The radiograph of a Ewing's tumor of bone usually reveals a poorly marginated, destructive lesion of the diaphysis of bone. [193,194] The erosion of the cortex and spread to the soft tissues surrounding the bone sometimes are accompanied by a multilaminated periosteal reaction (i.e., onion peel); the Codman's triangle of elevated periosteum may or may not be seen. Surrounding soft tissue mass often is disproportionately large as compared to the bony component. A sclerotic appearance may be present, especially in flat bones. Sclerosis is secondary to bony reaction, not tumor bone formation as is seen in osteosarcoma. However, distinguishing the ESFT and osteosarcoma radiologically is difficult. A plain radiograph with a marker or ruler to correct for magnification of the entire bone should be obtained to make the accurate measurements needed for limb-sparing resections and prosthesis if they are being considered.

MRI is the method of choice in the local staging of Ewing's sarcoma at diagnosis. [193,195] MRI displays the tumor in multiple planes and, with soft tissue contrast, can assess the intramedullary and extramedullary tumor extent. This is critical with regard to planning of (limb-salvage) surgery and irradiation. MRI is important in determining the relationship of the tumor to the adjacent physis, muscle compartments, joint, and neurovascular structures. [193] T1-weighted images are particularly accurate in assessing the intramedullary tumor extent. On T1-weighted images, the low signal intensity of tumor contrasts with the high signal intensity of the fatty bone marrow. Moreover, sagittal-coronal T1-weighted spin echo MRI has a sensitivity higher than that of transaxial CT, conventional radiography, and bone scintigraphy for the detection of intramedullary skip lesions in patients with Ewing's sarcoma. [196,197] T2 weighting displays both the interface between adjacent soft tissues and tumor and the anatomic relationship with the neurovascular structures. This allows differentiation between intracompartmental and extracompartmental disease.[197] MRI is superior in discerning between tumor and vascular structures. [193] Thus, angiography is not advocated any longer as a routine staging procedure for Ewing's sarcoma. In terms of identifying cortical bone involvement, this usually can be seen on a plain film, and large cortical lesions can be seen on MRI. If it is clinically necessary to determine whether a patient has a small cortical break, CT of the primary tumor may be necessary.

Besides local staging at diagnosis, MRI has an important role in monitoring the effects of chemotherapy. Most Ewing's sarcomas are accompanied by a substantial soft tissue mass seen on MRI. After chemotherapy, a significant decrease in tumor volume will be found in the majority of patients with Ewing's sarcoma. Additionally, changes in signal intensity within Ewing's tumors have been evaluated to allow prediction of response to chemotherapy. Fast dynamic contrast-enhanced MRI studies can distinguish good from poor responders.[193] With this technique, after a bolus injection of gadolinium contrast, an increase in signal intensity is plotted as a function of time. A time-intensity curve is produced, and a steeper slope presumably corresponds to more rapid uptake of the contrast agent, owing to increased vascularization and perfusion associated with viable tumor. [193] In addition, dynamic studies may help in the differentiation between residual tumor and reactive peritumoral edema. Compared with edema, viable tumor is characterized by an earlier, higher, and more rapid uptake of contrast agent. [193]

Distant metastases from Ewing's sarcoma most often become manifest in the lungs. CT is superior to conventional radiography for the detection of lung metastases. A routine CT scan of the chest to screen for pulmonary metastases at time of diagnosis is essential for early detection and is of critical value for prognosis.

Radionuclide bone scanning with technetium 99m methylene diphosphonate is used to define the bony extent of the tumor and to screen for metastases to distant bone. A bone scan must be performed at diagnosis to stage all Ewing's sarcoma patients accurately.

### *Initial Radiotherapeutic Evaluation*

Radiation oncologists should evaluate affected patients at the time of initial diagnosis, perform a physical examination, and review the laboratory and radiographic studies before therapy. Special attention should be given to the clinical features of such patients and to the tumor to determine suitability for delivery of radiotherapy. These factors include the patient's age, tumor site, tumor size, soft tissue extent of the tumor, extent of medullary cavity involvement in the affected bone, relation of the tumor to the epiphyseal plates and joints (in growing children), the possibility of sparing adjacent soft tissues and viscera from the high-dose region of the radiation field, the presence of pathologic fracture, and the functional status of the involved joint (especially limb) at the time of presentation. Radiation oncologists certainly should discuss with their surgical colleagues the feasibility of a complete resection and the probable functional outcome of the surgery before recommending radiotherapy as the principal local treatment.

### *Initial Surgical Evaluation*

Surgical resection, if used, usually follows neoadjuvant chemotherapy or radiotherapy (or both). [179,198,199,200,201 and 202] Nevertheless, surgeons who may be asked to intervene later should participate in the initial evaluation of affected patients to estimate and stage the local tumor extent and to perform the initial biopsy. Whenever possible, biopsies of suspected bone malignancies should be performed at the center at which the ultimate treatment will be rendered, as an improperly executed biopsy may render limb preservation difficult if not impossible. A poorly planned biopsy of a bony lesion may result in pathologic fracture or may contaminate other tissue planes, rendering resection difficult. Multiple cores or, preferably, an open biopsy should be performed to obtain enough material for diagnosis. Fine-needle aspiration cytology is not acceptable as the only diagnostic material and should be used only to sample metastatic sites or suspected sites of recurrence when the histologic diagnosis is known. Frozen-section analysis of all biopsy specimens is essential to determine whether adequate tumor has been obtained to yield satisfactory diagnostic material. Material is necessary for electron-microscopical studies, immunohistochemistry, RT-PCR, and cytogenetics. It is not unusual for a large portion of the tumor to be necrotic and thus nondiagnostic.

The biopsy site should be chosen carefully and placed in line with any potential resection incision site and radiation portals. If the ESFT is suspected, the biopsy

specimen should, if possible, be taken from the extraosseous component rather than from the underlying bone. A bony defect may not reossify if irradiation is required and is more likely to fracture after radiotherapy. If biopsy of the underlying bone is necessary, a small, rounded cortical window should be made. Regardless of the technique used, tumor cells contaminate all tissue planes and compartments traversed, and all biopsy sites, therefore, must be included en bloc when the tumor is irradiated or resected.

Because irradiation is included in the treatment of many patients with the EFST, it is important to remember that irradiated scars can be vulnerable to trauma. Scars placed directly over bone (e.g., tibial shin) are more prone to radiation injury than those placed in more richly vascularized soft tissue or connective beds. [203] Smaller biopsy incisions are less likely than larger incisions to break down after radiotherapy and chemotherapy.

Ewing's sarcoma can mimic osteomyelitis clinically and radiographically; for this reason, surgeons responsible for treating osteomyelitis should perform the incision and drainage with the idea that an affected patient might have a malignant bone tumor. Routine bacterial cultures should be obtained in case the lesion proves to be an osteomyelitis.[204]

### *Staging*

Although no commonly used staging systems exist for the ESFT, treatment protocols often are stratified for the presence or absence of metastatic disease and according to primary site. A useful pretreatment staging system would be based on the presence or absence of metastatic disease and on size, extent, and location of the primary lesion, similar to the system recently developed for rhabdomyosarcoma (see Chapter 32). Because a staging system would be helpful in comparing the results of clinical trials, it is hoped that such a system can be developed that will be accepted internationally.

## TREATMENT

### General Principles

The treatment goal for the ESFT is to cure the disease while preserving the patient's function and minimizing long-term sequelae. Approaching with noncurative intent a child with newly diagnosed ESFT disease is rarely, if ever, appropriate, because one cannot determine a priori whose disease will be cured. Even if cure is not realized, treatment usually results in tumor regression, which may translate into prolonged survival and an improved quality of life. Optimal outcome requires the close cooperation of members of a therapeutic team experienced in the treatment of these disorders. For this reason, the ESFT is best managed, from biopsy onward, in pediatric medical centers. Whenever possible, patients should be entered into a clinical research protocol.

ESFT is a systemic disease. Although most patients have no clinical evidence of metastatic disease at diagnosis, it must be assumed that every patient has microscopical metastases. Treatment is often conceptually compartmentalized into measures to effect either local or systemic control, but this is an oversimplification. Most modern treatment plans are neoadjuvant in design. Systemic chemotherapy, in addition to being the mainstay of treatment for microscopical and gross metastatic disease, usually is effective in reducing local tumor volume. Reduction of tumor mass may increase the likelihood of local control with radiotherapy and facilitate a surgical resection. Local control measures should not be allowed to compromise systemic therapy, as treatment failures usually are attributable to the development of distant metastatic disease. Surgical procedures that result in a protracted postoperative course and interruption in chemotherapy are likely to have an adverse effect on systemic control. For purposes of this discussion, we too compartmentalize therapy into local and systemic forms, but we emphasize strongly the critical nature of the interactions between these modalities.

### Local Control: General Considerations

In 1921, James Ewing[1] observed that “small-cell sarcoma of bone,” unlike osteosarcoma, was responsive to a radium implant. In the ensuing four or five decades, we came to recognize that although surgery and radiotherapy could control the local disease, more than 90% of patients eventually died from metastatic disease. [205,206] Local control of the primary tumor with radiotherapy ranged from 50% to 77%.

With the introduction of effective multi-agent chemotherapy, not only did the overall survival rates of patients increase because of eradication of microscopic metastatic disease, but an improvement in local control of the primary tumor was observed after radiotherapy. [176,184,207,208 and 209] In the IESS-1, the use of doxorubicin was shown to increase the local control rate. [209] Local control rate after chemotherapy and radiotherapy usually ranges from 75% to 90% ( Table 33-5).[207,208 and 209]

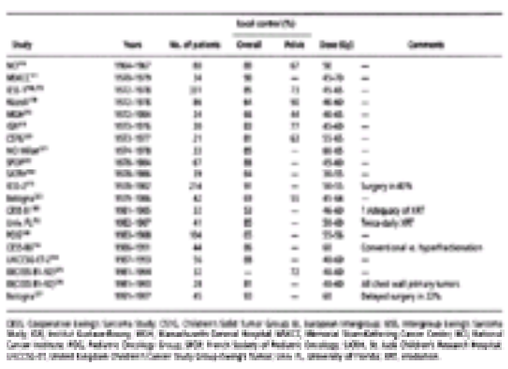

**TABLE 33-5. PRIMARY TUMOR CONTROL IN PATIENTS WITH LOCALIZED EWING'S SARCOMA TREATED BY IRRADIATION TO THE PRIMARY SITE IN CONJUNCTION WITH MULTI-AGENT CHEMOTHERAPY**

Factors other than chemotherapy probably also were responsible for the apparent improvement of local control after radiotherapy in the last two decades. These factors include more common use of CT and MRI to define the extent of tumor better and improved radiotherapy delivery techniques. The importance of technique is illustrated by the Cooperative Ewing's Sarcoma Study (CESS-81) of the German Cooperative Group. In the initial phase of this trial, the relapse-free survival rate of patients treated with radiotherapy was 50%, which was significantly lower than that for surgical therapy. [210] On review, the high rate of local failure after radiotherapy was largely attributed to geographic miss. After the initiation of a quality assurance program in 1984, the local control rate improved significantly, and the relapse-free survival rate increased to 80%.

Local control analysis in Ewing's sarcoma can be complicated by the difficulties encountered both in interpreting the diagnostic studies after combined-modality treatment and in assessing local control in patients who experience relapse with widely metastatic disease. Bone involved with tumor that is subsequently treated with chemotherapy and irradiation undergoes healing and remodeling. Regression of soft tissue masses and resolution of clinically evident swelling, pain, tenderness, and erythema accompany this healing. On plain radiographs, a predictable series of changes occur over approximately a year, eventually stabilizing and remaining constant in appearance unless relapse or second malignancy occurs. [174] However, the plain films, bone scans, CT scans, and MRI scans rarely return to normal after treatment. Changes in MRI signals of tumor-involved sites after chemotherapy or radiotherapy still are difficult to interpret definitively. Large tumors with significant soft tissue components often regress incompletely, with residual soft tissue masses on imaging studies. These abnormalities on imaging studies may represent tumor, fibrosis, necrosis, or osteomyelitis. Time-intensity curves derived from gadolinium-enhanced MRI studies correlate better with histologic response than do changes in tumor size.[193] Because of the potential morbidity from biopsies of irradiated bone and soft tissues, stable abnormalities on imaging studies should be monitored closely. Radiographic or clinical evidence of progression warrants biopsy of the area of abnormality. In patients who experience relapse with metastatic disease, the primary site is not necessarily reevaluated to assess local control unless it becomes symptomatic. Detection of local recurrence in such patients depends in part on the thoroughness with which the primary site is reevaluated by imaging or biopsy. An autopsy series from the National Cancer Institute (NCI) demonstrated an unexpectedly high proportion of patients (13 of 20) with tumor in the irradiated site after initial treatment with irradiation and chemotherapy. [202] The clinical relevance of this observation is not completely clear. The tumor cells in the irradiated area may have represented a local recurrence or reseeding of the primary site from widely metastatic tumor, or nonclonogenic cells. Despite this observation, the local control figures from the NCI series show only a 17% frequency of clinically evident local

recurrence.[211]

### Surgery versus Radiotherapy

Both surgery and radiotherapy are effective local treatment for Ewing's sarcoma. The relative roles of surgery and radiotherapy continue to be controversial. Because no randomized study has compared the two modalities directly, only a relative comparison can be made from retrospective studies, keeping in mind the various admixtures of known prognostic factors in the different series. Several reviews, including those from the Memorial Sloan-Kettering Cancer Center, [212] Mayo Clinic,[166] and Massachusetts General Hospital,[213] have suggested that surgery plus chemotherapy produces either better rates of local control or better survival rates than does radiotherapy plus chemotherapy. However, all these reports included smaller lesions in more favorable locations in the surgical group as compared to larger central and inoperable lesions in the radiotherapy group, thereby biasing the results in favor of surgery. In addition, some series (e.g., the series from Memorial) incorporated postoperative radiotherapy in some of the surgically treated patients. Similarly, 116 Ewing's sarcoma patients from a single institution were retrospectively reviewed by Aparicio et al.[214] and, although the patients undergoing surgical resection had a superior DFS, these patients often had favorable prognostic features (i.e. normal LDH, small tumors, local disease, and nonaxial site).

