIBG scintigraphy is readily available in Europe and is currently becoming more widely used in the United States and in some other countries. Those who have experience using MIBG for the evaluation of disease in patients with neuroblastoma find it a very useful technique, so it should be included (when it is available) in the routine evaluation of patients with suspected or proved neuroblastoma. In medical centers in which it is not readily available, technetium 99m diphosphonate scintigraphy remains the standard for evaluation of bone disease, and CT or MRI the standard for evaluation of soft tissue disease.

In the past, there has been considerable variation in the number of bone marrow aspirates or biopsies performed in different institutions for the assessment of bone marrow disease. Indeed, studies suggest that marrow biopsies add substantially to the detection of marrow involvement by tumor compared to marrow aspirates alone.[264,265] Furthermore, it is clear that obtaining more samples will increase the likelihood of detecting marrow involvement, but the clinical relevance of marrow involvement detected with additional studies is uncertain. To provide uniformity, the international conferees on neuroblastoma staging [235,236] recommend two marrow aspirates and two biopsies—that is, one aspirate and one biopsy from each of the iliac crests. Only a single study positive for tumor is required to document bone marrow involvement, but all four studies are required if the findings are negative. It is possible that “neuroblastoma-specific” immunocytology of marrow aspirates will soon obviate the need for marrow biopsies in most patients.[247,248,266]

Other controversial issues include the surgical and histological assessment of lymph node involvement, as well as assessment of the involvement of liver and other organs. Livers with diffuse enlargement or focal lesions should be biopsied, but random biopsies of apparently normal livers probably are unnecessary, especially in older children. Other sites of suspected tumor involvement should be sampled if possible, especially if the findings would alter the stage of the patient. International standardization of surgical approaches to these and other areas should be forthcoming. [267]

## STAGING

In the past, there were two major staging systems used for neuroblastoma throughout the world: (a) the Evans system used by the CCG and others,[203] and (b) the system used by St. Jude Children's Research Hospital and the POG.[268,269] Other systems have been based on these two systems or on the TNM classification.[270,271 and 272] In general, the various staging systems give reproducible results in distinguishing low-stage, good-prognosis patients from high-stage, poor-prognosis patients. Some of the differences between the staging systems are substantial, however, particularly as applied to patients with intermediate stages. For this reason, the results of one group could not be compared readily with another. Therefore, representatives of cooperative groups and countries from around the world met in 1987 and again in 1991 to formulate and then refine the INSS that would lead to uniformity in staging of patients with neuroblastoma for clinical trials and biologic studies around the world (Table 31-5).

| Stage | Description |
|---|---|
| 1 | Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with the primary tumor may be positive). |
| 2A | Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically. |
| 2B | Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor. Enlarged contralateral lymph nodes must be negative microscopically. |
| 3 | Unresectable unilateral tumor infiltrating across the midline,* with or without regional lymph node involvement; or lateralized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement. |
| 4 | Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, or other organs (except as defined for stage 4S). |
| 4S | Localized primary tumor (as defined for stages 1, 2A, or 2B), with dissemination limited to skin, liver, or bone marrow† (limited to infants aged <1 yr). |

Note: Multifocal primary tumors (e.g., bilateral adrenal primary tumors) should be staged according to the greatest extent of disease, as defined above, followed by a subscript M (e.g., 3M).
*The midline is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the opposite side of the vertebral column.
†Marrow involvement in stage 4S should be minimal (that is, less than 10% of total nucleated cells identified as malignant on bone marrow biopsy or on marrow aspirate). More extensive marrow involvement would be considered stage 4. The most sensitive examination can be performed should be negative in the marrow. Cytogenetic studies (see Chapter 62, Section A) on tumor cells may be helpful in establishing the clonal origin of marrow cells. [illegible] Brodeur GM, Pritchard J, Berthold F, et al. Revisions in the international criteria for neuroblastoma diagnosis, staging and response to treatment. J Clin Oncol 1993; 11:1466–1477; with permission.

**TABLE 31-5. INTERNATIONAL NEUROBLASTOMA STAGING SYSTEM**

Stage 1 is a localized tumor that is surgically resected.[235,236] Microscopic residual tumor at the margins is allowed. Stage 2 represents localized tumors with gross residual disease (2A) or localized tumors with ipsilateral lymph node involvement, regardless of resectability (2B). At the present time, it does not appear that there is a substantial prognostic distinction between 2A and 2B, at least in infants.[273] Stage 3 tumors show invasion across the midline, either on the basis of direct extension or by lymph node involvement. Most stage 3 tumors arise in the abdomen, because tumors crossing the midline by contiguous infiltration or by lymph node involvement are less common in the thorax. Infiltration is meant to indicate contiguous invasion of tumor across the midline (defined as the vertebral column) rather

than a pedunculated tumor that hangs over the midline.

Patients with disseminated disease involving distant lymph nodes, bone, bone marrow, liver, or other organs are categorized as having stage 4 disease (except as defined in stage 4S). This definition of stage 4 is essentially identical to stages IV and D, respectively, by the two major staging systems used previously. [203,239] There is some evidence that patients who have stage 4 on the basis of distant lymph node, liver, or marrow involvement (excluding 4S), especially patients younger than 2 years old, do better than those who have stage 4 disease on the basis of cortical bone involvement. [271,272] Because these distinctions may impact prognosis or choice of therapy, the criteria by which patients are considered to have stage 4 should be recorded. However, such distinctions may also be affected or obliterated by improvements in treatment.

Stage 4S (equivalent to IV-S or DS) has been retained as a distinct stage, based on the favorable outcome generally experienced with these patients, [274,275,276 and 277] and because of recent biologic evidence distinguishing these patients from infants with conventional stage 4 disease. For example, the majority of stage 4S tumors has a hyperdiploid DI, and less than 10% have *MYCN* amplification, in contrast to tumors from stage 4 infants, in which the DI is more often diploid and *MYCN* is amplified in approximately one-third. [97] The issue of bone marrow involvement has been clarified to mean that less than 10% of nucleated marrow cells are malignant cells. [236] Patients with more extensive marrow involvement should be classified as stage 4.

The efficacy of these staging definitions to define prognostic subsets of patients has been recently evaluated by POG and CCG by applying the INSS criteria to prospectively collected surgicopathologic data. In the POG study, 596 children with neuroblastoma were analyzed. [273] Patients with tumors that were localized or were disseminated to distant sites composed the most and least favorable groups, respectively. There was no difference in the EFS for infants having tumors with INSS stages 2A, 2B, or 3. In contrast, older children with INSS stage 2A/2B disease had a significantly better EFS when compared to those with INSS stage 3 tumors ( $p$ <.019). Of the 424 cases reviewed in the CCG study, concordance between INSS stages 1 and 4 and Evans stages I and IV was noted. [278] Furthermore, of the Evans stages II (n = 144) and III (n = 193) tumors, 89 were assigned to INSS stage 1 (relapse-free survival 82% to 85%) and 112 to INSS stages 2A/2B (relapse-free survival 61% to 70%). This experience with the INSS suggests that these new criteria clearly provide prognostic information that is at least equivalent or superior to the staging systems used previously. This is an important step toward furnishing a stable clinical background on which multivariate analyses can be performed to identify biologically based risk groups.

## DEFINITIONS OF RESPONSE TO TREATMENT

A variety of terms have been used to report the response of neuroblastoma patients to a given treatment regimen (see definitions and Table 31-6). [235,236] Despite their general use, the same term may have a different meaning when used by different groups. This is due in part to differences in the number and type of tests used for evaluation and the time at which the response is evaluated, which often varies considerably from one institution to another. The same tests that are used for determining extent of disease (Table 31-4) should be used to assess response of primary and metastatic sites to treatment. Table 31-6 lists internationally proposed criteria to determine response to therapy in patients with neuroblastoma. [236] It is important to note that a given level of overall response involves thorough assessment of both primary and metastatic sites. For example, a CR overall requires that the primary tumor and all metastatic sites fulfill CR criteria. A CR in metastatic sites and a PR in the primary tumor would be considered a PR overall. These criteria are very similar to the recently proposed response evaluation criteria in solid tumors that are being recommended for future clinical trials of pediatric cancers. [279] Evaluations for response in newly diagnosed patients are recommended at the end of induction (usually 3 to 4 months), at the end of treatment (usually 8 to 12 months), before and after surgical procedures, before stem cell transplantation, and as indicated clinically. Three-dimensional measurements should be possible for primary tumors and many metastatic lesions based on CT scans or other diagnostic imaging modalities.

| Response | Primary[a] | Metastases[a] | Markers[a] |
|---|---|---|---|
| Complete response | No tumor | No tumor (e.g., chest, abdomen, liver, bone, bone marrow, nodes) | MIBI/MMA normal |
| Very good partial response | Reduction >90% but <100% | No tumor (as above except bone); no new bone lesions; all preexisting lesions improved | MIBI/MMA decreased >90% |
| Partial response | Reduction 50-90% | No new lesions; 50-90% reduction in measurable sites; 0-ii bone marrow samples with tumor; bone lesions same as very good partial remission. | MIBI/MMA decreased 50-90% |
| Mixed response | — | No new lesions; >50% reduction of any measurable lesion (primary or metastases) with <50% reduction in any other; <25% increase in any existing lesion.[b] | — |
| No response | — | No new lesions; <50% reduction but <25% increase in any existing lesion.[b] | — |
| Progressive disease | — | Any new lesion; increase of any measurable lesion by >25%; previous negative marrow positive for tumor. | — |

**TABLE 31-6. PROPOSED DEFINITIONS OF RESPONSE TO TREATMENT**

## PROGNOSTIC CONSIDERATIONS

There has been substantial progress made in risk stratification for neuroblastoma patients based on the analysis of a panel of clinical and biologic variables. Indeed, there is an evolving list of prognostic markers that should be analyzed at diagnosis for each newly diagnosed patient to best assign intensity of therapy. This list will be refined over time based on prospective evaluation of additional variables postulated to be of clinical utility.

### Clinical Variables

The most important clinical variables predictive of disease outcome are the age of the patient and stage of disease at diagnosis. [191,231,280,281,282,283,284,285 and 286] These variables are of proven prognostic utility and will be the cornerstone of any risk stratification schema. For example, the 4-year EFS probability for patients with INSS stage 3 neuroblastoma ranged from 98% for infants to 75% for patients older than 2 years at diagnosis in a recent CCG study. [286] Tumor site has also been proposed to be prognostically important, with adrenal tumors reported to be associated with a more aggressive clinical course. In addition, for the subset of patients who present with metastatic disease, cortical bone involvement appears to be more closely associated with *MYCN* amplification and a poorer survival probability. [231] However, neither primary nor metastatic disease site appears to have an independent influence on outcome.

### Biologic Variables

Several previously studied biologic variables (pathology, serum markers, genetic features) appear to have prognostic value in patients with neuroblastoma. A new histopathologic classification, the International Neuroblastoma Pathology Classification, based on the original Shimada system, is likely to become the new international standard. The serum markers include ferritin, NSE, a cell membrane ganglioside ($G_{D2}$), and LDH. The genetic features of the tumor that have been proposed as prognostic markers include tumor cell DI, *MYCN* gene copy number, deletion or LOH involving 1p, unbalanced gain of 17q, and relative expression of the neurotrophin receptor *TRKA*. No study to date has examined all variables in a large set of patients, so it is difficult to say which single variable or combination of variables are the most powerful predictors of outcome in addition to the more conventional clinical features of patient age and stage.

#### *Tumor Pathology*

Differentiated histology, such as in ganglioneuroblastoma, generally is associated with localized tumors, but this type of histologic classification does not have prognostic value that adds significantly to age and stage. More detailed analysis of histology by the classifications of Shimada and colleagues [189] or Joshi and colleagues [190] have provided important prognostic information (see Pathology). However, these are being replaced by a new International Pathology Classification System that should provide worldwide uniformity in the application of this variable ( Table 31-7). [195,196]

| International Neuroblastoma Pathology Classification | | Original Shimada classification | Prognostic group |
|---|---|---|---|
| Neuroblastoma | Schwannian stroma-poor[1] | Stroma-poor | |
| Favorable | | Favorable | Favorable |
| <1.5 yr | Poorly differentiated or differentiating and low or intermediate MKI tumor | | |
| 1.5–5.0 yr | Differentiating and low MKI tumor | | |
| Unfavorable | | Unfavorable | Unfavorable |
| <1.5 yr | Undifferentiated tumor[2] High MKI tumor | | |
| 1.5–5.0 yr | Undifferentiated or poorly differentiated tumor Intermediate or high MKI tumor | | |
| >5 yr | All tumors | | |
| Ganglioneuroblastoma, nodular | (Composite Schwannian stroma-rich/stroma-dominant with stroma poor) | Stroma-rich nodular (unfavorable) | Unfavorable |
| Ganglioneuroblastoma, intermixed | Schwannian stroma-rich | Stroma-rich intermixed (favorable) | Favorable |
| Ganglioneuroma | Schwannian stroma-dominant | | |
| Maturing | | Well differentiated (favorable) | Favorable[3] |
| Mature | | Ganglioneuroma | |

MKI, mitotic karyorrhexis index.

**TABLE 31-7. INTERNATIONAL NEUROBLASTOMA PATHOLOGY CLASSIFICATION**

### *Serum Markers*

Serum markers that have been used in the past to predict outcome or follow disease activity include ferritin, NSE, LDH, and $G_{D2}$. Although each of these markers has prognostic value, at least in subsets of patients, none appears to have overall prognostic value comparable to newer genetic markers (e.g., *MYCN* amplification), and none is being used currently by major groups for risk stratification.

#### Ferritin

Ferritin may be increased in some patients with actively growing neuroblastomas, and those with increased levels have a much worse prognosis. [287,288,289 and 290] Serum ferritin may be particularly useful as a prognostic marker when combined with tumor histology. [192]

#### Neuron-Specific Enolase

NSE is a cytoplasmic protein with enolase activity that is associated with (but not restricted to) neural cells. Analysis of serum NSE from patients with neuroblastoma has indicated that survival is substantially worse in advanced patients with increased serum NSE levels. [291,292,293 and 294]

#### Lactate Dehydrogenase

Although not specific to neuroblastoma, serum LDH level has been used as a prognostic marker for neuroblastoma. Increased LDH levels may be a reflection of rapid cellular turnover or of large tumor burden. Indeed, assessment of serum LDH added significant predictive value to the clinical features of age and stage in some studies.[295,296,297 and 298]

#### $G_{D2}$

$G_{D2}$ is a disialoganglioside on most neuroblastoma cells to which several independently derived monoclonal antibodies have been raised. The presence of this ganglioside is useful for identifying neuroblastoma cells, and increased levels have been found in the plasma of patients with neuroblastoma.[299,300,301,302,303,304,305,306,307,308,309,310,311 and 312] Indeed, gangliosides shed by tumor cells may play a role in accelerating tumor progression. [303,304] Antibodies against $G_{D2}$ may be useful for therapy of neuroblastoma as well (see below).

### *Genetic Markers*

A variety of genetic markers have been identified that are highly correlated with tumor subsets that have characteristic clinical behavior. Those that have been shown to have prognostic value in several groups or countries include *MYCN* amplification, tumor cell DI, and allelic loss of 1p (see below). Others that are still under investigation or validation include unbalanced gain of 17q, allelic loss of 11q, and other patterns of genetic change.

#### *MYCN* Amplification

*MYCN* amplification in tumor cells is found predominantly in patients with advanced stages of disease and is generally associated with rapid tumor progression and a poor prognosis.[97,98,101,102 and 103,107,108 and 109,286,305,306 and 307] This adverse prognostic affect is especially evident in infants with stage 4 disease (see Fig. 31-12). Although not all patients with a poor outcome have *MYCN* amplification, the majority of patients with amplification treated with contemporary therapies has rapid progression and die, even patients with stage 4S disease.[98,308,309] There have been notable exceptions with localized disease [310,311] or stage 4S,[312] which may indicate that other favorable biologic factors override the negative impact of *MYCN* amplification on outcome. Nonetheless, *MYCN* amplification is considered a paradigm of the utility of tumor-specific genetic alterations for prognosis and is used currently used by all international cooperative groups for treatment stratification (see below).

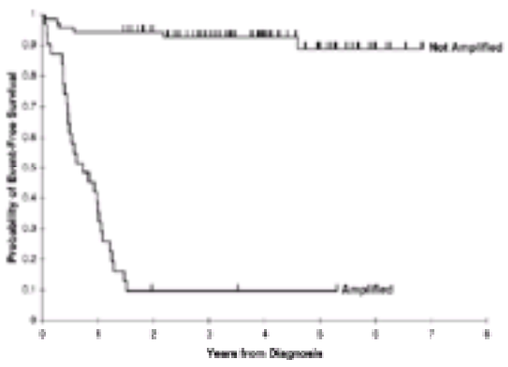

**FIGURE 31-12.** EFS for 102 infants with stage 4 neuroblastoma, stratified by *MYCN* gene status.[303] Not amplified: n = 71 pts; amplified: n = 31 pts; *p* <.0001. (Figure redrawn with permission from Mary Lou Schmidt, University of Illinois, Chicago.)

#### Hyperdiploid Karyotype

Tumor cells with a hyperdiploid karyotype (or increased DI) [96,97,104,105 and 106,160,305,313,314] are associated with a favorable outcome in infants with neuroblastoma. Look and colleagues[96,97] originally showed that infants with neuroblastoma and a tumor DI greater than 1 had a better outcome compared to infants with tumor DI of 1. Bowman and colleagues[315] reported the results of a prospective study of 113 infants with INSS stages 2A, 2B, 3, 4, and 4S in which treatment was determined according to tumor ploidy. After five cycles of cyclophosphamide/doxorubicin, CRs were attained in 98% of the 85 infants with tumor DI greater than 1, and all are surviving free of disease with a follow-up of 11 to 30 months. In contrast, only one-third of the 28 infants with a tumor DI of 1 achieved CR after treatment with cisplatin/teniposide, and 25% survived free of disease. In a study of 110 infants with stage 4S neuroblastoma, a DI of 1 was significantly associated with a decreased OS probability in univariate analysis, but four of five patients with a diploid DI also had *MYCN* amplification.[98] Prospective analysis of this prognostic variable is ongoing within the new COG, which represents a fusion of POG and CCG with the National Wilms' Tumor Study Group and the Intergroup Rhabdomyosarcoma Study

Group.

### Chromosomal Deletion of Allelic Loss

Chromosomal deletion or allelic loss has been shown in several studies to be correlated with a poor survival. [141,146,148,150,156,316] There is a strong correlation between 1p LOH and high-risk features, such as age older than 1 year at diagnosis, metastatic disease, and unfavorable histology. [150,152,153] In addition, there is a strong association between *MYCN* amplification and 1p deletion. Some cases of 1p deletion do not have *MYCN* amplification, but virtually every case with *MYCN* amplification has 1p deletion.[148,149 and 150,156,157 and 158,163] It remains controversial whether 1p allelic loss has independent prognostic significance after correction for the prognostic impact of *MYCN* amplification as well as the other currently used prognostic variables, [141,152,153,316,317] although recent data suggest that this abnormality might be an independent predictor for disease relapse in patients with locoregional disease. [150,318]

Although there was no survival disadvantage for patients whose tumors had 11q LOH in univariate analyses, there was a significant decrease in OS probability when the subset of patients without *MYCN* amplification was analyzed.[162,319] Thus, 11q is one of the most common regions of allelic deletion currently identified in primary neuroblastomas, and it may be a marker of an unfavorable phenotype independent of *MYCN* amplification. Allelic loss of 14q also appears to be inversely correlated with *MYCN* amplification but most likely has limited prognostic significance utility. [166]

#### *Other Biologic Markers*

Other biologic factors related to gene expression have been proposed to provide additional prognostic information for neuroblastoma patients. These include expression of the NGF receptor *TRKA*,[70,71,72,73 and 74] expression of genes related to the multidrug resistance phenotype (*MDR1* and *MRP*),[320,321,322,323,324 and 325] genes related to invasion and metastasis (nm23 and CD44),[326,327,328 and 329] or other genes related to neural differentiation (*HRAS*, *PTN*).[64,126,330] The data for *TRKA* are quite strong and consistent among the five groups that have now studied this feature. [70,71,72,73 and 74] The preliminary results investigating the prognostic value of *MRP* expression are also quite promising,[325] but there are conflicting results regarding the prognostic value of *MDR1* expression. The other biologic markers have shown promise, but most have been studied in only a limited number of cases or institutions.

## PRINCIPLES OF INITIAL THERAPY

The treatment modalities traditionally used in the management of neuroblastoma are surgery, chemotherapy, and radiotherapy. The role of each is determined by the anticipated clinical behavior of the tumor in individual cases considering stage, age, and biologic features.

### Surgery

Surgery plays a pivotal role in the management of neuroblastoma, both for diagnosis and for treatment. [331] The goals of primary surgical procedures, performed before any therapy, are to establish the diagnosis, to provide tissue for biologic studies, to stage the tumor surgically, and to attempt to excise the tumor without injury to vital structures. In delayed primary or second-look surgery, the surgeon determines response to therapy and removes residual disease when possible.

The operative protocol for surgicopathologic staging as recommended by the INSS criteria (see the section on staging) should include the following:

- The resectability of primary or metastatic tumor should be determined by tumor location, mobility, relationship to major vessels and nerves, ability to control blood supply, presence of distant metastases, and overall prognosis of the patient. With the efficacy of modern chemotherapy to consolidate and reduce the size of large primary tumors and lymph node metastases, sacrifice of vital structures to achieve resection at diagnosis should be avoided. This is particularly so in young children in whom the prognosis is excellent in most cases.
- Nonadherent, intracavitary lymph nodes should be sampled. Gross examination during surgery may be inaccurate for detecting or ruling out lymph node metastases in up to 25% of cases.[332] The status of lymph nodes adherent to and removed en bloc with the primary tumor seem to have little relevance in predicting outcome of the patient.[332] Ideally, lymph nodes superior and inferior to the primary tumor should be sought and sampled, with documentation of location. Problematic situations for lymph node sampling include patients with high thoracic, low cervical, or large abdominal primary tumors that are unresectable. In these cases, access to lymph nodes may be difficult. Because there are other prognostic factors that may be assessed in these cases, the value of additional information regarding lymph node involvement is questionable.
- In cases of abdominal tumors without metastatic disease by clinical evaluation, biopsy of the liver has been advocated at initial surgery. The usefulness of *random* liver biopsy was questioned in a study of 54 children older than 1 year at diagnosis with POG stage C disease (INSS stages 2B and 3) arising in the abdomen.[333] This study concluded that liver biopsy was only indicated in older children if there was gross or radiologic evidence of metastasis. In contrast, diffuse involvement of the liver may be missed by radiologic studies in infants, so random liver biopsies are still indicated in these patients. [331]

The importance of gross total resection in the management of disseminated neuroblastoma remains controversial. Haase and coworkers [334] noted improved disease-free survival in 39 children with complete resection versus 23 patients undergoing partial resection. Neither the timing of the surgery nor tumor *MYCN* copy number predicted resectability of primary tumors. In a retrospective review of 70 cases at Memorial Sloan-Kettering Cancer Center, gross total resection of the primary tumor correlated with improved survival ($p = .03$).[285] Due to the changing intensity of chemotherapy given over the time period of the review, however, it was not possible to detect whether surgical resection was an independent prognostic factor. Chamberlain and colleagues [335] noted superior rates of survival at 3 years (40% vs. 15%) in patients undergoing complete versus partial surgical resection. In contrast, the experience at Great Ormond Street did not confirm that such radical surgery provides a survival advantage in these patients. [336,337] Finally, Nakagawara and colleagues[338] noted that the degree of surgical resection of the primary tumor was directly related to improved survival in patients with Evans stages III and IV, *MYCN* amplified tumors, but not in tumors with normal *MYCN* copy number. Further examination of this area is needed, but it is likely that the biology of tumors may affect their resectability, accounting for the differences seen in some studies.

Surgical complications in neuroblastoma have been reported at rates from 5% to 25%. [269,333,339,340] The incidence is highest with aggressive attempts to resect abdominal tumors at diagnosis. Commonly encountered problems include nephrectomy, operative hemorrhage, postoperative intussusception or adhesions, injury to renal vessels with subsequent renal failure, and neurologic deficits such as Horner's syndrome. Because complications are more frequent in infants, who have a substantially better survival, avoidance of surgical risk is particularly important. Complications generally are lower for delayed or second-look procedures, after tumor shrinkage by chemotherapy.[339]

### Radiation Therapy

Neuroblastoma is generally considered a radiosensitive tumor, although local control of neuroblastoma on a clinical level has been variable. [341,342] Accepted tumoricidal doses of ionizing radiation range from 15 to 30 Gy, depending on patient age, tumor volume, and tumor location. [343,344] Fractionation of doses ranges from 150 to 400 cGy, again depending on tumor volume. Historically, radiation has been used in the multimodality management of residual neuroblastoma, bulky unresectable tumors, and disseminated disease. More recently, the role of radiotherapy in neuroblastoma continues to be refined with the improvement in multi-agent chemotherapy and the increasing trend toward developing risk-related treatment groups based on age, stage, and biologic features.

The role of radiation therapy for patients with locoregional disease has evolved. From a randomized trial in children with regional lymph node metastases (INSS stages 2B, 3), Castleberry and colleagues[333] initially reported statistically superior rates of CR (76% versus 46%, $p = .013$), EFS (59% versus 32%, $p = .009$) and survival (73% versus 41%, $p = .008$) in patients receiving low-dose, sequential cyclophosphamide/doxorubicin [345] in combination with local radiation (24 to 30 Gy) compared to the same chemotherapy alone. However, in the context of more dose-intensive chemotherapy, and accounting for the status of *MYCN* copy number, this may no longer be true. Strother and coworkers[346] reported a subsequent study from POG in which INSS stage 2B/3 tumors were treated with high-dose cisplatin and etoposide alternated with low-dose sequential cyclophosphamide plus doxorubicin. Radiation was given only if a CR was not achieved after 15 weeks of treatment plus second-look surgery. Sixteen of 21 patients without *MYCN* amplified tumors remain free of disease, most without radiotherapy, compared to only 1 of 11 with tumors having *MYCN* amplification. A similar adverse effect of *MYCN* amplification on outcome in stage 2 tumors was observed by West and colleagues [284] at the Dana-Farber Cancer Institute.

A clear indication for radiation therapy is for neonates with INSS stage 4S neuroblastoma who develop respiratory distress secondary to hepatomegaly and for whom

treatment with chemotherapy is ineffective.[276,277,282,295,347] Effective doses are 3 to 6 Gy in single or multiple fractions.[341] However, considering the potential long-term side effects, chemotherapy alone should remain the initial approach in these patients.

Total body irradiation represents another potential use of radiation in neuroblastoma patients. Doses of 7.5 to 12.0 Gy given in three to five fractions have been used as part of many preparative regimens for ABMT or stem cell transplantation.[348,349 and 350] The benefits of high-dose chemoradiotherapy relative to marrow ablative chemotherapy alone in the ABMT setting have not been established.

Traditionally, radiation alone or in combination with laminectomy has been used to rapidly reduce cord compression in children with dumbbell extension of neuroblastoma associated with spinal symptoms. Radiation doses used range from 7.5 to 30.0 Gy.[351] Although effective, both modalities are associated with a significant incidence of vertebral body damage, including growth arrest and instability leading to scoliosis. In newly diagnosed patients, the use of chemotherapy alone has been reported to be an efficacious alternative associated with fewer long-term side effects.[352,353,354 and 355]

Finally, for treating problematic metastatic disease at diagnosis or for palliative management of pain in end-stage disease, radiation in daily fractions to total doses of 4 to 32 Gy usually affords immediate relief of symptoms and may result in prolonged control at the site treated.[342]

**Chemotherapy**

Chemotherapy is the predominant modality of management in neuroblastoma patients who have intermediate- or high-risk disease (discussed in more detail in the section on risk-related therapy). Single-agent, phase II trials conducted in patients with recurrent or advanced neuroblastoma have identified a number of effective drugs that form the backbone of current induction chemotherapy regimens.[356,357,358,359,360,361,362,363,364,365,366,367,368,369,370,371,372,373,374,375,376,377,378,379,380 and 381] In particular, these data have established the activity of alkylating agents and platinum analogs in this disease. Cyclophosphamide, cisplatin, doxorubicin, and the epipodophyllotoxins have yielded CR and PR rates ranging from 34% to 45% in patients with refractory disease, and they have become the cornerstone of most multi-agent regimens.

The concept of an initial phase II window to evaluate single agents in previously untreated high-risk cancer patients has been applied to children with disseminated neuroblastoma.[381,382,383 and 384] Using this study design, it has been possible to determine response rates and acute toxicity of several agents in the context of chemotherapeutically naive tumors and patients who are not chronically ill from tumor or previous treatment ( Table 31-8). One concern regarding such a design is that single-agent treatment may have an adverse effect on subsequent multi-agent therapy. In the European study reported by Kellie and colleagues,[382] only 12 of 18 children had a response to OPEC or similar therapy after an initial two courses of ifosfamide alone, which appeared to be inferior to previous experience. However, in the POG experience, in which patients received similar multidrug induction chemotherapy with or without upfront single-agent treatment, there was no evidence of worsening response rates or outcome due to the use of the phase II window.[383,384] Such a study design seems an appropriate adjunct to future clinical trials for high-risk disease.

| Study | Reference | Drug and schedule | No. patients | CR + PR (%) |
|---|---|---|---|---|
| POG 8741 | 383 | Carboplatin 560 mg/m² | 49 | 54 |
| | | Ifosfamide 2 g/m² per d × 4 | 52 | 45 |
| | | Cisplatin 100 mg/m² | 54 | 40 |
| | | Epirubicin 90 mg/m² | 23 | 14 |
| European Neuroblastoma Study Group 3A | 382 | Ifosfamide 3 g/m² per d × 2 | 18 | 44 |
| POG 9341 | 384 | Topotecan 2 mg/m² per d × 5 | 33 | 38 |
| | | Topotecan 2 mg/m² per d × 5 and cyclophosphamide 250 mg/m² per d × 5 | 38 | 29 |
| | | Taxol 200 mg/m² | 33 | 18 |

CR, complete response; PR, partial response.

**TABLE 31-8. ACTIVITY OF AGENTS STUDIED IN PHASE II WINDOWS FOR NEWLY DIAGNOSED HIGH-RISK NEUROBLASTOMA PATIENTS**

**Concept of Risk-Related Therapy**

A large body of data supports the hypothesis that the clinical behavior of human neuroblastoma may be reliably predicted based on the analysis of a panel of prognostic variables.[102,319] Thus, most pediatric oncology clinical trials groups currently stratify patients into risk groups based on analysis of well-defined prognostic factors. The COG Risk Stratification System is based on the experience of both the POG and CCG ( Table 31-9).[269,286,306,311,333,385,386] This system uses analysis of the clinical factors of patient age at diagnosis and INSS stage and the biologic factors of tumor histopathology, DI, and *MYCN* amplification status to assign patients to one of three distinct risk groups (low, intermediate, and high). A major goal of ongoing clinical trials is to prospectively evaluate “candidate” prognostic markers, such as 1p36 LOH, unbalanced 17q gain, and *TRKA* expression for independent influence on patient outcome.

| Stage[a] | Low risk | Intermediate risk | High risk |
|---|---|---|---|
| 1 | All | None | None |
| 2A, 2B | Age < 1 yr; or<br>Age 1–21 yr; *MYCN* non-*AMP*; or<br>Age 1–21 yr; *MYCN AMP* and FH[c] | None | Age 1–21 yr with *MYCN AMP* and UH |
| 3 | None | Age < 1 yr and *MYCN* non-*AMP*; or<br>Age 1–21 yr; *MYCN* non-*AMP* and FH | Age 0–21 yr with *MYCN AMP*; or<br>Age 1–21 yr; *MYCN* non-*AMP* and UH |
| 4 | None | Age < 1 yr with *MYCN* non-*AMP* | Age < 1 yr and *MYCN AMP*; or age 1–21 yr |
| 4S | *MYCN* non-*AMP*; FH; DI < 1 | *MYCN* non-*AMP*; UH or DI > 1 | *MYCN AMP* |

[a]International Neuroblastoma Staging System.[26]
[b]*MYCN* amplification status: *AMP*, amplified; non-*AMP*, not amplified.
[c]Histopathologic classification[98]: FH, favorable histology; UH, unfavorable histology.

**TABLE 31-9. PROPOSED NEUROBLASTOMA RISK GROUPS BASED ON CLINICAL AND BIOLOGIC TUMOR FEATURES**

***Treatment of Low-Risk Disease***

Included in the low-risk disease group are the following patients: all patients with INSS stage 1 disease; patients with INSS stage 2 disease, except those patients older than 1 year at diagnosis with tumor *MYCN* amplification *and* unfavorable Shimada pathology; and infants with 4S disease with tumors with hyperdiploidy, favorable Shimada, and single-copy *MYCN* (Table 31-9).

Treatment of low-risk neuroblastoma consists of surgical removal of the primary tumor. Unique to neuroblastoma, a complete resection is unnecessary in the setting of localized disease and favorable biologic features. Patients with INSS stage 1 tumors (gross total resection) can be expected to have a relapse-free survival probability of greater than 90%, regardless of age.[311,387,388 and 389] Perez and colleagues[311] recently reported a 93% EFS rate for 141 Evans stage I patients. Six of the ten disease recurrences occurred at distant sites, but two of these occurred in patients with *MYCN* amplified tumors (see below). The OS rate for this cohort of patients was 99%. These data support surgery alone as effective initial therapy of INSS stage 1 neuroblastomas. Local recurrences can be managed with second surgeries, but even metastatic recurrences are often salvageable with chemotherapy.

Surgery alone is also the initial treatment of choice for the majority of patients with INSS stage 2 neuroblastoma. Historically, many of these patients were treated with chemotherapy, and survival results were excellent.[390] Several single institutions and cooperative groups have reported results of treatment with surgery only, however, and survival does not appear to be compromised.[311,387,389,391,392] In a recent prospective CCG study, 233 Evans stage II patients (56% INSS stage 2) with single-copy *MYCN* were managed with surgery alone.[311] Although the 4-year EFS rate was 81%, the majority of patients who experienced disease relapse was salvaged, as the 4-year OS rate was 98%. Thus, even in the setting of macroscopic residual disease, adjuvant chemotherapy or radiotherapy does not seem warranted for the vast majority of INSS stage 2 patients.

It remains controversial how best to manage the rare patients with INSS stage 1 or 2 neuroblastomas and *MYCN* amplification. Cohn and colleagues[393] reported that five of six patients with *MYCN* amplified INSS stage 1 (n = 3) or stage 2A (n = 3) tumors survived without evidence of disease at 7+ to 38+ months. However, Perez and colleagues[308] recently showed that four of seven INSS stage 1 (n = 4, all infants) and stage 2b (n = 3, two infants) cases with *MYCN* amplification had metastatic relapse at 2 and 22 months from surgery, and three of these patients died from disease progression. Likewise a French cooperative group reported that three of four patients with INSS stage 1 or 2 neuroblastoma and *MYCN* amplification relapsed and died from disease progression.[391] Thus, this rare clinical situation needs prospective evaluation under uniform therapeutic recommendations to arrive at a consensus treatment strategy.

The majority of patients with INSS stage 4S disease falls into the low-risk category. Retrospective analyses have shown OS rates ranging from 57% to 97% for stage 4S patients taken as a whole.[275,276] and [277,347,392,394,395,396,397,398,399] and [400] Recent prospective analyses have confirmed these observations and show OS probabilities of 85% (n = 110) to 92% (n = 80).[98,401] However, it has become clear that some infants with this unique pattern of disease are at much higher risk for life-threatening complications. First, the subset of patients diagnosed in the first 2 months of life appears particularly vulnerable to respiratory compromise secondary to rapidly progressive hepatomegaly.[98,400,401] In addition, there is a subset of stage 4S patients with unfavorable biologic features such as *MYCN* amplification that often shows rapid tumor progression or eventual disease relapse similar to “true” stage 4 disease.[98,308,401] These data emphasize the importance of biologic assessment of tumor tissue in patients with stage 4S disease.

The indications for intervening and the methods of managing infants with stage 4S neuroblastoma are becoming standardized. A diagnostic biopsy is indicated for evaluation of tumor biologic features, but resection of the primary tumor does not appear to influence outcome.[98,401] Thus, the safest surgical procedure, such as removal of a subcutaneous nodule, should be performed. Patients with favorable biologic features should be observed closely for symptomatology from tumor expansion, especially when younger than 2 months at diagnosis. If respiratory compromise becomes evident, moderately intensive chemotherapy is indicated, such as that currently recommended for intermediate-risk disease.[98,282,295,347,401] Radiation therapy should be reserved for those patients who progress despite chemotherapy. If necessary, a minimal dose of radiation, such as 450 to 600 cGy in three to four fractions is generally sufficient to halt tumor progression and induce regression. Lastly, the rare stage 4S patients with unfavorable biologic features should be considered for either intermediate-risk (diploidy or unfavorable Shimada pathology) or high-risk (*MYCN* amplification) treatment strategies.

Although neuroblastoma patients with intermediate- or high-risk disease features may present with intraspinal extension and cord compression, this clinical situation is most frequently identified in children who otherwise would be considered low risk. Many of these patients are quite young, so extensive laminectomies or radiation to the spine can result in long-term morbidity. Several groups have reported their retrospective experience with the management of intraspinal neuroblastoma.[352,353,354] and [355,402] In general, these studies show no survival or neurologic outcome advantage for neurosurgical decompression or external beam radiation therapy. In addition, Hoover and colleagues[355] documented mild to severe spinal deformities in 11 of 15 patients treated initially with laminectomy. The French NBL90 study prospectively evaluated the role of initial chemotherapy for 42 nonmetastatic neuroblastomas presenting with intraspinal extension.[354] They showed that chemotherapy alone was successful in reducing the tumor volume in 58% of cases and was associated with improved neurologic function in 92%. Thus, chemotherapy appears to be a safe and effective initial modality to manage spinal canal invasion, and it has less long-term morbidity than do surgery or radiation therapy.

### *Treatment of Intermediate-Risk Disease*

Included in the intermediate-risk disease group are the following patients: INSS stage 3 patients younger than 1 year with nonamplified *MYCN*, INSS stage 3 patients older than 1 year with nonamplified *MYCN* and favorable Shimada pathology, stage 4 infant patients with nonamplified *MYCN,* and nonamplified stage 4S patients with unfavorable Shimada histopathology, a DI of 1, or both (Table 31-9). The group of patients currently defined as INSS stage 3 have been treated in a heterogeneous fashion in past studies due to differences in the staging systems used by the various cooperative groups. Therefore, treatment results have been difficult to compare. International acceptance of the INSS system should allow for a more uniform approach to treatment planning for this subset of patients.

Matthay and colleagues[286] recently reported the CCG experience with Evans stage III disease, and because 92% of their patients were INSS stage 3, results can be extrapolated to the current risk stratification system. Of 228 Evans stage III patients prospectively evaluated for risk status by analysis of age, stage, *MYCN* amplification status, Shimada pathology,[403] and serum ferritin,[288] 143 met the current criteria for intermediate-risk disease. These 143 patients were treated with moderately dose-intensive chemotherapy including cyclophosphamide, doxorubicin, cisplatin and etoposide, as well as local radiation for any gross residual disease following delayed surgery. Patients with Evans stage III disease and normal *MYCN*, favorable Shimada, and low serum ferritin had a 4-year EFS of 100%. Infants with Evans stage III disease and at least one unfavorable biologic feature had 4-year EFS and OS rates of 90% and 93%, respectively. In contrast, patients with Evans stage III disease older than 1 year at diagnosis with at least one unfavorable biologic feature had 4-year EFS and OS rates of 65% and 75%, respectively, despite a much more dose-intensive treatment regimen. In multivariate analysis, age at diagnosis and *MYCN* status were the only factors independently prognostic in this group of patients.

The role of radiotherapy for advanced locoregional neuroblastoma remains controversial. Castleberry and colleagues[333] previously showed that addition of 24 to 30 Gy of external beam radiotherapy to the primary tumor bed and regional lymph nodes following moderately aggressive chemotherapy improved overall rates of both local and metastatic relapse for children with POG stage C disease (INSS stages 2B and 3). In this randomized study, 46% of 28 patients treated with chemotherapy alone achieved CR and 32% were free of disease at 2 years. In comparison, 75% of 29 children treated with chemotherapy plus radiation therapy achieved a CR, and 59% were free of disease at 2 years. In contrast, de Bernardi and colleagues[270] found no advantage for radiotherapy in a randomized trial (chemotherapy with or without radiotherapy) in 29 nonmetastatic patients with residual tumor or positive lymph nodes (INSS stages 2 and 3) following initial surgery. Furthermore, nonrandomized addition of radiation therapy for patients with gross residual disease following second surgery for Evans stage III disease had no apparent influence on disease outcome.[286] Currently, most cooperative groups are withholding radiation therapy for the majority of intermediate-risk patients, except for patients with disease progression despite surgery and chemotherapy or patients with unresectable primary tumors with unfavorable biologic features at the end of chemotherapy.

The majority of infants with INSS stage 4 neuroblastoma is currently categorized as intermediate risk. It is now clear that infants with metastatic neuroblastoma that is *MYCN* amplified uniformly have a highly malignant clinical course,[306,307,386,404] and therefore should be categorized as high risk. However, infants with neuroblastomas that do not have amplified *MYCN* typically have a much less aggressive clinical course and respond to moderate intensity chemotherapy. Schmidt and colleagues[303] reviewed the recent CCG experience and reported a 3-year EFS rate of 93% for infants with *MYCN* single-copy neuroblastomas treated with moderately intensive chemotherapy. This contrasts with the 10% EFS noted for those infants with *MYCN*-amplified tumors, many of whom were treated with much more intensive therapy (Fig. 31-12). These data compare favorably to previous reports from the POG,[398,399] perhaps because the CCG study used a somewhat more intensive chemotherapy induction regimen.

Taken together, these data support an approach to intermediate-risk neuroblastoma that centers on moderately intensive chemotherapy and avoids radical surgery and external beam radiotherapy in the majority of patients. Therefore, the current COG intermediate-risk neuroblastoma strategy consists of combination chemotherapy including carboplatin, etoposide, cyclophosphamide, and doxorubicin. This is designed to test the hypothesis that this regimen will provide a greater than 90% EFS rate with minimal treatment-related morbidity. In addition, it builds on the previous CCG and POG experience by providing a longer duration of therapy for patients in the intermediate-risk category but with unfavorable biologic features (e.g., stage 4 infants with unfavorable Shimada pathology).

### *Treatment of High-Risk Disease*

Included in the high-risk disease group are the following patients: INSS stage 4 patients older than 1 year at diagnosis, any INSS stage 3 patient with amplified *MYCN*, INSS stage 3 patients older than 1 year at diagnosis with unfavorable Shimada pathology, INSS stage 2 patients with amplified *MYCN* and unfavorable Shimada pathology, and INSS Stage 4S patients with amplified *MYCN* (Table 31-9).

Historically, high-risk neuroblastoma patients have had long-term survival probabilities of less than 15%. [197,345,376,405,406,407,408,409,410,411,412,413,414,415,416,417,418 and 419] With the advent of comprehensive treatment approaches that include (a) intensive induction chemotherapy, (b) myeloablative consolidation therapy with stem cell rescue, and (c) targeted therapy for minimal residual disease, OS rates have improved ( Fig. 31-13). However, the current survival rates remain unacceptable and have come at the expense of significant immediate and long-term morbidity.

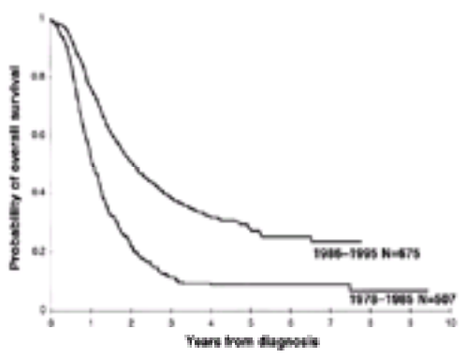

**FIGURE 31-13.** Improving survival for high-risk neuroblastoma patients. Comparison of 1,182 consecutive patients with stage 4 neuroblastoma diagnosed at age older than 1 year and treated at CCG institutions. (Redrawn with permission from Katherine Matthay, University of San Francisco, California.)

### Induction Therapy

The goal of induction therapy is to induce maximum reduction in tumor bulk at primary and metastatic sites. Neuroblastoma is typically sensitive to initial chemotherapy, even in cases with amplified *MYCN*. Retrospective analyses have shown an association of chemotherapy dose intensity with response and survival rates.[420,421] In particular, the dose intensity of the platinum compounds appears to correlate most significantly with disease outcome. [421] The appropriate duration of induction therapy is currently unknown, although it is generally agreed that it should be accomplished in as rapid a time frame as possible, before the acquisition of drug resistance.

The efficacy of induction chemotherapy regimens is assessed by the response rate, usually a combined measure of CR and PR and typically determined after a second surgical procedure. Although not definitively proven, there is a substantial body of evidence suggesting that the quality of remission at the end of induction chemotherapy is highly associated with long-term survival probability. [421,422,423,424,425,426,427 and 428] In a multivariate analysis performed with 549 high-risk neuroblastoma patients registered on the European Bone Marrow Transplantation Solid Tumor Registry, Ladenstein and colleagues [425] showed that persisting cortical bone lesions ($p$ = .004) and bone marrow involvement ($p$ = .03) were the only independent adverse prognostic factors. Thus, patients who achieve a CR or VGPR with induction chemotherapy have a better chance of cure, although some patients with a PR can be converted to CR with high-dose myeloablative therapy. [404,429]

Table 31-10 reviews the induction chemotherapy regimens used in the most recent cooperative group studies in the United States. It can be concluded from the U.S. experience that induction chemotherapy response rates were greatest in the regimens that contained higher overall dose intensities, especially in those with higher intensity of the platinum agents. For example, in POG 8742, regimen 1 contained almost twice the dose intensity of cisplatin and had nearly a 10% better induction response rate.[383] Future trials in the United States may further dose-intensify the platinum and alkylator components of induction therapy, although acute and long-term toxicities may limit this approach (see below).

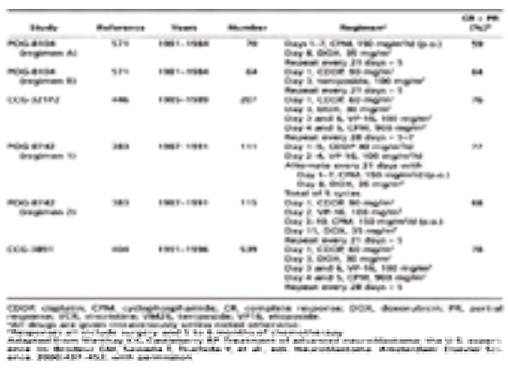

**TABLE 31-10. INDUCTION CHEMOTHERAPY REGIMENS AND RESPONSE RATES FROM RECENT PEDIATRIC ONCOLOGY GROUP AND CHILDREN'S CANCER GROUP COOPERATIVE GROUP TRIALS**

Experience from single-institution U.S. studies as well as multicenter studies in Japan and Europe suggest that alternate induction strategies may improve response rates and EFS. Kushner and colleagues[430,431] have reported that 21 of 24 patients achieved either CR or VGPR with an induction regimen that included a much higher dose intensity of cyclophosphamide, doxorubicin and cisplatin, but this may be associated with a significant risk of treatment-related leukemia. The Study Group of Japan for Advanced Neuroblastoma has reported a 92% CR + PR rate with six cycles of conventional doses of cyclophosphamide, vincristine, pirarubicin and cisplatin, although some of these patients may have progressed before consolidation therapy. [427] The ENSG has reported response rates between 69% and 96% for various induction regimens used in national trials. [428] Retrospective analysis showed a correlation between the cumulative drug doses and response rate. [428] The ENSG has directly tested the hypothesis that an increased dose intensity of induction chemotherapy improves response rate and survival in a recent randomized trial between two identical chemotherapy regimens that differed only in the rapidity of delivery [versus “rapid” COJEC (cyclophosphamide, vincristine [Oncovin], carboplatin [JM-8], etoposide [VP-16], and cisplatin)]. Results from this important trial should be available in the near future.

### Consolidation Therapy

The goal of consolidation therapy is to consolidate the response achieved during induction therapy by eliminating any remaining tumor, usually with myeloablative cytotoxic agents and stem cell rescue. The concept of eliminating resistant tumor clones with supralethal chemotherapy supported by ABMT has been actively investigated in neuroblastoma since the early 1980s. Since the first published trial of myeloablative consolidation therapy using high-dose melphalan alone, [432] multiple single-arm trials and registry reviews have been reported in the literature. [423,425,427,433,434,435,436,437,438,439,440,441,442,443,444,445,446,447,448,449,450,451 and 452] These studies are difficult to compare due to the heterogeneity of induction and consolidation regimens as well as varying strategies for stem cell harvesting and reinfusion. However, the majority of studies reported at least a trend toward improved survival probabilities compared to nonrandomized control groups and historical controls. The recent U.S. experience from trials involving 40 patients or more are listed in Table 31-11.

| Study | Reference | Number | Regimen[a] | 3-yr event-free survival[b] |
|---|---|---|---|---|
| POG-8340 | 349 | 81 | Melphalan, TBI | 38 |
| CCG-321P3 (Regimen 1) | 445 | 45 | Cisplatin, teniposide, doxorubicin, melphalan, TBI | 42 |
| CCG-321P3 (Regimen 2) | 445 | 54 | Cisplatin, etoposide, melphalan, TBI | 50 |
| CCG-321P3 (Regimen 3) | 445 | 48 | Carboplatin, etoposide, melphalan, TBI | 41 |
| CCG-3891 | 404 | 129 | Carboplatin, etoposide, melphalan, TBI | 43 |
| CCG-LA-6P | 572 | 77 | Carboplatin, etoposide, melphalan, local radiation | 62 |

**TABLE 31-11. CONSOLIDATION REGIMENS AND 3-YEAR EVENT-FREE SURVIVAL RATES FROM TIME OF AUTOLOGOUS STEM CELL TRANSPLANTATION FROM RECENT PEDIATRIC ONCOLOGY GROUP AND CHILDREN'S CANCER GROUP COOPERATIVE GROUP TRIALS**

There have been two randomized studies of ABMT for high-risk neuroblastoma. The ENSG reported a trial of either high-dose melphalan myeloablation with autologous, unpurged bone marrow rescue versus no further therapy for patients who achieved a CR with induction chemotherapy. [453] Of 140 infants and children with disseminated disease, 95 achieved CR and 65 were randomized. The projected disease-free survival favored the transplanted group compared to the group stopping treatment (50% vs. 27% at 2 years; $p = .03$), although firm conclusions could not be drawn due to the small number of patients randomized. Matthay and colleagues [404] recently reported the results of a 5-year CCG study that tested the hypothesis that consolidation with myeloablative chemotherapy followed by purged autologous bone marrow rescue would improve survival probability compared to continuation chemotherapy. It is important to note that the continuation therapy was fairly intense but nonmyeloablative. A total of 539 eligible patients were enrolled onto this clinical trial designed with two sequential randomizations (± autologous marrow rescue and ± 13-*cis*-retinoic acid). A total of 379 patients were randomly assigned to autologous marrow rescue (n = 189) or continuation chemotherapy (n = 190). An intent-to-treat analysis showed a significant improvement in 3-year, EFS probability for the patients assigned to myeloablative therapy (34 ± 4% vs. 22 ± 4%; $p = .034$; Fig. 31-14A). Importantly, autologous transplantation appeared to have the largest impact on survival for the ultra-high-risk subset of patients, such as those with *MYCN* amplified metastatic disease diagnosed after 2 years of age. However, follow-up is relatively short, and these data will need further analysis due to the potential for late relapse in the transplant group.

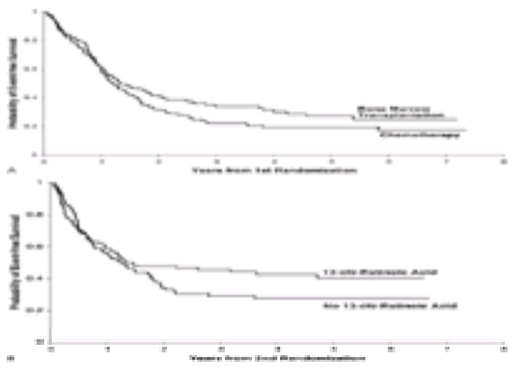

**FIGURE 31-14.** ABMT and 13-*cis*-retinoic acid improve event-free survival for high-risk neuroblastoma patients—results of CCG study 3891. [401] All patients were treated with identical induction chemotherapy and were first randomized to either purged ABMT or continuation chemotherapy, and then to either 13- *cis*-retinoic acid or no further therapy. **A:** Event-free survival for patients randomized to ABMT (n = 189) or intensive but nonmyeloablative continuation chemotherapy (n = 190) ( $p = .034$). **B:** Event-free survival from time of randomization to 13-*cis*-retinoic acid (n = 130) or no further therapy (n = 128) ($p = .027$). (Redrawn with permission from Dr. Katherine Matthay, University of San Francisco, California.)

It has recently become clear that using peripheral blood stem cells provides superior engraftment kinetics compared to conventional bone marrow grafts, and this technique might abrogate some transplant-related morbidity. [452,454] In addition, there is increasing experience with large-volume cytapheresis procedures in small children. [455] Last, there is the theoretical advantage that peripheral blood stem cell products are less likely to contain contaminating tumor cells, although Moss and colleagues [456] clearly demonstrated that circulating, clonogenic tumor cells may be present in patient peripheral blood samples obtained *at diagnosis*. Because peripheral blood stem cell harvests typically occur after two to four cycles of induction chemotherapy, and therefore follow an "*in vivo* purging," the majority of the pheresis products contains no contaminating tumor cells. [424,452,454] Thus, future clinical trials for high-risk neuroblastoma patients will most likely use autologous peripheral blood stem cells for myeloablative rescue.

The majority of high-risk neuroblastoma patients has metastases to the bone marrow at diagnosis. [231] Due to the unique expression of neural-specific antigens that are not normally present on the surface of hematopoietic cells, it is possible to detect submicroscopic neuroblastoma contamination of bone marrow (or peripheral blood) with monoclonal antibodies. [245,247] In addition, these neuroblastoma cells can be reliably depleted *ex vivo* using immunomagnetic purging. [458,459,460,461,462 and 463] There have been no randomized trials designed specifically to investigate the impact of *ex vivo* tumor cell purging of stem cell products on the outcome of high-risk neuroblastoma patients. However, there has been direct demonstration that contaminating neuroblastoma cells in autologous marrow samples contributed to disease relapse in three patients who received unpurged marrow infusions. [464] The recent randomized trial conducted by CCG for high-risk neuroblastoma patients that showed an advantage to myeloablative therapy compared to continuation chemotherapy used purged autologous marrow. [404] Thus, although most investigators agree that *ex vivo* immunomagnetic purging of bone marrow products is both safe and effective in depleting contaminating tumor cells, it is unclear what impact, if any, purging may have on peripheral blood stem cell products obtained after effective *in vivo* purging. A randomized clinical trial designed to test the efficacy of *ex vivo* purging of immunocytochemically negative peripheral blood stem cell products has recently been initiated by the COG.

In two relatively small studies, no evidence for a "graft-versus-tumor" effect could be found for high-risk neuroblastoma patients receiving allogeneic marrow transplants. A nonrandomized study was conducted by CCG comparing 20 patients receiving allogeneic marrows to 36 children undergoing ABMT after marrow purging. [442] The estimated progression-free survival at 4 years was 25% for the allogeneic group versus 49% for the autologous group ( $p = .51$). In a similar study from the European Group for Bone Marrow Transplantation, [441] the 2-year progression-free survival for 17 allogeneic transplants (35%) was not significantly different from that of 34 autologous transplants (41%). Thus, there is no evidence to support use of an allogeneic source of stem cells.

The potential that two myeloablative consolidations might be better than one is currently being investigated. The main theoretical advantage of a tandem transplant approach involves providing multiple non–cross-resistant agents at maximal doses in a relatively rapid sequence. Philip and colleagues [440] demonstrated that this approach, when supported by purged, autologous bone marrow, was associated with significant transplant-related morbidity and mortality, but also with an encouraging 5-year survival of 32% in a cohort of 33 very-high-risk patients with relapsed or refractory disease. More recently, Grupp and colleagues [454] showed that a tandem myeloablative consolidation with peripheral blood stem cell support was feasible with rapid myeloid engraftment in a limited institution pilot study of 39 patients. Transplant-related mortality was 8% (3 of 39) and the 3-year EFS was estimated at 58%. A randomized trial of single versus tandem myeloablative consolidations is necessary to determine the true impact of a tandem high-dose myeloablative consolidation strategy.

**Minimal Residual Disease Therapy**

The goal of this phase of therapy is to eradicate any residual tumor cells using agents that are typically not directly cytotoxic and therefore theoretically active against highly chemoresistant minimal residual disease.

Despite the improvements in induction chemotherapy response rates and efficacy of myeloablative consolidation procedures, the majority of high-risk neuroblastoma

patients experiences disease relapse. This is often despite the fact that many patients reach the end of consolidation therapy with no disease detectable by conventional methodologies. It is therefore assumed that microscopic residual disease is often present after myeloablative consolidation. In addition, cell lines derived from relapse specimens have been shown to be highly chemoresistant,[465] suggesting that selection for, or acquisition of, drug resistance are the major mechanisms by which these tumor cells survive intensive induction and consolidation therapies.

Several novel agents specifically targeted to the unique biology of neuroblastoma may be effective for eliminating minimal residual disease. The retinoids are a class of compounds that have been known for two decades to induce cellular differentiation with a concomitant decrease in proliferation of neuroblastoma cells *in vitro*.[466] A phase I trial of 13-*cis*-retinoic acid in neuroblastoma patients with any disease status after myeloablative consolidation defined a maximum tolerated dose of 160 mg per $m^2$ per day given on a twice-daily schedule.[467] Of ten patients with measurable disease at study entry, three had complete clearing of bone marrow metastases. The efficacy of 13-*cis*-retinoic acid was recently tested in a randomized trial using a factorial design following a randomization to myeloablative or continuation chemotherapy (see above).[404] A total of 130 patients were randomized to receive either six cycles of 160 mg per $m^2$ per day divided twice-daily schedule for 2 weeks per month or no further therapy. The cohort of patients assigned to receive posttransplant therapy with 13- *cis*-retinoic acid had a significantly improved EFS probability (46 ± 6% versus 29 ± 6% from second randomization; $p = .027$; Fig. 31-14B). Other retinoids such as 9-*cis*-retinoic acid, all-*trans*-retinoic acid, or fenretinide may also have activity for minimal residual disease in high-risk neuroblastoma patients.

An alternative strategy that appears promising for application during the minimal residual disease phase of therapy is targeted molecules directed against neuroblastoma-specific cellular antigens. Murine, chimeric, and humanized antibodies specific to the cell surface ganglioside $G_{D2}$, either alone or with cytokines, have shown activity in preclinical models[459,468,469,470 and 471] as well as phase I[472,473,474,475,476,477 and 478] and phase II[479,480] clinical trials. The murine monoclonal antibodies 3F8[468] and GD2a,[477] and the human-mouse chimeric monoclonal antibody ch14.18[473] have received the most clinical attention. Measurable responses have been observed in refractory neuroblastoma patients[474,475,480] justifying further examination in phase III clinical trials. Indeed, some investigators have suggested that antibody therapy alone may be effective to consolidate induction remission and may obviate the need for myeloablative chemoradiotherapy.[480] Limiting the broad application of this strategy are difficulties with antibody production and the fact that the majority of patients develops neutralizing antibodies, even to the chimeric molecules.[474,475,480] Neuropathic pain is also a significant immediate toxicity and can be dose limiting.[474,475 and 476,480] A randomized clinical trial designed to test the efficacy of ch14.18 with interleukin-2 and granulocyte-macrophage colony-stimulating factor versus no antibody/cytokine therapy after myeloablative chemotherapy is planned within the COG.

The appropriate methodologies to detect minimal residual disease are not yet decided. For residual cortical bone disease, MIBG may improve the sensitivity for detecting active disease, but may need to be combined with conventional bone scintigraphy.[475,481] Immunocytochemical analysis of bone marrow aspirates with a panel of monoclonal antibodies increases the sensitivity of detection to at least 1:100,000 nucleated cells and may be of prognostic value.[266] Additional sensitivity, perhaps greater than 1:1,000,000 nucleated cells, may be added with reverse transcriptase-polymerase chain reaction methodologies by targeting the expression of one or several tumor-specific messages such as tyrosine hydroxylase, PGP 9.5, GAGE, or MAGE.[482,483 and 484] However, the clinical significance of positivity at this level of sensitivity remains to be determined.

## TREATMENT OF RECURRENT DISEASE

A variety of approaches are available to treat patients with recurrent or refractory neuroblastoma. However, the ability to cure patients who recur after treatment for high-risk disease remains very low. Current innovative approaches include novel cytotoxic agents, targeted delivery of radionuclides, retinoids, and immune-mediated therapy.

### Novel Cytotoxic Agents

Topotecan, a topoisomerase I inhibitor, is a new agent that is currently in phase II trials and does not require dose-intensification for efficacy.[485,486] This agent is being evaluated alone or in combination with cyclophosphamide in an intergroup trial in POG and CCG (now COG), and early results are promising.[384,487,488 and 489] Other novel chemotherapeutic agents under investigation in selected institutions include paclitaxel (Taxol), irinotecan, and rebeccamycin.[384,490,491] Oral etoposide has also been used mainly as a palliative agent, and it is well tolerated.[492] A recent trial includes escalating doses of melphalan with BSO, a highly specific GSH inhibitor. BSO is designed to overcome alkylator resistance mediated through GSH-dependent alkylator efflux by depleting the cells of GSH.[493,494] This combination is a promising approach to the treatment of neuroblastoma, particularly in the context of marrow ablation with stem cell rescue.

### Targeted Delivery of Radionuclides

There are several approaches to targeted delivery of radiation to neuroblastoma cells. These include the attachment of radionuclides to MIBG,[495,496,497,498,499 and 500] to SS analogs,[90,501,502,503 and 504] or to anti-$G_{D2}$ antibodies.[474,475,480,505,506,507 and 508] Radioactive MIBG is used in some frontline therapy for high-risk neuroblastoma in Europe, but it is not in wide use in the United States except for recurrent or refractory disease, with or without stem cell rescue. Future trials may combine targeted radionuclides with conventional cytotoxic chemotherapy.

### Retinoid Compounds

Treatment with 13-*cis*-retinoic acid was not very effective against bulk disease, but it has proven to be an effective treatment in states of minimal residual disease.[404] Newer retinoids are being developed for use in neuroblastoma treatment, and fenretinide is currently the most attractive agent.[509,510,511 and 512] Unlike retinoic acid, which can induce differentiation of neuroblastoma cells in culture, fenretinide appears to primarily induce apoptosis, even in neuroblastoma cells that are resistant to 13-*cis*-retinoic acid.

### Immune-Mediated Therapy

Neuroblastoma can be treated with unlabeled antibody against the ganglioside $G_{D2}$. This antibody may have direct cytotoxic effects as well as induce antibody-dependent cellular cytotoxicity.[480,513] In addition, vaccine trials are being conducted that attempt to induce humoral and cellular responses directed to neuroblastomas.[514,515,516 and 517]

## COMPLICATIONS OF NEUROBLASTOMA AND ITS TREATMENT

A variety of complications of neuroblastoma and its treatment may occur that are not particularly unique to this tumor. These include late effects of chemotherapy, radiation therapy, and surgery.[518] Patients in the low-risk category will likely experience only the consequences of surgery, and because their prognosis is excellent, aggressive surgery should be minimized. Patients in the intermediate-risk category are exposed to surgery as well as moderately intensive chemotherapy. However, the overall regimen is short and well tolerated, and various pairs and combinations of drugs are used to minimize the likelihood of significant side effects of any one agent.

High-risk patients are at the greatest risk of experiencing complications of treatment. There are problems with linear growth, cardiac function, renal function, and other organs.[518] In addition, ototoxicity has been a particular problem from the use of platinum-containing regimens to treat very young children.[519] The extensive use of alkylating agents and topoisomerase II inhibitors results in a higher prevalence of sterility as well as second malignancies, particularly myelodysplastic syndromes and acute nonlymphoblastic leukemias.[431,518] However, the latter problem may be particularly regimen and schedule dependent.

Indeed, a number of different second neoplasms have been reported in patients with neuroblastoma after treatment, such as thyroid cancer, pheochromocytoma, brain tumors, acute leukemia, osteosarcoma, breast cancer, and renal cell carcinoma.[520,521,522,523,524,525,526,527 and 528] None of these second cancers has occurred with sufficient frequency to indicate a specific relationship between neuroblastoma and any other neoplasm.[529] Furthermore, patients with neuroblastoma do not appear to be at increased risk for developing specific second cancers other than the risk associated with certain chemotherapeutic agents or radiation therapy.

## NEUROBLASTOMA SCREENING STUDIES

One approach to improve the long-term outcome of patients with neuroblastoma is to identify patients earlier in the course of their disease. This assumes that (a) patients with more advanced stages of disease, and thus a higher risk of treatment failure, “progress” from more localized disease over time; and (b) that there is in interval during which they could be detected before progression and clinical presentation. Because neuroblastomas frequently produce increased levels of catecholamines whose metabolites are detectable in the urine, mass screening of infants for neuroblastoma has been investigated. Indeed, such a screening program has been ongoing in Japan for about 25 years.[530,531,532,533,534 and 535] Efforts have also been undertaken in North America and Europe to answer questions concerning the feasibility and utility of mass screening for neuroblastoma.[61,62,536,537,538,539,540 and 541]

Studies of the clinical and cytogenetic features of tumors identified as a result of mass screening of infants for neuroblastomas suggest that the majority of patients identified has lower stages of disease, and virtually all of the tumors are biologically favorable, with a DI in the hyperdiploid or near-triploid range and with a normal *MYCN* copy number.[533,542,543,544 and 545] Previous studies have demonstrated that such findings are generally associated with a very favorable outcome. Therefore, the results of the screening studies have suggested at least two possibilities: (a) that all neuroblastomas begin as tumors with a more favorable genotype and phenotype, and some evolve into more aggressive tumors with adverse genetic features; or (b) there are at least two different subsets of neuroblastoma, and the more favorable type presents earlier and therefore is the predominant type detected by screening. Current evidence is more consistent with the latter explanation and suggests that neuroblastomas detected by screening are predominantly of the most favorable biologic type (type 1; Table 31-2).[24,103,109]

In addition to the genetic data discussed above, the accumulating evidence suggests that the prevalence of neuroblastoma in screened populations is increased by 50% to 100% over that seen in unscreened populations, and that the prevalence and mortality of neuroblastoma in patients older than 1 year has not changed appreciably.[61,62 and 63,538,541] Taken together with the biologic information, this suggests that screening is detecting tumors in a substantial number of patients who likely would never develop symptomatic disease because their tumors would have regressed or matured without therapy. Many of the tumors detected by screening in patients aged 6 months have favorable biologic features [545] and could be cured easily with surgery or relatively mild therapy. Several studies in Japan and Europe are screening patients at a later time, such as at 8 to 14 months.[63,536,537,539,540,546] It appears that the prevalence of “overdiagnosis” by screening at a later time is lessened, and there is a greater frequency of patients with unfavorable clinical and biologic features. However, it remains to be determined whether early detection by screening will improve the outcome of patients whose tumors have unfavorable biologic features.