Recently, the M. D. Anderson Cancer Center reported their 20 years of experience with nonmetastatic Ewing's sarcoma, which included 85 patients. [215] All but 1 of the 85 patients received treatment with combination chemotherapy. All patients received x-irradiation as local treatment, either solely or in addition to surgical resection. A total of 20 patients underwent surgical resection as part of their local treatment. Patients who received surgery as part of the planned treatment of their primary tumor had significantly better local control and DFS than those who did not undergo resection. The authors point out that although this was not evaluated in a randomized study, it appeared that the patients who were subjected to surgery generally had large tumors.

In the aforementioned German CESS-81 trial, the local failure rate in the radiotherapy group was initially high owing to geographic misses. Because of the introduction of a central quality assurance program, the local control rate improved significantly. In the subsequent study, CESS-86, the 5-year relapse-free survival rates after chemotherapy plus radiotherapy and after surgery plus chemotherapy were comparable (67% and 65%, respectively).

It is generally agreed that dispensable bones such as fibula, rib, and small lesions of hands or feet are amenable to conservative surgery, especially in younger patients in whom radiotherapy could cause major growth and functional deficits. However, when a tumor is unresectable or to avoid a mutilating surgery, irradiation is a better option for local treatment. A large lesion that fails to respond to induction chemotherapy may also be considered for surgery and postoperative radiotherapy. Any lesions that are not controlled by chemotherapy plus radiotherapy are candidates for surgical salvage. [216] In making the ultimate decision regarding a local control strategy for each patient, the physician must weigh the imperative of attaining complete tumor eradication against the goal of maximizing function. An additional consideration is the likelihood of development of a second malignancy in the irradiated site within 20 years after treatment. These second malignancies usually are osteosarcomas that occur in previously irradiated bone. The incidence of bone tumors in the irradiated field has varied from study to study, with estimates at 20 years after therapy ranging from 10% to 30%.[19,217]

### Surgical Management

#### *General Principles*

The surgical treatment of Ewing's sarcoma consists of two distinct and opposed phases: adequate resection of the residual gross disease from the affected bone and soft tissue and reconstruction of the resulting injury to the musculoskeletal system. The goals of surgical treatment are complete extirpation of the primary tumor and restoration of the maximum possible level of function possible. When surgical treatment is selected for the patient with Ewing's sarcoma, the surgeon must plan an adequate resection margin separately and before he or she considers reconstruction options. The temptation to compromise tumor margins to facilitate limb-sparing surgery must be resisted.

The surgical principles applicable to the treatment of Ewing's sarcoma are similar to those followed in the treatment of osteosarcoma; however, three salient differences characterize the approach to Ewing's sarcoma: (a) Ewing's sarcoma is radiosensitive, whereas osteosarcoma is not; (b) Ewing's sarcoma tends to occur in a younger population than osteosarcoma; and (c) Ewing's sarcoma tends to arise in the diaphysis of long bones, whereas osteosarcoma has a predilection for the metaphyseal area.

The fact that Ewing's sarcoma is highly radiosensitive affords a reasonable and, in many cases, preferable, option for control of the primary tumor. [218] Radiotherapy obviates the need for a surgical incision and implants, with the consequent risk of infection. Indeed, the classical teaching has been that surgery is reserved for Ewing's sarcoma arising in “expendable” bones (i.e., fibula, clavicle, and rib) and that radiotherapy is the treatment of choice for all other locations. However, several disadvantages of radiotherapy have broadened the indications for surgery somewhat. The major problem with irradiation is the potential for late development of high-grade malignant tumors in the treatment field in approximately 15% to 30% of patients who survive their Ewing's sarcoma. [219] Postradiation sarcoma carries an extremely poor prognosis. Late disability owing to arthrofibrosis in irradiated joints, fibrosis and contracture of radiated muscles, lymphedema, and growth disturbance has been minimized, but not completely eliminated, with modern orthovoltage equipment and ultrafractionation dosage schedules. [220] Ewing's sarcoma arising in some anatomic locations, most notably the pelvis and spine, may require a combination of surgery and radiotherapy to optimize local control.

The fact that Ewing's sarcoma tends to occur in a younger patient with greater potential for skeletal growth poses a challenge to the surgeon responsible for reconstruction. When a physeal plate must be resected, the surgeon must address the potential for significant limb-length discrepancy in the process of planning treatment. This problem is especially significant when the distal femoral or proximal tibial growth plates are involved. Although expanding prostheses are available, the essential problem with long-bone growth is not longitudinal but circumferential enlargement. [221] All the currently available prosthetic devices are secured using sterns, which are either press-fit or cemented into the intramedullary canal of the affected bone. As the radius of the bone increases, the endosteal surface grows away from the implant, resulting in loosening. For this reason, implants requiring intramedullary fixation have limited application in young children in whom significant growth remains.

The third distinguishing feature of Ewing's sarcoma—the fact that it is more likely to arise in the central portion of bones—somewhat offsets the difficulties presented by skeletal reconstruction in the growing child. In cases in which the tumor is within no more than 4 cm of the adjacent growth plate, one can successfully excise the tumor-bearing bone with preservation of the physis. The surgeon may use a diaphyseal segment of allograft bone [222] or vascularized fibular autograft [223] to reconstruct the resulting bony defect.

#### *Principles of Surgical Resection*

Ewing's sarcoma frequently presents with a large mass extending into the soft tissues surrounding the involved bone. This mass is composed of tumor cells and reactive host inflammatory cells. The portion of the mass consisting of tumor cannot be distinguished radiographically from the inflammatory response. Typically, the mass rapidly resolves during preoperative chemotherapy. The MRI scan obtained as part of the staging workup before initiation of chemotherapy is important for planning the level of bone resection. The MRI scan obtained immediately preoperatively generally is used to plan the soft tissue resection. The entire length of the involved bone must be imaged preoperatively to rule out skip metastasis.[224] Rarely, the soft tissue mass will continue to enlarge on chemotherapy. In these cases, amputation may be necessary.

In the past, musculoskeletal oncologists have considered pathologic fracture through a Ewing's sarcoma an absolute indication for amputation. The rationale for this policy was that tumor cells are carried along tissue planes by the fracture hematoma, making adequate surgical resection impossible. A recent study demonstrated that minimally displaced or nondisplaced pathologic fractures may be resected using standard limb-sparing approaches without an increased incidence of local recurrence.[225]

#### *Principles of Surgical Reconstruction*

Reconstruction is not always possible or desirable after surgical removal of Ewing's sarcoma. A recommendation for amputation over limb salvage is most often prompted by a finding of (a) tumor invading major nerves, (b) inability to achieve acceptable reconstruction in the very young patient, or (c) tumors of the distal leg or foot. The guidelines for limb salvage after resection of one or more major nerves are site-specific and are discussed later. As previously noted, existing methods of prosthetic or allograft bone replacement are associated with a high failure rate in the rapidly growing young child. For tumors of the distal tibia or foot, function after

below-knee amputation is superior to the results obtained by limb-sparing surgery. Tumors of the distal fibula may be treated with conservative resection. [226]

### *Special Considerations by Anatomic Site*

#### Spinal Column

Ewing's sarcoma of the spinal column usually originates in the vertebral body and may extend into the posterior elements. Achieving an acceptable surgical margin (minimum 3-cm bone margin) is extremely difficult, if not impossible, under these circumstances. For this reason, radiotherapy either alone or in conjunction with surgery is the preferred method of local control in the spine. [227] Surgery involves resection of the entire vertebral body. Reconstruction is achieved using bone graft with spinal plates. Vascularized bone graft is preferred in a heavily irradiated area. Regardless of local treatment employed, Ewing's sarcoma of the spine carries a significantly worse prognosis than does Ewing's sarcoma of the appendicular skeleton. [228]

#### Pelvis

From the standpoint of reconstruction, the pelvis is divided into three zones. Zone I is the ilium, zone II the acetabulum, and zone III the ischium and pubis. Resection of either zone I or III in isolation requires no reconstruction. When the acetabulum is excised, either alone or in conjunction with zone I or III, reconstructive options include fusion of the femur to the pelvic remnant, allograft pelvic reconstruction, and leaving the femur free (“flail hip”). The latter approach ends in a very poor functional result with a grossly shortened extremity but is associated with the lowest risk of perioperative complications. Pelvic allografts carry a high risk of complications—infection, nonunion, and fracture—and may not be suitable in the very young child. [229,230] Additionally, allografts should generally be avoided in a previously irradiated area, because the risk of allograft fracture and nonunion is unacceptably high in this setting. Fusion provides a stable platform for ambulation and, when it is technically feasible, is probably the best choice for the young patient with Ewing's sarcoma of the pelvis. In light of the high complication rate and predictably poor functional outcome after surgery, radiotherapy should be strongly considered for local control of type II pelvic Ewing's sarcoma. Surgery, with or without radiotherapy, has been shown to be associated with no higher risk of local recurrence than radiotherapy alone. [231] Ewing's sarcoma of the pelvis is associated with a poor prognosis.[232,233]

#### Proximal Femur

When Ewing's sarcoma occurs in the proximal femur, the femoral head, neck, greater trochanter, and proximal femoral metaphysis will be removed. The resulting defect may be reconstructed with an allograft, proximal femoral replacement prosthesis, or allograft-prosthesis composite. The main determinant of postoperative function is integrity of the abductor mechanism of the hip. [234]

#### Distal Femur

For the older child, adolescent, or young adult, prosthetic reconstruction of the distal femur offers the best functional outcome with the lowest risk of complications. [235] An expandable prosthesis should be used in patients with significant growth potential. [236,237 and 238] In the very young child, van Ness rotationplasty may be used. [239] This operation advances the ankle joint to the level of the knee and functions more like a below-knee than an above-knee amputation.

#### Proximal Tibia

Osteoarticular allograft, proximal tibial prosthesis, allograft-prosthesis composites, and rotationplasty are the available modes of reconstruction in the proximal tibial area.[240] The primary determinant for function of the prosthetics or allografts is success of reconstituting a functional quadriceps mechanism. Soft tissue coverage is also a major consideration in this region. Gastrocnemius muscle flaps often are used to augment coverage of large implants or bone grafts and to provide an additional attachment site for the patellar tendon.

#### Distal Tibia and Foot

As previously noted, the expected function after below-knee amputation is superior to the result of limb-sparing reconstruction. Amputation therefore is preferred over reconstruction in patients with Ewing's sarcoma of the distal lower extremity.

#### Proximal Humerus

The reconstruction options after resection of the proximal humerus are similar to those following resection of the proximal femur: allograft-prosthesis composite, proximal humerus prosthesis, and fusion either to the scapula or clavicle. Achieving effective rotator cuff function after any of these methods is difficult.

#### Distal Humerus

Prosthetic elbow replacement is available for reconstructing the distal humerus. Osteoarticular allograft may also be considered but should not be used in young children with significant growth potential.

#### Scapula

If the glenoid can be spared, resection of the body of the scapula does not result in a major functional deficit. [241] When the glenoid must be removed, fusion of the humerus to the clavicle or leaving the shoulder flail are the available options. Fusion offers the best functional result when it is successful.

#### Fibula, Rib, and Clavicle

The fibula, rib, and clavicle, so-called expendable bones, may be resected with no need for reconstruction. [242]

### Radiotherapeutic Technique

#### *Treatment Planning*

The first step of treatment planning is a careful and complete review of the MRI and CT scans of the primary tumor ( Fig. 33-5). Information regarding the size and extent of the tumor in relation to adjacent normal tissue is essential in designing the treatment field during simulation. MRI has an additional advantage over CT in its ability to show the extent of bone marrow edema (presumably corresponding to intramedullary involvement by tumor) on T2-weighted images. Immobilization or positioning devices such as casts should be used whenever possible to aid in accurately reproducing the treatment position. Biopsy sites and surgical incisions should be marked for simulation so that they can be included in the treatment fields. Addition of contrast medium in bowel or bladder during simulation can help to identify and exclude these organs from the treatment fields. The planning CT scan with the patient in the treatment position usually is very helpful in treatment planning. Recently, CT simulators have become available that combine spiral CT technology with the capability of aligning and marking patients, conducting image reconstruction and computer virtual simulation, and networking to a treatment planning computer. The entire treatment planning process has become more sophisticated. If a planning CT study is not available, contour measurements can be taken at multiple levels to account for changes in dosimetry associated with changes in patient contour.

Complex field arrangements (i.e., wedged pairs, obliques, and rotational fields) can be used during computerized planning to improve dose distribution. Wedge filters and other beam modifiers should be used if necessary. The use of shaped fields with customized Cerrobend blocks usually is recommended to reduce the volume of uninvolved normal tissues in the field. Three-dimensional treatment planning programs now calculate, display, and allow evaluation of volumetric radiation dose distribution to the tumor target and to the surrounding normal tissues. Computer optimization algorithms are increasingly used to facilitate the planning process.