There have been several reports of the incidental prenatal detection of neuroblastoma by maternal ultrasound.[547,548,549 and 550] The majority of these patients has had cystic adrenal tumors with favorable biologic markers and an excellent outcome. However, a few have rapid tumor progression shortly after birth, especially those with extensive liver metastases. Because the quality of maternal ultrasound has improved and it is used more frequently, it is likely that more cases will be diagnosed. However, unless there is massive liver involvement or unfavorable biologic features (DI = 1, *MYCN* amplification), such cases can probably be managed conservatively and chemotherapy or radiotherapy can be avoided.

## FUTURE CONSIDERATIONS

Short-term improvements in the outcome of neuroblastoma patients are likely to come from more effective use of existing modalities, including newer agents (topotecan, fenretinide) as well as stem cell support for high-risk patients. Furthermore, the use and continued improvement of risk stratification schema should allow the most appropriate intensity of therapy to be selected, minimizing the likelihood of undertreatment or overtreatment. However, longer-term improvement in the management of neuroblastoma patients are likely to come from several other areas. These include (a) the identification of individuals with a genetic predisposition to develop this disease, (b) additional tumor markers to follow tumor response to treatment, (c) better biologic characterization of tumors for classification and prognostication, and (d) biologically directed therapy that would presumably be more effective and less toxic than current regimens.

### Neuroblastoma Predisposition

As improvements occur in the long-term outcome of neuroblastoma patients, it will become increasingly important to identify individuals who are predisposed to develop this tumor. This would be useful to determine risk for siblings of neuroblastoma patients and would provide useful information for genetic counseling of patients and their offspring. Maris and colleagues [48] have recently identified, using linkage analysis, a locus on 16p that may be responsible for the majority of hereditary neuroblastomas. Although a gene has not been identified yet, DNA polymorphisms closely linked to this predisposition locus could be used to identify predisposed individuals in informative families. Further analysis should determine if there are additional predisposition loci.

### Tumor Markers

Following the levels of urinary catecholamine metabolites of patients with neuroblastoma is not as sensitive as a-fetoprotein or b-human chorionic gonadotropin for following germ cell tumors. Measurement of several candidate serum markers has been proposed, including ferritin, NSE, $G_{D2}$, chromogranin A, and others, but none has yet emerged as sufficiently sensitive or specific to be useful in this context. As more is understood about the biology of neuroblastomas, additional secreted neural-specific proteins may be identified that could be used to follow response to treatment and to predict early relapse. Such markers might obviate the need for multiple diagnostic imaging studies and marrow sampling in patients both on and off therapy.

### Biologic Characterization of Tumors

Biologic markers such as DI, *MYCN* amplification, 1p deletion, unbalanced 17q gain, *TRKA* expression, and others have proven to be powerful prognostic variables. However, as the genetic and biologic complexity of neuroblastoma becomes better understood, it is likely that additional markers of low-, intermediate- and high-risk disease will be identified. It is likely that these additional biologic variables will replace such clinical distinctions as age and stage in determining the most appropriate type and intensity of treatment to optimize cure and minimize unnecessary side effects. Indeed, newer techniques such as microarray analysis of the genomic changes or expression profile of tumors may allow many variables to be analyzed simultaneously, providing a comprehensive genetic picture of each patient's tumor.[551,552,553 and 554]

### Future Treatment Strategies

#### *Anti-Angiogenesis Therapies*

In neuroblastoma, high-risk disease features are correlated with tumor vascularity, suggesting that angiogenesis inhibitors may be a useful addition to current therapeutic strategies.[555,556] Furthermore, there is evidence that angiogenic factors may be expressed at higher levels in more advanced stage or biologically unfavorable neuroblastomas.[557,558 and 559] Several groups have examined the efficacy of TNP-470 (TAP Pharmaceuticals, Deerfield, IL) in human and murine neuroblastoma xenograft models.[560,561,562 and 563] In general, TNP-470 inhibited the development of tumors or the growth rate of small tumors, and response was related to tumor burden. TNP-470 also significantly inhibited tumorigenicity when administered after cyclophosphamide.[561] These data show that TNP-470 is a promising inhibitor of human neuroblastoma growth, suggesting that it may be a useful adjunct for high-risk neuroblastoma patients. In addition, therapy aimed at integrins or vascular endothelial growth factor receptors may also be valuable approaches to inhibit angiogenesis of neuroblastomas.[564,565 and 566]

#### *Tyrosine Kinase Inhibitor Therapies*

Neuroblastomas frequently express Trk family tyrosine kinase receptors, which in turn regulate growth, differentiation, and cell death. CEP-751 (KT-6587), an indolocarbazole derivative, is an inhibitor of Trk family tyrosine kinases at nanomolar concentrations. Evans and colleagues [567] showed a significant growth inhibitory effect of CEP-751 on several human neuroblastoma cell lines growing as xenografts. Furthermore, inhibition of growth was greater in the SY5Y cell line transfected with *TRKB* compared to the untransfected parent cell line expressing no detectable *TRKB*. Finally, there was no apparent toxicity identified in any of the treated mice. These results suggest that CEP-751 or other TRK-specific kinase inhibitors may be useful therapeutic agents for neuroblastomas.

### *Induction of Differentiation or Cell Death*

Treatment with 13-*cis*-retinoic acid to induce differentiation appears to be effective in the setting of minimal residual disease. [404] Currently, no other agents are being used to induce neuroblastoma differentiation, but small peptides or molecules that are agonists of the *TRKA*/NGF pathway potentially would induce differentiation. Conversely, antagonists of *TRKA* or *TRKB* may induce programmed cell death by blocking critical survival pathways. In this regard, fenretinide, a retinoid that induces apoptosis in neuroblastoma cells, is being developed for treatment of high-risk patients, [509,510,511 and 512] and newer retinoids to induce differentiation of cell death are being investigated. Finally, betulinic acid is a novel agent that induces apoptosis by triggering release of pro-apoptotic factors from mitochondria, and this agent may have therapeutic value in neuroblastomas. [568,569 and 570]

In summary, considerable progress has been made in understanding the genetic basis of clinical heterogeneity in neuroblastomas. Tumors at diagnosis can be more accurately categorized as having a low, intermediate, or high risk of relapse, and this has resulted in less overtreatment or undertreatment than when therapy was based on clinical variables alone. Improvements have also occurred in the cure rates of these patients with more judicious use of conventional therapeutic agents, with or without cytokine support or stem cell rescue. The real challenge is to translate our new insights concerning the biology of this disease into novel approaches to treatment that target critical pathways involved in tumor cell survival or maintenance of the malignant state. It is encouraging that we are already beginning to meet this challenge, so the prospects for the future look promising.

# RHABDOMYOSARCOMA AND THE UNDIFFERENTIATED SARCOMAS

LEONARD H. WEXLER
WILLIAM M. CRIST
LEE J. HELMAN

## INTRODUCTION

A malignant tumor of mesenchymal cell origin is called a *sarcoma*. Mesenchymal cells normally mature into skeletal muscle, smooth muscle, fat, fibrous tissue, bone, and cartilage. Rhabdomyosarcoma (RMS) is believed to arise from immature mesenchymal cells that are committed to skeletal muscle lineage, but these tumors can arise in tissues in which striated muscle is not normally found, such as in the urinary bladder. Undifferentiated sarcomas are mesenchymally derived tumors that cannot be ascribed to any specific lineage. Some tumors also may display multilineage markers, including ectomesenchymomas, which are tumors with evidence of both skeletal muscle and neuronal lineage, and malignant Triton tumors, which are malignant peripheral nerve sheath tumors (schwannomas) with evidence of rhabdomyoblastic elements.

The incidence of RMS is slightly less than one-half that of all other forms of non-RMS soft tissue sarcoma (NRSTS) combined. Important epidemiologic, biologic, and treatment differences exist both within the family of RMS and between RMS and NRSTS. Although RMS traditionally has been staged by a unique surgicopathologic staging system [the clinical group (CG) system], a recent move has been made to adopt a more uniform, modified (site-based) tumor-node-metastasis (TNM) staging system comparable to what has been used for adult NRSTS. The development of increasingly intensive, large-scale, international, collaborative, multimodality therapeutic protocols for treating these tumors, particularly the Intergroup Rhabdomyosarcoma Studies (IRS), has led to a steady improvement in the curability of these neoplasms, especially for the group of patients with locally extensive but unresectable tumors. Along with the improvements in outcome, however, have come increases in both short- and long-term sequelae of therapy.

## EPIDEMIOLOGY AND GENETICS

The annual incidence of RMS in children 20 years of age or younger is 4.3 cases per million children, with approximately 350 new cases diagnosed in the United States each year.[1] Among the extracranial solid tumors of childhood, RMS is the third most common neoplasm after neuroblastoma and Wilms' tumor. Almost two-thirds of cases of RMS are diagnosed in children aged 6 years or younger, with a smaller incidence peak in early-midadolescence. The tumor is slightly more common in boys and males (11.8 per million) than in girls and females (10.3 per million).[1] An international study confirmed previous reports of racial and gender differences in the incidence of RMS.[2] In the United States, the incidence of RMS for black females was found to be only one-half that for white females, whereas the rate for males was similar in both ethnic groups. The incidence of RMS in most of Asia appears to be lower than among mainly white populations in Western industrialized countries, confirming an earlier finding of a lower relative frequency of RMS in children of South Asian ethnic origin residing in Britain.[3]

Although these tumors may arise virtually anywhere in the body, certain distinctive clusters of features emerge regarding age at diagnosis, site of primary tumor, and histology. For example, head and neck tumors are most common in children younger than 8 years and, if arising in the orbit, almost always are of the embryonal variety. On the other hand, extremity tumors are seen more commonly in adolescents and are more frequently of the alveolar subtype. A unique form of RMS arising from the bladder or vagina—the botryoid variant (so named because of its resemblance to a protruding cluster of grapes)—is seen almost exclusively in infants.

Until recently, published studies of potential etiologic factors related to the development of RMS were composed of relatively small series. Although the overwhelming majority of cases of RMS occur sporadically, the development of RMS has been associated with certain familial syndromes, such as neurofibromatosis and the Li-Fraumeni syndrome (LFS), which includes familial clustering of RMS and other soft tissue tumors in children, with adrenocortical carcinoma and early-onset breast carcinoma in adult relatives.[4,5] The LFS has been associated with germline mutations of the p53 tumor suppressor gene.[6] In a study of 33 cases of sporadic RMS, 3 of 13 children younger than 3 years at diagnosis (as compared with none of the 20 children older than 3 years) were found to have germline mutations in their p53 gene.[7] This finding suggests that at least some very young children with seemingly sporadic RMS may have a hereditary predisposition to cancer or, possibly, an increased susceptibility to potentially toxic environmental agents (discussed later). It also raises the difficult ethical questions of whether family members of children younger than 3 years of age with a diagnosis of RMS may benefit from cancer risk screening,[8] and whether children with germline p53 mutations should have their therapy altered to minimize or reduce their exposures to potentially carcinogenic interventions (e.g., ionizing radiation, alkylating agents, epipodophyllotoxins).

The overall risk of a genetic predisposition to cancer has been estimated to be 7% to 33%, a range based on the patterns of cancer in the families of 151 children with soft tissue sarcoma.[9] These tumors included syndromes that appeared to be independent of p53 abnormalities. Of further interest, RMS has been observed in association with the Beckwith-Wiedemann syndrome, a fetal overgrowth syndrome marked by abnormalities on 11p15, where the insulin-like growth factor-2 (IGF-2) gene is located.[10] Some factors that may play a role in these phenomena are discussed later.

In a study of fetal loss and infant deaths in families of children with soft tissue sarcomas (two-thirds of which were RMS), 50 of the 157 families were classified as being genetically predisposed to cancer; one-third of these families had either classic LFS or a variant of LFS.[11] Reproductive loss was not related to index histology but was significantly higher in families with genetic disease than in those with sporadic disease, with most of the excess risk concentrated among the families affected by neurofibromatosis. Results of a large, national case-control study were reported in 1993; this study involved 322 RMS patients younger than 20 years and enrolled in the third IRS study (IRS-III) and an equal number of randomly selected age-, gender-, and race-matched controls.[12] Use of marijuana by a mother in the year before a child's birth was associated with a threefold increased risk of RMS in the child, and maternal cocaine use was associated with a fivefold increased risk. Use of marijuana, cocaine, or any recreational drug by a father also was associated with an approximately twofold increased risk. Consistent with a potential interaction between genetic susceptibility (e.g., germline p53 mutations) and environmental factors in the development of some cases of RMS, use of cocaine by the mother and

use of marijuana by both parents were associated with a significantly earlier age at diagnosis of RMS (as compared with that of all children in IRS-III).

## MOLECULAR BIOLOGY

Multiple molecular genetic alterations involving both muscle differentiation pathways and cell proliferation pathways appear likely to lead to the development of RMS. As the details of these pathways become better defined, lesions at any point within a given pathway likely will have similar consequences; thus, an entire pathway will have to be evaluated rather than looking at an isolated genetic alteration. For example, if alterations in the pRB pathway are common in RMS, p16, pRB, and CDK4 all would have to be considered as targets within this pathway. Much has been learned in the last decade regarding the specific molecular genetic alterations associated with the development of this tumor. In this section, known genetic alterations that occur in RMS are reviewed, as are the alterations in growth factors, oncogenes, and tumor suppressor genes that have been described in these tumors.

The two major histologic subtypes of RMS—embryonal (ERMS) and alveolar (ARMS)—have been found to have characteristic but distinct genetic alterations presumed to play a role in the pathogenesis of these tumors. ARMS has been demonstrated to have a characteristic translocation between the long arm of chromosome 2 and the long arm of chromosome 13, designated in shorthand notation as t(2;13)(q35;q14).[13,14] This translocation has been cloned molecularly and has been shown to involve the juxtaposition of the PAX3 gene (or, rarely, the PAX7 gene located at chromosome 1p36), believed to regulate transcription during early neuromuscular development, and the FKHR gene, a member of the forkhead family of transcription factors.[15,16] Presumably, the consequence of this fusion transcription factor is the abnormal activation of transcription from a gene or genes that contribute to the transformed phenotype. Although the precise consequence of this tumor-specific translocation remains to be elucidated, cDNA microarray analysis has shown that the PAX-FKHR fusion expressed in fibroblasts specifically turns on an array of myogenic factors.[17] Furthermore,PAX3-FKHR has been found to up-regulate c-MET expression, a receptor tyrosine kinase that has been implicated in transformation.[18] The polymerase chain reaction is likely to be used more widely in the near future for precise confirmation of the diagnosis of ARMS on the basis of genetics. Recently, a novel amplicon has been identified at 13q31 in approximately 20% of cases of ARMS, suggesting that one or more genes at this locus contribute to the pathogenesis of these tumors.[19]

The other major histologic subtype—ERMS—is known to have loss of heterozygosity (LOH) at the 11p15 locus.[20,21] Furthermore, this LOH has been shown to involve loss of maternal genetic information with duplication of paternal genetic material at this locus.[22] This region is of particular interest because it is the location of the IGF-2 gene, which codes for a growth factor believed to play a role in the pathogenesis of RMS (discussed later). IGF-2 has been demonstrated to be imprinted with only the paternal allele being transcriptionally active.[23,24] Therefore, it is conceivable that in this tumor, LOH with paternal disomy may lead to overexpression of IGF-2. However, also possible is that LOH at 11p15 may reflect the loss of a tumor suppressor activity that has not been identified or that both activation of IGF-2 and loss of tumor suppressor activity result from LOH at 11p15 in ERMS.[25]

One recent pilot study used comparative genomic hybridization and fluorescent *in situ* hybridization to identify novel genomic imbalances in patients with ERMS.[26] One particularly interesting area of loss was identified at 9q22, corresponding to the location of a presumed tumor suppressor gene that has been implicated in RMS genesis in a murine model of Gorlin syndrome (see the section Animal Models).

Several preliminary reports in the last decade suggested that ploidy (the number of chromosomes present in the tumor cell, generally measured by flow cytometry) was associated favorably with prognosis in patients with ERMS.[27,28] Specifically, diploid tumors (tumors with 46 chromosomes) were thought to have a prognosis worse than that of hyperdiploid tumors (tumors with more than 51 chromosomes); however, additional data supporting these initial observations have not been forthcoming.

Both ARMS and ERMS appear to overproduce IGF-2, a growth factor that has been shown to stimulate the growth of these tumor cells.[29] Blocking monoclonal antibodies directed against the receptor for IGF-2 (type 1 IGF receptor) have been demonstrated to inhibit growth of RMS both *in vitro* and *in vivo*.[29,30] Therefore, IGF-2 appears likely to play an important role in the unregulated growth of these tumors. The mechanism that leads to overproduction of IGF-2 in these tumors is unclear, although loss of imprinting of this locus has been implicated as one potential mechanism of IGF-2 overexpression.[31] Normal tissue, including fetal muscle, expresses IGF-2 only from the paternal allele; several cases of both ARMS and ERMS have shown expression from both parental alleles, a phenomenon termed *loss of imprinting*. The mechanisms involved in normal imprinting and the abnormalities that lead to loss of imprinting currently are the subject of much investigation.

Of further note, PAX3/FKHR expression can increase both IGF-2 expression and an IGF-binding protein, IGFBP-5.[17] The p53 tumor suppressor gene pathway has been implicated also in RMS. RMS tumors and cell lines evaluated have had loss-of-function p53 mutations that were diverse in nature.[32] Of interest is the finding of a codon-248 mutation in one RMS cell line, because a mutation at this codon has been observed also as a germline mutation in a case of LFS in which the index case was an RMS. Not known, however, is whether alterations in p53 function are primary events in the pathogenesis of these tumors or whether these alterations are associated more often with progression events. The true frequency of p53 mutations in RMS is unclear, but it appears to be relatively common.[33,34] As noted, to discern truly the role of p53 alterations in RMS, one needs to evaluate other molecules involved in p53 regulation. The two most prominent regulators of p53 function are MDM2 and $p19^{ARF}$. MDM2 negatively regulates p53, and this gene has been found to be amplified in RMS.[35,36 and 37] Another protein, $p19^{ARF}$, negatively regulates MDM2; thus, loss of $p19^{ARF}$ could be equivalent to MDM2 amplification or p53 loss. To date, the status of $p19^{ARF}$ has not been systematically evaluated in RMS.

The oncogene abnormalities observed most frequently in RMS are RAS mutations. Activated forms of both N-RAS and Kirsten-RAS (K-RAS) have been isolated from both RMS cell lines and tumor specimens.[38,39] A survey of ERMS tumor specimens found a 35% incidence of either activated N-RAS or K-RAS.[40] As with the p53 tumor suppressor gene, whether these alterations are involved primarily in the pathogenesis of these tumors or reflect secondary abnormalities that occur during progression events is not known. HER-2/neu gene amplification has not been studied well in RMS; only one of nine cases studied was demonstrated to have gene amplification in the one report published to date.[41]

The discovery of the myogenic basic helix-loop-helix (bHLH) MyoD family of proteins (including MyoD, myogenin, myf5, and MRF4) has greatly enhanced understanding of normal skeletal muscle differentiation.[42] These proteins function to commit mesenchymal cells to a skeletal muscle lineage and to activate their terminal differentiation program by inducing transcription of skeletal muscle–specific proteins, such as myosin and creatine kinase. The almost universal expression of MyoD family proteins in RMS provides further strong evidence of the skeletal muscle lineage of these tumors and has allowed for further refinement in the classification of pediatric sarcomas. For example, some cases that previously would have been called *undifferentiated sarcomas* can be classified as RMS on the basis of expression of these lineage-specific transcription factors.

However, the failure of RMS cells to differentiate terminally and the growth arrest that occurs despite the expression of these bHLH proteins has raised the question of what is altered in this pathway as compared with normal skeletal muscle cells. Initial studies aimed at answering this question suggested that RMS cells may lack a factor necessary for MyoD activity.[43] More recently, several investigators have suggested that MyoD may activate expression of p21, a cyclin-dependent kinase inhibitor that appears to function as a cell cycle arrest signal.[44,45 and 46] One possibility is that in normal skeletal muscle, bHLH proteins activate expression of p21, which leads to cell cycle exit, and also activate the expression of skeletal muscle–specific proteins, whereas some component of this pathway is defective in RMS cells, leading to continuous cell cycling despite expression of muscle-specific proteins. However, examination of p21 in 12 RMS tumor specimens failed to reveal the presence of mutations on either the coding region or promoter region of this gene.[47]

Abnormalities in the Rb pathway also have been implicated in RMS. In addition to RB, this pathway involves CDK-4/6, $G_1$ cyclins, and $p16^{INK4a}$. Both pRB and CDK-4 have been shown to be involved directly in normal myogenesis.[48,49,50,51 and 52] Although no mutations in RB have been demonstrated in RMS,[40,53] CDK4 has been shown to be amplified in RMS cell lines,[54] and loss of $p16^{INK4a}$ has been seen also in RMS cell lines and tumors.[55]

## ANIMAL MODELS

Several genetic models of RMS were created recently in mice. An earlier report demonstrated that SV40 T-antigen transgene, which can inactivate both p53 and pRB, led to the development of RMS at various anatomic sites.[56] More recently, a heterozygous knockout mouse lacking the PTC gene was shown to develop RMS at high frequency.[57] This is interesting, because the PTC gene is known to function as the receptor for Sonic Hedgehog, a known mediator of early skeletal muscle development.[58] Finally, a combined transgenic-knockout model wherein HGF is the transgene and the INK4 locus is knocked out, also has been found to lead to a high frequency of RMS (G. Merline, *personal communication*, 2000). Taken together, these mouse models of RMS provide evidence of the involvement of p53, pRB, and muscle differentiation pathways in the development of these tumors. Also likely is that these models will provide additional information regarding the

pathophysiology of RMS.

## PATHOLOGY

RMS falls into the broader category of small, round blue-cell tumors of childhood. The role of pathologists is to identify characteristic features, both by conventional light-microscopical techniques and by newer immunohistochemical, electron-microscopical, and molecular genetic techniques that allow a tumor to be classified as an RMS. The characteristic feature that permits such classification is the identification of skeletal myogenic lineage.

Typically, this classification consists of the light-microscopical identification of cross-striations characteristic of skeletal muscle, or characteristic rhabdomyoblasts. Immunohistochemical staining is a useful and reliable adjunctive means of identifying skeletal muscle and muscle-specific proteins or genes. These proteins include muscle-specific actin and myosin, desmin, myoglobin, Z-band protein, and MyoD.[59,60 and 61] Recently, myogenin expression was demonstrated to be present in 22 of 26 RMS specimens; however, it appeared that expression is significantly higher in ARMS than in ERMS.[62] Electron microscopy can provide additional information if light microscopy and immunohistochemistry results are ambiguous. The finding of actin-myosin bundles or Z-band material on electron-microscopical analysis provides strong support for a diagnosis of RMS.

Traditionally, RMS was classified according to the system of Horn and Enterline as embryonal, botryoid (a subtype of embryonal), alveolar, and pleomorphic.[63] The two major variants of RMS—embryonal and alveolar—have relatively characteristic histologic appearances and have specific and distinctive molecular genetic abnormalities, as described (Fig. 32-1). Histologic appearance, which is based on the identification of typical cytologic and architectural features, usually is sufficiently distinctive to permit straightforward categorization of the two subtypes. However, at times, establishing a specific diagnosis is more difficult. An international pathology study to assess agreement within and between groups of pathologists specializing in the classification of RMS highlighted the proliferation of subtle differences in diagnostic criteria that had developed since the publication of the Horn and Enterline schema.[64,65 and 66] This prompted the development of a new International Classification of Rhabdomyosarcoma schema that was demonstrated to be both highly reproducible and prognostically useful.[67] Four broad subtypes of RMS were established: (a) botryoid and spindle-cell RMS (both less common variants of ERMS), generally having a superior prognosis; (b) ERMS, generally having an intermediate prognosis; (c) alveolar (including the solid alveolar variant) RMS, generally having a poorer prognosis; and (d) undifferentiated sarcoma, also generally having a poorer prognosis. Finally, a category of sarcoma not otherwise specified was created for tumors that could not be classified into a specific subtype.

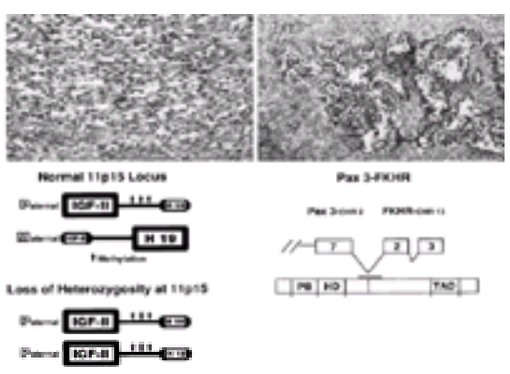

**FIGURE 32-1.** Light-microscopical appearance and genetic alterations indicative of embryonal and alveolar rhabdomyosarcoma (RMS). Embryonal RMS ( **A, C**): Typical spindle-shaped cells with stromal-rich appearance, characterized by loss of the maternal allele [loss of heterozygosity (LOH)] at 11p15 with duplication of the paternal allele. Note the paternal allele is characterized by expression of insulin-like growth factor-2 (IGF-2), whereas the maternal allele is characterized by expression of H19. Thus, LOH with paternal duplication leads to alleles with IGF-2 expression. Alveolar RMS ( **B, D**): Typical small round cells with dense appearance, lined up along spaces resembling pulmonary alveoli. These tumors are associated with a characteristic chromosomal translocation between the long arms of chromosomes 2 (more rarely, chromosome 1) and 13. This translocation fuses the paired-box (PB) and homeodomain (HD) DNA binding regions of the PAX3 gene with the transcriptional activation domain (TAD) of the FKHR gene. Horizontal line indicates fusion region of messenger RNA. (From Wexler LH, Helman LJ. Soft tissue sarcomas of childhood. In: Bast RC, Kufe DW, Pollock RE, et al. Cancer medicine, 5th edition. Hamilton: BC Decker Inc, 2000:2199.)

Under this new classification schema, embryonal tumors are diagnosed if the tumor has a stroma-rich, less dense, spindle-cell appearance and shows no evidence of an alveolar pattern. Variant forms of ERMS include the botryoid and leiomyomatous (spindle-cell) subtypes. The botryoid tumors have a particularly favorable prognosis and tend to arise almost exclusively from the bladder or vagina in infants and young children or from the nasopharynx in slightly older children.[68] Microscopically, they present as a polypoid mass growing under an epithelial surface and have as their characteristic feature the presence of a dense tumor cell layer under the epithelium (the cambium layer). The spindle-cell variants tend to arise disproportionately in the paratesticular region but may be seen also in the head and neck, extremities, and orbit.[69] These cells have a characteristic elongated, spindle appearance and grow either in a storiform pattern, with abundant collagen between the tumor cells, or in bundles, with a low to moderate amount of collagen. They almost always are associated with limited disease; they appear to have a pattern of behavior that is less aggressive than that of the classic embryonal tumors and an extremely good prognosis. Approximately two-thirds of newly diagnosed cases of RMS are of the embryonal subtype (Fig. 32-2).

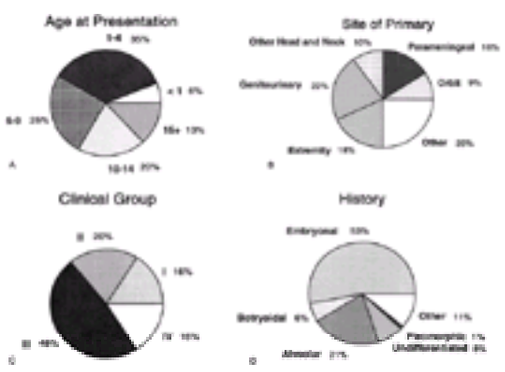

**FIGURE 32-2.** Clinical features of rhabdomyosarcoma (pooled data from Intergroup Rhabdomyosarcoma Studies I, II, and III[76,77 and 78]). **A:** Age at presentation. The median age at diagnosis is 5 years, and disease is diagnosed in almost two-thirds of patients before 10 years of age. **B:** Site of primary tumor. Approximately 35% of tumors arise in the head and neck (e.g., orbit, parameningeal sites); next most common are genitourinary tract tumors, followed by tumors of the extremities. **C:** Clinical group. Approximately half of all patients have unresectable tumors (clinical group III) at presentation. **D:** Histology. Although diagnostic criteria have evolved over time, more than 50% of all tumors are of the embryonal variety.

The presence of any alveolar pattern is sufficient to categorize the tumor as an alveolar subtype. Typically, these tumors are composed of densely packed, small, round cells lining septations that appear histologically reminiscent of pulmonary alveoli. A variant form, known as *solid ARMS*, has been identified in tumors that lack the characteristic architectural appearance (i.e., the alveolar septations) but have cells that are small, round, and densely packed.[65] The clinical behavior of the solid alveolar variant appears to be identical to that of the conventional alveolar subtype. Among newly diagnosed cases of RMS, 20% to 30% are of the alveolar subtype. Undifferentiated sarcomas generally are lacking in any defining cytologic or architectural features and fail to express antigenic markers that otherwise would allow their more precise classification. Although diagnosed largely by exclusion, these tumors generally are composed of diffuse, closely packed, large, round cells, with scanty to moderate cytoplasm and with nuclei that typically are larger than those seen in RMS. This subtype appears to have a prognosis somewhere between that of ERMS and ARMS.[70] Pleomorphic RMS is diagnosed only rarely today; if anaplastic cells are present in large aggregates or diffuse sheets, this subtype also appears

to have a poor prognosis.[71]

When the diagnosis of RMS is uncertain or in need of further support, the application of molecular diagnostic approaches is helpful. The characteristic t(2;13)(q35;q14) abnormality can be determined by reverse transcriptase–polymerase chain reaction techniques and provides definitive evidence of an ARMS. This approach often requires the availability of fresh frozen tumor tissue for RNA extraction but increasingly can be carried out on material obtained from paraffin blocks. With ERMS, the availability of highly polymorphic markers at the 11p15 locus allows for the application of polymerase chain reaction technology for rapid identification of LOH of 11p15 in paraffin sections.[72]

Evidence has been conflicting concerning the prognostic significance of histology. [65,73] Although histology was found to be an important prognostic variable in IRS-II, its significance no longer was seen with the more intensive, risk-based therapy of IRS-III (see the section Prognostic Considerations).[74,75,76,77 and 78] Previous analyses of the prognostic significance of histologic subtype in noncontemporaneously treated patients may have suffered from differences in diagnostic criteria. [68,79,80,81,82 and 83] More recent data, however, strongly support the independent prognostic significance of histology. Investigators from the National Cancer Institute and St. Jude Children's Research Hospital evaluated a group of 159 patients with RMS treated at the two institutions over a 15-year period. [65] Among patients with nonmetastatic tumors, histology was found to be an independent prognostic variable, with embryonal tumors having an outcome better than that of the identically behaving alveolar or solid alveolar tumor variants (6-year survival rate, 60% vs. 25%; $p = .001$). In a study of outcome among 264 patients with orbital RMS treated on IRS-I through IRS-III and IRS-IV pilot, the 5-year survival for the 221 patients with ERMS (and variant subtypes) was 94% versus 74% for the 24 children with ARMS ( $p<.001$).[84] Finally, a preliminary report from IRS-IV (in which, unlike that in IRS-III, treatment was identical regardless of histology) suggests that alveolar histology truly does define a population of patients' tumors that are more aggressive and have a poorer prognosis. [85]

One important caveat in the interpretation of these preliminary data is the need to perform multivariate analyses to account for the clustering of histologic subtype with site and tumor size and invasiveness. For example, a report of outcome among 139 patients, who had extremity RMS (more than two-thirds of whom had ARMS) and were treated on IRS-IV, identified group (extent of initial surgical resection) and stage (tumor size or regional lymph node positivity, or both), but not histologic subtype, as the variables most predictive of outcome.[86]

The application of molecular pathology to classification of RMS subtypes may help to resolve some of these controversies by the use of more objective criteria based on genetic differences between alveolar and embryonal tumors. It also may address questions regarding the pathogenesis of these tumors and may prove useful at defining distinct prognostic subgroups within categories of histologic subtype. For example, one recent study suggested that patients with the variant PAX7-FKHR translocation have a more favorable prognosis than do those with the more common PAX3-FKHR translocation.[87] Even more intriguing is a preliminary report suggesting a strikingly better outcome among patients with metastatic disease and variant-translocation-positive ARMS (estimated 4-year overall survival, 75% vs. 8% for patients with PAX3-FKHR-positive ARMS; $p = .0015$).[88]

## PATTERNS OF SPREAD AND CLINICAL PRESENTATION

The biologic behaviors of RMS and undifferentiated sarcoma are similar and have become increasingly well understood in the last 30 years as treatment techniques have improved. In the early prechemotherapy era, RMS had a uniformly high rate (65% to 80%) of eventual metastasis after local control measures alone. [89,90 and 91] In the current combined-modality therapy era, the development of effective adjuvant chemotherapy regimens has led to a clearer picture of the patterns of metastatic spread after treatment failure.[92,93 and 94] Fewer than 25% of patients with newly diagnosed disease have distant metastases, and almost one-half of those patients have only a single site of involvement (most commonly consisting of one or more pulmonary metastases). The lung is the most frequent site of metastasis (40% to 50%); less common sites, either isolated or in conjunction with multimetastatic disease, are bone marrow (20% to 30%), bone (10%), and, depending on the site of the primary tumor, lymph node (up to 20%).[95,96,97,98 and 99] Visceral organ metastases are rare in patients with newly diagnosed disease. These same sites are common locations for distant failure in patients who relapse after receiving systemic therapy; however, preterminally, visceral metastases (e.g., brain, liver) may be seen in up to 25% of patients.[74]

RMS and undifferentiated sarcoma produce clinically evident signs and symptoms in two main ways: the appearance of a mass lesion in a body region without history of temporally associated trauma and the disturbance of a normal body function by an otherwise unsuspected, critically located enlarging tumor (or enlarging regional or distant lymph nodes).[98,99] Typical signs, symptoms, and patterns of spread are discussed in terms of the primary tumor and are summarized here.