### *Treatment Delivery*

During treatment, weekly port films should be obtained to verify treatment accuracy. If there is a change in patient contour caused by tumor regression, resimulation is required. Close communication between the pediatric and radiation oncologists is important during treatment delivery. Patients should wear soft, loose cotton garments that will not abrade the skin in the radiation portal. Coarse fabric such as denim should be avoided. Careful evaluation of the skin on a regular basis is important.

### *Treatment by Site*

For extremity lesions, a strip of unirradiated tissue should be preserved to prevent the development of edema or fibrosis after circumferential irradiation. A bolus should be used over the biopsy incision or surgical scar unless it is crossed by the radiation beam. Uninvolved epiphyseal plates and joint spaces should be excluded from the radiation field whenever possible. [243] The Achilles tendon, which can undergo late fibrosis after radiation, should be excluded from the treatment volume, if possible. Testicular shielding should be considered for thigh and pelvic lesions. [244] Selected patients with primary lesions of the hand and foot can be treated with radiation and have an excellent functional outcome. [245,246] Sarcomas suitable for this approach are smaller lesions (soft tissue masses less than 3 to 4 cm in diameter) that permit considerable sparing of normal tissue. Because of the continued trauma associated with weight bearing, attempts should be made to spare the sole of the foot. Efforts also should be made to exclude the nail beds from the irradiation fields. Patients with extensive soft tissue involvement that would require circumferential irradiation of the hand or foot or irradiation of a large portion of the sole of the foot and Achilles tendon are not suitable for this approach. Patients presenting with major pretreatment functional deficits related to tumor infiltration of vessels or nerves may also be better served by amputation. Lesions of the calcaneus can be treated unless there is extensive bony destruction or soft tissue distention. There will be moderate loss of heel-pad thickness, but this has been associated with only mild functional impairment. [246]

For pelvic and central axis lesions, special attention to soft tissue extension visualized by MRI is critical. CT treatment planning and complex beam arrangements can minimize the volume of normal tissue (heart, lung, kidney, liver, bladder, bowel, and rectum) in the high-dose region. The buttocks should be taped apart to avoid bolus effect and unacceptable skin reaction. Adequate hydration and use of mesna during cyclophosphamide or ifosfamide administration are advised to minimize the chance of hemorrhagic cystitis, which can be exacerbated by irradiation if the bladder is in the radiation field.

Because of an unexpected finding of central nervous system relapse in the early NCI study, prophylactic cranial irradiation was incorporated in several of the subsequent NCI studies. [216] Central nervous system recurrence without skull bone involvement is now recognized to be extremely rare, and routine use of prophylactic cranial irradiation is unnecessary. [187]

In the IESS-1 study, prophylactic whole-lung irradiation (15 to 18 Gy) was used in one of the treatment arms. Although this treatment decreased subsequent pulmonary recurrence, significant pulmonary toxicity occurred when such irradiation was combined with multi-agent chemotherapy. In addition, doxorubicin [Adriamycin (Adr)], as a component of multi-agent chemotherapy, was shown to reduce recurrences in both the lungs and the bones. On the other hand, a German study in patients with pulmonary metastatic disease at diagnosis showed improved survival for those who received 18 to 21 Gy as compared to those receiving 12 to 14 Gy or no irradiation.

### *Treatment Volume*

The traditional wisdom is to include the entire medullary cavity for at least part of the treatment and a 3- to 5-cm margin beyond the soft tissue extension. In IESS-1, an increase in local recurrence was noted with treatment fields that did not include the opposite epiphysis. However, three studies in the 1980s have shown that less than whole-bone radiotherapy can be as effective as whole-bone irradiation for lesions smaller than 8 or 9 cm in diameter. In the St. Jude Children's Research Hospital study, local control was achieved in this manner in 12 of 14 patients with lesions smaller than 9 cm. [247] Investigators in the University of Florida also reported excellent local control using tailored radiation fields, although in patients with tumors larger than 8 cm, total body irradiation (TBI) was added, thus delivering some radiation to the entire bone. [216] The POG prospectively tested whole-bone versus tailored irradiation fields (2-cm margin around the pre-chemotherapy tumor). After the preliminary analysis showed that limited treatment volume was as effective as whole-bone irradiation, the randomized study was modified to a single-arm study using only tailored fields. [167,248]

Currently, tailored radiotherapy fields are recommended whenever possible. The initial treatment volume for patients should include the entire bony lesion, as demonstrated by initial imaging studies, with a 2-cm margin. If a 2-cm margin necessitates irradiation of the epiphysis of an adjacent bone and there is no extension across the joint space, a smaller margin should be used to include the adjacent epiphysis. Whether the initial soft tissue extension plus a 2-cm margin should be irradiated is subject to debate. Depending on the size of the initial soft tissue mass, the volume of irradiation could be substantial if the entire volume is to be covered: For example, the volume could involve the entire circumference of an extremity or the entire pelvis. In the pelvis, at least, most experts would agree to use the postinduction soft tissue volume for radiation treatment planning, to reduce bowel or bladder toxicity. In any case, if the volume of tumor (bone and soft tissue) at diagnosis is included in the initial radiation treatment volume, the boost fields could certainly allow a field reduction that takes into consideration the response of the soft tissue component to chemotherapy. If the initial soft tissue mass extends into a body cavity such as the pelvis or lung, the recommended treatment volume includes a 2-cm margin around the post–induction chemotherapy soft tissue volume, so as to minimize normal tissue morbidity.

Because the bony component of the tumor seldom shows a change in dimension on CT or MRI scans after induction chemotherapy, no field reduction for the bony component is possible in most cases. If gross residual disease is noted after resection, the initial postoperative radiotherapy volume should be the initial bony and soft tissue volume plus a 2-cm margin. After this, the site of gross residual disease should receive a boost treatment with a 2-cm margin. The presence of any microscopic residual disease (e.g., positive or inadequate surgical margin) after resection dictates that the postoperative radiotherapy volume be similar to that described for gross residual disease. A boost treatment with a 2-cm margin around the site of microscopic disease (if known) should be considered.

TBI or sequential hemibody irradiation as part of systemic treatment for patients with high-risk features or metastatic disease has been investigated in a limited fashion in the Princess Margaret Hospital, [249,250] NCI, [251] and Universityof Florida studies. [252] TBI has not contributed significantly to the control of metastatic disease, although definitive conclusions are difficult to ascertain from these single-arm studies.

### *Dose*

In the IESS-1 study, no clear dose-response relation was noted in the 40- to 60-Gy range. With few local recurrences and 50% of patients dying from distant disease within 3 years of entry into the study (perhaps before they survived long enough to manifest a local recurrence), correlating local control with total dose was difficult. An analysis of control of pelvic lesions also did not demonstrate any dose-response relation in the 40- to 60-Gy range. [253] Data from Massachusetts General Hospital showed no difference between doses of less than 60 Gy and doses of more than 60 Gy in providing local control of lesions measuring less than 1,000 cc. [213] Patients with localized extremity Ewing's sarcoma on IESS-1 were randomly assigned to receive total radiation doses of 46 or 60 Gy. Local recurrences were seen in five of nine and five of eight patients, respectively, at these two dose levels. Because of the inadequacy of the radiotherapy volume in the initial portion of this study (as described previously), a meaningful conclusion regarding dose response is not possible.

At the Instituto Rizzoli, investigators noted a 41% local recurrence rate at doses of 40 to 55 Gy, as compared with 30% at doses of 56 to 60 Gy in patients whose primary tumors were treated with irradiation alone. [198]

Despite lack of definitive data, a common pattern of practice has emerged: Where whole-bone irradiation is performed, 40 to 50 Gy is delivered to the entire medullary cavity, followed by a boost of 10 to 15 Gy to the primary tumor, resulting in a total tumor dose of 55 to 60 Gy.

Lower doses (30 to 36 Gy; mean, 35 Gy) have been investigated at the St. Jude Children's Research Hospital. [247] For small lesions (less than 8 cm) and a favorable response to induction chemotherapy, local control was 90%. However, local control was inferior for lesions larger than 8 cm (52%; $p = .054$). Further studies are needed before lower doses of radiation can be accepted as standard practice.

Currently, use of tailored fields with a dose of 45.0 Gy (at 1.8 Gy per fraction) is recommended. An additional 10.8 Gy should be delivered to the boost volume. The total tumor dose is 55.8 Gy. In patients in whom the soft tissue mass shows less than 50% regression after induction chemotherapy, a surgical resection or a final

tumor dose of 60 Gy (or both) should be considered.

Patients with gross residual disease after surgery should receive 45 Gy to the initial treatment volume, as described previously, with a boost of 10.8 Gy to areas of residual disease. For postoperative treatment of microscopic disease, 45 Gy to the initial tumor volume currently is recommended. A boost of 5 Gy to the site of microscopic disease, if known, is advisable.

***Schedule***

A conventional schedule of radiotherapy is 1.8 to 2.0 Gy per fraction, once daily, 5 days per week. A hyperfractionated schedule of 1.2 Gy twice daily, 6 hours apart, has been tested in three protocols at the University of Florida. [252] Those patients who did not have a soft tissue mass at diagnosis or whose soft tissue mass completely responded after induction chemotherapy received 50.4 Gy; those who experienced 50% or greater resolution of the soft tissue mass received 55.2 Gy; and those in whom less than 50% regression of the soft tissue mass was demonstrated or who experienced progressive disease during induction chemotherapy received 60 Gy. All patients with high-risk features also received TBI. The 5-year local control rate ranged from 80% to 92% in these protocols. In patients evaluated for limb function, the late effects were reported to be minimal and no treatment-related pathologic fractures were noted. These results indicate that hyperfractionated radiotherapy with small treatment fraction size can potentially reduce late morbidity without sacrificing local tumor control. However, this approach must be studied in a larger group before it can be recommended.

In the CESS-86 study, an accelerated fractionation schedule of 1.6 Gy twice daily to a total of 60 Gy was used. The final analysis showed no differences in local control between this schedule and the conventional once-daily radiotherapy schedule. [254] In irradiated patients, hyperfractionated split-course irradiation and conventional fractionation yielded the same results: 5-year overall survival of definitively irradiated patients, 63% after conventional fractionation and 65% after hyperfractionation; relapse-free survival, 53% versus 58%; and local control, 82% versus 86% (not significant). [254] On the basis of this study, it can be hypothesized that accelerated clonogenic repopulation between treatment fractions and overall treatment time may not be important factors in the local control of Ewing's sarcoma.

Single large-fraction (10- to 20-Gy) intraoperative radiotherapy has been studied in a limited number of patients. The NCI group reported use of intraoperative radiation (20 Gy) in two patients with large pelvic sarcomas that had completely regressed and were positive on biopsy after induction chemotherapy and 60-Gy external-beam irradiation; the lesions converted to completely responsive after intraoperative irradiation. [255] Calvo et al.[256] reported the use of induction chemotherapy plus external-beam irradiation (40 to 50 Gy), followed by partial or total surgical resection plus intraoperative irradiation of 10 to 15 Gy, in eight previously treated patients and re-induction chemotherapy plus 20-Gy intraoperative irradiation in three patients with local recurrence. With a median follow-up time of 18 months, local control was achieved in 10 of 11 patients. Whether this approach truly offers benefit in patients with large lesions that fail to regress with initial induction chemotherapy and whether the incidence and severity of late morbidity are increased require further study.

***New Radiation Approaches***

Three-dimensional treatment planning computer programs with beam's-eye view capability allow for even more complex design of multiple coplanar or non-coplanar treatment fields that can more effectively reduce the radiation dose to critical adjacent normal structures. These computer programs are particularly useful in planning the treatment of central lesions (e.g., in the pelvis or trunk). Multileaf collimators that can be programmed to shape the treatment fields obviate the need for Cerrobend blocks, and their use can be incorporated into many of the three-dimensional treatment planning programs. Generically, this form of sophisticated radiotherapy is called *conformal radiotherapy*, which consists of precision treatment designs that conform the spatial distribution of high radiation doses to the target volume while concomitantly excluding as much of the surrounding normal tissue as possible.

Intensity-modulated radiotherapy is the latest technology for conformal radiation planning and delivery. [257] Multiple small radiation beams of differing intensities are combined to create the dose envelope around the target. Because of the large number of iterations needed to find the right combination of these beamlets, one form or another of computer optimization algorithms generally is required in the planning process. A specialized intensity-modulated radiotherapy system combining such features as spinal CT and an intensity-modulated multivane collimator is being constructed, and clinical testing will begin in the near future.

A unique conformal radiotherapy system called the *Peacock* now is undergoing clinical investigation. [258] This system uses dynamic radiation intensity modulation and computer optimization. *Dynamic intensity modulation* means varying the amount of radiation delivered in a continuous fashion as the linear accelerator rotates around the patient. A special multivane collimator can generate a combination of $3.6 \times 10^{22}$ dose intensity patterns. The computer program finds the solution by choosing the appropriate dose intensity patterns needed to create the desired dose envelope that conforms to the shape of the target. Conceptually, this process is similar to putting together a three-dimensional jigsaw puzzle using a variety of small pieces of different sizes, each representing a different amount of radiation. Clinical situations exist in which conventional radiotherapeutic technique could not avoid significant morbidity if the tumor were to be adequately irradiated. The Peacock system could generate a better treatment plan. For example, in Ewing's sarcoma in the posterior aspect of a rib, conventional radiotherapy would irradiate a large volume of lung as well as the breast, but the conformal techniques such as Peacock allow significant lung sparing ( Fig. 33-10). Increasing use of such advanced systems is anticipated and will provide better radiotherapy for Ewing's sarcomas, especially those involving the trunk and pelvis.

**FIGURE 33-10.** A Peacock treatment plan for a posterior rib tumor on an axial computed tomographic image. The 75% isodose wraps around the target. The 45% isodose curves avoid the spinal cord and generally spare the heart and anterior left lung.

**Chemotherapy**

Before the routine use of adjuvant chemotherapy for the treatment of the ESFT, only 10% of patients survived 5 years. [205,206,259,260] In the early 1960s, cyclophosphamide (C), actinomycin-D (A), and vincristine (V) were found to be active against Ewing's sarcoma. By the late 1960s, patients were treated with these drugs as adjuvants to local therapy at the NCI, St. Jude Children's Research Hospital, and a few other institutions. [261,262,263 and 264] A number of patients so treated remained free of disease for more than 2 years, a previously rare event. The investigators involved in these cases recognized that chemotherapy was having an impact on the disease process, and the subsequent studies were expanded. It was demonstrated that doxorubicin (D) was also active against Ewing's sarcoma of bone, and this drug was incorporated into the adjuvant regimens. Long-term follow-up from the early adjuvant trials at the NCI demonstrates that Ewing's sarcoma of bone can be cured, with 33% of patients surviving free of disease for 15 years after treatment onset. [176,265] Clinical trials during the last two decades have focused on identifying more effective drug regimens.

Table 33-6 lists the activity of drugs against the ESFT as determined by phase II studies. Classic alkylating agents such as cyclophosphamide, ifosfamide, and high-dose melphalan are among the most active agents. Recent phase II studies involving these diseases have been carried out in patients with tumors resistant to intensive multi-agent regimens. For example, cisplatin, topotecan, and thiotepa have been found to be inactive against refractory or recurrent Ewing's sarcoma. [266,267 and 268] Cisplatin, which has been determined to be active against osteosarcoma, rhabdomyosarcoma, and neuroblastoma, showed little activity against drug-resistant Ewing's sarcoma of bone.[268] However, cisplatin might be active in a newly diagnosed case of the ESFT. Likewise, the demonstration of a high level of activity for the drug combination ifosfamide and etoposide in patients with recurrent disease classified among the ESFT was impressive [269] and led to the use of this combination in

newly diagnosed cases.[270,271] and [272] Meyer et al.[272] at St. Jude treated with ifosfamide and etoposide (before other agents) 26 patients with newly diagnosed Ewing's sarcoma and PPNET, to determine the rate of response. They found that 25 of 26 evaluable patients demonstrated at least a partial response. [272] No additional drugs have been recognized to be active against the ESFT in the last several years.

| Agent and studies | Response (no. responding/total) | Response rate (%)[a] |
|---|---|---|
| Cyclophosphamide[329-333] | 17/36 | 47 |
| Doxorubicin[334-340] | 25/60 | 42 |
| Ifosfamide[341-343] | 12/37 | 32 |
| Vincristine[332,344-346] | 4/10 | 40 |
| Actinomycin-D[331,342,348] | 3/16 | 19 |
| BCNU[331,349] | 6/18 | 33 |
| 5-Fluorouracil[350,351] | 4/10 | 40 |
| 5-Fluorouracil/leucovorin[352] | 0/12 | 0 |
| Etoposide[353,354] | 3/10 | 30 |
| Cisplatin[308,355-357] | 2/27 | 7 |
| Carboplatin[358] | 0/7 | 0 |
| Melphalan (high-dose)[359,360] | 9/11 | 82 |
| Ifosfamide/etoposide[355] | 18/30 | 60 |
| Topotecan[361] | 1/26 | 4 |
| Thiotepa[356] | 0/10 | 0 |

**TABLE 33-6. SINGLE-AGENT AND COMBINATION ACTIVITY IN EWING'S SARCOMA IN PHASE II STUDIES**

### *Combination Chemotherapy Studies*

The major combination chemotherapy studies are summarized in Table 33-7. One of the first such studies of Ewing's sarcoma of bone was carried out at the NCI. Patients were treated with VAC with or without doxorubicin and concomitant local irradiation. [176] These chemotherapeutic regimens were of relatively low intensity when judged by today's standards. Nonetheless, one-third of the patients were long-term survivors. Results were best in patients with nonmetastatic extremity tumors.[189]

**TABLE 33-7. OUTCOME OF MAJOR MULTIMODALITY STUDIES**

### Nonmetastatic Disease

In 1973, the first IESS study (IESS-1) was initiated to compare results of three adjuvant treatment regimens for nonmetastatic Ewing's sarcoma of bone. [183] This national study was a collaboration by three multi-institution groups: the Children's Cancer Study Group (CCSG), the Southwest Oncology Group, and the Cancer and Acute Leukemia Group B. Because the initial goal was to test the value of adjuvant chemotherapy, one-third of the patients were to be randomized to receive no chemotherapy. After two of the first three patients who did not receive chemotherapy experienced a relapse, the study was amended to include three groups: VAC (vincristine, actinomycin-D and cyclophosphamide) alone, VAC plus Doxorubicin (D) or VAC plus bilateral pulmonary irradiation. [183]

The results of this study have been updated with a median follow-up time of 6 years for surviving patients ( Fig. 33-11).[208] VAC plus D was more effective than VAC plus pulmonary irradiation, which in turn was superior to VAC alone, with 5-year relapse-free survival rates of 60%, 44% and 24% respectively. The majority of failures was attributable to metastatic disease, which occurred in 44% of the patients, whereas 15% of failures was attributable to local disease. The frequency of lung metastases was the same for those receiving VAC alone and those receiving VAC plus pulmonary irradiation.

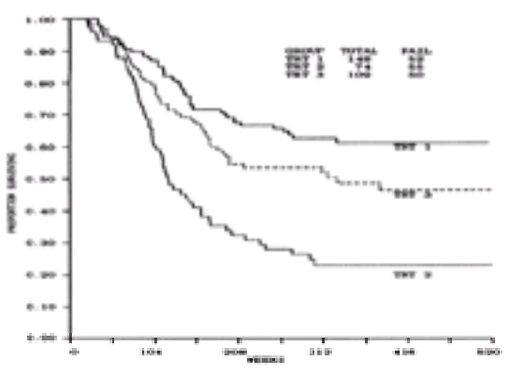

**FIGURE 33-11.** Actuarial survival of patients treated on Intergroup Ewing's Sarcoma Study 1. Treatment 1 (TRT1) consists of vincristine, actinomycin-D, and cyclophosphamide (VAC) plus doxorubicin; TRT2 is VAC plus lung irradiation; TRT3 is VAC alone.

Having established a role for doxorubicin in the treatment of Ewing's sarcoma of bone, a second IESS study (IESS-2) was launched in 1978 to compare the efficacy of high-dose intermittent versus moderate-dose continuous VAC plus D in patients with localized, nonpelvic Ewing's sarcoma of bone. [273] The major difference between the two regimens was a 150% increase in doxorubicin dose intensity during the initial 36 weeks of therapy. The relapse-free survival rate at 5 years was significantly higher among patients treated with the high-dose intermittent regimen (73% vs. 56%; $p = .03$) thus indicating that increasing doxorubicin dose intensity and administering it early in the course of therapy is beneficial. As in IESS-1, the majority of treatment failures was metastatic.

Investigators at St. Jude developed an alternative VDCA (vincristine, doxorubicin, cyclophosphamide and actinomycin-D) regimen that included induction with oral cyclophosphamide daily for 7 days, followed by intravenous doxorubicin on day 8. This well-tolerated regimen was delivered every three weeks. After 3 months, a second-look surgical procedure was performed, and radiotherapy was administered. [275] The excellent response and progression-free survival rates achieved with this regimen prompted the POG to use it in a protocol that included a randomized radiotherapy question. [248] This study achieved a 3-year EFS of 54% for patients with localized tumor; the majority of the failures was systemic. These disappointing results led the POG to abandon this regimen in favor of high-dose intermittent VDCA in the subsequent study.

Most recently, two strategies for improving the outcome of patients with localized ESFT have been tested. The first strategy was tested in two historically controlled

studies which investigated the efficacy of substituting ifosfamide (Ifos) for cyclophosphamide in the VDCA regimen. The German Pediatric Oncology Group's CESS-86 study reported a minimally improved 3-year DFS rate with ifosfamide, whereas the French Society of Pediatric Oncology reported no benefit. [210,276] In European Intergroup Cooperative Ewing's sarcoma study 92, which is a project of the German and British societies for pediatric oncology, 470 patients with localized ESFT were stratified into two treatment groups based on tumor volume (less than and at least 100 mL); standard-risk or high risk categories. Standard-risk patients were randomized to cyclophosphamide-versus ifosfamide-based maintenance after induction with VDIfosA (vincristine, doxorubicin, ifosfamide, actinomycin-D). The EFS at 5 years for the standard-risk patients was 75%. In regard to the randomization, the 5-year EFS was 71% for VDCA and 79% for VDIfosA ( $p = .37$). High-risk patients were randomized to VDIfosA versus the addition of etoposide. The EFS at 5 years for the high-risk patients was 58%, and the randomization results were 54% for VDIfosA and 62% for etoposide, VDIfosA ($p = .60$).[280] The substitutionof ifosfamide for cyclophosphamide did not improve on outcome.

The second strategy examined more recently has been whether the addition of ifosfamide and etoposide to the VDCA regimen improves survival. The phase II results that demonstrated a high degree of activity of ifosfamide and etoposide in patients with recurrent ESFT led to studies at the NCI and St. Jude that integrated these agents into VDCA regimens for patients with newly diagnosed disease.[270,272]

A phase III POG-CCG intergroup clinical trial (IESS-3) completed in 1992, compared the efficacy of VDCA with and without ifosfamide and etoposide in ESFT. [277] The study accrued 398 nonmetastatic patients (median age, 12 years; range, 0 to 28 years); 188 extremity tumors and 93 pelvic tumors were included. The 5-year EFS rate for nonmetastatic patients was 54% for VDCA and 68% for VDCA, ifosfamide, and etoposide ($p = .0042$) (Fig. 33-12). Overall survival rates were 61% and 72%, respectively ($p = .01$). For the entire group, failures were local in 27%, systemic in 63%, and combined in 10%. This study substantiates the benefit of the addition of ifosfamide and etoposide for patients with localized ESFT.

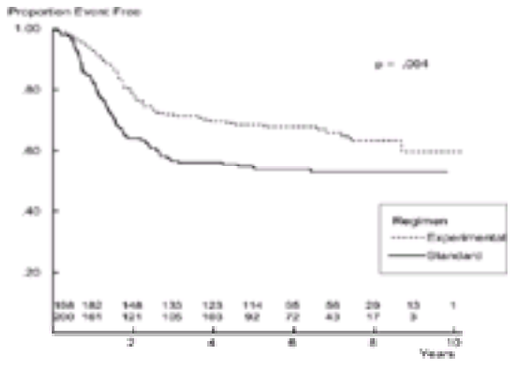

**FIGURE 33-12.** Results of Intergroup Ewing's Sarcoma Study 3. Event-free survival comparing outcome by regimen. Standard arm represents those patients receiving vincristine, doxorubicin, cyclophosphamide, and actinomycin-D (VDCA). Patients on the experimental arm received alternate courses of VDCA and ifosfamide and etoposide used in combination.

The Orthopedic Institute from Rizzoli conducted two sequential studies in which the addition of ifosfamide and etoposide to the VDCA regimen in the neoadjuvant treatment of ESFT seemed to confer no advantages.[281] The first study (REN-1) involved 108 patients with ESFT between 1983 and 1988 and used VDCA. The second study (REN-2) involved 82 patients with ESFT treated between 1988 and 1991. The chemotherapy used was VDCA and ifosfamide and etoposide. No advantage was observed when ifosfamide and etoposide were added to the VDCA regimen. The 5-year DFS and overall survival in REN-2 were 54% and 59% respectively, and in REN-1 were 50% and 56%, respectively. Because these two studies were performed in the same institute, the choice of local treatment followed the same criteria. Additionally, the distribution of patient characteristics (i.e., tumor site, tumor volume, and serum LDH values) was similar in the two studies. Although the results of REN-1 and REN-2 appear on first glance to contradict IESS-3, there are a number of reasons for the different results. First, more cycles of the combination ifosfamide and etoposide were given in IESS-3 than in REN-2 (ten cycles vs. three cycles); second, in IESS-3, the ifosfamide-etoposide combination was initiated during induction, whereas in REN-2, ifosfamide and etoposide therapy was begun during the maintenance phase. [277] The additionof ifosfamide and etoposide to the backbone of V, D, and C has become the current standard of care for patients with localized ESFT.

Because ESFT are very sensitive to alkylating agents, which have a steep dose-response curve, the use of dose intensification to improve DFS in patients with ESFT is of much interest. Increasing the dose intensity means increasing the quantity of a drug per unit of time. Granulocyte colony-stimulating factor (G-CSF) has made the dose-intensive protocols possible by reducing the duration of neutropenia, which is the most dangerous side effect of dose-intensive therapy. St. Jude Hospital investigators recently published their experience with dose intensification for pediatric patients with ESFT. [282] From 1992 to 1996, St. Jude treated 51 patients with ESFT with their dose-intensified Ewing's protocol, in which the dose intensity was 1.5 (minimum increase in ifosfamide) to 2.5 times (maximum increase for cyclophosphamide) higher than that delivered on the St. Jude protocol in the prior Ewing's sarcoma study. [272] Dose intensity was achieved by increasing the total doses of drugs administered. Toxicity was considerable in this study, particularly infectious complications. Fourteen patients developed sixteen episodes of bacteremia, six of which were associated with septic shock. From this group of patients, it appeared that dose intensification was feasible during induction, with very few delays in therapy, but that, in the maintenance phase after radiotherapy had been given, dose intensification was feasible for only a small percentage of patients. Estimated 3-year survival and EFS were 72% and 60%, respectively. The authors conclude that because the toxicity of dose intensification is high, it will be important to first determine its impact on DFS before deciding whether to place patients on these toxic regimens.