In the first three IRS trials, approximately 35% to 40% of all tumors arose from a site in the head or neck region (orbit, parameningeal, other head and neck); slightly fewer than 25% from the genitourinary tract (bladder and prostate, vagina and uterus, paratesticular); approximately 20% from an extremity; and the remainder from truncal primary tumors and other miscellaneous sites (approximately 10% each; Fig. 32-2).[76,77 and 78]

### Head and Neck Region

Approximately 25% of head and neck sarcomas arise in the orbit, 50% in other parameningeal sites, and 25% in nonorbital, nonparameningeal locations, such as the scalp, face, buccal mucosa, oropharynx, larynx, and neck (Fig. 32-3).[100] The gender ratio is almost equal, and the median age at diagnosis is approximately 6 years. Orbit-eyelid tumors produce proptosis and, occasionally, ophthalmoplegia. [101] Tumors in this site usually are diagnosed before distant dissemination has taken place. Regional lymph node spread is unusual, probably because the orbit is supplied only scantily with lymphatic channels. Nonorbital parameningeal sarcomas arise most commonly in the nasopharynx and paranasal sinuses, the middle ear and mastoid region, and the pterygoid-infratemporal fossae. These tumors usually produce nasal, aural, or sinus obstruction, with or without a mucopurulent and sometimes sanguinous discharge. Cranial nerve palsy, sometimes multiple, indicates direct extension toward the meninges.[102,103,104 and 105] Headache, vomiting, and systemic hypertension may result from intracranial growth of tumor after erosion of contiguous bone at the cranial base.[105,106] Autopsy studies show diffuse involvement of the cranial and spinal meninges reminiscent of central nervous system leukemia. [107] These tumors can spread also distantly, primarily to lungs or bones.[108] Craniocervical sarcomas arising in areas other than the orbit and parameningeal sites usually present as painless, progressively enlarging growths and tend to remain localized. [109,110]

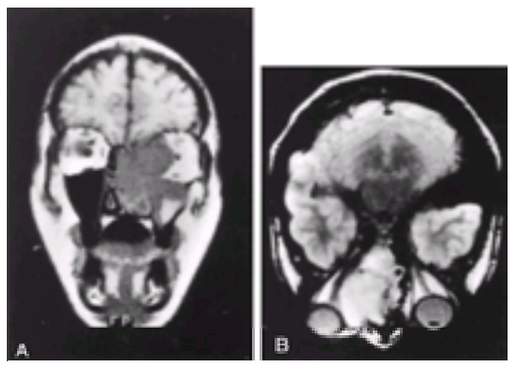

**FIGURE 32-3.** Radiographic appearance of TNM stage 3 rhabdomyosarcoma of the head and neck (parameningeal) region. **A:** Large tumor (>5-cm maximum diameter) originating in the ethmoid sinus, invading the left orbit (T2b), and eroding through the base of skull. Ipsilateral cervical lymph nodes (not shown) were clinically enlarged and pathologically involved by tumor (N1). The patient was treated for sinusitis for 1 month before the correct diagnosis was made. **B:** The tumor caused significant proptosis and nasal congestion, both of which resolved within 72 hours after the initiation of systemic chemotherapy. (From Wexler LH, Helman LJ. Pediatric soft tissue sarcomas. CA Cancer J Clin 1994;44:211, with permission.)

### Genitourinary Tract

Genitourinary tract sarcomas are seen most frequently in the bladder and prostate ( Fig. 32-4, Fig. 32-5).[111] Bladder tumors tend to grow intraluminally in or near the trigone and have a polypoid appearance on gross or endoscopic examination. Hematuria, urinary obstruction, and, occasionally, the extrusion of mucosanguineous

tissue can occur, particularly if the tumor is botryoid. Affected children usually are younger than age 4. Prostate tumors usually produce large pelvic masses with or without urethral strangury; constipation may occur. These tumors can occur in infants or older children; even adults may be affected. [112] Bladder tumors tend to remain localized, but prostate tumors often disseminate early to lungs and sometimes to bone marrow or bones. [113,114]

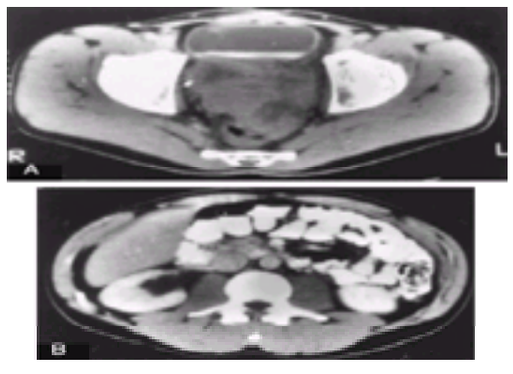

**FIGURE 32-4.** Radiographic appearance of rhabdomyosarcoma of the bladder-prostate region. **A:** This patient presented with a large infiltrating, unresectable tumor (T2b, TNM stage 3, clinical group III) causing obstipation and a palpable mass on rectal examination. **B:** These tumors can grow very large before they are detected, often leading to obstruction of the ureters and hydronephrosis (seen in the right kidney). Cystectomy or pelvic exenteration rarely is indicated in the primary surgical management of these tumors. (From Wexler LH, Helman LJ. Pediatric soft tissue sarcomas. CA Cancer J Clin 1994;44:211, with permission.)

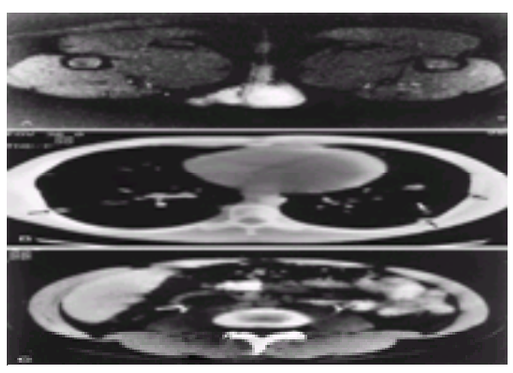

**FIGURE 32-5.** Radiographic appearance of rhabdomyosarcoma of the paratesticular region. **A:** This patient presented with a firm, nontender, small scrotal mass (T1a) that was completely resected (clinical group I). He subsequently was found to have distant pulmonary **(B)** and lymph node **(C)** metastases (*black and white arrows*) and multiple bony metastases (not shown), which increased the stage of the lesion to TNM stage 4.

Male and female genital tracts can harbor sarcoma. [115] Vaginal tumors commonly are botryoid and are found almost exclusively in very young children who may have a mucosanguineous discharge reminiscent of that seen with a foreign body. [116] Cervical and uterine sarcomas are diagnosed more commonly in older girls than in infants and present with a mass, with or without vaginal discharge. Regional nodal involvement is uncommon. [98,99] Paratesticular tumors usually produce painless, unilateral scrotal or inguinal enlargement in prepubertal or postpubertal male patients. The risk of tumor dissemination to regional retroperitoneal lymph nodes appears to be linked closely to age at diagnosis, being distinctly uncommon in boys younger than age 10 and being present in 50% or more of older boys. [117] Alveolar histology is distinctly unusual in sarcomas of the genitourinary tract. [111]

### Extremities

Sarcomas of the extremity are characterized by swelling in the affected body part (Fig. 32-6). The male-female ratio is approximately 1:1. Pain, tenderness, and redness may occur. Between one-half and three-fourths of these tumors are alveolar. [86,118] Regional lymph node spread may be found in up to one-half of patients undergoing surgical exploration and is more likely if the primary tumor is an ARMS rather than an ERMS or undifferentiated sarcoma. [86,92,118,119 and 120] The tumors can be extensive because of their propensity to spread along fascial planes. The fact that injuries are frequent and expected on the extremities of school-aged children may lead to a delay in diagnosis.

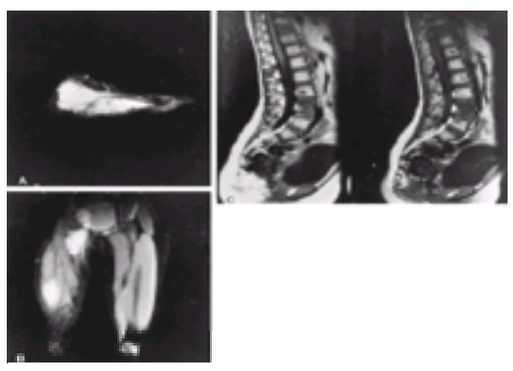

**FIGURE 32-6.** Radiographic appearance of rhabdomyosarcoma of the extremity. This patient presented with a painless, rapidly enlarging mass of the plantar surface of the right foot **(A)**. Biopsy of the mass revealed it to be an alveolar rhabdomyosarcoma. These tumors typically develop in adolescents and are associated with an aggressive clinical course and a propensity to spread to lymph nodes. Physical examination and radiographic staging studies demonstrated the presence of soft tissue and lymph node metastases in the popliteal fossa (not shown) and in the distal anterior thigh and inguinal pelvic region **(B)**, as well as osseous metastases involving numerous vertebral bodies **(C)**. (From Wexler LH, Helman LJ. Pediatric soft tissue sarcomas. CA Cancer J Clin 1994;44:211, with permission.)

### Trunk

Truncal sarcomas are similar in evolution to those of the extremities in that they exhibit all histologic types and have a tendency for local recurrence despite wide local excision and for distant spread. They are of relatively large diameter as compared with tumors of the head and neck or of the bladder. [121,122] Contiguous involvement of the thoracolumbar spine may exist, depending on the location of the primary lesion, but regional lymph node spread is unusual.

### Other Sites

#### *Intrathoracic and Retroperitoneal and Pelvic Regions*

Intrathoracic and retroperitoneal-pelvic tumors can become large before a diagnosis is made because they are deep within the body. [123] They often are incompletely accessible to a surgeon, because vital vessels usually are surrounded and wide infiltration is the rule; however, more recent data fail to support the notion that

differences in outcome for patients with thoracic tumors are accounted for by a higher proportion of patients with unresectable disease. [124] Patients with tumors in these locations have a higher-than-expected risk of local recurrence despite combined-modality treatment. Aggressive attempts at initial or delayed surgical resection, combined with appropriate postoperative radiotherapy (RT), may improve prognosis. [125]

### *Perineal and Perianal Region*

Lesions in the perineal-perianal region are unusual. They can mimic abscesses or polyps and often are alveolar. [126] In the IRS, a relatively high incidence of regional lymph node involvement was reported for the first series of patients with disease located in this region. [127]

### *Biliary Tract*

Biliary tract tumors are even rarer than perineal-perianal tumors. They often produce obstructive jaundice, spread within the liver, and then spread to the retroperitoneum or lungs.[128,129 and 130] Aggressive surgical resection appears to be less important to good outcome for tumors in this location. [131]

### *Miscellaneous Potential Sites of Spread*

Occasionally, the liver, brain, trachea, heart, breast, or ovary may harbor a primary sarcoma. [132,133,134,135,136 and 137] In some cases, no definite primary site can be determined.[138]

## METHODS OF DIAGNOSIS

The differential diagnosis of RMS and undifferentiated sarcoma includes other oncologic entities and an assortment of nononcologic conditions. Trauma may produce an enlarging soft tissue mass, especially over the extremities, face, or trunk. Usually, a history of an accident is available, and an associated hematoma is tender and discolored. Sarcomas usually are nontender and impart no unusual hue to the overlying skin or subcutaneous tissue. Growth of a nontender mass, especially without a clear-cut history of trauma, always should alert the examiner to consider biopsy, especially if expansion is confirmed by repeated observations over 1 to 2 weeks. A mass within a body cavity can produce obstruction or discharge; both mandate a biopsy.

On rare occasions, cystitis may produce imaging and cystoscopic findings that mimic the appearance of RMS of the bladder; however, follow-up imaging almost always shows a return to normal over the course of 1 to 2 weeks, precluding the need for biopsy under those circumstances. [139] Occasionally, a histologically benign lesion, such as a lipoma, rhabdomyoma, or neurofibroma, may be diagnosed; if so, complete surgical removal should be performed if mutilation can be avoided. Rarely, an unusual condition, such as myositis ossificans, pyogenic myositis, or inflammatory myofibrohistiocytic proliferation (also known as *pseudosarcomatous myofibroblastic tumor* or *inflammatory pseudotumor of the bladder*), may be discovered.[140,141,142,143 and 144] This last condition is a recently described, rare, benign lesion that may create difficulty in differentiation from RMS by conventional diagnostic techniques. [145] It may present as an ulcerated, hemorrhagic, polypoid growth with intraluminal invasion that is found in the course of routine radiologic evaluation of hematuria and dysuria (not uniformly associated with documented cystitis).

Biopsy should be considered also if a young person has a mass and is failing to thrive, even if the affected region is tender and the patient is febrile (if appropriate studies for infection have been nonproductive), because a treatable neoplasm may be the underlying disorder. Other childhood malignancies can mimic RMS or undifferentiated sarcoma. Non-Hodgkin's lymphoma, neuroblastoma, and Ewing's sarcoma can simulate sarcoma at the light-microscopical level, and special stains, electron-microscopical ultrastructure studies, monoclonal antibody assays, and collection of urine for catecholamine excretion studies may be necessary to differentiate these entities. Occasionally, a leukemic chloroma or collection of histiocytes (e.g., Langerhans' cell histiocytosis) can produce unilateral proptosis or a mass in another body region, which should undergo biopsy to establish the correct diagnosis. [146,147]

After the diagnosis of RMS or undifferentiated sarcoma has been entertained and even without confirmatory pathologic material, several clinical and radiographic studies may be in order to define the limits of the lesion and to seek evidence of spread. A complete physical examination should be performed, with particular attention paid to regional lymphatic structures and to the surrounding tissues. Laboratory studies that should be obtained simultaneously include a complete blood count with differential count, serum electrolytes, blood urea nitrogen and creatinine levels, liver function tests, serum calcium, phosphorus, and magnesium levels, and a uric acid level, in anticipation of chemotherapy. Patients with bone marrow metastases from a primary sarcoma may have altered peripheral blood values, but bilateral bone marrow aspirations and core needle biopsies should be performed routinely even in the absence of altered blood counts or obvious metastases. Although disseminated intravascular coagulation is uncommon, even among patients with bone marrow involvement, baseline coagulation studies (prothrombin time, activated partial thromboplastin time, fibrinogen) should be performed in all patients, and appropriate supportive care measures should be initiated if evidence of the condition is found. [111] Metastatic bone involvement rarely can be complicated by hypercalcemia. [148,149]

Radiographic studies should include plain films of the affected part and a skeletal survey. Nuclear medicine scans using technetium-99m diphosphonate may be useful in the search for osseous metastases. [150] Technetium-99m bone scans are highly sensitive and relatively specific for detecting osseous metastases and probably are more reliable than a routine skeletal survey. [151,152] Gallium-67 can be concentrated in the bowel and in areas of inflammation, and it is not usually a routine part of the diagnostic workup. [152]

Computed tomography scans, with or without contrast enhancement, long have been the standard imaging modality. Preoperative scanning is critical to enable the radiation therapist to assess the volume at risk for subclinical tumor invasion and to plan treatment fields. [153] Imaging of the abdomen and pelvis also may be useful for detecting clinically occult abnormalities of the genitourinary tract. Ultrasonographic examinations may be especially useful as an adjunct to computed tomography in serial assessment of tumors of the pelvis (including the bladder, prostate, and retroperitoneum), because the characteristic water density of the urine-filled bladder helps in localization. [154] Ultrasonography does not use radiation, and dye injection is unnecessary. Magnetic resonance imaging is increasingly becoming the imaging modality of choice, especially for head and neck, extremity, and pelvic tumors, because of its multiplanar capability, its ability to attenuate bone artifact, and the superior soft tissue contrast that it provides. [155,156,157 and 158]

### Staging

Assessing the extent of the tumor in every patient is critical, because therapy and prognosis depend on the degree to which the mass has spread beyond the primary site. Patients with localized, surgically removable tumors have a prognosis better than that in those whose disease has produced clinically detectable metastatic deposits. Two major staging systems currently are employed in combination: the older Children's Oncology Group surgicopathologic staging system (designated by the phrase *clinical group*, or *CG*, followed by a number), developed by the IRSG in 1972 (Table 32-1), and the more recent pretreatment, site-modified TNM staging system (indicated simply by the word *stage* followed by a number), developed by the IRSG for use in IRS-IV (Table 32-2).[159] The CG system defines patients by the extent of their initial surgery, further subclassifying patients with microscopic residual disease (CG II) with or without regional nodal involvement (IIB, C, or IIA, respectively). The TNM system, which was evaluated retrospectively by numerous investigators and was shown to be highly predictive of outcome, divides patients into favorable and unfavorable sites and requires up-staging of patients with unfavorable-site tumors that are large (more than 5 cm) or have clinical evidence of regional nodal involvement (N1).[81,82 and 83,159] Favorable sites include the orbit and eyelid and other nonparameningeal head and neck structures, as well as nonbladder, nonprostate genitourinary locations (paratesticular and vulva, vagina, or uterus). Among the unfavorable sites are the extremities (including the buttocks and perineum), urinary bladder and prostate, cranial parameningeal sites, and the trunk and retroperitoneum.

| Clinical group | Extent of disease and surgical result |
|---|---|
| I | A. Localized tumor, confined to site of origin, completely resected<br>B. Localized tumor, infiltrating beyond site of origin, completely resected |
| II | A. Localized tumor, gross total resection, but with microscopical residual disease<br>B. Locally "extensive" tumor (spread to regional lymph nodes), completely resected<br>C. "Extensive" tumor (spread to regional lymph nodes), gross total resection, but with microscopical residual disease |
| III | A. Localized or locally extensive tumor, gross residual disease after biopsy only<br>B. Localized or locally extensive tumor, gross residual disease after "major" resection (>50% debulking) |
| IV | Any size primary tumor, with or without regional lymph node involvement, with distant metastases, irrespective of surgical approach to primary tumor |

**TABLE 32-1. CLINICAL GROUP STAGING SYSTEM EMPLOYED IN INTERGROUP RHABDOMYOSARCOMA STUDIES I THROUGH III**

| Stage | Sites | T Invasiveness | T size | N | M |
|---|---|---|---|---|---|
| 1 | Orbit<br>Head and neck[b]<br>Genitourinary[c] | T1 or T2 | a or b | N0, N1, or Nx | M0 |
| 2 | Bladder/prostate<br>Extremity<br>Cranial parameningeal<br>Other[d] | T1 or T2 | a | N0 or Nx | M0 |
| | | T1 or T2 | b | N0, N1, or Nx | M0 |
| 4 | All | T1 or T2 | a or b | N0 or N1 | M1 |

[a]T (tumor): T1, confined to anatomic site of origin; T2, extension; a, ≤5 cm in diameter; b, >5 cm in diameter. N (regional nodes): N0, not clinically involved; N1, clinically involved; Nx, clinical status unknown. M (metastases): M0, no distant metastases; M1, distant metastasis present.
[b]Excluding parameningeal.
[c]Nonbladder/nonprostate.
[d]Includes trunk, retroperitoneum, and so on.

**TABLE 32-2. TNM STAGING[a] OF RHABDOMYOSARCOMA: TNM PRETREATMENT STAGING CLASSIFICATION FOR INTERGROUP RHABDOMYOSARCOMA STUDY IV**

The likelihood of infiltration of regional lymph nodes or adjacent structures varies with the site of the primary tumor, ranging from as low as 5% for head and neck tumors to as high as 50% for extremity and paratesticular tumors (in older boys).[86,98,99] Imaging studies and physical examination findings usually are adequate for establishing the presence of regional nodal involvement. Any palpably or radiographically enlarged regional lymph node at any site should be removed and submitted for pathologic examination. Routine surgical sampling of radiographically “benign” regional nodes is unwarranted with two important exceptions: All cases of extremity RMS should undergo aggressive sampling of regional nodal basins, and older boys (age 10) with paratesticular tumors should undergo ipsilateral lymph node dissection. RT is delivered to the region if tumor involvement of nodes is found on pathologic examination. Radiographic studies and bone marrow examination are used to ascertain whether distant metastases are present; histologic verification of radiographic abnormalities is not required. However, where treatment issues will be determined by the presence or absence of metastatic disease, surgical evaluation of an equivocal radiographic abnormality may be warranted. Histologic subtype does not affect either the stage or clinical group, although it may have an impact on systemic or local treatment choices [e.g., the use of local irradiation in completely resected (group I), low-stage (1 to 2) ARMS].[160]

### Prognostic Considerations

The identification of prognostic variables is of major importance in understanding the behavior of sarcomas and developing careful clinical trials, the goals of which are to improve survival for all patients with RMS and undifferentiated sarcoma and to reduce morbidity. Several key prognostic variables have been identified and currently are being used in IRS-V to define risk-adapted therapy ( Table 32-3). These variables, which define distinct groups of patients with excellent, very good, intermediate, and poor prognoses, include (a) the presence or absence of distant metastases (with two important exceptions, discussed later); (b) site (favorable vs. unfavorable, with the most favorable site being the orbit); (c) surgical resectability (groups I and II vs. group III, excluding the orbit); (d) histology (ERMS and variants vs. ARMS and undifferentiated sarcoma); and (e) age.[161] As discussed, recent data suggest that the specific type of molecular abnormality present in ARMS may be prognostically significant, particularly for patients with metastases.

**TABLE 32-3. PROGNOSTIC STRATIFICATION FOR RHABDOMYOSARCOMA**

Patients with no detectable metastases at diagnosis fare much better than do those with widespread disease ( Fig. 32-7).[76,77] and [78,162] Among patients with localized sarcoma, those with completely excised tumors (CG I) have a survival rate better than that of those with microscopic residual tumor or with excised but regionally extensive lesions (CG II). Among patients with microscopic residual disease, those without regional nodal involvement (CG IIA) or with completely resected regional nodes (CG IIB) fare better than do those with both [CG IIC; 5-year failure-free survival (FFS), 75% vs. 74% vs. 58% for patients with CG IIA, IIB, and IIC, respectively; $p = .004$].[163] Patients with gross residual disease (CG III) do not fare as well; however, for patients with ERMS, outcome within this group varies according to whether the tumor originates in a favorable site (92% 3-year FFS) or an unfavorable site (75% 3-year FFS). [164] Although young patients (younger than age 10) with metastatic ERMS[165] and those with variant-translocation-positive (PAX7-FKHR) metastatic ARMS[88] may have an intermediate prognosis (approximately 50%), the prognosis for most patients with metastatic RMS remains grim. The most meaningful prognostic variable is the response to treatment, because those in whom complete obliteration of the tumor never is achieved (i.e., a complete pathologic response to therapy) do not survive. Early response to treatment appears to correlate with a better outcome.[166]

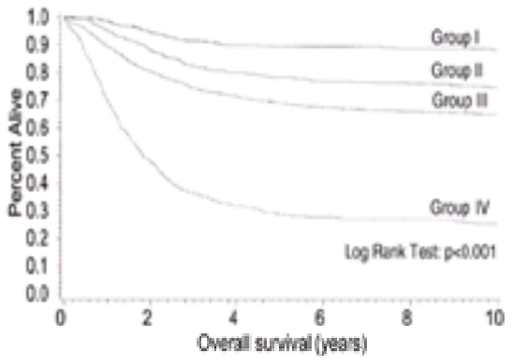

**FIGURE 32-7.** Survival of patients treated on Intergroup Rhabdomyosarcoma Studies (IRS)-I, -II, -III/IV-P (IV pilot), and -IV by clinical group at diagnosis. A significant difference is seen in outcome by extent of initial surgical resection, with the best outcome among patients with completely resected tumors (group 1), followed by those with microscopical residual (group 2) and gross residual (group 3) disease. Patients with metastatic disease (group 4) at diagnosis fare poorly. (JR Anderson, *personal communication,* 2000.)

## TREATMENT

The three currently recognized modalities of treating children with sarcomas are surgical removal (if feasible), RT for control of residual bulk or microscopic tumor, and systemic chemotherapy for primary cytoreduction and eradication of gross metastases and micrometastases. Much of the information regarding current use of these modalities derives from therapeutic programs developed by the IRSG.

### Principles of Surgical Management

Surgery is the most rapid way to ablate the disease, and it always should be used if subsequent function or cosmesis will not be greatly impaired. In some sites, such as the vagina and female genital tract, the urinary bladder, the orbit, and the biliary tract, aggressive surgical treatment is unwarranted. In other sites, such as the head and neck, a diagnostic incisional biopsy may be the only feasible surgical procedure because of proximity to vital blood vessels and nerves, cosmetic considerations, or both. If microscopic residual disease is found after an initial excision or if the initial operation was carried out without knowledge of the type of neoplasm involved, reexcision of the area may be indicated. In localized lesions of the trunk and extremities, improvement in survival time can be produced by primary surgical reexcision of all residual tumor before the initiation of chemotherapy. [124,167] Occasionally, debulking surgery is used to reduce the volume of residual tumor beyond that which would remain after incisional biopsy alone. Carefully reviewed data in support of this theoretically reasonable maneuver for children with RMS or undifferentiated sarcoma are not available.

Second-look surgical procedures have been evaluated in three clinical circumstances: (a) to verify pathologically the completeness of an apparently complete clinical (radiographic) remission for the purpose of then eliminating further local control measures, such as RT; (b) to resect any residual viable tumor cells that have survived after induction chemotherapy and local irradiation; and (c) to permit a reduction in the dose of radiation in patients who initially present with group III tumors.

The International Society of Pediatric Oncology enrolled 425 patients in their 1984 Malignant Mesenchymal Tumors Study, which consisted of nonradical surgery or biopsy followed by three to six cycles of induction chemotherapy with vincristine, actinomycin-D, and ifosfamide (VAI). [168] Definitive local treatment (surgery or RT) depended on the response to chemotherapy. Additional local therapy was not given to patients having no evidence of residual tumor after induction therapy. Of 237 patients with initially incompletely resected, nonparameningeal localized tumors, 140 (including 92 with RMS) achieved a complete clinical response to induction chemotherapy. Approximately one-half of these patients, who received no further local therapy, ultimately had local recurrence, and no difference was noted in the local recurrence rate between patients undergoing biopsy confirmation of complete remission status (26 of 52) and those followed up clinically (18 of 39). Therefore, as a strategy to permit the withholding of definitive local therapy after the achievement of a complete clinical response, biopsy confirmation is inappropriate because of the high rate of false-negative results and the unacceptable local relapse rate when such an approach is followed.

Data regarding the role of secondary (second-look) operations to resect residual viable tumor after the administration of definitive local therapy were collected in CG III patients enrolled in IRS-III, for whom a delayed resection of the residual primary tumor was recommended, whenever possible, after the first 20 weeks of treatment (i.e., after the completion of induction chemotherapy and local RT). Second-look operations were found to produce complete responses by removing residual tumor after primary chemotherapy and RT and to improve the accuracy of clinical and radiologic assessment of response by providing tissue for pathologic examination.[78,169,170] Sixty-four percent of CG III patients who underwent secondary operations in radiographic partial remission were found to be in complete remission and, more important, 52% of those who underwent secondary operations after achieving only a minor response (less than 50% regression in cross-sectional tumor diameter) were converted to complete remission status by the procedure. These findings formed the basis of the IRS committee's cautious endorsement of the role of second-look surgery for CG III patients in partial remission after induction chemotherapy and RT. The committee acknowledged, however, that the contribution of second-look surgery to the improvement in long-term survival of these patients could not be assessed adequately because of the frequent concomitant use of alternative induction therapy in those same persons. [78]

Finally, investigators at St. Jude Children's Research Hospital reported maintenance of local control in 22 of 28 patients with initial group III tumors treated with lower-than-standard dose irradiation after being rendered free of gross disease with chemotherapy alone (n = 16) or in conjunction with surgery (n = 12). [171] A trend occurred toward improved local control within this group among patients receiving 40 Gy versus those receiving less than 40 Gy (15 of 17 vs. 7 of 11; $p<.14$). These preliminary results form the basis for a more formal evaluation of the role of second-look surgery in reducing the risk of local recurrence (and the dose of local irradiation) in patients with initially unresectable tumors being treated on IRS-V.

#### *Tumors of the Head and Neck*

Head and neck tumors, with the exception of those arising in relatively superficial locations, rarely are amenable to wide local excision. Incisional biopsy for diagnostic purposes usually is all that is feasible and, in the case of orbital tumors, it is all that is necessary, given the excellent results achieved with chemotherapy and RT regimens. Unless clinically suspicious nodes are present, routine cervical lymph node sampling is unnecessary, because the incidence of regional lymph node involvement is fairly low. The availability of highly skilled otolaryngology and craniofacial reconstruction teams at select institutions may permit the resection of some tumors that otherwise would be unresectable.[172]

#### *Tumors of the Genitourinary Tract*

### Paratesticular Tumors

Paratesticular tumors should be removed by radical inguinal orchidectomy with resection of the entire spermatic cord. An inguinal approach is used to avoid scrotal contamination, which is likely if a transscrotal biopsy is performed. The necessity of subsequent retroperitoneal lymph node dissection (RPLND), which is undertaken to determine whether regional retroperitoneal lymph nodes harbor tumor deposits, has been controversial. Although at least one European study had advised avoidance of RPLND if radical inguinal orchiectomy resulted in complete microscopic excision and if radiographic imaging studies were normal, [173] the IRS committee continued to recommend the procedure in IRS-III. RPLND was performed in 121 patients with nonmetastatic paratesticular RMS treated on IRS-III. [174] Only 14% of patients without radiographic evidence of lymph node involvement were found to have pathologically involved nodes, whereas 94% of those with radiographically enlarged nodes were confirmed to have nodal involvement. Only patients with pathologically confirmed positive nodes received RT in addition to postoperative adjuvant chemotherapy. The 5-year survival rate was significantly better for those patients with clinically negative lymph nodes than for those with clinically positive nodes (96% vs. 69%; $p<.001$); however, treatment failures were usually caused by distant, not locoregional, lymph node disease recurrence. Therefore, routine RPLND was not recommended in the IRS-IV trial for patients with completely resected localized tumors and negative imaging studies, although systematic retroperitoneal lymph node sampling *was* recommended, including ipsilateral high and low infrarenal (caval, interaortocaval, and aortic) and bilateral iliac nodes. A preliminary analysis of IRS-IV data suggested that this approach resulted in a dramatic down-staging of patients (from group II to group I) and was associated with a

worse outcome, particularly for boys age 10 or older who were treated with two-drug (VA) chemotherapy.[175] These findings form the basis of the current IRS recommendation to perform ipsilateral RPLND in all boys who are at least 10 years of age at diagnosis. Surgical resection of enlarged lymph nodes in younger boys also is warranted to down-stage them from group III to group II. Given the inferior outcome of older boys treated on IRS-III (wherein surgical exploration was required),[174] an alternative approach to ipsilateral RPLND in such patients is the routine administration of more intensive three-drug chemotherapy (VA plus cyclophosphamide or ifosfamide).[176] Similarly, the necessity of postoperative irradiation in such patients with intensively treated resected retroperitoneal nodes has been called into question.[176] The small number of patients with known nodal tumor renders execution of a controlled study difficult.[177,178]

**Vulvar, Vaginal, and Uterine Tumors**

Wide local excision of vulvar and vaginal tumors rarely is indicated before the commencement of primary chemotherapy. These tumors usually respond sufficiently well to induction chemotherapy to render them easily resectable, often with histologically negative margins. Tumors of the proximal vagina may require hysterectomy with partial or complete vaginectomy. Uterine tumors usually are managed without oophorectomy in the absence of overt ovarian involvement. Most patients are not managed initially with hysterectomy but, for those in whom hysterectomy is performed, distal vaginal preservation usually is possible. Second-look surgery and radical resection of lesions in these areas usually are reserved for patients who have gross residual disease after the initial surgical resection and have either failed to achieve a complete radiographic response within 6 months after the completion of induction chemotherapy and RT or have had early disease progression after the commencement of chemotherapy and RT. Two recent reports have further clarified the role of conservative surgery in the management of these tumors.[179,180]

**Bladder and Prostate Tumors**

Management of tumors arising in these locations has evolved from a primary surgical approach (pelvic exenteration and total cystectomy) to a multimodal approach at present.[181,182,183] and [184] Radical surgical methods resulted in excellent rates of local control, but the morbidity of these operations was considered unacceptable. Current guidelines recommend complete resection for only those patients in whom preservation of bladder and urethral function can be assured.[185,186] Partial cystectomy, which usually is reserved for tumors arising in the dome of the bladder, can be performed either before the onset of chemotherapy and RT or after induction chemotherapy with or without RT. This approach results in no compromise in the survival rate but a comparable or perhaps even higher rate of preservation of bladder function than with other treatment modalities.[181,182] Total cystectomy and anterior pelvic exenteration are reserved for patients who do not achieve local control with the combination of chemotherapy and RT and have been reported to result in survival rates higher than 80% if they are performed in the absence of distant dissemination.[183,184]

***Tumors of the Extremities***

Initial complete surgical removal of extremity sarcomas should be attempted, provided that limb function will not be greatly impaired, because the prognosis is considerably worse if grossly visible tumor is left behind.[167,168] Because up to one-half of patients with extremity tumors have regional lymph node involvement, [86] sampling of clinically negative regional lymph nodes was recommended in IRS-IV and is required in IRS-V. Biopsy of clinically suspicious lymph nodes should commence with the most proximal nodes before proceeding to dissection or aggressive nodal sampling. Involvement of the ipsilateral supraclavicular lymph nodes for upper extremity tumors and iliac or para-aortic lymph nodes, or both, for lower extremity tumors is considered evidence of distant spread (stage 4). Amputation usually is not necessary, although it may be considered for patients with extensive lesions involving the bone or major neurovascular structures and for patients for whom RT probably will result in significant impairment of limb function.

***Tumors Arising in Other Sites***

Surgical removal should be attempted for truncal lesions.[188] Tumors arising in the pelvis, retroperitoneum, or intrathoracic area often cannot be removed completely because of infiltration or encirclement of major blood vessels or nerves or because of a surgeon's unwillingness to perform exenteration for pelvic-retroperitoneal tumors. Wide local resection of chest wall tumors consists of removal of the entire soft tissue mass and a bloc of uninvolved tissue extending at least one rib above and below the lesion.[125] An analysis of outcome among 84 IRS-II and IRS-III patients with thoracic sarcomas demonstrated inferior outcome among group I patients (7 of 13 suffered local recurrence), suggesting that microscopic residual disease is present in some patients and supporting the more routine application of primary reexcision, particularly in the presence of a question about the adequacy of margins.[124]

***Surgical Management of Metastatic Disease***

The role of surgical metastectomy in improving the outcome of patients with distant tumor spread is unclear. In a retrospective study of outcome after resection of pulmonary metastases in 152 patients with childhood sarcomas (Ewing's sarcoma, osteosarcoma, RMS, and other high-grade NRSTS) treated at the National Cancer Institute, Temeck et al.[189] found a uniformly poor outcome among patients with RMS. Nonetheless, given the poor outcome with conventional chemotherapy alone for such patients, removal of metastatic deposits (e.g., pulmonary nodules) may be beneficial in selected patients who otherwise have responded well to induction chemotherapy, particularly if potentially active chemotherapeutic agents or RT approaches still are available.

***Complications of Surgery***

Complications of operative management are related to tumor sites. Any procedure involving the skin and subcutaneous tissue produces a scar and loss of tissue in the region from which bulk tumor is removed. A surgeon's experience is critical in executing the proper operation. Radical regional lymph node dissections are discouraged because of subsequent scarring and lymphedema and because no convincing data substantiate that radical node dissection is therapeutic in treating pediatric RMS or undifferentiated sarcoma. Skill is especially important in the surgical exploration of lesions arising in the head and neck, where major blood vessels and important nerves are so closely apposed. In the genitourinary region, total cystectomy for bladder or prostate tumors currently is deferred until viable malignant cells clearly have persisted despite chemotherapy and RT. In patients with paratesticular sarcoma, bilateral RPLND can produce retrograde ejaculation and therefore is discouraged.

**Principles of Radiotherapy**

RT is a major tool in the treatment of children with RMS and undifferentiated sarcoma. RT can eradicate residual tumor cells from sites at which surgical therapy alone cannot ablate the mass, especially in the head, neck, and pelvis. Soft tissue sarcomas infiltrate so widely that after simple excision or enucleation, without wide excision, RT, or chemotherapy, local recurrence rates approximate 75%.[190] Soft tissue sarcomas were considered insensitive to RT before 1960, when Dritschilo et al.[191] first reported a local control rate of 96% for 27 children who were younger than age 16, had RMS or undifferentiated sarcoma, and received 5,500 to 6,500 cGy, delivered by a 4-mV or 8-mV accelerator.

Current RT guidelines have evolved over time from the logical and stepwise approach of the sequential Intergroup studies.[192,193,194,195,196,197,198,199] and [200] Daily fractions of between 180 and 200 cGy are standard; smaller daily fractions of 150 cGy may be used when large fields (e.g., entire abdomen) must be treated. A cumulative dose of between 41.4 and 45.0 Gy generally is sufficient to control microscopic residual disease, whereas higher cumulative RT doses of between 50.4 to 54.0 Gy are needed to control gross residual disease. It is important that accurate pretreatment images be obtained and that the treatment field encompass both the initial pretreatment tumor volume and a margin (usually 2 cm) of normal surrounding tissue. A “cone-down” or “shrinking-field” technique may be used at doses in excess of 36 to 41 Gy for patients whose initially unresectable tumors have responded to neoadjuvant therapy. With the exception of patients who have invasive parameningeal tumors (base-of-skull erosion, intracranial extension, cranial neuropathies), for whom treatment usually is commenced within the first several days to weeks, most patients can have treatment delayed safely until 9 to 12 weeks after diagnosis, after a period of neoadjuvant chemotherapy, during which tumor regression is the norm. Delaying the initiation of RT beyond 18 weeks may be associated with a reduced likelihood of achieving local control and should be avoided except in the rarest of circumstances. In the absence of overt meningeal involvement, whole-brain irradiation is unwarranted for cranial parameningeal tumors.

RT guidelines have been much simplified in the current IRS-V, with an underlying strategy of reducing the dose of radiation for most patients. This is being accomplished primarily in conjunction with delayed surgical resection for patients with alveolar tumors and those with initially unresectable embryonal tumors at unfavorable sites. In other locations, such as the orbit, a radiation dose reduction to 45 cGy is being evaluated prospectively in an effort to reduce late effects.

The role of RT in the local management of patients with initially completely resected tumors (CG I) recently was elucidated in a report from the IRSG looking at

outcome in 439 patients treated in IRS-I to IRS-III.[160] Pretreatment factors that were identified as being associated with inferior outcome were tumor size greater than 5 cm, sites other than the genitourinary tract, and alveolar or undifferentiated histology. ARMS patients who received RT had a significantly improved outcome as compared to those who did not. Current IRS-V treatment guidelines, therefore, recommend that virtually all patients with completely resected ARMS and undifferentiated sarcomas receive postoperative RT to a dose of at least 36 Gy. An analysis of local treatment failure among patients with CG III tumors treated in IRS-II reported an overall local control rate of 78%; a subset of patients with bulky tumors (greater than 10 cm) or tumors originating in unfavorable sites (chest, pelvis, extremity, trunk) were identified as being at especially high risk of local treatment failure. [199]

One of the major therapeutic objectives of IRS-IV was to evaluate the effect on local control of conventional fractionation RT (using daily fractions of 180 cGy to a cumulative dose of 50.4 Gy) versus hyperfractionated RT (HFRT; using twice-daily fractions of 110 cGy, separated by at least 6 hours, to a cumulative dose of 59.4 Gy) for patients with group III tumors.[200] This approach was piloted by investigators at St. Jude Children's Research Hospital, who demonstrated an absolute 2-year continuous local tumor control rate of 75% with minimal late radiation morbidity in 14 patients with CG III and CG IV tumors and persistent gross residual disease after induction chemotherapy.[201] A pilot study (IRS-IV-P) of HFRT confirmed the feasibility of administering concurrent HFRT and intensive chemotherapy and suggested that the acute toxicities of hyperfractionation were less severe than those seen with conventional fractionation RT protocols. [200] A formal analysis of local disease control in IRS-IV by type of RT administered has not yet been published. It is, however, possible to infer from the results of other recently published reports that HFRT is unlikely to have resulted in a significant improvement in local disease control. [86,164]

Sequelae of treatment are numerous. RT can produce an acute reaction characterized by erythema and swelling of the irradiated volume, which can lead to desquamation if extreme. The later effects of radiation are loss of function or growth, chiefly because of fibrosis, which increases with increasing dose and volume and diminishes with increasing age of the patient. [202,203] Fully 70% of patients with orbital RMS have impaired vision; almost one-half of patients with nonorbital RMS fail to maintain their initial height velocity, and treatment with supplemental growth hormone is not uncommon. [204,205,206] and [207]

Other controversies in the area of RT for the local control of RMS include the role of primary RT for patients with orbital tumors, [208,209] the problem of poor local control (and overall survival) in patients with cranial parameningeal tumors and extensive bony erosion, [106,210] the issue of the optimal timing of local irradiation relative to the initiation of postoperative systemic chemotherapy,[211] and the related questions of what constitutes the minimally acceptable dose of RT that can be administered without compromising local control and under what circumstances such reduced-dose radiation can be administered safely. [212,213] and [214] Although differences in practice continue within the international community, data are convincing that local RT improves outcome for patients with parameningeal RMS. [215] The role of whole-lung RT (generally to a cumulative dose of 1,440 cGy) for patients who present with overt pulmonary metastases is unclear; however, some treatment protocols continue to recommend it—a reasonable practice if a state of minimal residual disease can be achieved—given the radiosensitivity of RMS.

Techniques other than traditional external-beam megavoltage RT sometimes may be considered. One technique employs radiation implants, especially for children with small, critically located tumors of the head and neck, bladder, prostate, vagina, or extremity. [216,217,218] and [219] Because the dose is delivered to a carefully restricted volume, adjacent normal structures receive less scattered radiation and may be expected to have less fibrosis. Another newer approach for large, deeply seated tumors is treatment of the tumor by a radiotherapist under direct vision while it is exposed in the operating room. More data regarding pediatric patients are needed to assess the utility of this method.[220]

Finally, advances in the ability to incorporate three-dimensional imaging into radiation treatment planning have led to exploration of the use of three-dimensional conformal RT and intensity-modulated RT as particularly promising approaches to maximize the dose of radiation delivered to tumor-bearing tissue while minimizing the dose received by normal surrounding structures. [221,222] and [223] At present, only limited data address the use of these techniques in treating RMS. [224,225] and [226] Still newer biologically functional imaging techniques, such as positron emission tomography and nuclear magnetic resonance imaging and spectroscopy may be combined with the “dose-sculpting” ability of intensity-modulated RT to generate highly precise delivered dose distributions. [227]

**Principles of Chemotherapy**

Early clinical trials evaluated the activity of single chemotherapeutic agents in children with recurrent or metastatic tumors. Few patients were cured with such an approach. The most active single agents that were identified in this manner were actinomycin-D, cyclophosphamide, vincristine, and doxorubicin. [228,229,230,231,232,233,234] and [235] Combinations of these agents led to improvements in response rates. [236,237] and [238] Wilburet al.[239] pioneered the administration of repetitive doses of vincristine, actinomycin-D (or dactinomycin), and cyclophosphamide (the VAC regimen) to children with advanced RMS. Of 24 children with inoperable localized tumors (16 patients) or metastatic deposits at diagnosis (8 patients), 16 (67%) were alive and well at a median follow-up approaching 2 years. [239] The benefit of systemic therapy on prolonging and improving overall survival was confirmed in numerous studies involving limited numbers of patients. [240,241,242,243,244] and [245]

Multicenter studies evaluating larger numbers of patients subsequently were initiated to ascertain better methods of treatment and to learn more about potential prognostic factors. In 1972, members of the Children's Cancer Study Group (CCSG) and the pediatric divisions of the Southwest Oncology Group and the Cancer and Acute Leukemia Group B banded together to form the IRS group. More than 3,500 patients with RMS and undifferentiated sarcoma have been treated on one of the four IRS investigations that have been completed since that time.[76,77] and [78,164] Accrual to IRS-V is expected to continue until 2002 or 2003. These studies have been instrumental in improving outcome, identifying important prognostic variables, and developing risk-based therapies for patients with RMS ( Fig. 32-8).

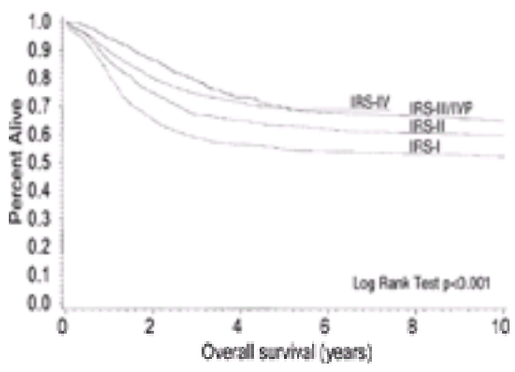

**FIGURE 32-8..** Survival of patients treated on Intergroup Rhabdomyosarcoma Studies (IRS)-I, -II, -III//IV-P (IV pilot), and -IV. Improvements were seen for each successive study from IRS-I through III/IV-P, but no significant improvement in outcome was seen with IRS-IV. (JR Anderson, *personal communication*, 2000.)

The goal of identifying additional active agents is to be able to incorporate as many active agents as possible, ideally without overlapping toxicities, into the frontline management of patients with newly diagnosed disease to avoid the development of multidrug resistance. [246,247] Cisplatin, etoposide, and dacarbazine have been shown to be active, singly and in various combinations, over the last two decades. [248,249,250,251,252,253] and [254]

Ifosfamide, alone and in combination with etoposide or doxorubicin, has been shown to be highly active in both newly diagnosed and recurrent RMS. [251,255,256] and [257] These observations formed the rationale for the basic experimental design of IRS-IV in which the efficacy of equitoxic doses [258] of cyclophosphamideversus ifosfamide (VAC) versus vincristine, actinomycin D, and ifosfamide (VAI) versus vincristine, ifosfamide, and etoposide (VIE) was evaluated.

One obvious problem with treating patients with recurrent tumors is that an agent's true activity may be underestimated grossly because such tumors are likely to have developed complex mechanisms of resistance to a broad spectrum of agents[259] and because such patients are less likely to tolerate treatment with sufficiently high doses of potentially active agents. In conjunction with a highly predictive murine xenograft model of RMS, [260,261] and [262] phase II window studies have been used to identify several agents with moderate to high activity, including melphalan, [263] methotrexate[264] and, most recently, topotecan,[265,266] which were “inactive” in previously treated patients.[252,267] Although a follow-up study by this same group failed to show a similarly improved response rate after dacarbazine and doxorubicin were administered to patients with newly diagnosed disease, [268] the concept of alternative induction therapy, consisting of the early introduction of pairs of active drugs, was

incorporated into the design of IRS-III for patients who had failed to achieve a complete response by week 20. The results of the three, two-drug, phase II window studies that were conducted in IRS-IV identified the combination of ifosfamide plus doxorubicin as a potentially significant drug pair for improving outcome in patients with metastatic RMS.[269,270]

More recently, the camptothecin analogs—topotecan and irinotecan—have been identified as particularly promising new agents. These compounds inhibit the DNA repair enzyme topoisomerase I and have both striking activity in the murine xenograft model[262] and encouraging responses in phase I and phase II window testing.[266,271,271a] Two major objectives of the IRS-V series of studies will be to evaluate the activity of irinotecan (given on a daily × 5 × 2 schedule) in patients with newly diagnosed metastatic RMS and to evaluate the efficacy of adding topotecan (on a daily × 5 schedule in combination with cyclophosphamide) to the standard three-drug VAC regimen for patients with intermediate-risk tumors.

Paclitaxel (Taxol) and its semisynthetic analog, docetaxel (Taxotere), are unique tubulin-binding compounds that produce cytotoxicity by blocking dividing cells at either the $G_2$ or the M phase of the cell cycle and have demonstrated significant antitumor activity against a variety of neoplasms.[272] Reports of antitumor responses in phase I studies in pediatric patients with recurrent solid tumors,[273,274] including those with RMS, have generated significant enthusiasm for additional clinical evaluation of these agents, used both singly and in combination with other drugs.[275,276] Both compounds are undergoing traditional phase II testing in treating RMS and other pediatric solid tumors, and phase II window testing also is planned. Finally, vinorelbine, a semisynthetic vinca alkaloid with unique pharmacologic principles, also was described recently as having promising activity in 17 patients with refractory and recurrent RMS or soft tissue sarcomas.[277]

**Combined-Modality Therapy**

The general principle of complete surgical removal of tumor, if feasible, should be emphasized. Patients whose tumors are removed at the outset continue to fare better than do those with gross residual sarcoma, especially with primary tumors of an extremity. Operative removal of residual tumor may be performed from weeks to months after completion of chemotherapy and RT and may help to eradicate resistant cells that otherwise may contribute to relapse.[278]

The timing of RT in relation to chemotherapy has been somewhat variable. RT was historically begun at the same time as chemotherapy for patients with group I or group II sarcomas but was delayed until week 6 for those with group III or group IV tumors to assess the response to chemotherapy, to exploit potentially the booster effect of certain drugs (e.g., actinomycin-D), and to minimize mucositis or other damage.[279,280] Currently, in the IRS-V series of studies, RT commences immediately for select high-risk patients with locally advanced cranial parameningeal tumors, at week 3 for appropriate patients on the low-risk study, at week 12 for patients on the intermediate-risk study, and at week 15 for patients on the high-risk study.

Because most relapses occur within 2 to 3 years of diagnosis, two to five chemotherapeutic agents historically have been administered for 12 to 24 months. The duration of therapy possibly may be shortened significantly without jeopardizing outcome as multi-agent regimens become increasingly risk-based and intensive. In IRS-IV, selected groups of patients with highly favorable prognosis (CG I and CG II patients with primary orbit or eyelid tumors and CG I patients with paratesticular tumors) received only 36 weeks of chemotherapy with just vincristine and actinomycin-D, and the duration of therapy for all other patients was reduced to approximately 1 year. Drugs, doses, and schedules vary among institutions. Select patients with extremely favorable prognoses (orbital and completely resected paratesticular tumors) generally can be treated safely without an alkylating agent (i.e., with just vincristine and actinomycin); other patients with “favorable” localized tumors (incompletely resected ERMS tumors arising in favorable locations and completely or gross totally resected ERMS tumors arising in unfavorable locations) generally will do well with the gold-standard three-drug regimen of VAC. Optimal therapy for patients with unresectable ERMS in unfavorable sites and for patients with ARMS and for those with metastatic tumors remains to be defined. Treatment guidelines from IRS-IV are summarized in Table 32-4. Treatment programs for RMS and undifferentiated sarcoma are still evolving, and the suggestions in Table 32-4 should not be considered definitive.

**TABLE 32-4. IRS-IV RECOMMENDATIONS FOR THERAPY FOR RHABDOMYOSARCOMA AND UNDIFFERENTIATED SARCOMA IN CHILDHOOD**

**Treatment Results**

Results of IRS-III are summarized in Table 32-5.[78] These results confirmed the major findings both of most other single and limited institution studies and of the earlier IRS series concerning the relation between outcome and the extent of initial surgical resection and site of the primary tumor.[76,77,241,242,245,281,282 and 283] Even after the difference in the distribution of patients by CG is taken into account, the overall outcome for patients treated in IRS-III was significantly better than that in IRS-II: 5-year progression-free survival (PFS), 65% ± 2% versus 55% ± 2% ($p$ <.001; Fig. 32-9). Most of the improvement in outcome was explained by the significantly improved results among selected groups of higher-risk patients, specifically those with CG III special pelvic tumors (5-year PFS, 74% ± 4% vs. 58% ± 5% in IRS-II; $p$ = .01); unfavorable histology CG I and CG II (71% ± 6% vs. 59% ± 5% in IRS-II; $p$ = .002); and CG III tumors excluding special pelvic, orbit, and selected head sites (61% ± 3% vs. 52% ± 3% in IRS-II; $p$ = .01; Fig. 32-10A). As compared with earlier series, outcome was improved for patients with localized tumors at virtually all sites, but no improvement in outcome was seen among patients with metastatic tumors. Outcome was best among patients with primary tumors of the orbit or nonbladder, nonprostate genitourinary tract; was intermediate among patients with tumors arising in other head and neck sites and in the bladder or prostate; and was worst among patients with extremity, cranial parameningeal, and other (trunk, pelvis-perineum, retroperitoneal, and paravertebral) sites (Fig. 32-10B). With the development of more effective doxorubicin-based systemic therapy and the use of local irradiation in all patients, alveolar histology was found to be associated no longer with adverse prognostic significance.

**TABLE 32-5. SUMMARY OF RESULTS FROM THE THIRD INTERGROUP RHABDOMYOSARCOMA STUDY (IRS-III) AND COMPARISONS, WITH IRS-II**

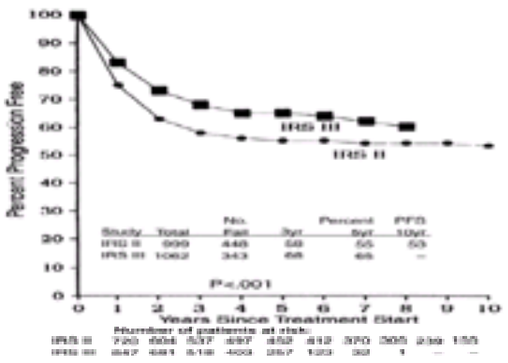

**FIGURE 32-9.** Progression-free survival (PFS) for all patients treated on Intergroup Rhabdomyosarcoma Studies (IRS)-II and -III. Even after adjustment for differences in clinical group distributions (resulting from changes in the primary surgical approach to certain tumors), the overall outcome of therapy in IRS-III was significantly better than in IRS-II (65 ± 2% vs. 55 ± 2%, *p* <.001). (From Crist W, Gehan EA, Ragab AH, et al. The Third Intergroup Rhabdomyosarcoma Study. J Clin Oncol 1995;13:610, with permission.)

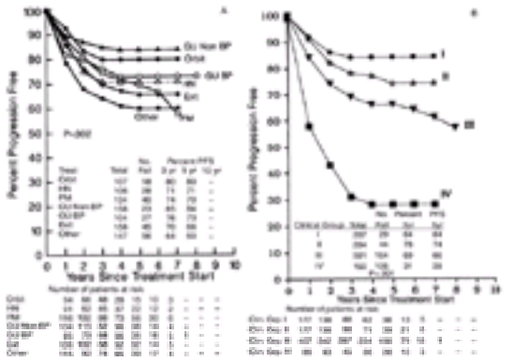

**FIGURE 32-10.** Progression-free survival (PFS) on Intergroup Rhabdomyosarcoma Study (IRS)-III by extent of initial surgical resection (clinical group) and site of primary tumor. **A:** Outcome according to site of primary tumor for patients with localized tumors (clinical groups I–III). Patients with localized tumors originating in nonbladder, nonprostate genitourinary sites (GU Non BP) or the orbit had the most favorable prognosis. In contrast to the results in IRS-II, patients with bladder or prostate tumors (GU BP) had outcomes that were comparable to those of patients with tumors in head and neck sites (HN). Patients with tumors arising in an extremity (Ext) or parameningeal (PM) or other site (e.g., retroperitoneum, trunk, pelvis, paraspinal region) fared least well. **B:** Outcome according to clinical group. Patients with completely (clinical group I) and gross totally (clinical group II) resected tumors did significantly better than did those with more advanced disease (clinical group III). Patients with metastatic disease (clinical group IV) fared significantly worse than all other patients. (From Crist W, Gehan EA, Ragab AH, et al. The Third Intergroup Rhabdomyosarcoma Study. J Clin Oncol 1995;13:610, with permission.)

One major question that was left unanswered by IRS-III and was not addressed in IRS-IV is the roles, if any, that cisplatin (with or without etoposide) and doxorubicin have in the frontline management of selected patients with RMS. As compared with the standard VAC regimen, the inclusion of cisplatin and etoposide did not appear to improve the complete response rate or PFS; however, differences in outcome among patients receiving doxorubicin were seen in two distinct groups of patients (Table 32-5). The inclusion of doxorubicin (with cisplatin) for patients with unfavorable histology CG I and CG II was associated with a significant improvement in outcome as compared with the results seen in IRS-II. It may ultimately be impossible to distinguish how much of this improvement was caused by the use of more effective systemic chemotherapy and how much by improved local control resulting from the uniform use of local irradiation.

The second group in whom treatment with doxorubicin was found to be associated unexpectedly with improved outcome consisted of patients with favorable histology CG II tumors, excluding orbit, head, and paratesticular sites. These patients were assigned randomly to receive regimen 33 (vincristine, actinomycin-D, and doxorubicin), and their 5-year PFS and overall survival rates were 77% ± 6% and 89% ± 5%, respectively. The IRS committee ultimately dismissed these findings after determining the absence of a significant difference between the results of regimen 33 and the combined results of the two vincristine–actinomycin-D regimens, regimen 32 in IRS-III and regimen 23 in IRS-II (5-year PFS and overall survival rates of 63% ± 8% and 73% ± 8%, respectively; *p*= not significant). However, the fact remains that a significant difference was seen when the findings of regimen 33 were compared only with the results among those patients who received regimen 32 and were treated concurrently (5-year PFS and overall survival rates of 56% ± 10% and 54% ± 13%; *p*= .08 and .03, respectively). The design of IRS-IV, in which doxorubicin is used only in one of three drug-pair phase II windows, did not include a follow-up evaluation of the role of doxorubicin in improving outcome for patients with limited-stage tumors, who appeared to benefit from the inclusion of doxorubicin in IRS-III.

Preliminary results of IRS-IV have begun to emerge in the last year and, with few exceptions, little to no improvement in outcome has been seen for most patients as compared to the results of IRS-III (Fig. 32-8). The major therapeutic objectives of IRS-IV were to compare randomly the efficacy of three regimens using three drugs—VAC, VAI, and VIE—and two schedules of RT (conventional and hyperfractionated). Three-year FFS figures for patients with low- or intermediate-risk RMS were 88% and 76%, respectively, not significantly improved from the results for comparable patients treated in IRS-III. [164] Outcome for patients with ARMS was unchanged as compared to that in IRS-III.[284] Subset analysis did, however, reveal two groups of patients with ERMS, representing approximately 25% of all patients with nonmetastatic tumors, for whom outcome in IRS-IV was improved.[164] Stage 1 patients with node-positive resectable or unresectable (CG III) tumors arising at certain favorable sites (head and neck but not orbit or eyelid and not cranial parameningeal) experienced an improvement in 3-year FFS from 72% in IRS-III to 92%. Three-year FFS was improved also for stage 2 and stage 3 patients (tumors arising in unfavorable sites) with completely or gross totally resected (CG I and CG II) tumors, increasing from 71% in IRS-III to 86%. The addition of an alkylator (cyclophosphamide or ifosfamide) to patients with group III orbital tumors produced a 3-year FFS of 100%.[285] Thus, although select groups of patients appear to have benefited from the increased alkylator intensity of IRS-IV, this strategy did not improve outcome for the majority of patients who present with either unresectable (group III) ERMS tumors arising in unfavorable locations (stages 2 and 3) or those with ARMS. For example, 3-year FFS among 139 patients with extremity RMS and treated in IRS-IV, 71% of whom had ARMS and 23% of whom had stage 4 disease, was 55%.[84] Again reflecting the clustering of clinical variables, the probability of treatment failure was greater than 50% in patients with large (5-cm), invasive (T2), node-positive (N1) unresectable (group III) tumors. None of the three-drug regimens was clearly superior to the others. Three-year FFS similarly was unchanged among patients with metastatic disease at diagnosis, for whom one of three phase II windows was employed: vincristine plus melphalan, ifosfamide plus etoposide, or ifosfamide plus doxorubicin. However, treatment on the vincristine plus melphalan arm appeared to be associated with a somewhat worse outcome than was treatment on either of the other two arms, perhaps owing to cumulative hematologic toxicity after early treatment with melphalan. [269,270]

The results of other international collaborative studies also have been published in the last several years. The International Society of Pediatric Oncology treated 186 patients with newly diagnosed nonmetastatic RMS in its MMT-84 study.[286] Treatment consisted of three courses of IVA for patients with completely resected tumors and six to ten courses of IVA for those with incompletely resected tumors. The major difference in therapeutic approach between the MMT-84 study and the IRSG studies was the omission of RT (or second-look surgery) for patients achieving a complete remission with chemotherapy alone; radiation was, however, given to patients younger than 5 years having parameningeal tumors, reflecting the recommendations of an international workshop on the management of such tumors, [215] and to patients older than 12 years having tumors in any site. With a median follow-up of 8 years, the 5-year event-free survival (EFS) was 53%, and overall survival was 68%. With the exception of the excellent outcome (5-year EFS of 85% ± 12%) among the small number of patients (n = 27) having completely resected tumors and receiving three cycles of VAI over 2 months, EFS in all other groups was inferior to that of similar-risk patients treated in IRS-III and IRS-IV, largely owing to a significantly greater risk of local relapse. Nearly one-third of patients (54 with local tumors only, 7 with local plus distant tumors) experienced an isolated local relapse, and most subsequently did not achieve long-term disease-free status even after the application of aggressive local RT or surgery (or both). As in the IRSG studies, factors associated with improved prognosis included embryonal histology (56% 5-year EFS vs. 33% for patients with ARMS; *p* = .001) and favorable site (orbit and genitourinary/nonbladder-nonprostate sites). Although the intent of avoiding the late effects of potentially “unnecessary” RT was laudable, the inability to salvage the majority of the large number of patients with disease that relapses with this approach suggests that it represents a suboptimal strategy for the vast majority of patients

with newly diagnosed RMS.

The German Soft Tissue Sarcoma Study (CWS-86) treated 310 eligible patients, including 286 with RMS (251 with localized disease), with four-drug chemotherapy (vincristine, doxorubicin, ifosfamide, and actinomycin-D) for varying periods (ranging from 16 to 40 weeks) based on the initial extent of disease. [287] The use of local RT was stratified by stage of disease, primary tumor site, response to neoadjuvant chemotherapy, and the results of second-look surgery: "Good responders" received 32.0 Gy, whereas "poor responders" received 54.5 Gy in split courses of accelerated hyperfractionation. Children younger than 2 years did not receive RT, and those between the ages of 2 and 3 did so on a case-by-case basis. More than one-half of all patients had tumors that were unresectable or metastatic (or both) at diagnosis. Five-year EFS for all RMS patients was 60% ± 3% and, for those without metastases, it was 68%. As in the IRSG and the International Society of Pediatric Oncology studies, outcome was related closely to stage of disease at diagnosis, ranging from 83% in patients with stage I disease (n = 46) to 67% in patients with stage II disease (n = 56) to 63% in patients with stage III disease (n = 149). The risk of local relapse clearly was related to failure to administer consolidative local RT in patients with either positive margins or gross residual disease. Better outcome was seen among the patients with ERMS than among those with ARMS (67% ± 4% vs. 41% ± 6%; *p*= .01) and among patients with genitourinary (nonbladder and nonprostate) tumors. Other factors that were found to correlate with improved outcome differed according to stage at diagnosis: Among patients with stage I disease, only tumor size of at least 5 cm was associated with an adverse outcome, whereas for patients with stage III tumors, female gender, tumor size of at least 5 cm, alveolar histology, and all sites other than genitourinary (nonbladder and nonprostate) were associated with poorer outcome.

Smaller, limited, and single-institution pilot studies, primarily of patients with intermediate-risk RMS, have achieved encouraging results using five-drug chemotherapy consisting of alternating cycles of vincristine, doxorubicin, and cyclophosphamide and ifosfamide and etoposide. Arndt et al. [288] treated 30 patients with intermediate-risk tumors (14 with parameningeal primary tumors, 6 with extremity primary tumors, 5 with bladder or prostate tumors, 12 with ARMS, and 2 with undifferentiated sarcoma) with 14 cycles vincristine, doxorubicin, and cyclophosphamide alternating with ifosfamide and etoposide; most patients received 5,040 cGy for local control beginning immediately after week 12 and cycle 5 of chemotherapy. [288] Three-year EFS in this group of high-risk patients with nonmetastatic tumors was 85% (95% confidence interval, 72% to 99%). Similar encouraging results were seen in 15 patients with intermediate-risk RMS treated on granulocyte colony-stimulating factor–supported "interval compression" variation of the same basic five-drug regimen. [289] Although the results of these nonrandomized pilot studies cannot be compared directly to those seen in IRS-IV and other international cooperative group studies, they nonetheless lend support to the observation made in IRS-III that the use of doxorubicin may improve outcome for select groups of intermediate-risk patients (unfavorable site or histology, or both, and unresectable disease).

For patients at high risk of treatment failure, primarily those with metastatic disease at diagnosis, consolidation with high-dose chemotherapy and autologous bone marrow or peripheral blood stem-cell rescue (so-called bone marrow or stem-cell transplantation) has been studied as a way of improving outcome by overcoming intrinsic or acquired drug resistance through delivery of what otherwise would be "lethal" doses of chemotherapy (generally including one or more alkylating agents)—with or without total-body irradiation—and then "rescue" of the patient by infusing previously cryopreserved hematopoietic progenitor cells. A series of small studies, with differing eligibility criteria, different myeloablative regimens, and different subsets of patients with metastatic disease have failed to demonstrate any significant benefit of such transplantation in this setting ( Table 32-6).[282,290,291,292,293 and 294] Thus, this strategy, although still being pursued, must be considered of no proven benefit and highly experimental.

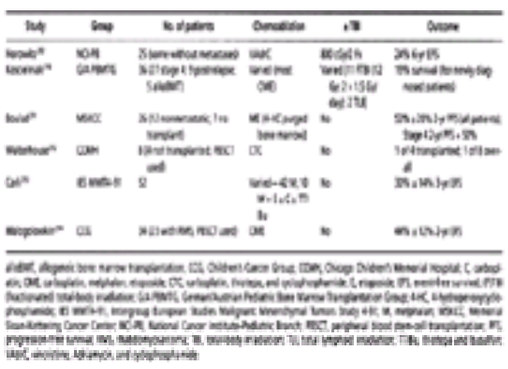

**TABLE 32-6. SUMMARY OF RESULTS OF MEGATHERAPY CONSOLIDATION WITH AUTOLOGOUS HEMATOPOIETIC BONE MARROW AND STEM-CELL SUPPORT FOR PATIENTS WITH RHABDOMYOSARCOMA**

## Complications of Therapy

Complications of therapy include residual effects of operative management, RT, and chemotherapy (see also Chapter 10, Chapter 12, Chapter 13, and Chapter 49). Clearly, the extent of surgical treatment has a bearing on the functional outcome. Extremity amputations and extensive formal lymph node dissections are performed rarely for that reason. Infection, anemia, and bleeding can result from intensive drug combinations. Infants may develop more toxicity than do older children. [295] Leukoencephalopathy, which is very uncommon, can be seen in patients with cranial parameningeal sarcoma given intensive chemotherapy and RT, including repeated doses of intrathecal methotrexate, hydrocortisone, and cytosine arabinoside. [296] Ascending myelitis of the cervicothoracic region has been observed in 5 of 149 children treated between 1972 and 1984 with intensive chemotherapy and irradiation for high-risk cranial parameningeal sarcoma. [297] Fibrosis, diminished growth of underlying or surrounding structures, cataracts, disturbed dentition, and growth hormone deficiency have been reported in children receiving multimodality therapy for tumors arising in the head and neck.[298,299] Combined therapy with drugs and irradiation can produce severe fibrosis and limitation of function in irradiated sites. For orbital tumors, the severity of radiation-related complications may be reduced by the avoidance of simultaneous administration of irradiation and sensitizing chemotherapy (e.g., actinomycin-D or doxorubicin).[209]

With modern therapy, a minority of patients with tumors of the bladder or prostate require total or partial cystectomy. [78,300] Nonetheless, approximately 25% of those who do retain their bladders suffer from significant bladder dysfunction (incontinence, frequency, nocturia), and all patients with bladder or prostate tumors are at risk for hematuria, structural renal abnormalities, and delayed growth and pubertal development requiring sex hormone replacement therapy. [301,302] The incidence of hematuria after cyclophosphamide therapy can increase as much as fourfold if pelvic irradiation is used, but the use of the bladder protectant mesna has all but eliminated this potentially life-threatening complication. [303,304] Infertility can result from gonadal effects of cyclophosphamide or RT or from surgical interruption of nerves conveying impulses for antegrade ejaculation, as in boys with pelvic or paratesticular sarcoma. [305]

Several reports have described a broad spectrum of late complications, including small-bowel obstruction, esophageal and common bile duct strictures, inguinal nerve entrapment syndrome, and lymphedema of the leg in patients treated with multimodality therapy for paratesticular RMS. [306,307] Among the newer active agents, ifosfamide can cause renal tubular dysfunction, which may be severe, with aminoaciduria, glycosuria, cation leakage, increased serum creatinine, and acidosis with growth failure.[308] Renal toxicity data recently were reported for 194 previously untreated patients enrolled in one of two ifosfamide-containing pilot regimens in IRS-IV.[309] The overall incidenceof any nephrotoxicity was 14% (28 patients), with the most frequent toxicities being renal tubular dysfunction and decreased glomerular function. Preexisting renal abnormalities (primarily hydronephrosis) and age younger than 3 years (especially for those who received a cumulative ifosfamide dose of more than 72 g per $m^2$) greatly increased the risk of renal tubular dysfunction.