A POG-CCG Ewing's sarcoma study recently closed, which compared a 48-week standard regimen of VDC alternating with ifosfamide and etoposide with G-CSF with a 30-week dose-intensified regimen of the same chemotherapeutic agents. The experimental regimen had fewer cycles with higher doses of cyclophosphamide and ifosfamide, so that the total drug doses in the two regimens were the same. Preliminary data indicate that there is no difference in the EFS of patients treated over 48 weeks versus 30 weeks.

A prospective pilot study from the Children's Hospitals of Philadelphia and Seattle achieved dose intensification through interval compression (decreasing intervals between cycles while maintaining conventional doses). [283] Interval compression allows dose intensification of all chemotherapeutic agents, not just the alkylators, and it limits the time in which partially drug-resistant cells have to recover from one cycle of chemotherapy before they are attacked by the subsequent cycle. This pilot study included 73 children and adolescents with Ewing's sarcoma, rhabdomyosarcoma, and miscellaneous soft tissue sarcomas. [283] The data demonstrated that compression of the interval between chemotherapy cycles using G-CSF is a well tolerated and practical method of increasing the dose intensity of chemotherapy. In the induction phase, the median chemotherapy cycle interval was 16 days, with a median average relative dose intensification of 1.27 as compared with every-21-days therapy. Although the primary objective of this study was practicality, some survival information was also gleaned. Of the 73 patients, 30 had localized ESFT and two-thirds of these patients were at relatively high risk secondary to axial primary lesions. For the 30 patients with localized ESFT, the EFS was 73%, and the overall survival was 85% at a median follow-up of 30 months.283 This regimen is not less effective than previous protocols.

The Children's Oncology Group (COG) has begun a Ewing's sarcoma study for patients with localized disease. The study is a randomized controlled trial comparing interval compression with standard every-3-weeks chemotherapy. In the COG study, the objective will be to evaluate the effect of interval compression with G-CSF support on the EFS and overall survival of patients with ESFT.

### Metastatic Disease

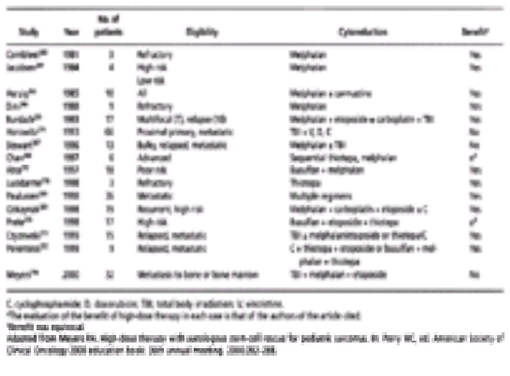
Results of the treatment of patients with clinically overt metastatic disease at diagnosis are significantly less favorable than are the results for patients with localized disease (Table 33-7). For example, only 2 of 27 patients with metastatic Ewing's sarcoma of bone who were treated at the NCI from 1968 to 1980 were surviving 5 years after diagnosis, as opposed to 41% of patients with localized disease ( $p < .0001$).[176] An intergroup study for patients with metastatic Ewing's sarcoma of bone, conducted from 1975 to 1977, achieved complete responses in 31 of 44 evaluable patients with a regimen that included VAC plus D and irradiation of the primary site and a maximum of four metastatic sites.[175] If lung metastases were present, bilateral pulmonary irradiation was administered. In both studies, approximately 30% of patients were recurrence-free at 3 years after diagnosis. Age was a significant prognostic factor: More than 40% of those younger than 11 years at treatment were alive 10 years later in contrast to fewer than 20% of the older children. A higher proportion of the younger children had rib primary lesions and pleural effusions as the sole site of metastasis, which is a more favorable group. The best results reported for metastatic Ewing's sarcoma of bone were achieved with a sequential C plus D induction regimen administered by the St. Jude Children's Research Hospital. [284] The researchers reported a favorable DFS rate of 55% at 47 months for 18 patients

with metastases.[174] This protocol was used subsequently in the multicenter French Society of Pediatric Oncology (SFOP) trial EW88; however, a DFS of only 21% was reached at 3 years.[285,286] Finally, the addition of ifosfamide and etoposide has not improved the outcome for patients with metastatic disease at diagnosis. [277,278]

Many groups have supplemented chemotherapy with irradiation to sites of gross metastatic disease in addition to the primary site. [178,185,287] Patients with solitary or circumscribed bony lesions can be irradiated at those sites to doses in the range of 40 to 50 Gy, in addition to irradiation of the primary tumor. Low-dose (15 to 18 Gy in 150-cGy fractions), bilateral pulmonary irradiation in conjunction with intensive chemotherapy has been reported to be efficacious in controlling gross metastatic disease in the lungs without significant pulmonary toxicity. [287] Additional small, field boost doses to a total of 40 to 50 Gy can be provided to large, focal lung lesions.

Discouraging results with conventional chemotherapy and irradiation for metastatic ESFT have led to the consideration of novel approaches. Because the ESFT are relatively radiation-sensitive, the use of radiotherapy as a systemic treatment for the ESFT has long been of interest. [249,288,289] Initial approaches entailed the use of sequential hemibody irradiation; recent studies have used TBI as a systemic agent in conjunction with chemotherapy and bone marrow transplantation as a rescue. A protocol conducted at the NCI from 1983 to 1986 treated patients who had high-risk Ewing's sarcoma of bone with high-dose VDC, irradiation to local and metastatic sites, and intensification with a final cycle of VDC and TBI (800 cGy over 2 days), followed by autologous bone marrow re-infusion. [178] Although preliminary results were encouraging, therapy has failed in more than 80% of patients with metastatic Ewing's sarcoma and PPNET.[279,290]

The potential therapeutic benefit of very-high-dose chemotherapy regimens in combination with stem-cell rescue for patients who have metastatic disease, refractory or relapsed disease, or large axial inoperable tumors has been under evaluation by multiple centers worldwide ( Table 33-8). Comparing these studies is difficult because they do not share common eligibility criteria. Across the series of studies that have been completed, no consistent definition of what constitutes a high-risk Ewing's sarcoma patient appears. This point is particularly important, because patients with pulmonary metastases reportedly have a somewhat improved prognosis over patients with bone and/or bone marrow metastases.[299,300] Additionally, different regimens for cytoreduction have been used, as have various sources for stem cells. This makes very difficult the interpretation of the data and the drawing of any sound conclusions of the benefit of very-high-dose chemotherapy in combination with stem-cell rescue. Burdach et al.[291] treated 17 patients who had multifocal Ewing's sarcoma or who had experienced relapse within 2 years of diagnosis with TBI (1,200 cGy hyperfractionated) and myeloablative chemotherapy (melphalan, 30 to 45 mg per $m^2$ per day on 4 consecutive days followed by one dose of etoposide 40 to 60 mg per $m^2$). The relapse-free survival rate was 45% ± 12% at 6 years after the last event before transplant. [291] Atra et al.[292] studied 18 patients with poor-risk disease classified within the ESFT who received consolidation therapy with busulfan and melphalan. After a median follow-up of 2 years, 13 surviving patients remained in complete remission. Lucidarme et al.[293] reported on a phase II study of high-dose thiotepa and autologous rescue in three patients with refractory metastatic Ewing's sarcoma, two of whom went into partial remission and one of whom experienced progressive disease. One patient is still alive more than 28 months after re-infusion.[293]



| Study | Year | No. of patients | Eligibility | Cytoreduction | Benefit* |

**TABLE 33-8. HIGH-DOSE THERAPY WITH AUTOLOGOUS STEM-CELL RESCUE FOR HIGH-RISK EWING'S SARCOMA**

The CCG recently completed a prospective trial of high-dose chemotherapy and radiotherapy as consolidation for patients with high-risk Ewing's sarcoma. [294] In this study, the high-risk group included patients who presented with primary Ewing's sarcoma of bone and metastases to bone marrow or to bony sites distant from the primary tumor. Thirty-two patients were eligible and entered into the study. These 32 patients were given induction therapy with three cycles of VDC, which were alternated with two cycles of ifosfamide and etoposide. Local control included surgery for selected patients and radiotherapy to the primary tumor and selected sites of metastases. The patients then received TBI in 3 days, followed by melphalan and etoposide over 3 days, followed by peripheral blood stem-cell re-infusion. Of the cohort of 32 patients, 8 did not receive high-dose therapy because of incomplete response, progressive disease, or toxic death. Twenty-four received TBI, melphalan, etoposide, and stem-cell re-infusion. The EFS for the cohort of 32 patients was 16% at 2 years after diagnosis, which was similar to the EFS achieved in the national trial of conventional chemotherapy and radiotherapy. [295] Induction chemotherapy followed by melphalan, etoposide, TBI, and peripheral blood stem-cell support did not improve prognosis for patients with newly diagnosed high-risk Ewing's sarcoma.

The results from the European Bone Marrow Transplant Solid Tumor Registry were similarly disappointing in regard to patients with metastatic ESFT. Patients in their first complete remission but who had metastases at diagnosis (32 patients) achieved a 5-year survival rate of 21%. [286]

Currently, no conclusive evidence supports the contention that high-dose therapy for patients at high risk of failure is beneficial. To date, the myeloablative regimens used have been too varied to permit meaningful comment. More homogeneous therapy is needed if we are to accumulate sufficient patients for randomized studies in this subject.

### *Treatment of Peripheral Primitive Neuroectodermal Tumor*

PPNET responds to the same chemotherapeutic agents as are used in the treatment of Ewing's sarcoma of bone. The German Society of Pediatric Oncology retrospectively reviewed their experience with 42 patients having this tumor, most of whom were treated on their cooperative group protocols for Ewing's sarcoma with VAC plus D or V-ifosfamide-C plus D.[181] Sixty-three percent of the 32 patients with localized disease were in continuous complete remission, whereas treatment failed in nine of ten patients presenting with metastatic disease; these results are similar to those for patients with Ewing's sarcoma on the same protocol.

At the NCI, 17 patients with PPNET were treated on the same protocol as were those with Ewing's sarcoma, which included an intensive VDC regimen, local irradiation, and TBI (800 cGy) for patients with metastatic disease at diagnosis or high-risk primary sites such as the central axis. [177] Just as for those with Ewing's sarcoma, approximately one-half of the patients with localized disease remain in continuous complete remission, whereas more than 90% of those with metastatic disease at diagnosis have experienced disease recurrence.[290]

At St. Jude Children's Research Hospital, investigators retrospectively reviewed 14 patients with PPNET diagnosed between February 1988 and January 1992. [296] These patients all were enrolled in the “Ewing's 87” (EWI-87) protocol at the hospital. Of the 14 patients, three had metastatic disease and 11 had localized disease. Of the patients with local disease, eight demonstrated no evidence of disease at a median of 59 months, and one of the three with metastatic disease also exhibits no evidence of disease. This study shows that Ewing's sarcoma–directed multimodality therapy can cure approximately two-thirds of patients with PPNET. This figure is comparable to the outcome of patients with EES treated on rhabdomyosarcoma protocols and to that of patients with osseous Ewing's sarcoma. No data are available to suggest that PPNET should be treated differently from Ewing's sarcoma.

### *Treatment of Extraosseous Ewing's Sarcoma*

EES has, until recently, been treated on protocols for rhabdomyosarcoma (RMS). In the Intergroup Rhabdomyosarcoma Studies (IRS), the basic local control strategy was an attempted wide local excision of the primary site, to be followed by postoperative irradiation in the case of a positive margin, positive nodes, or gross residual disease. One hundred thirty patients with EES were registered on three intergroup RMS clinical trials (IRS-I, -II, and -III) from 1972 to 1991. One hundred fourteen of these patients had localized disease. All patients were given multi-agent chemotherapy, and most received irradiation. One hundred seven (82%) achieved complete remission. At 10 years, 62%, 61%, and 77% of the patients were alive after treatment on IRS-I, IRS-II, or IRS-III, respectively. This is similar in percentage to all IRS

patients.[297] This series indicates that EES in children is similar to RMS in its response to multimodality therapy.

Current POG-CCG Ewing's sarcoma studies accept these patients as well. St. Jude placed three children with localized EES (primary sites: chest wall, back, and pelvis) on EWI-87 study and all three had no evidence of disease after a median follow-up of 77 months. [296] Ahmad et al.[298] recently reported on 24 patients with EES. The average length of follow-up of survivors was 64 months. This study included five patients with metastatic disease at diagnosis. With multimodal therapy, the overall 5-year survival rate was 61%, and the DFS rate was 54%. The results of these studies demonstrate that EES should be treated with multimodality therapy and that the results are similar to those in patients with osseous Ewing's sarcoma.

### *General Guidelines for Treatment*

Patients with the ESFT should, if possible, be treated on protocols specifically designed for these diseases. If such clinical trials are not available, therapy should be guided by the following principles: First, the patient should be evaluated as thoroughly as possible, as described in this chapter, to establish an accurate pretreatment baseline. Second, that baseline should guide local therapy, which should be administered under the guidance of physicians with special expertise in these diseases. Third, systemic chemotherapy should include VDC and, for those patients with localized tumors, ifosfamide and etoposide. The specific doses and their frequency are, to some extent, dictated by the institution's ability to support the patient through episodes of neutropenia. Although dose intensity may be important, under certain circumstances a higher dose intensity may be achieved with a lower-dose regimen given more frequently, as opposed to a high-dose regimen that may result in infection and consequent treatment delays.

## Prognostic Factors

The most important prognostic factor for patients with the ESFT is the presence or absence of clinically detectable metastatic disease at diagnosis. [176,214] Although the majority of patients with these tumors likely has microscopic metastatic disease at diagnosis, the presence of tumor demonstrable by clinical imaging techniques decreases the likelihood of long-term survival, from between 50% and 70% in modern series to less than 30%. [185] This stark dichotomy exists for most of the other childhood sarcomas and suggests that metastatic tumors are not just those detected later but are, in fact, biologically different from those still localized at diagnosis. The prognosis in patients whose disease is disseminated appears to depend additionally on the metastatic pattern of the disease. [299] The European intergroup found in patients with primary lung metastases that the 5-year and 10-year relapse-free survival rates were 36% and 30%, respectively. This finding contrasts to patients with metastatic disease to bone and bone marrow, for whom the 10-year EFS was 16% ($p$ = .0001).[300]

Among patients with localized tumors, primary site is related to outcome, with the least favorable site being the pelvis and most favorable sites distal bones, ribs, and cutaneous and subcutaneous sites.[163,164,176,208,301] Tumor size also has been found to be an important prognostic factor in some studies, although this criterion still is fairly controversial. The CESS-81 study demonstrated that patients with localized Ewing's sarcoma of bone smaller than 100 cc had DFS significantly better than that in patients with tumors larger than 100 cc.[181] Analysis of prognostic factors in CESS-86 confirmed large tumor volume to be the one factor influencing prognosis most significantly, but the tumor volume found to be critical and of poor significance was a volume greater than 200 cc. [164] Bacci et al.[163] did not find tumor volume, at least at 100 mL, to correlate with prognosis. Age at diagnosis was a significant prognostic factor in IESS-1 and IESS-2, with younger patients faring better than older patients in both studies.[185,208,273] Craft et al.[302] reported that patients who had the ESFT and were younger than 10 years had a prognosis better than that of older patients (relapse-free survival of 86% for younger patients vs. 55% for older patients). [302] This finding has been confirmed in other recent studies. [163,303]

Patients with elevated serum lactate dehydrogenase levels fare worse than do those with normal levels. [163,189,214] As discussed, the degree of neural differentiation no longer appears to be of prognostic significance. Rather, histologic response to chemotherapy after surgical resection appears to be an important prognostic indicator.[162] Additionally, as detailed, patients with tumors expressing a type 1 EWS-FLI1 transcript appear to have a better outcome. [89,93]

## Treatment of Recurrent Disease

Patients with a suspected recurrence must be evaluated fully both at the primary site and for the presence of metastatic disease before a plan of treatment can be formulated. The majority of patients with local treatment failure have concomitant gross or microscopic metastatic disease. The detection and treatment of a local recurrence may be difficult. Imaging studies often are not helpful in determining local recurrence, because interpreting clinical and radiographic examinations of irradiated areas is difficult. MRI has not proven as useful as originally hoped because of the marked skin and muscle changes after irradiation or surgery. [304] A persistent soft tissue mass often may be a residual fibrotic mass rather than a tumor. Determination of intraosseous recurrence is even more difficult. Plain radiographs show a variety of responses and patterns of reossification. If cortical destruction or increasing lysis occurs, an intraosseous recurrence must be suspected. Bone scans that show markedly increased activity suggest local recurrence. Second-look bone biopsies are associated with a high rate of local morbidity, wound problems, and secondary fracture and are fraught with the problem of sampling error.

The prognosis for patients with recurrent disease is poor. The length of survival depends on the site and extent of recurrence, the aggressiveness of the tumor, the previous treatment, and time to failure. The likelihood of response to retreatment increases with increasing duration of disease control. If disease progression or recurrence occurs during the initial therapy, the likelihood of a subsequent response to chemotherapy is nil. [284]

The choice of chemotherapeutic agents is dictated in part by affected patients' prior treatment. If such patients have not yet received agents with known activity against the ESFT, these agents should be used first. For example, if a patient previously has received VDC plus A alone, ifosfamide and etoposide should be considered at the time of recurrence, because they have demonstrated activity in this situation. [269] For those patients who have received intensive treatment with all known active agents that fails on or near the completion of therapy, retreatment with previously used agents is likely to be of little more than transient benefit. Such patients should be considered for entry into phase I or phase II new-drug studies. [305] The St. Jude group treated the only series of patients reported in the literature to have achieved significant benefit from retreatment with previously used agents. [284] This group reported that 0 of 18 patients with relapsing disease on therapy achieved a second complete response, versus 26 of 34 patients whose tumors recurred while they were off treatment, with 12 remaining in second remission from 5 months to 19 years from relapse. In some of the patients, third and even fourth remissions were obtained. The majority of the patients with favorable outcomes were those with relapse of a single pulmonary nodule. In many of them, the second complete response was obtained with surgery. Little information is available regarding the utility of resection of pulmonary nodules in patients with recurrent Ewing's sarcoma. Its value has been documented in such tumors as osteosarcoma but is less clear in cases of the ESFT. Bacci et al.[306] reported that 5 of 12 patients survived 3 to 14 years after pulmonary surgery for lung relapse of Ewing's sarcoma.

Management of a local recurrence may include surgery or radiotherapy (or both). A local recurrence in the extremity may require amputation, because surgery in a heavily irradiated field has little chance of success, especially if a prosthesis is required. If the recurrence involves the pelvis or proximal femur, a hemipelvectomy often is required. Local recurrence outside of the original irradiation field (marginal recurrence) may be salvaged with additional irradiation [245] or surgery. Sparse experience is reported for irradiation salvage of local recurrences after surgery to the primary lesion. The suitability of such cases for salvage by irradiation depends on limb function at the time of recurrence, the presence of a pathologic fracture, the ability to spare a strip of irradiated tissue, the ability to define accurately the recurrence with imaging studies, the exact anatomic location of the recurrence, and the age of an affected patient. Such decisions are best individualized and made after discussions among the pediatric oncologist, radiation oncologist, orthopedic surgeon, rehabilitation physician, patient, and family.

The European Bone Marrow Transplant Solid Tumor Registry analyzed information regarding 31 patients with relapsed ESFT. [286] These patients at first relapse were treated with megatherapy followed by bone marrow or peripheral stem-cell rescue between 1982 and 1992. Patients in second complete remission achieved a 32% EFS rate at 5 years. Local relapse was associated with a prognosis worse than that of distant recurrence and, not surprisingly, a favorable outcome was limited to relapsed patients with localized disease at diagnosis. Time to relapse in this study was not recognized as a prognostic factor. Others have attempted to use high-dose therapy with autologous stem-cell rescue for relapsed Ewing's sarcoma (Table 33-8). At this time, the data are too heterogenous to interpret.

## Complications of Treatment

The acute and chronic effects of the chemotherapeutic agents used to treat the ESFT are described in Chapter 10 and Chapter 9. Of particular concern for patients with primary tumors of the chest wall are the combined effects of doxorubicin, cyclophosphamide, and radiation to the heart, which produce a higher incidence of myocardial damage and congestive heart failure. The incidence of this complication may be decreased by the use of continuous-infusion doxorubicin [307] or the cardioprotector ICRF-187 (dexrazoxane, Zinecard).[308] A statistically significant increase in the risk of toxicity is associated with the combination of high individual dose and shorter interval between doxorubicin doses as measured by the dose intensity. [309] All patients who have received doxorubicin should have routine surveillance of

their cardiac function, because late congestive heart failure is increasingly being observed.

Toxicities of high-dose irradiation given in conjunction with intensive chemotherapy can be separated into acute and late complications. The severity of both can be limited by careful technique. Acute reactions are those occurring during or shortly after completion of radiotherapy. The most prominent acute side effects occur in tissues in the radiation field with rapidly dividing cells. Therefore, desquamation of the skin, mucositis, diarrhea, proctitis, or dysuria may be seen. The severity of these effects depends on the amount of normal tissue in the radiation field, radiation fraction size, and the timing of chemotherapy in relation to the radiation. Actinomycin-D and doxorubicin enhance acute radiation reactions. If these agents are to be administered during a course of radiotherapy, a planned break of several days in the radiation treatments may help to limit the severity of the interaction. Acute reactions usually are self-limited and resolve within 10 to 14 days of completion of irradiation. Dry desquamation can be managed with skin cream to soothe and moisten the affected area. When this reaction appears, a short break in the radiotherapeutic schedule may prevent progression to moist desquamation; if the latter occurs, a radiation treatment break and clean, wet soaks to the affected area three times daily are necessary. Mucositis and diarrhea require appropriate hydration and supportive care.

Late reactions are those occurring months to years after completion of a course of irradiation. The pathophysiology of late effects is understood incompletely but may be related to radiation injury to less rapidly proliferating supportive stroma or normal tissue. [310] Their severity is not always predicted by the severity of acute effects.

Reports of late functional deficits related to the combination of irradiation and intensive chemotherapy vary substantially in the frequency and severity of limitations reported.[243,252,311,312,313] and [314] Technique, treatment volume, and total dose are related to functional outcome, as are patient age, pretreatment functional status, presence of pathologic fracture at presentation, and the prescription and adherence to a rehabilitation program. Younger, prepubertal children are at greater risk of suffering radiation-induced arrest of bone growth. [313] Doses of 60 Gy or greater are associated with more complications, including markedly increased induration and fibrosis.[311,312,313,314] and [315] Circumferential irradiation of the extremity has been associated uniformly with fibrosis, edema, and poor function. [243,311] Late contractures are more apparent in less physically active patients. Higher radiation doses and a greater extent of cortical bone destruction by tumor or biopsy procedure have been associated with a higher frequency of fractures in the radiation field. [311,316] Weight-bearing lower extremities are at greater risk for complications than are the upper extremities.

An older series in which radiation dose, volume, and technique differed considerably from current standards described major radiation-related complications in 29% of patients. The most pronounced deficits occurred in the dose range of 6,500 to 7,800 roentgens. This finding contrasts to recent series that show that excellent functional results can be obtained in the majority of patients irradiated for Ewing's sarcoma. Jentzsch [311] reported that 13 of 22 patients treated with 50 Gy to the entire bone using shaped fields in conjunction with chemotherapy had essentially normal limb function with no more than minimal functional limitation or leg length discrepancy; only 1 patient had a functional impairment severe enough to warrant an amputation.

Sparing of uninvolved epiphyseal plates minimizes leg shortening secondary to irradiation. [315] The application of CT-directed treatment planning, by limiting the volume of normal tissue in the field, appears to offer further improvements in functional outcome. Appropriate case selection and application of careful radiotherapy technique in a series of patients with sarcomas of the hand and foot resulted in normal function in five of seven patients and only minor impairment in the remaining two. Experience with twice-daily radiotherapy (120 cGy twice daily to 50.4 to 60 Gy) for Ewing's sarcoma has demonstrated excellent functional outcome. [252] No pathologic fracture was seen in 18 patients with extremity primary lesions. Eight patients with extremity primary lesions underwent a formal evaluation of limb function between 2 and 7 years after radiotherapy. One patient showed a minor (1.5-cm) leg length discrepancy. Six of eight patients showed slight difference in extremity circumference, with an average circumference deficit of 0.87 cm in the treated extremity. Essentially, no detectable fibrosis or noticeable stiffness occurred in the treatment field.

An active physical therapy program should be established for each patient to maximize functional outcome. The program should include active joint extension and flexion. Rehabilitation should be started as soon as possible and should include weightbearing after involved bone has healed adequately (see Chapter 45). The patient should continue on a physical therapy regimen even after the completion of treatment to maximize long-term limb function. High-impact sports that pose the risk of traumatic fracture should be avoided during and after treatment.

The NCI completed a comprehensive case-control study of late effects in patients who had the ESFT and were treated at the NCI from 1965 to 1992. The study demonstrated multiple late effects in the ESFT survivors as compared to sibling controls. It also demonstrated that long-term survivors of the ESFT had educational achievements and income similar to those of their siblings; however, they were less likely than sibling controls to be employed full time. A lower likelihood of marriage was seen in this study, and fewer case subjects had children. Survivors of the ESFT reported multiple cancer- and treatment-related difficulties, such as hair and skin changes, lung problems, neurologic problems, visual difficulties, second malignancy, and amputation. Functional status, measured by Karnofsky performance scale, also was affected adversely in case subjects. Case subjects did not differ from sibling controls in health care insurance status or in use of health services.