The most devastating late complication of therapy is the development of a second malignant neoplasm. Twenty-two of these neoplasms developed among 1,770 patients entered into IRS-I and IRS-II, including 11 radiation-related bone sarcomas and 5 cases of acute nonlymphoblastic leukemia, at a median of 7 years after therapy.[310] The observation that three of the affected patients had neurofibromatosis and that the families of seven of the affected patients had histories compatible with LFS raises the possibility that genetic susceptibility plays a significant role in the development of a second malignant neoplasm after treatment for RMS. Early results from IRS-III described the early occurrence of five cases of acute myeloid leukemia (AML) in children and one case of osteosarcoma and one case of myelodysplastic syndrome (MDS).[311] A preliminary report of second malignant neoplasm in IRS-IV found 14 cases in 13 patients at a median of 3.2 years from diagnosis.[312] The 7.2% riskof secondary leukemia (MDS/AML and acute lymphatic leukemia) in patients treated with melphalan (as part of the phase II window strategy for patients with metastatic disease) was significantly greater than that for all other treatment arms. Early concerns about an increased risk of AML/MDS in patients receiving etoposide did not appear to be substantiated; however, prospective monitoring of the contribution of a strong family history of cancer to the risk of

developing a treatment-related second malignant neoplasm is prudent. [313]

The development of risk-based therapies clearly is the most important strategy to minimize the risk of late treatment-related complications. As was demonstrated in IRS-III and IRS-IV and is being evaluated further in IRS-V and in studies in several European countries, selected groups of patients with favorable prognosis can be identified; for them, the elimination of one or more chemotherapeutic agents does not appear to affect ultimate outcome adversely. Although this approach does not appear to have been successful for special pelvic tumors, possibly individual components of the multimodality treatment regimens can be withheld from the frontline management of patients without compromising ultimate outcome. Such an approach has been tried for patients with orbital RMS and, despite a local recurrence rate of 45% in patients not receiving initial RT, long-term survival does not appear to have been compromised. [208]

Patients with adverse prognostic features are being treated increasingly with more intensive and complex therapies. As therapy for even high-risk patients becomes more successful, it is increasingly important to monitor these patients for the development of other, potentially life-threatening, late treatment-related adverse events and to understand better the relation between genetic susceptibility and the development of second malignant neoplasms. Identifying people for whom the selective elimination of one category of antineoplastic agents (e.g., epipodophyllotoxins, alkylating agents) is appropriate may be possible because of the presence of high-risk genetic markers. Improvements in evaluation of the presence or absence of microscopic (residual) disease (e.g., with the use of molecular genetic markers unique to the tumor cell) may permit individualization of the duration of therapy. The goal of all these therapeutic maneuvers is the identification of better treatments (i.e., treatments that achieve maximum long-term survival with minimum short- and long-term morbidity).

## Treatment of Recurrent Disease

The management of patients with recurrent or unresponsive sarcoma is problematic. Although rare after 3 or 4 years from diagnosis, recurrence can take place many years after apparently successful treatment.[314,315] and [316] Recurrence connotes relative or absolute resistance to the chemotherapy or irradiation used in initial therapy. Among the various molecular mechanisms that may play a role in the development of drug resistance are overexpression of P-glycoprotein (the mediator of the multidrug resistance phenotype), hypermethylation of the tumor cells' DNA, elevated levels of DNA polymerase-a and -b and topoisomerase II, overexpression of O6-methylguanine-DNA methyltransferase, and constitutive expression of the c-H-*ras* oncogene.[317,318,319,320,321,322,323] and [324]

The optimal treatment of patients with recurrent tumor is, at best, imprecisely defined. Patients with suspected recurrent disease must be evaluated fully and staged before the formulation of a treatment plan. Recurrence always should be documented by biopsy or fine-needle aspiration. At a minimum, imaging studies (plain films, computed tomography, or magnetic resonance imaging) should be performed to evaluate the lungs, site of primary tumor, and any sites suggested by the history and physical examination. Hematologic abnormalities should be followed up with a bone marrow biopsy. After pathologic verification of recurrent disease, factors that should be considered in the formulation of a treatment plan include the timing of the recurrence relative to the completion of therapy (i.e., progression or recurrence while on therapy, within the first 6 to 12 months off therapy, or after more than 12 months off therapy), the extent of disease at recurrence (localized vs. disseminated), the extent of disease at diagnosis, and the nature of prior therapy (extent and intensity of chemotherapy, sites and doses of previous irradiation). Achieving long-term survival is difficult, particularly in patients whose disease progresses on therapy or shortly after treatment completion and in patients who initially had unresectable or metastatic sarcoma.[279] The 3-year post-relapse survival rates for patients treated in IRS-III were 48% ± 12%, 12% ± 9%, 11% ± 5%, and 8% ± 4%, for patients with CG I, II, III, and IV disease, respectively ($p$ <.001 in favor of CG I).[78]

Several recent reports have better defined the risk of death from disease after relapse. Post-relapse survival was analyzed in 605 children who previously had been treated in IRS-III, IRS-IV pilot, and IRS-IV (1984 to 1997). [325] Ninety-five percent of all relapses occurred within 3 years of diagnosis; the latest reported recurrence was at 9 years. The median survival time from first recurrence was 0.8 years; fewer than 20% of patients were projected to be alive 5 years after relapse. Post-relapse treatment was nonuniform. Subset analyses were able to identify groups with different prognoses. Approximately one patient in five, primarily those with ERMS who initially presented with stage 1 or group I disease, had a relatively “favorable” 5-year survival rate of approximately 50%, and the likelihood of subsequent survival appeared to correlate with whether the relapse was local (72%), regional (50%), or distant (30%). The estimated 5-year post-relapse survival for patients with stage 2/3 or group II/III tumors was 20%, and for those with group IV disease, it was 12%. For this latter group of patients, the type of relapse (local vs. regional vs. distant) was not prognostically relevant. Patients with recurrent ARMS had a worse prognosis, with only those who initially had group I disease enjoying a relatively favorable prognosis (40% 5-year survival vs. 3% for groups II to IV). Although potentially important treatment variables existed, similar findings were reported by the CWS group.[326] Forty-four patients (17 with ERMS, 13 with ARMS) with relapsed soft tissue sarcomas were treated with multi-agent chemotherapy; 5-year EFS appeared to be better in patients with ERMS (41% ± 12%) than in those with ARMS (23% ± 12%). The administration of post-relapse irradiation (presumably given to those who previously had not been irradiated and, therefore, were at greater risk of locoregional relapse after presenting with limited-stage disease) was associated with improved outcome.

### *Localized Recurrence*

An aggressive multimodality approach should be considered for patients with an isolated site of recurrent disease. The best chance for long-term survival is a situation in which a complete surgical resection can be accomplished, potentially followed by adjuvant postoperative irradiation and chemotherapy, in patients with an initial stage 1 or group I ERMS tumor. For example, for patients with vaginal and paratesticular localized recurrences, long-term survival still can be achieved with this aggressive approach.[327] The choice of a salvage chemotherapeutic regimen depends on the previous chemotherapy and the timing of the relapse. There are well-described examples of durable responses achieved in patients with recurrence off therapy using the same drugs as those previously administered. [328] For patients who have not previously received known active agents, such as ifosfamide, doxorubicin, or etoposide, or such newer agents as topotecan or irinotecan, these agents should be considered strongly in choosing a regimen, although the tolerability and activity of these agents are likely to be reduced in heavily pretreated patients. [329] In patients who already have received all known active agents and who have recurrence during or shortly after completion of therapy, investigational phase I and phase II agents should be considered.

### *Disseminated Recurrence*

In contrast to localized recurrence, in which the chance of long-term survival is a small but real possibility, recurrence that develops with metastatic disease is essentially incurable. Surgical resection of metastatic lesions, even if complete, is unlikely to be of benefit with regard to curative potential, although low-morbidity procedures may be useful for palliative purposes.[189,330,331] and [332] Chemotherapy is the primary therapeutic modality, with palliative RT usually reserved to treat painful lesions or to prevent spinal cord compression. The choice of chemotherapeutic agents should be guided by the same principles listed previously.

Although high-dose chemotherapy with autologous bone marrow or peripheral blood progenitor cell support has not been demonstrated to be efficacious in the setting of patients with newly diagnosed metastatic disease, the efficacy of programs incorporating these strategies for children with recurrent soft tissue sarcoma is unclear, because few studies have been undertaken and, with rare exceptions, only short-term results are available. [333,334] and [335] Because soft tissue sarcomas usually are less sensitive to irradiation than are leukemia or neuroblastoma cells, total-body irradiation may be less effective in eradicating recurrent sarcoma. [282] Further investigation of consolidation with high-dose chemotherapy and bone marrow or peripheral blood stem-cell rescue for select patients with recurrent RMS is not unreasonable, given the current lack of good therapeutic options. One possible advantage of such an approach, particularly in heavily pretreated patients who are relatively intolerant of additional myelosuppressive chemotherapy, is to use growth factor–supported autologous peripheral blood progenitor cell transfusions to permit repetitive monthly cycles of myeloablative chemotherapy.[336]

## Immunotherapy and Other Biologic Interventions

Recent advances in understanding the basic biology of RMS have led to the possibility of novel therapeutic interventions, including specific antitumor immune responses and interruption of autocrine growth factor loops. The recognition that intracellular proteins can be processed and presented as peptides on the cell surface by major histocompatibility complex class I molecules has suggested the possibility that tumor-specific mutant gene products may be targets for cytotoxic T cells.[337,338] For example, investigators have shown that a peptide derived from a mutant p53 protein is recognized specifically by cytotoxic T cells. [339,340] In a similar way, translocation-specific fusion proteins also could be targeted potentially by cytotoxic T cells. Specifically, the PAX-FKHR fusion protein generated by the t(2;13)(q35;q14) translocation in ARMS is a potential target for cytotoxic T cells therapeutic approaches. Pilot clinical studies using PAX-FKHR specific peptide, pulsed, dendritic cell vaccinations are ongoing (C. Mackall et al., *personal communication*, 2000). The success of this approach will depend on the ability of tumor cells to present a processed fusion peptide bound to major histocompatibility complex on the cell surface. If this can occur, multiple approaches could be taken to overcome potential deficits that allowed the tumor initially to escape cellular immunity. [341,342]

Because an IGF-2 autocrine pathway has been demonstrated to play a role in the growth of RMS, [30,31] disruption of this pathway offers another potential therapeutic target. Blockade of the IGF-1 receptor, a ligand-inducible tyrosine kinase receptor that mediates the IGF-2 mitogenic signal, has been shown to inhibit the growth of established human RMS tumors in nude mouse xenografts.[30] These experiments used mouse monoclonal antibodies, which generally have not proven to be of clinical utility. However, the rapid development of human antimouse antibodies allows for the generation of humanized monoclonal antibodies, which holds some promise for the clinical application of this approach, as has been demonstrated using several antibodies now in routine clinical practice (e.g., including Herceptin and Rituxan).[343,344] Of further interest, recent reports have suggested that antibodies directed against a growth factor receptor may act synergistically with standard cytotoxic chemotherapy.[345,346 and 347] Indeed, a variety of compounds designed to block specific growth factor pathways now are in preclinical or clinical development. [348] Compounds with tyrosine kinase or farnesyl transferase inhibitory activity currently are being developed in the hope that these compounds may be able to block specific growth factor or oncogene pathways, respectively. [349,350]

A relatively new approach to treatment of many solid tumors that has shown great promise in model systems is the use of angiogenic inhibitors. Compounds with inherent anti-angiogenic activity, including endostatin and angiostatin, [351] and agents inhibiting pro-angiogenic signaling, such as humanized vascular endothelial growth factor antibodies,[352] currently are in various stages of development. Although these agents have not been tested directly against RMS, other anti-angiogenic compounds have been reported previously to have activity against RMS xenografts. [353] Finally, camptothecin (irinotecan) and topotecan, agents currently in clinical trial in patients with RMS, have been demonstrated to have significant anti-angiogenic activity, raising the possibility of achieving an “accidental” inhibitory effect, particularly with protracted low-dose drug administration. [354,355]

## PERSPECTIVES

The published results of the IRS-IV study now are beginning to appear, and accrual of patients in the three IRS-V studies probably will continue for 2 more years. Great progress has been made in the treatment of RMS, and most patients with nonmetastatic tumors now are cured. These improvements have been based largely on a foundation of empiric observations achieved in the setting of well-designed clinical studies rather than basic insights resulting from epidemiologic and laboratory studies of the underlying biology of RMS. Although important clues now are being discovered correlating distinct molecular abnormalities with both pathogenesis and prognosis, a plateau appears to have been reached, particularly for the majority of patients who present with unresectable ERMS in unfavorable sites and for those with ARMS of any site. Improvements in both local and systemic disease control still are needed for these groups of patients. Local and locoregional recurrences continue to represent an unacceptably high proportion of all treatment failures. Although better ways of preserving the bladder and female genitourinary structures have become the norm, newer treatment modalities are needed to lessen the late adverse effects on structures in the head and neck.

As new agents with antisarcoma activity become available, possibly RT can be reduced still further (e.g., in patients with orbital lesions). Given the constraints of study design and the relatively small differences that may be expected for patients with localized tumors with favorable prognosis, future clinical studies probably will continue to focus on questions of therapeutic equivalence (i.e., treatments that maintain excellent outcome while reducing the short- and long-term complications of therapy). For patients with intermediate-risk tumors, including the majority of those with unresectable ERMS arising in unfavorable locations and patients with ARMS, the current IRSG strategy to improve outcome includes the evaluation of the efficacy of adding the two-drug combination of topotecan and cyclophosphamide to standard VAC chemotherapy and the role of the more aggressive use of delayed surgical resection in patients with initially unresected tumors.

Single investigational drugs or drug pairs are being assessed increasingly in the setting of a phase II window before introduction of standard therapy in patients with newly diagnosed metastases. This approach will continue in the high-risk arm of IRS-V where, currently, the activity of irinotecan is being evaluated. Although this strategy has been shown to be useful in identifying highly active compounds, it is doubtful whether the addition of conventionally dosed supplemental agents with similar mechanisms of action will improve the outlook significantly for patients with metastases at diagnosis. Significant improvements in outcome probably will not be achieved in such patients until the current generation of etiologic and epidemiologic studies, as well as tumor biologic studies exploring basic molecular mechanisms of tumorigenesis and metastatic spread, begin to yield their fruit.

## INTRODUCTION

Ewing's sarcoma of bone originally was described in 1921 by James Ewing,[1] who characterized it as a tumor of the shaft of long bones that, in contrast to osteosarcoma, was sensitive to radiation. Ewing speculated that this tumor was of endothelial origin, an idea that prevailed until the mid-1980s. Recent evidence reviewed in this chapter confirms a neural origin for Ewing's sarcoma. Although Ewing's sarcoma most commonly is an undifferentiated tumor of bone, it may arise also from soft tissues [extraosseous Ewing's sarcoma (EES)]. A more differentiated form of this entity, known as *peripheral primitive neuroectodermal tumor* (PPNET), or *neuroepithelioma*, occurs as a primary tumor of bone or soft tissues. Both Ewing's sarcoma and PPNET share the same histochemical staining profile and a unique nonrandom translocation. This chapter provides an integrated discussion of the Ewing's sarcoma family of tumors (ESFT), which is now accepted to be a spectrum of a single neoplastic entity.[2]

The discussion in this chapter uses specific terminology. *Ewing's sarcoma* is a tumor of that histology of bone or soft tissue origin. Ewing's sarcoma of bone is a primary bony tumor, and extraosseous Ewing's sarcoma is a soft tissue tumor. PPNET is synonymous with peripheral neuroepithelioma and may be of bone or soft tissue origin. A general term is needed to refer to any of these tumors arising in any site, because most of the literature does not make these relatively recent histologic distinctions. Also, the clinical features of the diseases probably relate more to their primary sites and extent than to their histologic differences. The general term we have chosen is *Ewing's sarcoma family of tumors*.

## EPIDEMIOLOGY

ESFT (Ewing's sarcoma and PPNET) are the second most common primary osseous malignancy in childhood and adolescence. Classically, they are believed to originate in bone, although these tumors can occur also in soft tissue. The annual incidence in the United States is 2.1 cases per million children.

ESFT occur most commonly in the second decade of life. Nearly one-half of all patients with ESFT are between 10 and 20 years of age, and 70% are younger than 20. ESFT rarely develop in adults older than 30 years or in very young children.[3,4 and 5] As with many pediatric tumors, ESFT show a slight male predominance.

Racial and ethnic factors are important in Ewing's sarcoma. Particularly, the ESFT affect whites and are extremely rare among blacks in the United States and in Africa.[6,7 and 8] These tumors have been reported in India and Japan but are distinctly uncommon in China.[9]

The ESFT have not been associated with a familial cancer syndrome.[10] The risk of malignancy in mothers of children with Ewing's sarcoma is not in excess of that expected.[10,11] The ESFT have been reported in siblings, although the incidence is very low.[12,13] One study did show a significant increase in neuroectodermal tumors and stomach cancers in families of patients with Ewing's sarcoma.[14] The ESFT are not commonly associated with other congenital diseases of childhood. Reports of association with skeletal abnormalities (e.g., endochondroma, aneurysmal bone cyst), genitourinary abnormalities (e.g., hypospadias, reduplication of the renal collecting system), Down syndrome, and hereditary retinoblastoma exist but are uncommon, suggesting chance occurrences rather than a biologic basis.[15,16] Other than a single report of trisomy 21, other constitutional chromosomal abnormalities have not been reported in patients with the ESFT.

In terms of environmental factors in the etiology of Ewing's sarcoma, a recent case-control study of 153 children with Ewing's sarcoma did not identify any important environmental or familial risk factors for the development of this neoplasm.[17] Moreover, radiation exposure does not appear to be a common cause of Ewing's sarcoma. For example, no increase in the incidence of Ewing's sarcoma was reported after exposure to nuclear fallout in Japan.[18] In a large study of secondary bone tumors after radiotherapy, 3% were identified as Ewing's sarcoma, whereas 69% of the tumors were diagnosed as osteosarcoma.[19]

The tumor may occur as a second malignant neoplasm; however, the incidence is fairly low. Ewing's sarcoma has presented as a second malignant tumor in previously irradiated areas and in nonirradiated areas.[20,21]

## BIOLOGY

## Histogenesis

Since the initial description of this unique bone and soft tissue neoplasm as a diffuse endothelioma, [1] considerable effort has been expended in an attempt to define the cell of origin. Although the histogenetic origin of Ewing's sarcoma has been ascribed over the decades to endothelial, mesenchymal, and hematopoietic stem cells,[22,23,24,25,26 and 27] recent evidence from immunocytochemical, cytogenetic, and molecular genetic investigations indicates a neural crest origin for the ESFT.[28,29,30,31,32,33,34,35,36 and 37]

Derivation from a primitive, pluripotent, neural crest cell line is supported by the fact that these tumors synthesize acetylcholine transferase, which is essential to acetylcholine synthesis.[29,30,36] Because of the ability to synthesize acetylcholine transferase and the lack of appreciable synthesis of adrenergic pathway precursors, the ESFT are believed to be derived from postganglionic parasympathetic primordial cells located throughout the parasympathetic autonomic nervous system. The variety of soft tissue and bony locations may be explained in part by the wide distribution of these pluripotent stem cells throughout the parasympathetic autonomic nervous system. In contradistinction, neuroblastomas synthesize neurotransmitters associated with the sympathetic autonomic nervous system. [29,30] The origin of neuroblastoma is believed to be from adrenergic or mixed cholinergic-adrenergic primordial cells composing the sympathetic nervous system, including the adrenal medulla and paraspinal ganglia. In addition, Ewing's sarcoma and PPNET produce a different insulin-like growth factor-1 (IGF-1) than that synthesized by neuroblastoma (IGF-2).[38,39 and 40] IGF receptor is expressed in Ewing's sarcoma and allows for a self-stimulatory (autocrine) growth loop, with the IGF-1 produced by the neoplastic cells binding to their own cell-surface receptors. Similarly, gastrin-releasing peptide and its receptor are found with Ewing's sarcoma but not with other small round-cell tumors of childhood, including neuroblastoma. [41] This provides another autocrine growth mechanism, ensuring continuous growth in Ewing's sarcoma. Gastrin-releasing peptide is further proof of a neuroectodermal origin, because this peptide normally is expressed in brain and neuroendocrine cells in the lungs, pancreas, and gastrointestinal system. It is an autocrine growth factor in small cell lung carcinoma and other neuroendocrine malignant tumors. Unlike neuroblastomas, which may show amplification of N-*myc*, the ESFT do not amplify N-*myc*; rather these tumors possess high levels of c-*myc* RNA with or without amplification.[42,43 and 44] These differences in histogenesis between the ESFT and neuroblastoma are supported by cytogenetic, proto-oncogene, histopathologic, ultrastructural, and immunophenotyping data.

Although atypical Ewing's sarcoma and PPNETs (peripheral neuroepithelioma, peripheral neuroectodermal tumors, and Askin tumor) possess certain neural features, as demonstrated by the presence of Homer Wright rosettes, neural processes, neurosecretory granules, and neural immunocytochemical markers, “classic” Ewing's sarcoma has been defined as a tumor composed of primitive cells purportedly lacking neural differentiation. [45] However, the parasympathetic nervous system origin is supported by the ability of cell culture lines derived from undifferentiated Ewing's sarcoma tumors to undergo neural differentiation. [30,33,34,35,36 and 37] Undifferentiated Ewing's sarcoma cell lines develop neural processes, neurosecretory granules, and neurofilament triple proteins and secrete neurosecretory granules when induced by various agents (serum-depleted medium, tissue plasminogen activator, retinoic acid, nerve growth factor, and dibutyryl cyclic adenosine monophosphate). After exposure to these neural inducing agents, undifferentiated Ewing's sarcoma cell lines have been shown by phase-contrast microscopy and both transmission and scanning electron microscopy to possess branching neurite-like processes with varicosities, neurofilaments, and electron-dense neurosecretory granules. [33,34,35,36 and 37] With transfer into a typical serum-based growth media without inducing agents, the “differentiated” cell lines revert to their more primitive forms. Neural differentiation is inhibited by phorbol myristate acetate, a putative tumor promoter.[33] In addition, Ewing's sarcoma cell lines possess receptors for neuropeptide Y, a parasympathetic regulatory polypeptide.[32] Furthermore, both b-adrenergic and dopamine D-1 receptors have been identified in cultured Ewing's sarcoma cell line. [46] Cholecystokinin expression also is present and suggests that these cells originate from a postganglionic parasympathetic progenitor. [29,30] The neural crest parasympathetic origin is supported further by the fact that Ewing's sarcoma cell lines rapidly incorporate choline into acetylcholine and phosphorylcholine. [36] Morphologically undifferentiated Ewing's sarcoma cell lines are capable of acetylcholine synthesis, express markers for synaptic vesicles, and possess proteins associated with calcium-dependent release; however, these cell lines lack an organized mechanism for acetylcholine release. [36] This information and cytogenetic, proto-oncogene, and certain immunocytochemical similarities provide evidence that the ESFT represent a continuum from typical undifferentiated (classic) Ewing's sarcoma to atypical poorly differentiated Ewing's sarcoma to differentiated PPNET (peripheral neuroepithelioma, peripheral neuroectodermal tumor).

## Cytogenetics and Molecular Genetics

Incredible advances have been made in defining soft tissue tumors on the basis of chromosomal translocations, employing both cytogenetic and molecular genetic techniques. Recurring, nonrandom chromosomal translocations and fusion genes have been identified for alveolar rhabdomyosarcoma [t(2;13)(q35;q14), PAX3-FKHR; t(1;13)(p36;q14), PAX7-FKHR]; neuroblastoma [t(1p36;17q)]; malignant melanoma of soft parts [t(12;22)(q13;q12), EWS-ATF1]; desmoplastic small round-cell tumor [t(11;22)(p13;q11-12), EWS-WT1]; myxoid liposarcoma [t(12;16)(q13;p11), TLS-CHOP; t(12;22)(q13;q12) EWS-CHOP]; synovial sarcoma [t(X;18)(p11.2;q11.2), SYT-SSX-1, and SYT-SSX2, t(5;18)(q11;q11), SYT-Unknown)]; extraskeletal myxoid chondrosarcoma [t(9;22)(q22;q12), EWS-CHN]; congenital fibrosarcoma and mesoblastic nephroma [t(12;15)(p13;q25), ETV6-NTRK3]; dermatofibrosarcoma protuberans [t(17;22)(q22;q13), COL1A1-PDGFB]; hemangiopericytoma [t(12;19)(q13;q22)]; and others.[47,48,49,50,51,52,53,54,55,56,57,58,59,60 and 61] Likewise, the ESFT that include Ewing's sarcoma, PPNET, and Askin tumor express five reciprocal translocations (Table 33-1), with EWS-FLI1 [t(11;22)(q24;q12)] being most frequent. This chromosomal translocation (EWS-FLI1) is present in 90% to 95% of tumors within the Ewing's sarcoma family. The second most common translocation is EWS-ERG [t(21;22)(q22;q12)], which occurs in 5% to 10% of tumors. Rarely, Ewing's sarcoma will express three other translocations, including EWS-ETV1 [t(7:22)(p22;q12)], EWS-EIAF [t(17;22)(q12;q12)], and EWS-FEV [t(2;22)(q33;q12)]. In addition to these tumor-defining chromosomal translocations, other complex nonrandom translocations are associated with this family of tumors[60,61,62,63 and 64] and include [t(11;14;22)(q24;q11;q12)], [t(10;11;22)(p11.2;q24;q12)], [t(11;17;22)(q24;q22;q12)], [t(11;18;22)(q24;q22;q12)], and [t(4;11;22;)(q21;q24;q12)]. As noted, the majority of variant or complex translocations in the ESFT includes EWS-FLI1 [t(11;22) (q21;q12)]; however certain tumors have been shown to have the chromosomal translocations EWS-ERG, EWS-ETV1, EWS-EIAF, and EWS-FEV, which do not involve chromosome 11 by cytogenetic detection means.[47,48,49,50,51,52,53,54,55,56,57,58,59,60,61,62,63,64,65 and 66] A second nonrandom translocation (Table 33-1), der(16)t(1;16), has been described in a subset of typical Ewing's sarcomas and PPNETs that also possess characteristic tumor-defining translocations. [67,68,69,70 and 71]

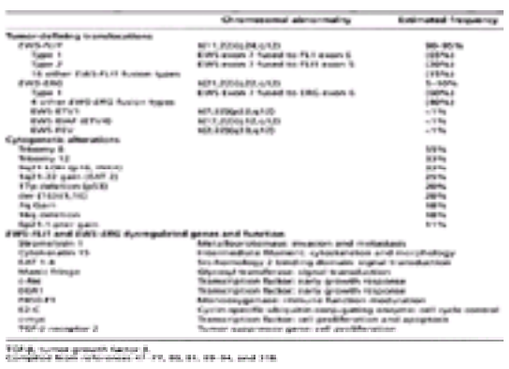

**TABLE 33-1. CYTOGENETIC AND MOLECULAR CHARACTERISTICS OF EWING'S SARCOMA FAMILY OF TUMORS**

Other chromosomal abnormalities include trisomy of chromosomes 8 and 12 and deletion of chromosomes 22, 16q, and 1p36. [51,68,69,70,71 and 72] The ESFT have nonrandom gains, losses, deletions, and loss of heterozygosity at specific chromosomal loci ( Table 33-1), which result in dysfunction of tumor suppressor genes, cell cycle regulators, signal transduction pathways, and yet-to-be-identified genes. In fact, trisomy 8 and 12, loss of 16q and 1p36, and gain of 1q21-22 are linked to distant disease development, relapse, disease progression, and an unfavorable outcome. Consistent nonrandom translocations (EWS-FLI1 and EWS-ERG) in the vast majority (more than 95%) of tumors and nonrandom cytogenetic alterations support a common histogenesis in the ESFT and provide unique diagnostic characteristics to discriminate these tumors from other childhood small round-cell tumors.

Molecular cloning of the breakpoints of the t(11;22)(q24;q12) translocation has localized the rearrangement sites to the EWSR1 region on chromosome 22 and the EWSR2 region on chromosome 11 (Fig. 33-1).[47,48,49,50,51,52,53,54 and 55,73,74,75,76,77,78,79,80 and 81] The EWSR1 region is nested within the novel gene *EWS* on chromosome 22. This gene produces a protein that has homology with other proteins, such as polymerase II, that interact with double-stranded DNA. The EWSR2 region on chromosome 11 contains a subfamily member of the *ets* oncogene superfamily that has 97% homology with the murine friend leukemia integration-1 locus (FLI1).

FLI1 proteins bind to DNA in a sequence-specific manner via the 3'-ets domain and function as a transcriptional activator via the 5'-ets domain. The t(11;22)(q24;q12) chromosomal translocation present in the majority of the ESFT results in rearrangement of the *FLI1* gene with fusion of the carboxy-terminal region of FLI1 with the amino-terminal region of EWS. Because the EWS domain is substituted for a portion of the FLI1 transcriptional domain, the EWS-FLI1 fusion alters the transcriptional activation property usually associated with FLI1. The EWS-FLI1 fusion results in a chimeric protein, which is capable of transforming NIH3T3 fibroblasts in cell culture. Deletion analysis indicates that the EWS segment in the *EWS-FLI1* gene functions as the regulatory or modulating domain. Although the chimeric gene product of the EWS-FLI1 fusion is capable of transforming cell lines, neither EWS nor FLI1 gene products alone have this capability. In the subgroup of the ESFT having the t(21;22)(q22;q12) translocation (Fig. 33-1), EWS from chromosome 22 fuses with another subfamily member of the *ets* oncogene superfamily, ERG, located on chromosome 21.[55,56,81,82] Both ERG and FLI1 are members of the same *ets* oncogene subfamily and have a high degree of homology. The chimeric protein derived from the EWS-ERG fusion is fairly similar to that for the EWS-FLI1 gene product, with EWS replacing the transcriptional domain of ERG. At least 18 EWS-FLI1 and 5 EWS-ERG transcript types have been identified on the basis of the exact fusion exon sites between EWS and the *ets* subfamily member. Despite these differences in transcript types, these chimeric fusion products are capable of transforming cell lines equally well and result in dysregulation of many genes associated with cell signaling, cell proliferation and growth, apoptosis, tissue invasion, and tumor metastasis (Table 33-1).

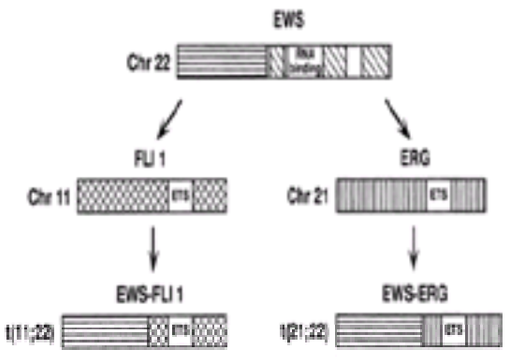

**FIGURE 33-1.** Ewing's sarcoma family of tumors and tumor-defining t(11;22) and t(21;22) translocations resulting in *EWS-FLI1* and *EWS-ERG* gene fusion.

Less common translocations in the ESFT (Table 33-1) have been identified, and the resulting chimeric proteins possess transforming abilities.[51,52,53,54,55] and [56,58] EWS-ETV1 [t(7;22)(p22;q12)] results from fusion of EWS exon 7 with ETV1, which has homology with both FL1 and ERG and is a member of the *ets* oncogene superfamily. Fusion of EWS exon 7 with the adenovirus E1A enhancer-binding protein creates the EWS-EIAF [t(17;22)(p22;q12) translocation. EIAF activates metalloproteinase genes, including stromelysin 1, associated with tissue invasion and tumor metastasis. FEV fuses with EWS exon 7 to create the fifth *ets* superfamily oncogene that results in a tumor-defining translocation [t(2;22)(q33;q12)] in Ewing's sarcoma. Under normal cell conditions, FEV acts as a transcriptional repressor in the adult prostate and small bowel. These three lesser-known Ewing's sarcoma translocations are very infrequent; however, when identified, they represent tumor-defining genetic abnormalities.