Several studies have estimated an increased cumulative risk of secondary malignancies after Ewing's sarcoma. [19,217,301] Radiation-induced osteosarcoma and therapy-related (alkylating agents and epipodophyllotoxins) acute myeloblastic leukemia (AML) are the most frequent second malignant neoplasms reported. [317] In a recent multi-institutional review of 266 survivors of Ewing's sarcoma with a median follow-up duration of 9.5 years, the estimated cumulative incidence rates at 20 years for any second malignancy and for secondary sarcoma were 9.2% (standard deviation, 2.7%) and 6.5% (standard deviation, 2.4%), respectively. [217] The median latency to the diagnosis of the second malignancy was 7.6 years (range, 3.5 to 25.7). Sixteen patients developed second malignancies, and the majority (n = 10) developed sarcomas: five osteosarcomas, three fibrosarcomas, and two malignant fibrous histiocytomas. All the secondary sarcomas occurred at or near the primary tumor site of Ewing's sarcoma and within the primary irradiated field. The cumulative incidence rate of secondary sarcoma was radiation dose–dependent, with no secondary sarcomas developing among patients receiving less than 48 Gy. Six other malignancies were reported: AML, acute lymphoblastic leukemia, meningioma, bronchoalveolar carcinoma, basal cell carcinoma, and carcinoma *in situ* of the cervix. Recently, Dunst et al.[317] reported on the CESS-studies (CESS 81 and CESS 86) and second malignancies. From 1981 through 1991, 674 patients were registered in the two sequential multi-institutional Ewing's sarcoma trials. The median follow-up at the time of the analysis was 5.1 years; the maximum follow-up was 16.5 years. Eight of 674 patients developed a second malignancy. Four of these were AML: one myelodysplastic syndrome and three sarcomas. The interval between diagnosis of Ewing's sarcoma and the diagnosis of the second malignancy was 17 to 78 months for the four AMLs, 96 months for the myelodysplastic syndrome, and 82 to 136 months for the three sarcomas. The cumulative risk of a second malignancy was 2.9% after 10 years and 4.7% after 15 years. All three patients with secondary sarcomas had received radiotherapy. The authors noted the relatively low risk of second tumors in their irradiated patients, at least in the first 10 to 15 years after diagnosis, and this finding may have been derived from those patients who were treated with doses from 36 to 60 Gy.[317] Their data demonstrating a cumulative risk of fewer than 5% sarcomas over the first 10 to 15 years are similar to the result cited by Kuttesch et al.[217] for this dose range. These studies demonstrate that long-term oncologic follow-up is necessary in this group of patients.

## FUTURE CONSIDERATIONS

As discussed in detail, we now have a better understanding of the nature of the molecular mechanisms that cause the ESFT. Accumulated data indicate that the rearrangement of the *EWS* gene with either the *ets* oncogene *FLI1* or, in rarer cases, one of the other related *ets* transcription factor genes constitutes a rate-limiting step in Ewing's sarcoma pathogenesis. This knowledge allows speculation on possible specific treatment strategies that have as their common mechanism the prevention of the production or activity of the protein that results in the malignant process. For instance, production of the protein may be prevented through antisense blockade of the chimeric mRNA. The activity of the protein may be inhibited through specific monoclonal antibodies. Such monoclonal antibodies directed toward the chimeric protein also may be specific for ESFT cells, allowing the *ex vivo* purging of marrow or stem-cell collections or the *in vivo* targeting of tumors with radioisotopes. The chimeric protein may be the target also of a tumor vaccine. Another potential avenue of investigation is development of an assay that allows the screening of drugs to identify one that specifically interferes with the activity of this aberrant protein. We are at the beginning of a new era in the treatment of the ESFT. This disease may serve as a model for what can be accomplished through the molecular genetic-based therapy of cancer.

BHASKAR N. RAO

## INTRODUCTION

The nonrhabdomyosarcomatous soft tissue sarcomas (NRSTSs) are a rare and heterogeneous group of neoplasms of mesenchymal origin, which account for approximately 5% of all cancers in patients younger than 20 years.[1] The incidence of specific subtypes of soft tissue sarcomas is age dependent. For example, rhabdomyosarcoma accounts for 60% of cases of soft tissue sarcomas in children younger than 5 years; in contrast, more than three-fourths of all soft tissue sarcomas in patients aged 15 to 19 years are NRSTSs (Fig. 34-1, Fig. 34-2, and Fig. 34-3).[1] Furthermore, the distribution of histologic subtypes of NRSTS is also age

dependent (Fig. 34-2 and Fig. 34-3). Fibrosarcomas predominate in children younger than 1 year, whereas synovial sarcomas and malignant peripheral nerve sheath tumors (MPNSTs) are more frequently encountered in patients older than 10 years (Table 34-1).[1,2]

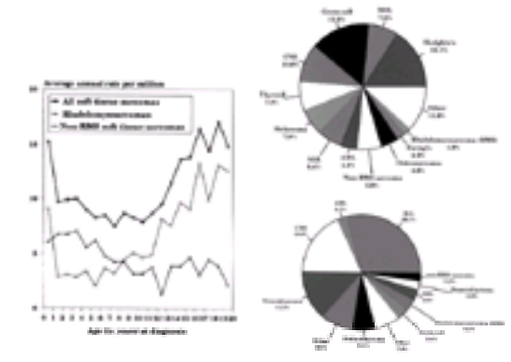

**FIGURE 34-1.** Graph **(A)** shows the incidence rates for soft tissue sarcomas by single year of age. Note the rising incidence of nonrhabdomyosarcomatous (non-RMS) soft tissue sarcomas among children older than 10 years. **(B)** shows the incidence of specific cancers for the period 1986–1995 in children aged 15 to 19 years. Note that non-RMS soft tissue sarcomas account for nearly 6% of all cancers in this age group. In contrast, rhabdomyosarcoma is the predominant soft tissue tumor in children younger than 5 years **(C)**. ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; CNS, central nervous system; NHL, non-Hodgkin's lymphoma.

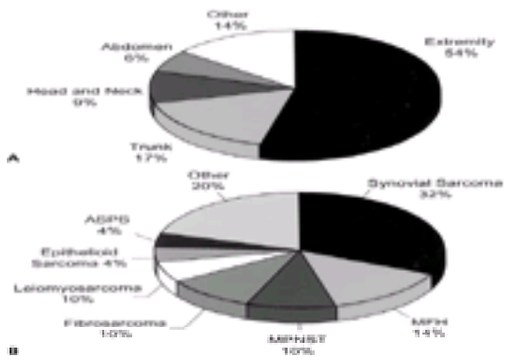

**FIGURE 34-2.** Distribution by histologic subtype **(B)** and primary tumor site **(A)** in children with surgically resected (groups I and II) nonrhabdomyosarcomatous soft tissue sarcoma. ASPS, alveolar soft part sarcoma; MFH, malignant fibrous histiocytoma; MPNST, malignant peripheral nerve sheath tumor. (From Spunt SL, Poquette CA, Hurt YS, et al. Prognostic factors for children and adolescents with surgically resected nonrhabdomyosarcoma soft tissue sarcoma: an analysis of 121 patients treated at St. Jude Children's Research Hospital. J Clin Oncol 1999;17:3697–3705; and Pratt CB, Pappo AS, Gieser P, et al. Role of adjuvant chemotherapy in the treatment of surgically resected pediatric nonrhabdomyosarcomatous soft tissue sarcomas: a Pediatric Oncology Group study. **TABLE 34-1. CLINICAL FEATURES OF THE COMMON SOFT TISSUE SARCOMAS IN CHILDREN**

Because NRSTSs are more common in adults, with approximately 6,000 new cases per year, much of the information regarding their natural history and treatment has been derived from single-institution or cooperative adult trials. In some specific circumstances, however, the prognosis for children with individual soft tissue sarcomas is much better than that for adults, resulting in markedly different treatment recommendations.[3,4,5,6] and [7] The difference in prognosis is most pronounced for infants and young children, whose tumors often have a benign behavior and excellent prognosis with surgery alone. In contrast, NRSTS that occur in adolescents often behave more like the sarcomas that occur in adult patients,[5,6,7,8] and [9] and their management reflects that used in adults.

## EPIDEMIOLOGY, GENETICS, AND BIOLOGY

Specific chromosome translocations define many of the soft tissue sarcomas in children (Table 34-2).[10,11] and [12] For example, the t(X;18)(p11; q11) occurs in more than

90% of synovial sarcomas.[12,13] Molecular studies reveal that two novel genes are rearranged: SYT on 18q11 and SSX on Xp11. [14] Furthermore, two alternative forms of the SYT-SSX fusion transcript, SYT-SSX1 and SYT-SSX2, have been described and are related to histologic and clinical features of the tumor: SSX1 associated with both biphasic and monophasic tumors and SSX2 with monophasic tumors.[15,16] This suggests that the two altered genes have different quantitative or qualitative effects on the epithelial differentiation of this tumor. [16] Liposarcoma is similarly characterized by a translocation t(12;16)(q13; p11), resulting in the fusion of a transcription factor essential for adipocytic differentiation to EWS or TLS, known oncogenes. [16,17] and [18] EWS is similarly involved in fusion genes associated with other sarcomas, including Ewing's sarcoma and desmoplastic small round cell tumor.[12,20,21]

| Tumor | Translocation | Fusion protein |
|---|---|---|
| Clear cell sarcoma | t(12;22)(q13;q12) | EWS-ATF-1 |
| Extraskeletal myxoid chondrosarcoma | t(9;22)(q22;q12) | EWS-CHN |
| | t(9;17)(q22;q11.2) | RBP56-CHN |
| Synovial sarcoma | t(X;18)(p11;q11) | SYT-SSX1, SSX2 or SSX4 |
| Myxoid liposarcoma | t(12;16)(q13;p11) | TLS-CHOP |
| | t(12;22)(q13;q12) | EWS-CHOP |
| | t(12;22;16)(q13;q12;p11) | EWS-CHOP |
| Congenital fibrosarcoma | t(12;15)(p13;q25) | ETV6-NTRK3 |
| Dermatofibrosarcoma protuberans | t(17;22)(q22;q13) | COL1A1-PDGF |
| Malignant peripheral nerve sheath tumor | Loss or rearrangement of 10p, 11q, 17q, and 22q | ? |
| Inflammatory myofibroblastic tumor | 2p rearrangements | TPM3-ALK |
| | | TPM4-ALK |
| Alveolar soft part sarcoma | t(X;17)(p11.2;q25) | ASPL-TFEB |
| Leiomyosarcoma | 13q rearrangements, loss of 1q, 4q, 11p, and 22q | ? |

From Ladanyi M, Lui MY, Antonescu CR, et al. Cloning of the der(17)t(X;17)(p11.2;q25) of alveolar soft part sarcoma identifies the ASPL-TFE3 gene fusion, a new molecular diagnostic marker. Mod Pathol 2001;14(abstr 30); Fletcher CDM, Dal Cin P, de Wever I, et al. Correlation between clinicopathological features and karyotype in spindle cell carcinoma: a report of 130 cases from the CHAMP study group. Am J Pathol 1998;154:1841–1847; Shapiro DN, Chen CH. Cytogenetics and the biologic basis of sarcomas. Curr Opin Oncol 2000;12:310–322; and Lawrence B, Perez-Atayde A, Hibbard MK, et al. TPM3-ALK and TPM4-ALK oncogenes in inflammatory myofibroblastic tumors. Am J Pathol 2000;157:377–384, with permission.

**TABLE 34-2. CHROMOSOMAL TRANSLOCATIONS AND CURRENTLY IDENTIFIED FUSION PROTEINS IN SOFT TISSUE TUMORS**

Many NRSTSs are associated with loss of heterozygosity, the clearest clinical example being the association of these tumors with the familial cancer syndrome described by Li and Fraumeni.[22,23,24] and [25] Further supporting this hypothesis is the strong association of MPNSTs with von Recklinghausen's disease (neurofibromatosis type I, or NF1), a common autosomal dominant disorder associated with abnormalities mapped to 17q11.2. [26,27] Furthermore, nerve sheath tumor has been shown by direct sequence analysis to have a point mutation at the p53 locus at 17p13, suggesting a role in pathogenesis. [27] Homozygous gene deletions of both the long and short arms of chromosome 17 have been observed in MPNSTs arising in patients with neurofibromatosis. [27] A somatic deletion of the NF1 gene has also been reported in an MPNST not associated with NF1. [28] Because other sarcomas, including rhabdomyosarcoma and malignant fibrous histiocytoma (MFH), have also been associated with neurofibromatosis, it is very likely that loss of heterozygosity of a tumor suppressor gene on chromosome 17 or at other sites is at least a factor in the development of most of the sarcomas in this genetically inherited autosomal dominant syndrome. Furthermore, it is likely that these sarcomas, especially MPNSTs, arising in individuals who do not have neurofibromatosis also have loss of heterozygosity of a tumor suppressor gene or genes within the tumor cells, caused by two somatic mutations. Further support for this hypothesis comes from the observation that the MPNSTs arising in patients with neurofibromatosis occur at an earlier age than those arising in patients without neurofibromatosis. [29,30,31,32] and [33]

NRSTSs, most commonly MFH, may be associated with prior irradiation for a primary tumor.[34] The origin of these tumors may be mediated in part through genetic events induced by the radiation. The observation that radiation is implicated in the development of sarcomas in patients with the Li-Fraumeni family cancer association and hereditary retinoblastoma further supports this hypothesis. Leiomyosarcomas arise both within and outside the radiation fields of children with hereditary retinoblastoma, however, suggesting that multiple factors are involved in the etiology of this tumor. Furthermore, leiomyosarcoma has been observed in children infected with the human immunodeficiency virus (HIV) and the Epstein-Barr virus (EBV), [36,37] in a patient with leukemia,[38] and in a child undergoing immunosuppression to prevent renal allograft rejection.[39] This raises the possibility that the occurrence of this soft tissue sarcoma may be related to a lack of immunocompetence of the host or to a retroviral infection.

There are dramatic differences in biology and natural history of soft tissue sarcomas when they arise in infants and young children compared to those that arise in adults. For example, infantile fibrosarcoma, in contrast to its adult counterpart, rarely metastasizes and is almost always cured if complete surgical removal can be accomplished.[40,41,42] and [43] The consistent genetic events found with infantile fibrosarcoma, but not with the fibrosarcoma arising in adults, are an important clue that there are fundamental differences between these two clinical presentations of fibrosarcoma. [44] Although infantile hemangiopericytoma rarely metastasizes and usually can be successfully managed by surgery alone,[45] the adult form of hemangiopericytoma is highly malignant in behavior and frequently metastasizes. [46,47] These observations strongly suggest that in spite of a very similar histologic appearance, there are important biologic differences between tumors arising in infants and those arising in adults. The prognosis and natural history of soft tissue sarcomas arising in older children and adults are very similar, suggesting a common biology.