Because hybrid transcripts from the fusion of EWS-FLI1 and EWS-ERG have been defined, it is possible to determine the presence or absence of these products in tumor cells. Two molecular genetic techniques commonly are employed. Reverse transcriptase-polymerase chain reaction (RT-PCR) and fluorescent *in situ* hybridization (FISH) may be used to detect the specific EWS-FLI1 or EWS-ERG hybrid transcript expressed by the tumor.[82,83,84,85,86,87] and [88] RT-PCR depends on reverse transcription of RNA from tumors into complementary DNA and amplification of the chimeric transcripts to detect the gene products. Using primers derived from the genes participating in the chromosomal translocation carries out amplification of only the specific fusion sequence. Such a technique has been shown to be fairly specific and highly sensitive in detecting hybrid transcripts.[60,82,83,84,85] and [86] In fact, a hybrid transcript for either EWS-FLI1 or EWS-ERG may be identified in more than 95% of typical or atypical Ewing's sarcomas and PPNET tumors.[51,52,53,54,55,56,57,58,59] and [60] Within one particular study, hybrid transcripts were identified by RT-PCR in 40% of undifferentiated tumors, allowing for reclassification of these tumors into the ESFT. A high correlation level of RT-PCR detection of hybrid transcripts with cytogenetic findings is present for both typical t(11;22)(q24;q12) or t(21;22)(q22;q12) and complex or variant translocations, with EWS-FLI1 or EWS-ERG fusion transcripts identified in 98% of cases. Perhaps even more intriguing is the identification of EWS-FLI1 or EWS-ERG products in 75% of the ESFT with no cytogenetic evidence of structural rearrangement for chromosomes 11, 21, or 22. Similarly, hybrid transcripts may be localized and identified by FISH with a similar degree of sensitivity and specificity.[86,87] and [88] With FISH, neoplastic cells are hybridized directly with probes for the two involved loci, EWS-FLI1 and EWS-ERG. Gene fusion is evaluated by direct visualization of fluorescent labeling in interphase cells. Translocation has occurred if the bivariate hybridization labels are adjacent to each other on the same chromosome.

With the ability to determine the precise EWS-FLI1 and EWS-ERG fusion transcript type, the distribution of transcript types within Ewing's sarcoma tumors has been determined (Table 33-1).[51,52,53,54,55] and [56,58,89,90,91,92,93] and [94] The clonality of Ewing's sarcoma is emphasized by the fact that only a single specific type of fusion transcript is identified in an individual tumor. This specificity applies to both primary and metastatic tumors in the same patient and in tumor at relapse. Type 1 and type 2 transcripts occur in most (85%) of EWS-FLI1 Ewing's sarcomas, whereas EWS-ERG type 1 fusion transcript accounts for 60% of EWS-ERG tumors, with four non–type 1 transcripts comprising the remaining 40%. More importantly, clinicopathologic studies indicate that EWS-FLI1 type 1 transcript (EWS exon 7 fusion with FLI1 exon 6) is associated independently with stage of disease at diagnosis, improved prognosis, increased overall and disease-free survival (DFS), relapse, and reduced metastatic potential, when compared with non–type 1 EWS-FLI1 transcripts.[89] Median survivals for either all patients or those with only localized disease were identical: 27 months for non–type 1 transcripts and 113 months for type 1 transcript. The risk ratio for developing metastatic disease was reduced by almost threefold in those with type 1 fusion transcripts. The reason that type 1 EWS-FLI1 transcripts provide a more favorable clinical course is not known with certainty. Native FLI1 exons 4 to 8 contribute to transactivation, and exons 5 to 8 modulate protein-protein interactions with a serum response factor. Structural features of FLI1 are controlled by exon 5 (helical domain) and exons 6 and 7 (predicted turn). The absence of exon 6 may affect the spatial relationship of the chimeric EWS-FLI1 protein's DNA-binding domain with the corresponding target's transactivation domain. Ewing's sarcoma and NIH3T3 cell culture investigations have shown a less active chimeric transcription factor, with type 1 EWS-FLI1 transcript and reduced transactivation of FLI1-responsive reporter constructs. This implies that exon 6 may have a modulating or inhibitory effect on transactivation with EWS-FLI1 type 1 and that this may be reflected as a more favorable clinical course. At present, treatment decisions have not been based on specific EWS-FLI1 transcript types; however, fusion transcript types may play a role in future therapy.

EWS-ERG fusion type analysis has identified at least five distinct transcripts.[51,54,55,92] As noted, 60% are type 1 EWS-ERG transcripts (EWS exon 7 fused with ERG exon 6). The number of tumors with the EWS-ERG translocation is fairly small in comparison with those having the EWS-FLI1 translocation. Differentiation between EWS-ERG fusion types with respect to clinical features will require accumulation of an adequate number of cases to provide statistically meaningful data. However, comparison of clinical factors between EWS-FL1 and EWS-ERG fusion transcripts found no differences in age at diagnosis, gender, primary tumor site, metastatic disease at diagnosis, relapse rates, event-free survival (EFS), or overall survival. Similarly, EWS-FL1 type 1 and EWS-ERG type 1 fusion transcripts had similar clinical phenotypes. EWS-FLI1 and EWS-ERG appear to result in similar clinical presentations and outcomes.[92] This finding implies that the transcripts from EWS-FLI1 and EWS-ERG have comparable functions in tumorigenesis.

RT-PCR and FISH for EWS-FLI1 and EWS-ERG fusion transcripts may provide the diagnostic information necessary to confirm the histopathologic suspicion of Ewing's sarcoma in particularly difficult cases.[51,52,53,54] and [55,59,60] The benefit of both RT-PCR and FISH is that the detection of a t(11;22) or t(21;22) translocation may be performed in a considerably shortened period when compared with cytogenetic culture means. In addition, certain tumors without chromosome 11, 21, or 22 abnormalities may express hybrid transcripts that are detected only by RT-PCR, FISH, or other molecular techniques. Aspiration or fine-needle biopsies of tumors may be evaluated readily by RT-PCR and FISH to confirm the diagnosis of the ESFT.[59,95,96] and [97] This is especially useful when limited tissue is available for diagnosis or cytogenetic cultures fail to reveal tumor-defining translocations.

Peripheral blood and bone marrow evaluation for the presence of Ewing's sarcoma cells is possible with RT-PCR for EWS-FLI1 and EWS-ERG fusion products.[98,99,100] and [101] Some data are controversial regarding the utility of these studies in predicting relapse, metastatic disease, and outcome. Circulating Ewing's sarcoma cells in peripheral blood may be detected in 30% of patients with localized disease and in 50% of patients with metastatic/relapsed disease.[99,100] Likewise, Ewing's sarcoma cells identified by RT-PCR have been found in 19% of patients with localized disease and in 33% of patients with metastatic/relapsed disease. Peripheral blood or bone marrow (or both) was positive in 25% of patients with localized disease as compared with 50% for patients with metastatic/relapsed disease identified by RT-PCR. Overall survival at 18 months was not statistically different between those with RT-PCR–negative and RT-PCR–positive peripheral blood.[99] In

contrast, RT-PCR–positive bone marrow resulted in a significant reduction in overall survival over a limited 12-month period. [99] Another study showed that all individuals with RT-PCR–positive peripheral blood and bone marrow test results became negative after chemotherapy. [101] After a median follow-up of 30 months, relapses were observed in three of seven patients with RT-PCR–positive bone marrow test results, as compared with 2 of 16 patients with RT-PCR–negative bone marrow test results. In this 30-month study, bone marrow involvement was determined not to allow prediction of early relapse. These studies do highlight the fact that in a substantial portion of localized disease cases, Ewing's sarcoma is a systemic disease with circulating tumor cells and reinforces the need for systemic chemotherapy in controlling and eradicating the neoplastic cells. [98,99,100 and 101] Further studies of a more longitudinal nature are needed to determine the significance of RT-PCR–positive peripheral blood and bone marrow.

Timing of peripheral blood collection in RT-PCR studies is important. Ewing's sarcoma cells have been identified in peripheral blood immediately after biopsy. [98] No such cells were detected by RT-PCR before or 6 days after tumor biopsy. Perhaps, peripheral blood or bone marrow RT-PCR for EWS-FLI1 and EWS-ERG transcripts may be more appropriate for postchemotherapy evaluation of patients with no evidence of disease or with stable disease. This may allow for early detection of relapse or minimal residual disease.

Use of molecular techniques has defined a biphenotypic sarcoma of possible neural crest origin that expresses both the tumor-defining cytogenetic translocation [t(11;22)(q24;q12)] and the EWS-FLI1 fusion transcript characteristic for the ESFT. [102] These particular tumors were classified previously as embryonal and alveolar rhabdomyosarcomas on the basis of morphologic, immunocytochemical, and ultrastructural features. In addition, these tumors possessed neural differentiation, as shown by immunoreactivity for neurofilaments and the presence of primitive neurites and neurosecretory dense core granules by electron microscopy. By RT-PCR and Northern analyses, neural-associated gene expression for choline acetyltransferase, chromogranin A, neuron-specific enolase (NSE), and human neurofilaments intimately linked with the ESFT were identified. Myogenic regulatory genes ( *MYF5*, myogenin, and *MYOD1*) were assayed by Northern analysis. These biphenotypic tumors expressed *MYF5* and myogenin, but *MYOD1*, which characteristically is present in rhabdomyosarcoma, was not found with these tumors. Also, *MYOD1* expression in cell lines from these biphenotypic tumors using media known to promote myogenic differentiation could not be induced. The implication from this multimodal investigation is that the EWS-FLI1 oncoprotein may inhibit *MYOD1* expression while promoting neural differentiation as evidenced in the ESFT. Similar suppression of *MYOD1* expression has been found with other oncogenes and proto-oncogenes, in particular *Ras* and c-*fos*.[103] These biphenotypic tumors potentially represent “primitive” malignant ectomesenchymomas related to the ESFT.[102] Typical malignant ectomesenchymoma tumors are neural crest–derived, are composed of neoplastic cells with neural differentiation, and contain one or more malignant mesenchymal components, often including rhabdomyosarcoma. At least 10% of primitive sarcomas with myogenic differentiation have been estimated to be biphenotypic sarcomas with *EWS-FLI1* gene fusion.[102,104] These biphenotypic sarcomas appear to be related to the ESFT. In addition to biphenotypic sarcomas, other small round-cell tumors may represent variants within the ESFT. Certain polyphenotypic tumors, rare mixed alveolar and embryonal rhabdomyosarcomas, malignant ectomesenchymomas, and olfactory neuroblastomas (esthesioneuroblastoma) possess the *EWS-FLI1* translocation.[105,106] Diagnoses in these particular cases must be predicated on histopathologic, immunocytochemical, and genotypic features. These recent revelations emphasize the utility of molecular genetics in conjunction with morphologic analyses in the classification and understanding of the pathobiology of solid childhood tumors.

Although certain tumors are associated with overexpression of mutated forms of tumor suppressor genes, such as mutated *Rb* or *p53*, relatively few tumors and cell lines within the ESFT have been evaluated. Molecular studies have shown that although mutated *p53* expression is relatively common in Ewing's sarcoma tumor cell lines, it is a rare event in primary tumors. [107,108] It was surmised that tumor cells in cell cultures with a mutated *p53* gene (chromosome 17p13) might dominate over cells with an intact wild-type *p53* gene. This theory is corroborated also by the failure to show a significant number of primary tumors with mutated *p53* gene product expression by PCR. The most likely explanation for the increased expression of mutated *p53* in cell cultures is that these mutations are acquired at a later stage in tumorigenesis and may be involved in progression of an already established tumor. Additional data regarding this well-known tumor suppressor gene and other tumor suppressor genes and their role in the ESFT undoubtedly will be forthcoming in the near future.

Finally, the neoplasms composing the ESFT are distinct from neuroblastoma with respect to N-*myc* expression.[42,43 and 44] Molecular studies have shown that the ESFT do not exhibit N-*myc* amplification and also lack high levels of c-*src* tyrosine kinase activity and c-*cts*-1 oncogene expression.[42,43 and 44,109] In contrast, the ESFT express relatively high levels of c-*myc*, which are not found in neuroblastoma. Other small round-cell tumors of childhood, such as rhabdomyosarcoma and lymphoma, possess increased expression of c-*myc* as well.[109,110,111 and 112] N-*myc* and c-*myc* are oncogenes that are amplified in neoplastic processes and participate in transformation, proliferation and may have prognostic significance. N-*myc* is associated classically with neuroblastoma, located on chromosome 2 (2p24) and, when amplified, is associated with a poor prognosis. C-*myc* is found with several neoplastic processes, including leukemias, lymphomas, and carcinomas of the lung, esophagus, cervix, oral mucosa, and ovary. This oncogene is located on chromosome 8 (8q22). In pediatric neoplasia, c-*myc* is found in Ewing's sarcoma and not in neuroblastoma and may be helpful in differentiating between these neoplasms because neuroblastoma expresses N-*myc*. Likewise, the *dbl* oncogene has been detected in both the ESFT and neuroblastoma.[28,29 and 30,33,113] Although lack of N-*myc* amplification in Ewing's sarcoma may be helpful in differentiating neuroblastoma from this tumor, it is helpful only when N-*myc* amplification is present with an undifferentiated tumor. The absence of N-*myc* amplification is not useful in an undifferentiated neoplasm, which lacks morphologic, immunocytochemical, and ultrastructural features of Ewing's sarcoma. In such cases, the role of cytogenetics and molecular genetics in providing a definitive diagnosis is paramount.

The application of molecular genetics, in particular RT-PCR and FISH, renders possible the evaluation of tumors that in the past failed to establish the cell growth necessary for typical cytogenetic studies. With rapid advancement in molecular techniques, such instruments will play a prominent role in diagnosis, follow-up, and evaluation of residual, recurrent, and metastatic disease in childhood tumors.

## DNA PLOIDY AND PROLIFERATIVE INDICES

A paucity of studies has analyzed DNA indices and proliferative indices in the ESFT. [114,115,116,117,118,119 and 120] The majority of studies include only a few cases along with other bone tumors and soft tissue sarcomas. Comparison of DNA content by cytophotometric and flow cytometry in a retrospective study has provided interesting results in 37 patients with Ewing's sarcoma of bone.[114] Diploid tumors were identified by cytophotometry and flow cytometry in 67% and 69% of cases, respectively. Of diploid cases, 58% of individuals in the cytophotometry group and 53% in the flow cytometry group were alive 7.5 years and 8.2 years after diagnosis, respectively. All patients with aneuploid tumors died of disease, with a mean survival of 32 months in those in the cytophotometry group and 35 months in those in the flow cytometry group. A relatively small number (n = 13) of PPNET and EES were included in a separate flow-cytometric study [116] of childhood soft tissue sarcomas. Slightly more than 75% of tumors were diploid or near-diploid (DNA index, 1.00 to 1.09), with 23% of tumors being aneuploid. The median S-phase value was 9.7%. Survival statistics and comparison with DNA data were not performed for PPNET and EES.

Using proliferating cell nuclear antigen (PCNA) and Ki-67 (MIB1) antibody, a clinicopathologic study [115] evaluated proliferation-associated markers in Ewing's sarcomas of bone in a pediatric population. PCNA/cyclin is a nonhistone nuclear protein that functions as a cofactor with DNA polymerase delta. [121] This protein may be detected in cells within the proliferating phases of the cell cycle ($G_1$ through $G_2$/M), with the highest level of detection from mid-$G_1$ through S phases. Quiescent cells ($G_0$) do not express this protein. The monoclonal antibody Ki-67 detects an antigenic epitope of a nuclear protein associated with cell proliferation. This protein may be detected from mid-$G_1$ through $G_2$/M.[121] Noncycling ($G_0$) and early $G_1$ phase cells are nonreactive with the Ki-67 antibody. The tumors showed a relatively high level of expression of both PCNA and Ki-67 detectable proteins by immunocytochemical techniques. [115] Elevated PCNA and Ki-67 proliferation marker expression and survival were associated, in that statistically significant differences were noted between a group that included individuals who either died of disease or were alive with disease, and a group that showed no evidence of disease. Individuals with higher proliferative indices were more likely to die of disease or be alive with disease, and those with lower proliferative indices were more likely to have no evidence of disease. This finding implies that proliferation markers or the proportion of neoplastic cells in the S+$G_2$/M phase of the cell cycle (or both) should be assessed and may provide some insight into the aggressiveness and prognosis in Ewing's sarcoma.

As discussed, EWS-FLI1 type I fusion is associated with improved prognosis. Evaluation of Ki-67 expression in EWS-FLI1 and EWS-ERG was compared with special reference to EWS-FLI1 type 1 tumors. Ki-67 expression was increased significantly in non–type 1 EWS-FLI1 type 1 tumors (24%) as compared with both EWS-FLI1 type 1 (15%) and EWS-ERG (35%) Ewing's sarcomas.[122] Categorical evaluation of all tumors with low (less than 15%) and high (more than 15%) expression of this proliferation marker indicated that 67% of EWS-FLI1 type 1 fusions had low expression, whereas 60% of type 2 EWS-FLI1 and 79% of EWS-ERG tumors had high Ki-67 expression.

Of particular interest was the significant correlation between Ki-67 and IGF-1 receptor immunoreactivity with EWS-FLI1 type 1 tumors (IGF-1R, 65%; Ki-67, 15%) as compared with non–type 1 EWS-FLI1 tumors (IGF-1R, 82%; Ki-67, 24%).[122] With all Ewing's sarcomas, IGF-1R was expressed in more than 50% of tumor cells when Ki-67 was detected in more than 20% of tumor cells. When less than 10% of tumor cells expressed Ki-67, IGF-1R was detected in fewer than 40% of tumor cells. *In situ* DNA nick end labeling analysis for apoptosis in EWS-FLI1 and EWS-ERG found a trend toward increased apoptosis in EWS-ERG (10.1%) as compared with

EWS-FLI1 type 1 (2.4%) and non–type 1 tumors (5.3%).[122] The overexpression of proliferation markers in non–type 1 EWS-FLI1 and EWS-ERG tumors would appear to be mediated by an IGF-1R pathway. IGF-1 and IGF-1R are known to participate in the neoplastic process by autocrine and paracrine mechanisms. However, other regulators of the cell cycle also may contribute to an increase in Ki-67 protein production, such as mutated *p53* (11% of tumors) and INK4A (17% of tumors).[122] Overexpression of both Ki-67 and IGF-1R is associated with tumor progression and portends a poor prognosis. EWS-FLI and EWS-ERG chimeric proteins may modulate expression of the *IGF-1R* gene. Inhibition of *IGF-1R* may lead to reduced proliferation and increased apoptosis in Ewing's sarcoma.

In addition to PCNA and Ki-67, other proliferation markers[121] are available and may become important in evaluating the ESFT. A thymidine analog 5-bromodeoxyuridine (BrdU) requires incubation with fresh viable tissue and is taken up by synthetically active (S phase) cells. The incorporation of BrdU may be demonstrated by immunocytochemistry, immunofluorescence, and flow cytometry. This monoclonal antibody has, to a great extent, replaced tritiated thymidine as a proliferation marker. DNA polymerase alpha is expressed in proliferating cells from $G_1$ through $G_2$/M and is a cell cycle–related enzyme involved with DNA synthesis. This proliferation marker has a sensitivity that is two to three times less than that for PCNA and requires frozen tissue for analysis. Monoclonal antibody p105 is directed against two proliferation-associated nuclear proteins of 105 kD and 41 kD. This flow-cytometric and immunocytochemical antibody reacts with a nuclear antigenic epitope within chromatin granules of the nuclear matrix involved with RNA synthesis. The detected protein p105 may modulate regulatory functions involved with terminal RNA transcript production required for progression in the cell cycle. This protein is expressed in all proliferating cell phases ($G_1$ through $G_2$/M) but has its greatest expression in late S and M phases. Immunoreactivity to p105 and Ki-67 has been shown to correlate well. This antigen withstands formalin fixation and paraffin embedding of the tissue. However, optimal use of this monoclonal antibody has been with bivariate flow cytometry.

DNA flow cytometry and proliferation markers, such as Ki-67 (MIB1), PCNA, and BrdU, have been employed in numerous clinicopathologic studies and have predictive value. Clinical stage, histologic grade, tumor recurrence, and survival have been linked to increased expression of these monoclonal antibodies and both DNA ploidy (aneuploidy) and elevated proliferative fraction (S+$G_2$/M) status within a variety of tumors.[121] At present, relatively few clinicopathologic studies have been performed with the ESFT,[114,116,117,118,119 and 120] and the role of DNA ploidy and proliferative index markers is in the process of being defined.

## PROSPECTIVE INNOVATIVE BIOLOGY-BASED THERAPY

With the identification of EWS-FLI1 and EWS-ERG chimeric proteins' transforming ability in Ewing's sarcoma, creation of antisense oligodeoxynucleotides to these proteins allows for prevention of messenger RNA (mRNA) translation. *In vitro* studies with Ewing's sarcoma cell lines expressing EWS-FLI1 have found a 40% to 60% reduction in fusion protein production in the presence of antisense material directed toward EWS-FLI1.[123,124 and 125] In addition, tumor cell growth was inhibited by 25% to 40%. The ability to transfect Ewing's sarcoma cell lines with EWS-FLI1 and EWS-ERG antisense using plasmids has shown encouraging results. Previously tumorigenic cell lines after transfection have proved to be nontumorigenic in an athymic murine model. These transfected cell lines also have impaired colony formation, anchorage-independent growth on soft agar, and a ten- to 20-fold decrease in clonogenic efficiency. Along with these phenotypic changes, a significant loss of EWS-FLI1 and EWS-ERG fusion protein expression occurred. Other alternatives to antisense in down-regulating the transforming EWS fusion products include ribozymes, neutralizing antibodies, truncated *ets* oncogene domain–binding molecules, and novel drugs.

Several cell-surface receptors that participate in signal transduction and cell growth are expressed in Ewing's sarcoma and also may be therapeutic targets.[38,39,40 and 41,126,127 and 128] Ewing's sarcoma cell lines and tumors display receptors for IGF-1, gastrin-releasing peptide, transforming growth factor-b type II, CD40, and Fas.[38,39,40 and 41,126,127 and 128] These neoplastic cells also interact with G protein–coupled receptors that regulate signal transduction and cell growth.[126] This particular receptor is modulated by a protein tyrosine kinase (Pyk2) that regulates the interaction of RNA-binding protein EWS with G protein–coupled receptors. Treatment of Ewing's sarcoma with ligands to these various receptors may derail the signal transduction effect of EWS fusion proteins. Apoptosis also may be induced via the Fas receptor expressed on tumor cell surfaces.[128] Several Ewing's sarcoma cell lines possess Fas ligand that is faulty and is incapable of inducing apoptosis in cytotoxic lymphocytes (Jurkat cells). Ewing's sarcoma cell lines serve as stimulators for generation of cytotoxic effector lymphocytes and are susceptible to lysis. Immunotherapy would appear possibly to be effective in treatment of Ewing's sarcoma. With the numerous receptors and growth factors interacting with EWS fusion proteins, the need for characterization of individual tumors may be necessary in the near future to direct biologically based therapy.

## PATHOLOGY

### Classification

The ESFT represent a spectrum from undifferentiated Ewing's sarcoma to poorly differentiated atypical Ewing's sarcoma to differentiated PPNET. Differentiation in this family of tumors is based on expression of morphologic, immunocytochemical, ultrastructural, and molecular neural features. The term *PPNET* includes soft tissue and bone neoplasms previously termed *peripheral neuroepithelioma*, *adult neuroblastoma*, and *malignant small-cell tumor of the thoracopulmonary region (Askin tumor)*, which is associated with the chest wall and thoracic cavity. The ESFT include both osseous and extraosseous forms. Before sophisticated cytogenetic and molecular techniques, a number of undifferentiated tumors were included in EES. With the currently available diagnostic instruments, tumors within this category are less likely to include neoplasms that do not meet the criteria for the ESFT. As noted, such additional tumors as the biphenotypic sarcoma may be related to the ESFT and could in the future represent a distinct subtype, especially if clinical behavior and response to oncologic management are similar to those for the ESFT.

### Triaging Tissue and Processing of Biopsy and Resection Specimens

At initial tumor biopsy, a pathologist must assess the quantity of viable tumor tissue submitted to determine whether it is adequate for diagnosis and various studies. Tissue should be submitted for (a) cytogenetic (karyotype) studies in tissue culture media; (b) molecular, RT-PCR, and specialized immunocytochemical studies (cryopreserved at –70°C); (c) flow-cytometric studies for DNA ploidy and proliferation fraction in tissue culture media; (d) ultrastructural examination in glutaraldehyde; (e) light-microscopical examination and routine immunocytochemical and FISH studies in 10% buffered formalin and alcohol; and (f) cytologic imprints (alcohol-fixed and air-dried) for FISH studies. If a needle biopsy is performed, multiple tissue cores are necessary to allow for cytogenetic, molecular, routine, and ultrastructural studies.[59,120] In a cytologic study of 20 extraskeletal Ewing's sarcomas, diagnostic tumor material for routine light-microscopical and immunocytochemical studies was available in all cases.[97] EWS-FLI1 translocations were identified within the ten tumors from which tissue was available for cytogenetic and molecular evaluation.

Surgical resection of the tumor after chemotherapy induction requires that soft tissue, bone marrow, and bone surgical margins be assessed thoroughly to determine negative surgical margins and the distance of the tumor to the closest surgical margin. The attached skin and soft tissue containing the original biopsy site is sampled thoroughly for residual tumor. If tumorous tissue is readily accessible, tumor tissue should be submitted for cytogenetic and molecular analysis, especially if they were not performed on the initial biopsy or if prior studies failed to identify a tumor-defining translocation. Cytogenetics may be informative regarding additional chromosomal abnormalities associated with treatment effect, progressive disease, and prognostic implications. Likewise, tissue for DNA ploidy and proliferation fraction may be informative if not completed previously. Before sectioning, the specimen should undergo radiographic examination in at least two planes to determine residual tumor location and extent. The entire specimen is frozen at –70°C for several hours. The frozen specimen then is sectioned serially in a longitudinal direction, allowing for exposure of the maximum dimension of the tumor. The tumor size is measured in three dimensions. The entire longitudinal section containing the maximum tumor area is mapped diagrammatically, is photographed, and is submitted in multiple blocks for evaluation of the histologic response to therapy. All areas of this longitudinal section, including the medullary canal contents, residual tumor, cortical bone, surgical margin, and immediately surrounding soft tissue, are fixed in buffered formalin. The calcified tissue blocks undergo decalcification with a formic acid-formalin solution before processing. The degree of decalcification may be determined by radiographic evaluation of the blocks. Other selected areas of interest from the remaining longitudinal sections of the specimen are submitted for evaluation also.

### Gross Appearance

Both soft tissue and osseous ESFT have a similar appearance (Fig. 33-2). Even with a primary tumor that originates intraosseously, a soft tissue component may be present owing to extension through the cortical plate. Likewise, some tumors may arise from soft tissue and invade the adjacent bone. These neoplasms are composed of firm, gray-white soft tissue with a glistening, moist appearance on sectioning. Extraosseous tumors tend to have a less firm texture and are more friable. Hemorrhage and cystic degeneration secondary to tumor necrosis are a common feature as well. With intraosseous neoplasms, the medullary cavity often is involved diffusely, and the extent of tumor involvement is considerably greater than that appreciated on conventional radiographs.

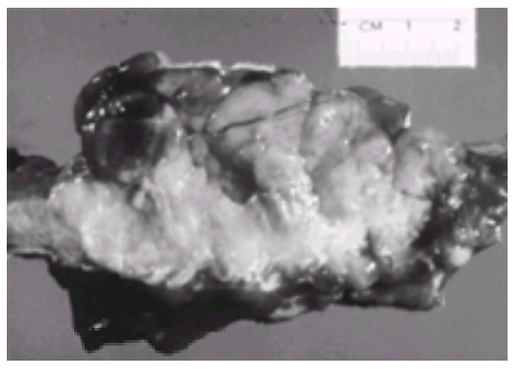

**FIGURE 33-2.** Typical gross appearance of Ewing's sarcoma family of tumors.

### Histopathologic Features

The histopathologic features of the ESFT, as determined by light microscopy, are summarized in Table 33-2.

| Feature | Ewing's sarcoma | | PPNET |
|---|---|---|---|
| | Typical | Atypical | |
| Light microscopy | | | |
| Pattern | Sheets of cells | Usually nesting | Alveolar, rosettes, organoid, or lobular pattern |
| Intercellular matrix | Absent | Usually present | Present |
| Cell size | Small | Small to large | Small to large |
| Cell shape | Exclusively round | Predominantly round | Predominantly round |
| Cytoplasm | Scant | Scant to easily identifiable | Easily identifiable |
| Nucleus | Round/smooth | Round, occasionally oval | Round, occasionally oval |
| Mitoses | <2 per high-power field | <2 per high-power field | <2 per high-power field |
| Electron microscopy | | | |
| Cell shape | Round/smooth | Round to oval, irregular | Round to oval, irregular, cell processes |
| Nuclear shape | Round | Round to oval | Round to oval |
| Neurosecretory granules | Absent | Absent | Present |
| Organelles | Sparse | Moderate | Moderate to many |
| Filaments | Absent | Absent to few | May be present |
| Glycogen | Present | Present | Present |
| Attachments | Primitive | Primitive to moderately developed | Moderately to well developed |
| Basal lamina | Absent | Absent | Absent |
| Extracellular matrix | Absent | Variable | Variable |

PPNET, peripheral primitive neuroectodermal tumor

**TABLE 33-2. EWING'S SARCOMA FAMILY OF TUMORS: HISTOPATHOLOGIC AND ULTRASTRUCTURAL FEATURES**

#### *Typical Undifferentiated and Atypical Poorly Differentiated Ewing's Sarcoma*

As initially described by James Ewing[1] in 1921, typical undifferentiated Ewing's sarcoma is composed of broad sheets of polyhedral cells with small hyperchromatic nuclei, relatively well-defined cell borders, amphophilic cytoplasm, a high nuclear-cytoplasm ratio, and absence of intercellular material ( Fig. 33-3). Additional cytologic features include a monomorphous appearance of the tumor cells, scant cytoplasm, homogenous nuclear basophilia with inconspicuous nucleoli, and rare mitotic figures (fewer than two mitoses per high-power field).[45,59,120,129,130,131,132,133,134,135] and [136] The cells are in close proximity to each other with no detectable intervening stromal supporting elements, even with reticulin staining. The broad sheets of tumor cells occasionally are interrupted by delicate fibrovascular septa containing small-caliber vessels and capillaries. Usually, considerable areas of hemorrhage and associated tumor necrosis are present. The amphophilic or clear nature of the cytoplasm is due to the abundance of glycogen.[59,120,129,130,131] and [132] The presence of glycogen may be demonstrated by periodic acid–Schiff (PAS) staining without diastase digestion. Although most tumor cells contain intracytoplasmic glycogen, formalin fixation may result in suboptimal fixation of glycogen and loss of PAS positivity for glycogen. Preservation of glycogen is accomplished by alcohol-based fixation. Although many individuals equate abundant cytoplasmic glycogen in a small blue-cell tumor of childhood with Ewing's sarcoma, this finding alone is not sufficient for the diagnosis and cannot differentiate this tumor from other childhood small blue-cell tumors. The tumor typically invades the adjacent normal tissue by compression, giving the tumor a “pushing” type of margin. An infiltrative pattern also may be seen but more commonly is seen with atypical poorly differentiated Ewing's sarcoma.

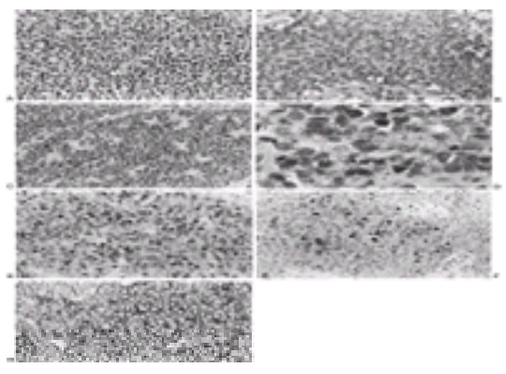

**FIGURE 33-3.** Histopathologic and immunocytochemical appearance of Ewing's sarcoma family of tumors. **A:** Typical undifferentiated Ewing's sarcoma. **B:** Atypical poorly differentiated Ewing's sarcoma. **C:** Peripheral primitive neuroectodermal tumor (differentiated Ewing's sarcoma). **D:** Detection of glycogen in typical undifferentiated Ewing's sarcoma (periodic acid–Schiff histochemistry). **E:** Proliferating cell nuclear antigen (PCNA) expression in typical Ewing's sarcoma from patient who died of disease (PCNA immunocytochemistry). **F:** PCNA expression in typical Ewing's sarcoma from patient who has no evidence of disease at follow-up (PCNA immunocytochemistry). **G:** Diffuse cell membrane immunoreactivity for glycoprotein p30/32$^{MIC2}$ in Ewing's sarcoma family of tumors (HBA-71 immunocytochemistry).

Atypical poorly differentiated Ewing's sarcoma (Fig. 33-3B) is characterized by an increase in overall cell and nuclear size, cellular pleomorphism with ovoid cell shape, and irregular nuclear contours and an increased mitotic rate (greater than two mitoses per high-power field). [45,59,120,129,130,131,132,133,134,135] and [136] The nuclei show a dispersed chromatin appearance with relatively prominent nucleoli. Rare or complete absence of glycogen on PAS staining is characteristic. Atypical Ewing's sarcoma may be arranged in sheets, or have an organoid, lobular, or alveolar architectural pattern. The presence of an organoid, lobular, or alveolar pattern qualifies the tumor as an atypical poorly differentiated form even if cytologic features resemble typical undifferentiated Ewing's sarcoma. Detectable intervening eosinophilic supporting stroma are seen between groups or individual tumor cells. Focal tumor necrosis and hemorrhage also may be seen. Spindle cells may be present at the periphery of the tumor, and these tumor cells invade the adjacent tissue in an infiltrative pattern. Both typical (undifferentiated) and atypical (poorly differentiated) Ewing's sarcoma lack morphologic features of neural differentiation, such as pseudorosettes, true rosettes, or a neuropil background.

EES may be classified using the same criteria but more commonly has an organoid, alveolar, lobular, or even a pericytic architectural pattern. [45,120,129,130,131,132,133,134,135] and [136] Differentiation from other soft tissue masses and small blue-cell tumors of childhood are dependent on immunocytochemical, ultrastructural, cytogenetic, and molecular genetic findings.

#### *Peripheral Primitive Neuroectodermal Tumor (Differentiated Ewing's Sarcoma)*

The PPNET member of the ESFT may have histopathologic features that resemble typical undifferentiated or atypical poorly differentiated Ewing's sarcoma; however, a neural immunophenotype or neural differentiation on ultrastructural examination will be present. [45,59,120,129,130,131,132,133,134,135] and [136] On the basis of histopathologic

criteria alone, Flexner-type rosettes or Homer Wright–type pseudorosettes may be present in PPNET ( Fig. 33-3C). Flexner rosettes are glandlike structures that are seen infrequently in neural tumors, whereas Homer Wright pseudorosettes are annular arrays of tumor cells surrounding central zones of eosinophilic fibrils. Rarely will true rosettes be identified. More typically, the neoplastic cells are organized into an organoid, alveolar, or lobular pattern ( Fig. 33-3) with infrequent to rare pseudorosettes. This differentiated form of the ESFT lacks mature neural elements, such as ganglion cells, nerve fascicles or bundles, and a neuropil background. The background is composed of a fibrovascular network with eosinophilic supporting stroma. Focal regions of tumor necrosis and hemorrhage also may be seen. Increased mitotic activity is present. Included within this category is the malignant small-cell tumor of the thoracopulmonary region (Askin tumor) that involves the chest wall more commonly in adolescent women and is believed to be derived from pluripotent cells along intracostal nerves.

### Ultrastructural Features

The ultrastructural features of the ESFT, as determined by electron microscopy, are summarized in Table 33-2.

#### *Typical Undifferentiated Ewing's Sarcoma and Atypical Poorly Differentiated Ewing's Sarcoma*

Typical undifferentiated Ewing's sarcoma ( Fig. 33-4A) is composed of small homogenous cells with round to oval nuclei with smooth nuclear contours. [45,59,120,129,130,131 and 132,137,138,139 and 140] The nuclei have dispersed chromatin with relatively little peripherally placed heterochromatin. Occasional nucleoli are seen. The cytoplasm is relatively bland with sparse organelles and only occasional mitochondria, lipid droplets, and polyribosomes. The predominant cytoplasmic feature is relatively abundant glycogen deposition with some areas described as glycogen pools or lakes. Intermediate filaments, neurofilaments, and extracellular matrix are not appreciated. Neurites or cell processes are rare to absent. The tumor cells are in close proximity and have rudimentary cell attachments.

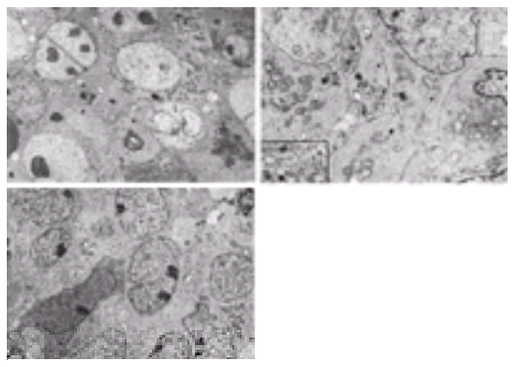

**FIGURE 33-4.** Ultrastructural appearance of Ewing's sarcoma family of tumors. **A:** Typical undifferentiated Ewing's sarcoma composed of round primitive cells with scant cytoplasm containing glycogen. **B:** Peripheral primitive neuroectodermal tumor with prominent neurite-like cell processes containing dense core neurosecretory granules (*inset*). **C:** Atypical poorly differentiated Ewing's sarcoma composed of cells with slightly irregular nuclear contours, decreased cytoplasmic glycogen, and occasional rudimentary cell processes.

Atypical, poorly differentiated Ewing's sarcoma is composed of larger cells with a moderate degree of cellular and nuclear pleomorphism ( Fig. 33-4C).[45,59,120,129,130,131 and 132,137,138,139 and 140] The cell borders are irregular, with areas of cellular molding and intervening cell processes. The cell processes rarely show dense core granules and filaments. An increase in peripherally placed heterochromatin and more prominent nucleoli are present. The cytoplasm contains a reduced amount of glycogen as compared with typical (undifferentiated) Ewing's sarcoma. Rudimentary cell attachments are more frequent and easily recognized. The extracellular space may show occasional areas of collagen deposition. No other tumor-defining characteristics are seen.

#### *Peripheral Primitive Neuroectodermal Tumor (Differentiated Ewing's Sarcoma)*

Intertwining neurite-like processes with dense core granules ( Fig. 33-4B) are seen with PPNET (differentiated Ewing's sarcoma). [45,59,120,129,130,131 and 132,137,138,139 and 140] These cytoplasmic processes are organized in a haphazard manner, and occasional processes will contain neurofilaments and microtubules. The dense core granules are reduced in number and usually exhibit an angulated or pleomorphic morphology as compared with those present in neuroblastomas. The cytoplasm may contain occasional small aggregates of glycogen. The nuclei tend to be ovoid to slightly elongated and are somewhat irregular in contour. Prominent nucleoli and peripherally placed heterochromatin characterize the nuclear morphology. Relatively well-developed cell attachments are seen. Occasional pseudorosettes with central areas composed of intertwining cell processes may be present. Fusiform cells resembling fibroblasts or Schwann cells may occupy the stromal areas, and both typical and long-spacing collagen deposition occasionally is found. No other tumor-defining characteristic is present.

### Immunocytochemistry

Differentiation of the ESFT from other small round-cell tumors of childhood may prove to be difficult on the basis of morphologic features alone. Monoclonal and polyclonal antibodies for various differentiation markers [45,59,120,129,130,131 and 132,135,136,137,138,139,140,141,142,143,144,145,146,147,148 and 149] may provide diagnostic clues. Table 33-3 presents a comparison of immunoreactivity for various markers within the ESFT and among other small blue-cell tumors of childhood. In the past, typical undifferentiated Ewing's sarcoma was defined as a neoplasm that had immunoreactivity only for vimentin and was negative for NSE. Atypical poorly differentiated Ewing's sarcoma was immunoreactive for vimentin and NSE or a single neural marker. In contrast, PPNET (differentiated Ewing's sarcoma) reacted with vimentin and with a number of neural markers and could possess rosettes and pseudorosettes morphologically. The expression of neural markers would be expected to increase with neural differentiation from undifferentiated Ewing's sarcoma to PPNET (differentiated Ewing's sarcoma). Although differentiating rhabdomyosarcoma is possible on the basis of desmin, myoglobin, muscle-specific antigen, smooth-muscle actin, and other myogenic antibodies, always a certain small percentage of cases may have aberrant immunoreactivity. Some cases of rhabdomyosarcoma have been reported to be immunoreactive for NSE. Other neural markers, such as protein gene product 9.5, HNK-1, neurofilament triple proteins, synaptophysin, chromogranin, and S-100 protein, may provide evidence for neural differentiation in Ewing's sarcoma; however, these agents alone will not provide a definitive diagnosis.

| Marker | Ewing's sarcoma | | PPNET | Neuroblastoma | Rhabdomyosarcoma | Lymphoma[a] |
|---|---|---|---|---|---|---|
| | Typical | Atypical | | | | |
| NSE | - | +/- | + | + | +/- | - |
| S-100 | - | +/- | + | + | +/- | - |
| MFP | - | - | +/- | + | +/- | - |
| Desmin | - | - | +/- | - | + | - |
| Actin | - | - | +/- | - | + | - |
| Vimentin | + | + | +/- | - | + | + |
| Cytokeratin | +/- | +/- | +/- | - | +/- | - |
| CD | - | - | +/- | - | - | + |
| HNK-1 | +/- | +/- | + | + | + | - |
| L-Microglobulin | + | + | +/- | -/+ | +/- | + |
| HLA-71 | + | + | +/- | - | +/- | - |

PPNET, peripheral primitive neuroectodermal tumor; -, negative; +/-, positive in greater than 10% of cases; +/-, positive in less than 10% of cases; +, positive.
[a]Nonhistiocytic.
[b]Only in ganglion cells, Schwann cells, and atypical MFS.
[c]Only well-differentiated rhabdomyoblasts.

**TABLE 33-3. IMMUNOCYTOCHEMISTRY OF EWING'S SARCOMA FAMILY OF TUMORS AND OTHER SMALL BLUE-CELL TUMORS OF CHILDHOOD**

In the majority of cases, a hematopoietic malignancy may be eliminated by including leukocyte common antigen in the immunocytochemical panel. Vimentin is helpful in two ways. First, it allows determination of whether antigens have survived formalin fixation and tissue processing. Second, even though vimentin is present in many

tumors, it is absent in the vast majority of neuroblastomas and expressed fairly highly by Ewing's sarcoma.

The ESFT may be differentiated from neuroblastoma on the basis of immunoreactivity for a major histocompatibility class I antigen, b $_2$-microglobulin.[59,120,129,146] This antigen is expressed in the ESFT but is not present in neuroblastoma. Neuroblastoma may be discriminated also from Ewing's sarcoma by using monoclonal antibody NCL-NB84, which is expressed in more than 90% of neuroblastomas but has not been identified within the ESFT. [59,145]

Introduction of monoclonal antibodies that recognize glycoprotein p30/32 $^{MIC2}$ (CD99; Fig. 33-3G) has proved to be useful in confirming the diagnosis of the ESFT.[54,55,59,120,148,149,150,151,152,153,154,155,156,157,158 and 159] This cell-surface glycoprotein encoded by the pseudoautosomal *MIC2* gene on chromosomes Xp and Y is expressed to a high degree by neoplasms in the Ewing's sarcoma family. CD99 is considered to be a rather primitive marker and is highly expressed in early CD34-negative hematopoietic precursor cells. This transmembrane glycoprotein is involved with cell-to-cell adhesion during hematopoietic cell differentiation, apoptosis of immature thymocytes, and transmembrane protein transport. Roles in cell cycle progression control, cell morphology determination and differentiation, Rac-Rho signaling pathway control, and cytokinesis have been demonstrated. A number of monoclonal antibodies (HBA71, 013, 12E7, RFB1) to this glycoprotein are available and are immunoreactive with 95% to 100% of Ewing's sarcomas and PPNETs. However, this surface glycoprotein (CD99) is expressed also by other tumors and normal tissue (Table 33-4), including the nonblastomatous portions of Wilms' tumors, lymphoblastic lymphoma and leukemia, clear-cell sarcoma of the kidney, pancreatic islet cell tumors, immature teratomas, testicular embryonal carcinoma, malignant triton tumor, ependymomas, and choroid plexus papillomas. [59,153,154,156] The level and degree of expression in these tumors are considerably less than those in Ewing's sarcoma. Also, CD99 reacts with the cytoplasmic membrane of Ewing's sarcoma cells, imparting a honeycomb staining pattern (Fig. 33-3G). This contrasts with the diffuse CD99 staining of the cytoplasm in most tumors and normal tissues. Furthermore, other tumors may be differentiated readily from Ewing's sarcoma and PPNETs on the basis of morphologic, immunocytochemical, and ultrastructural features. The overexpression of this p30/32 $^{MIC2}$ protein is not related to the tumor-defining translocations in the ESFT. [54,55,59,150,151,152,153,154 and 155] However, an association between the HBA71 epitope and the growth-promoting effects of IGF-1 have been established. [158] Expression of the HBA71 antigen epitope is modulated positively by IGF-1 and insulin, resulting in cell proliferation, and modulated negatively by human growth factor and dexamethasone, resulting in growth inhibition. In contrast, HBA71 monoclonal antibody in cell cultures inhibits growth of Ewing's sarcoma and PPNET cell lines while down-regulating the IGF-1 receptor. Perhaps the overexpression of glycoprotein p30/32 $^{MIC2}$ by the ESFT may be due to the influence of growth factors, such as IGF-1 and insulin, promoting proliferation via the HBA71 epitope receptor.

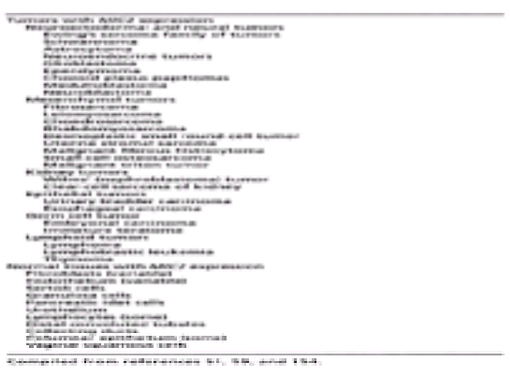

**TABLE 33-4. *MIC2* (CD99, P30/32$^{MIC2}$) EXPRESSION IN TUMORS AND NORMAL TISSUE**

A novel immunocytochemical marker for the ESFT recently was evaluated.[147] This antibody is directed toward b$_1$-integrin–linked protein kinase (ILK). With Ewing's sarcoma, an intense cytoplasmic staining pattern is present in all Ewing's sarcomas and PPNETs examined, similar to that seen with CD99 (p30/32 $^{MIC2}$). However, approximately one-third of neuroblastomas and all medulloblastomas also reacted with ILK. ILK is believed to be a possible marker of primitive neural differentiation. On the mRNA level, ILK is expressed in a wide variety of normal human tissues. This antibody does react with formalin-fixed, paraffin-embedded normal skeletal and cardiac muscle. ILK immunoreacts with well-differentiated rhabdomyoblasts but not with undifferentiated rhabdomyoblasts, which more typically are present with childhood small round-cell tumors. All lymphoblastic lymphomas and leukemias failed to immunoreact with ILK. Other tumors that may be confused with the ESFT and were negative for ILK included mesenchymal chondrosarcoma, osteosarcoma, retinoblastoma, and osteoblastoma. ILK may be a marker also for anchorage-independent cell growth and increased motility in Ewing's sarcoma. Overexpression of ILK inhibits adhesion to integrin substrates and is associated with dysregulation of integrin-mediated signal transduction. The *ILK* gene locus (11p15) is in close proximity to the *FLI1* gene locus (11q24).

The diagnosis of undifferentiated tumors in childhood very obviously requires a multimodal approach to reach a definitive diagnosis. Histopathologic, ultrastructural, and immunocytochemical information provides supporting evidence for a specific tumor entity. In addition, cytogenetic and molecular cytogenetics, including RT-PCR and FISH, supply additional information that will characterize the neoplasm further and, in some cases, provide the tumor-defining genetic abnormality. So that all avenues are available for diagnosis, it is important that tissue be set aside and properly handled for each of the diagnostic instruments.

### Histopathologic Evaluation and Prognosis

With certain tumors, pathologic variables have been associated with clinical course and survival. In the case of the ESFT, a paucity of studies that have been performed indicates a link between tissue studies and clinical outcome. [45,47,48,49,50,51,52 and 53,59,119,120,132,160,161,162,163,164 and 165] As mentioned, proliferative indices may play a role in assessing outcome; however, relatively few studies have been performed on a limited number of cases. [114,115,116,117,118,119,120 and 121] Whether DNA ploidy status or proliferative indices, such as PCNA (Fig. 33-3E, F) or Ki-67 expression, will prove to be beneficial will depend on well-controlled longitudinal studies.

In the past, classification of the ESFT [45,120] into typical undifferentiated Ewing's sarcoma, atypical poorly differentiated Ewing's sarcoma, and PPNET (differentiated Ewing's sarcoma) has been shown to be an independent prognostic factor in patients with localized primary tumors of distal extremities. Patients with tumors defined to be typical Ewing's sarcoma had a significantly improved overall survival as compared with those with either atypical Ewing's sarcoma or PPNET. Survival with localized PPNET was decreased significantly as compared with either typical or atypical Ewing's sarcoma. Although these results apply only to localized disease, histopathologic evidence of metastatic disease was identified as a significant independent factor in decreased survival.

This particular clinicopathologic study reported metastatic disease in approximately 10% of typical Ewing's sarcomas, whereas metastases were identified in slightly more than 35% of atypical Ewing's sarcoma and PPNET. Even though these results are derived from a limited number of cases with primary tumors of distal extremities, which had undergone different oncologic and surgical management, with the ESFT, a progression has been implied to more aggressive biologic behavior with increasing neural differentiation. Similar findings regarding neural differentiation and links to prognosis and clinical outcome also have been reported. [47,48,49,50,51,52 and 53,132] In fact, attempts to link the immunoreactivity of certain polyclonal and monoclonal markers to biologic behavior have shown that expression of a certain neural marker (HNK-1, Leu-7) may be associated with more aggressive behavior, whereas another neural marker (S-100 protein) may be linked to a more favorable outcome.[47] The findings in these studies are suspect, owing to the inclusion of many cases that had not undergone similar surgical or oncologic management.

More recently, comprehensive evaluations of the ESFT receiving uniform oncologic management found that neuroectodermal differentiation did not predict tumor behavior. These evaluated clinicopathologic studies determined neural differentiation by immunocytochemical (CD57, S-100 protein, neurofilament protein, and synaptophysin) and ultrastructural means.[148,149] Electron-microscopical evaluation significantly increased the likelihood of classifying tumors as PPNETs and was considered to be the optimal method for defining neuroectodermal differentiation. However, no significant difference in 5-year EFS or overall survival in patients with localized or metastatic disease was identified between those with and without neural features. At present, the overall consensus is that neuroectodermal differentiation does not affect outcome and should not direct therapy in the ESFT.

### Histologic Response to Therapy and Prognosis

Of particular interest is determination of the prognostic significance of histopathologic response to preoperative chemotherapy in individuals with resectable Ewing's sarcoma tumors.[120,160,161,162,163,164 and 165] The relative percentage or grade of tumor necrosis and fibrosis after preoperative chemotherapy appears to be related to

clinical outcome. Three separate histologic response grading systems have been used. [120,160,161 and 162] The first uses a three-tiered grading (Picci) system. [160,161] GradeI histologic response is assessed when macroscopic foci of viable tumor cells composed of large individual nodules or smaller scattered nodules occupy an area greater than a 10× objective magnification field. Grade II histologic response is defined as isolated microscopic foci of viable tumor cells that occupy an area less than a 10× objective magnification field. Grade III histologic response occurs when no viable tumor can be identified.

At surgical resection, the distribution of histologic response to induction chemotherapy has been found to be 37.5% grade I (poor responder), 24% grade II (good responder), and 38.5% grade III (good responder). EFS after 5 years for localized disease was 82% for grade III, 74% for grade II, and only 28% for grade I ( $p$ <.001 between grades I vs. grades II and III). With those who died of relapsed disease, survival time was 51 months for good responders (grades II and III) as compared with 33 months for poor responders (grade I; $p$ <.03). By both univariate and multivariate analyses, this histologic response grading system proved to be a prognostic factor in survival, with a 2.6-fold decrease in EFS for individuals with poor histologic response ( $p$ <.001).

The second histologic response grading method used the existing four-tiered semiquantitative (Huvos) grading system for osteosarcoma treatment effect. [162] Grade I is tumor necrosis of less than 50% of the tumor. Grade II is tumor necrosis of more than 50% to less than 90%. Grade III is tumor necrosis of 90% to 99%. Grade IV is tumor necrosis of 100%. After induction chemotherapy and surgical excision, the distribution of histologic response was 19% grade 1, 22% grade II, 18% grade III, and 42% grade IV. EFS at 5 years was 0% for grade I histologic response, 37.5% for grade II histologic response, and 84% for grades III and IV histologic response ($p$ = .0001). No significant difference in survival could be determined between grade III and grade IV responders (good histologic responses). EFS was significantly different between grades III and IV as compared with grades I and II ($p$ = .0001) and also between grades I and II ($p$ = .007). The relative risk for systemic recurrence was increased by 25.0-fold and 8.3-fold for grade I and grade II, respectively, with tumors smaller than 8 cm in maximum dimension, when compared with grades III and IV.

The third grading method was used in the Pediatric Oncology Group–Children's Cancer Group (POG-CCG) intergroup Ewing's sarcoma study and uses a modified Huvos system (grade IV, 100% tumor necrosis; grade III, 91% to 99% necrosis; grade IIB, 11% to 90% necrosis; grade IIA, 1% to 10% necrosis; grade I, no necrosis).[120] Survival at 3 years was 100% for grade IV, 73% for grade III, 49% for grade IIB, and 30% for both grades IIA and I.

The importance of histologic response assessment to chemotherapy after surgical resection is illustrated by these studies. Evaluation of chemotherapy-induced necrosis is of prognostic value and may help to direct further oncologic therapy. Current studies are attempting to compare chemotherapy response by dynamic magnetic resonance imaging (MRI) with histologic response after resection. If dynamic MRI correlates well with histologic response, it may provide a method by which to assess chemoresponsiveness, to identify poor responders during therapy, and to alter the oncologic regimen to effect an improved response.

## CLINICAL FEATURES

### Primary Sites

Data compiled from 18 studies published over a 10-year period in the United States, Europe, and Japan included 1,505 patients with the ESFT.[27,166,167,168,169,170,171,172,173,174,175,176,177,178,179,180,181 and 182] The data compiled from these patients with the ESFT revealed that the primary sites were divided almost evenly between the extremities (53%) and the central axis (47%). The extremity tumors were distal in 52% and proximal in 48%. The central axis tumors were of the pelvis (45%), chest wall (34%), spine or paravertebral region (12%), and head or neck (9%). The 74 PPNETs most commonly were of the central axis (74%); of these, most arose in or around the chest (60%). EES occurred in the extremities in 36% of cases and in central locations in the remainder. Often, determining whether a tumor is of bony or soft tissue origin is difficult, because the bony ESFT characteristically have extensive soft tissue components, and soft tissue tumors may invade bone secondarily.

### Signs and Symptoms

At diagnosis, signs and symptoms are both constitutional and related to the sites of disease. Pain or swelling (or both) at the site of the primary tumor most often are the presenting symptoms. Of 140 patients treated at the Mayo Clinic for Ewing's sarcoma of bone, 96% presented with pain, 61% with a palpable mass, 16% with a pathologic fracture, and 21% with fever.[166] Of 42 EES patients reported by the Mayo Clinic, 75% presented with a palpable mass and 66% with pain. Additionally, hemorrhage and necrosis are seen commonly within the ESFT, which may result in localized warmth and edema. Discerning Ewing's tumor from infection can be difficult because of these symptoms.

Patients can present with symptoms from their metastatic sites rather than pain at the primary site. Back pain may represent the first symptom of spinal cord compression secondary to a primary or metastatic spine tumor and requires an emergency evaluation and therapy before irreversible neurologic damage develops. Primary or metastatic tumors to the bony pelvis may cause leg pain secondary to peripheral nerve involvement. Bony metastasis may be palpable on the skull, ribs, or any superficial bone. Unexplained fevers may be the first sign of disease recurrence.

Often, a delay in Ewing's sarcoma occurs between the first symptoms and diagnosis. Forty-eight percent of 331 patients treated on the Intergroup Ewing's Sarcoma Study 1 (IESS-1) study had symptoms for more than 3 months before diagnosis.[183] In a report from Denmark, the duration of symptoms before diagnosis averaged 9.6 months, with a range of 4.0 weeks to 4.0 years.[184] One reason for the delay may have been that the pain was intermittent in 68%, providing false reassurance to physicians, patients, and family. Delay was much shorter in those with a palpable mass than in other patients (3.2 versus 10.1 months, respectively). Often, a delay can occur in the diagnosis of pelvic tumors, because they frequently are not palpable until the tumors are fairly large.

### Patterns of Spread

The high rate of distant failure (more than 80%) noted in patients who received local treatment alone before the advent of systemic chemotherapy supports the notion that most patients with the ESFT have, at a minimum, microscopic metastases at diagnosis. Approximately 25% of patients with the ESFT present with overt metastases at diagnosis. Metastases primarily follow the hematogenous route, although metastases through direct extension can occur. The most common sites of metastases are the lung (38%), bone (31%), and bone marrow (11%).[185] The spine is one of the more common sites of bone metastasis.[166] Lymph node (7%) and liver metastases are uncommon.[178] Intra-abdominal metastases to the peritoneum or gastrointestinal tract have been reported in EES. [173] Metastases to the central nervous system are rare, occurring in fewer than 5% of cases. A recent review at St. Jude Children's Research Hospital of all patients treated for Ewing's sarcoma over a 36-year period revealed that of 335 Ewing's sarcoma patients, 11 (3.3%) had brain metastases. [186] All these patients demonstrated clinical neurologic signs. Historically, prophylaxis with radiotherapy and intrathecal methotrexate does not prevent central nervous system metastases from occurring. [187] Patterns of metastasis are more likely a function of the primary site than of the specific histology. For example, a common site of spread for primary ESFT of the chest wall is to the adjacent pleural space.

### Differential Diagnosis

If Ewing's sarcoma or PPNET presents as a tumor of bone, the differential diagnosis includes a variety of benign and malignant processes. An important consideration is osteomyelitis, especially if an affected patient is febrile. Benign tumors of bone that can present as a lytic bone lesion include eosinophilic granuloma and giant-cell tumor. Malignant tumors that should be considered include osteosarcoma, primary lymphoma of bone, spindle cell sarcomas of bone (e.g., malignant fibrous histiocytoma), and metastases from a nonbone tumor, especially neuroblastoma. Neuroblastoma can present with an asymptomatic abdominal or thoracic mass, which may go undetected, and a single symptomatic bony metastasis. EES and PPNET must be differentiated from benign and malignant soft tissue tumors (see Chapter 32 and Chapter 34).

### Evaluation

The evaluation of a patient with a lesion that is suspected or confirmed to be in the ESFT has four goals. First, the full extent of the primary tumor must be defined as accurately as possible through the use of a variety of imaging techniques and histologic sampling. Second, a metastatic workup should determine whether clinically evident metastases are present and should define the sites and extent carefully. Third, because the patient is likely to undergo rigorous treatment, a physiologic evaluation should determine baseline cardiovascular, pulmonary, renal, and hepatic functioning. Fourth, any neurologic, musculoskeletal, or psychological problems that may interfere with the patient's rehabilitation must be identified so that appropriate interventions are initiated as early as possible.

### *Laboratory Studies*

Neither a blood test nor a urine test provides specific markers of the ESFT. Laboratory studies should include a complete blood count, baseline chemistries, and an erythrocyte sedimentation rate analysis. An elevated erythrocyte sedimentation rate can be found in up to 50% of cases. [188] Because an elevated serum lactate dehydrogenase level has been demonstrated to have adverse prognostic significance, a baseline analysis should be obtained. [189] If neuroblastoma is in the differential diagnosis, urine catecholamine levels may be useful because they are normal in the ESFT but usually elevated in neuroblastoma.

Bilateral iliac bone marrow aspirations and biopsies should be performed to evaluate the bone marrow for metastatic disease. MRI is sensitive to abnormalities within the marrow, but the changes seen are not specific. Any decrease in fat within the marrow may alter the signal, creating difficulty in differentiating tumor from increased hematopoiesis.

Gene fusions that result from the nonrandom chromosome translocations found in the ESFT provide tumor-specific markers that can be used to detect the presence of the tumor cells. RT-PCR allows detection of tumor cells in peripheral blood, bone marrow, and stem-cell collection. This approach permits the detection of one tumor cell in more than $10^6$ mononuclear cells, as shown by serial dilution of Ewing's cells in control peripheral blood. [190] RT-PCR provides an extremely sensitive and specific method for molecular staging and monitoring treatment response. Zoubek at al. [101] confirmed an association of bone marrow positivity by RT-PCR with bone or bone marrow metastasis. Additionally, one-third of this study's patients with localized disease had bone marrow positivity on RT-PCR testing. Preliminary statistical evaluation suggested a nonsignificant tendency toward adverse outcome in this group of patients with localized disease. [101] Several researchers have demonstrated that minimal disease can be detected in bone marrow and peripheral blood, although at present how these factors may contribute to patient management remains controversial.[99,191] Another important application of RT-PCR is in the testing of stem-cell collections before transplantation. By using RT-PCR, peripheral blood stem-cell harvests have been found to be contaminated with tumor cells. [192]

### *Diagnostic Imaging*

The diagnostic imaging evaluation should consist of a thorough examination of the primary site and a search for metastatic disease ( Fig. 33-5, Fig. 33-6, Fig. 33-7, Fig. 33-8, and Fig. 33-9). The importance of fully defining the extent of disease at the primary site before therapy cannot be overemphasized. The planning and delivery of optimal local therapy require documentation of the initial extent of the tumor, which can be expected to decrease after chemotherapy. Plain films, MRI of the primary site, computed tomography (CT) of the chest, and bone scans are necessary for the staging work-up for the ESFT.

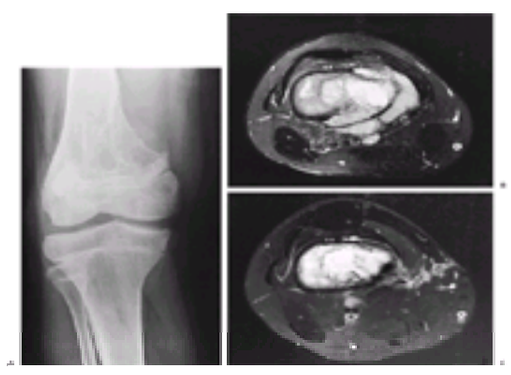

**FIGURE 33-5. A:** Plain radiograph of distal femur showing involvement of the metaphysis by Ewing's sarcoma, with significant destruction of cortical bone and soft tissue swelling. **B:** Magnetic resonance image through distal femur of same patient at time of presentation, again demonstrating femoral involvement by tumor and adjacent soft tissue mass. **C:** Magnetic resonance image through distal femur of same patient after 12 weeks of chemotherapy with vincristine, Adriamycin, and cyclophosphamide alternating with ifosfamide and etoposide. Note regression of soft tissue mass. (Courtesy of T. Chung, M.D., Baylor College of Medicine, Houston, TX.)

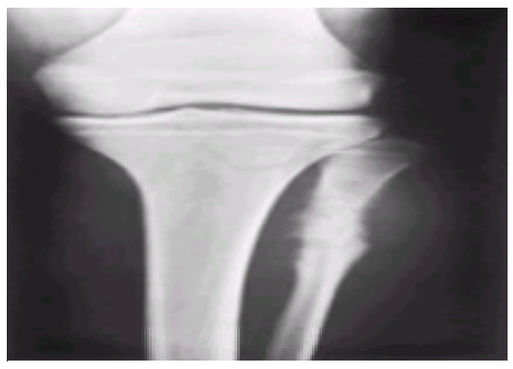

**FIGURE 33-6.** Ewing's sarcoma of the fibula, a favorable site for resection. A wide excision with negative margins can often be obtained.

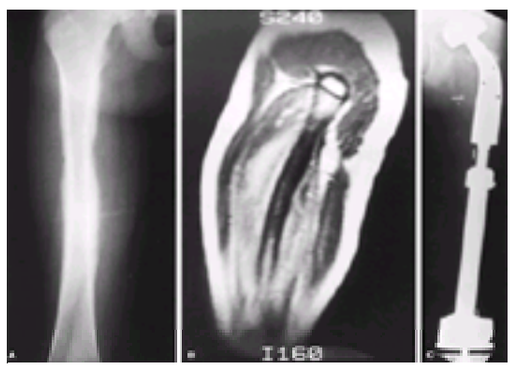

**FIGURE 33-7. A:** Plain radiograph of Ewing's sarcoma of the femur occurring in a 10-year-old child. **B:** Magnetic resonance image of the femur demonstrating almost total intraosseous involvement and a large extraosseous component. **C:** Postoperative radiograph after resection of the entire femur and replacement with an expandable total femoral prosthesis.

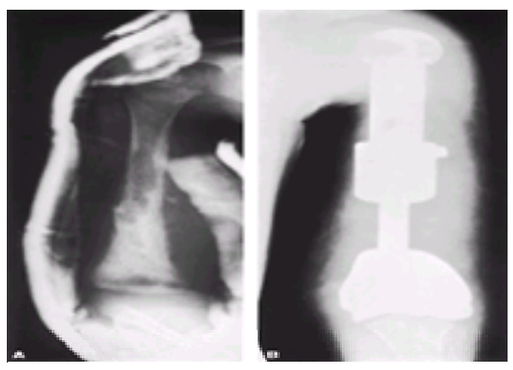

**FIGURE 33-8. A:** Plain radiograph of Ewing's sarcoma of the humerus in a 4-year-old patient. This was treated by induction chemotherapy followed by resection of the entire humerus. All margins were negative. Radiation was not used because of the child's age. **B:** Postoperative radiograph showing an expandable total humeral prosthesis. (Courtesy of J. Eckardt, M.D., University of California, Los Angeles, CA.)

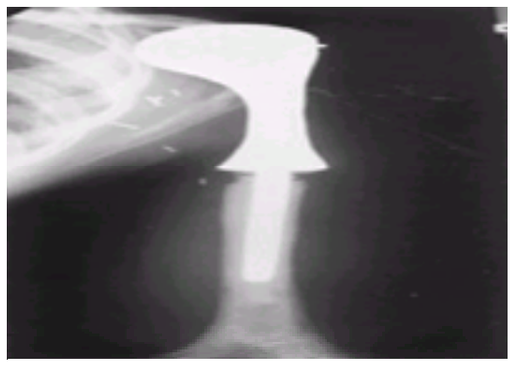

**FIGURE 33-9.** Plain radiograph after resection and replacement of the proximal humerus for a large Ewing's sarcoma. This patient was treated with a combination of preoperative chemotherapy and radiotherapy. The radiograph shows the result at 8 years after treatment.