## CLINICAL PRESENTATION

NRSTSs may arise in any part of the body; however, the most common sites are the extremities and trunk (Fig. 34-2). Most soft tissue sarcomas present as painless, asymptomatic masses; however, if symptoms occur, they are usually due to local invasion of adjacent structures. Invasion of cranial and peripheral nerves often results in pain or weakness in the distribution of the nerve. MPNSTs typically arise in a peripheral nerve, often the sciatic nerve, with both motor and sensory involvement. Systemic symptoms such as fever, night sweats, and weight loss are rare, although occasionally they are seen in patients with widely metastatic disease. Hypoglycemia has been seen occasionally with advanced hemangiopericytoma and other soft tissue sarcomas; the insulin-like growth factor-1 receptor has been implicated in the pathogenesis of this complication.[48] Hyperglycemia has been observed in association with fibrosarcoma of the lung. [49] Hypophosphatemic rickets has been associated with hemangiopericytoma.[50]

## STAGING

There are a variety of staging systems for NRSTS. Although the staging systems used for adults differ from those used in pediatric patients, they all allow identification of subgroups of patients who are at different risks of treatment failure. For adult NRSTS, the most recent American Joint Committee on Cancer unified staging system[51] and the Memorial Sloan-Kettering Cancer Center staging system incorporate histologic grade, tumor size, compartmental localization, and metastatic disease to define the risk of relapse. The Surgical Staging System of the Musculoskeletal Tumor Society is based on tumor grade and tumor compartment status only. Recently, these staging systems were evaluated in 300 adults with newly diagnosed nonmetastatic soft tissue sarcoma of the lower extremity. This report concluded that grade, depth, and size were the most important predictors of clinical outcome.[52] The Memorial Sloan-Kettering Cancer Center staging system proved to be superior to the other two systems for predicting metastases-free survival. In this staging system, adults with no adverse prognostic factors as defined by histologic grade, depth, and size had an estimated 5-year metastases-free survival of 100%, whereas those with three adverse factors had a 49% 5-year metastases-free survival.[52]

Pediatric NRSTSs have traditionally been staged according to the Intergroup Rhabdomyosarcoma Study Group surgicopathologic staging system and the International Union Against Cancer staging systems (Table 34-3 and Table 34-4).[53,54] The impact of the extent of residual tumor after initial surgical procedures and the presence or absence of metastases is presented in Table 34-3.[53] According to the International Union Against Cancer staging system, which incorporates size (a or b), nodal status (N0 or N1), invasiveness (T1 or T2), and the presence or absence of metastases, patients with localized small noninvasive tumors (T1a) fare better than those with invasive large tumors (T2b) (Table 34-5).[55]

| Group | Description | 5-Yr event-free survival (%) | 5-Yr survival (%) |
|---|---|---|---|
| I | Localized disease, completely resected | 72–83 | 88–90 |
| II | Microscopic residual<br>Completely resected with nodes<br>Nodes involved with microscopic residual | 65–72 | 84–88 |
| III | Incomplete resection | —[a] | 35–54[a] |
| IV | Distant metastases | 15 (2-yr) | 34 (2-yr) |

[a]No data on N1 patients; however, the new American Joint Committee on Cancer staging system for adults considers N1 patients as stage 4 (5-yr survival 34%).

Histologic grading has been used in both adult and pediatric studies as an adjunct to clinical staging because it is highly predictive of clinical outcome. [55],[56] and [57] The system developed by the National Cancer Institute of the United States (NCI) by Costa and colleagues stratifies soft tissue sarcoma into three different grades based on histologic subtype and a composite of histopathologic parameters that includes tumor necrosis, cellularity, pleomorphism, and mitosis. [55]

The Pediatric Oncology Group (POG) developed and prospectively tested a pediatric grading system for NRSTS [58] (Table 34-6 and Table 34-7) based on the histopathologic system developed by Costa and colleagues.[55] This grading system identified three different grades of tumors based on histopathologic subtype: amount of necrosis, number of mitoses, and cellular pleomorphism (Table 34-6). Infantile tumors such as hemangiopericytoma and fibrosarcoma are considered grade 1 in this classification despite their aggressive appearance on histologic examination. This is the system most commonly used to grade pediatric NRSTSs.

| Grade | Description |
|---|---|
| 1 | Myxoid and well-differentiated liposarcoma<br>Well-differentiated or infantile (age ≤4 years) fibrosarcoma<br>Well-differentiated or infantile (age ≤4 years) hemangiopericytoma<br>Well-differentiated malignant peripheral nerve sheath tumor<br>Angiomatoid malignant fibrous histiocytoma<br>Deep seated dermatofibrosarcoma protuberans<br>Myxoid chondrosarcoma |
| 2 | Soft tissue sarcomas in which<br>•<15% of the surface area shows necrosis<br>•The mitotic count is <5/10 high power fields using a 40× objective<br>•Nuclear atypia is not marked<br>•The tumor is not markedly cellular* |
| 3 | Tumors with the following diagnosis<br>Pleomorphic or round cell liposarcoma<br>Mesenchymal chondrosarcoma<br>Extraskeletal osteogenic sarcoma<br>Malignant triton tumor<br>Alveolar soft part sarcoma<br>Any other sarcoma not in grade 1 with ≥15% necrosis or ≥5 mitoses/10 high power field using a 40× objective |

*Necrosis and mitotic count are by far the most important parameters in making this assessment. The other parameters are of borderline significance and may be helpful in a case that is difficult to grade using necrosis and mitotic count alone. Specific diagnoses included in grades 1 or 3 are excluded from grade 2.

## PROGNOSTIC FACTORS

Although the clinical outcome for children with completely excised NRSTS is excellent ( Table 34-8), more than 20% of these children eventually develop disease recurrence and ultimately die from their disease.[59,60 and 61] Identification of risk factors associated with an increased likelihood of tumor recurrence in patients with complete surgical excision disease is pivotal when selecting patients for adjuvant trials that incorporate chemotherapy, radiotherapy, or both ( Table 34-9). Adult trials have demonstrated that the risk factors for local recurrence differ from those for metastatic recurrence and death due to disease. The most significant adverse prognostic factor for distant recurrence and death is high histologic grade; however, the relative contribution of this variable to disease recurrence decreases over the first 30 months after initial surgery. The size of the lesion becomes as important as grade in determining the risk for distant recurrence thereafter. The number of adverse prognostic factors is also significantly associated with the risk of disease recurrence and death.

**TABLE 34-8. PEDIATRIC SERIES OF NONRHABDOMYOSARCOMA SOFT TISSUE SARCOMAS**

**TABLE 34-9. PEDIATRIC AND ADULT SERIES THAT HAVE ANALYZED PROGNOSTIC FACTORS IN NONRHABDOMYOSARCOMATOUS SOFT TISSUE SARCOMAS**

A relatively small number of pediatric trials, most of them retrospective in nature, have investigated the relative contribution of various prognostic factors in predicting clinical outcome.[59,62,63] In the largest retrospective single-institution study of its kind, investigators at St. Jude found that the risk factors associated with a local recurrence differed from those associated with distant relapse or survival. [59] In this series, clinical group, lack of radiotherapy use, large tumor size, and intra-abdominal primary site predicted local recurrence, whereas tumor size, invasiveness, and high histologic grade predicted distant failure. Other single-institution and cooperative group trials have also shown that histologic grade is an important predictor of distant recurrence. These findings are of significant relevance when planning prospective randomized multi-institutional trials. Patients at increased risk for local recurrence might benefit from novel approaches to local control, whereas those at increased risk for distant failure might benefit from adjuvant therapies including chemotherapy or anti-angiogenic agents. The risk factors associated with local and distant recurrence and those associated with survival in children with surgically resected NRSTS are summarized below. [59]

Factors associated with increased risk of local recurrence:

- Microscopically positive margins
- Intra-abdominal primary tumors
- No radiotherapy
- Tumor size >5 cm

Factors associated with increased risk of distant recurrence:

- Tumor size >5 cm
- Invasive tumors
- High histologic grade

Factors associated with decreased survival:

- Microscopic positive margins
- Tumor size >5 cm
- High histologic grade
- Intra-abdominal primary tumor site

Metastatic disease at the time of initial presentation occurs in approximately 15% of children with NRSTS. [62] The lung is the most common site of distant metastases, although metastases to bone, liver, and mesentery have also been reported. Lymphatic spread is rare with most histologies; however, it is commonly associated with high-grade lesions, synovial sarcoma, angiosarcoma, and epithelioid sarcoma histologies. The prognosis for patients with lymphatic metastases is comparable to that of patients with metastatic disease at other sites.

## GENERAL TREATMENT CONSIDERATIONS

The standard approach to management of these tumors in adults has undergone significant debate. The optimal management and treatment strategies are related to anatomic site and extent of both local and systemic disease. The relative rarity of these tumors and the heterogeneity of the histologic diagnoses entered onto these adult trials obfuscate to some degree the therapeutic results of these trials for specific tumor types. Because even smaller numbers of children develop NRSTS, it is essential that uniform treatment strategies be evaluated in multi-institutional trials.

The mainstay of therapy, as in adults, is surgical resection with or without radiotherapy. The primary tumor is excised with wide margins, and radiation therapy (RT) is usually added to the regimen if limb-sparing procedures are performed or the margins are close. [64,65 and 66] In some centers, the initial treatment is preoperative irradiation followed by surgery and then completion of RT using external beam and interstitial irradiation. [66,67] In other centers, preoperative intravenous chemotherapy

using a variety of regimens, or intraarterial chemotherapy consisting of cisplatin with or without doxorubicin (Adriamycin), is used to reduce the size of the local tumor and provide systemic therapy. This neoadjuvant chemotherapy is then followed by surgery; irradiation is used only if the surgical margins are inadequate. Although all of these approaches have resulted in excellent local control (less than 10% local failure rate), none has had a major impact on overall survival, [66,67,68 and 69] especially for large tumors.

Although the general approach to children with these tumors is often similar to that for adults, important differences exist. [6,7,8 and 9] First, the biology of the childhood NRSTS may differ significantly from that of the adult counterpart. Second, the morbidity of RT in a young and rapidly growing child may be much greater than that in an adult, depending on the site that requires irradiation. Third, successful limb-sparing procedures in young, growing children are more difficult to perform; however, newer techniques and expandable prostheses may allow a greater number of limbs of children to be salvaged. Finally, the long-term consequences of irradiation, especially if given at high dose, [70] and of chemotherapy are of greater concern in children whose potential survival after successful therapy is much longer. To achieve the goal of maximum tumor control with minimum morbidity in both the short and the long term, children with these tumors must be studied prospectively.

The most important theme of most reports is that the ability to surgically extirpate the tumor is the most critical prognostic factor. In a retrospective review of 121 surgically resected cases of childhood NRSTS from St. Jude Children's Research Hospital, the estimated 5-year survival was 89%, with 12.8% of patients experiencing a local failure and 11.8% a distant failure. [59] In contrast, only half of patients with unresected disease and 34% of those with metastatic disease were alive at 5 and 2 years, respectively. [62,63] Another study conducted by the POG revealed similar results with an 84% 5-year survival rate for children with surgically resected disease and a 4-year survival rate of 30% for patients with unresected or metastatic disease. [71]

## SURGERY

Much of the current approach regarding surgical management of these tumors has derived from the adult experience. [72,73,74 and 75] Surgery remains the mainstay of therapy for NRSTS. Surgical approaches vary by age, histology, site, and grade of the tumor. For example, the clinical behavior of infantile fibrosarcoma, infantile hemangiopericytoma, and angiomatoid MFH is different from that of other high-grade malignancies and therefore can often be treated without the use of mutilative surgery.

With adult NRSTS, local recurrence rates of less than 10% can be achieved with the use of surgery with or without irradiation. [67,76,77] In addition, most tumors that arise in the extremities can be managed successfully without amputation.[66] However, systemic metastases occur in up to 40% of adult patients who initially present with localized disease. The integration of effective systemic therapy into the management of children with NRSTS without compromising the local control that can be achieved with irradiation and surgery alone is essential if the overall outcome of these children is to be improved.

### Biopsy

A carefully planned diagnostic biopsy is very important to avoid misdiagnosis, delayed diagnosis, or complications that interfere with or in some cases even prevent limb salvage surgery. If an NRSTS is suspected, it is advisable to perform a thorough radiographic evaluation, including magnetic resonance imaging (MRI) of the primary site, before the biopsy is performed. In most instances a minimum of a fine-needle aspiration or Tru-Cut needle biopsy is warranted. A frozen section analysis of the specimen is desirable to be certain viable tumor rather than the necrotic portion of the tumor is obtained. Tru-Cut biopsies using diagnostic imaging for guidance are useful for intracavitary lesions. Although needle track recurrences have been documented, these are extremely rare in sarcomas. [78] Tru-Cut biopsies are also indicated for bulky, deep-seated lesions on the extremity, invasive truncal lesions, for those who present with metastatic disease, or where technical considerations do not favor an open incisional biopsy.

In most instances, an open biopsy is performed. Excisional biopsy is reserved generally for small (less than 2.5 cm) superficial lesions. In all other instances, an incisional biopsy is the approach of choice. In extremity lesions the incision is placed longitudinally or parallel to the neurovascular bundle. Transverse or inappropriately placed incisions can traverse multiple tissue compartments and may preclude limb salvage procedures. Similarly, an inappropriately placed incision on the trunk or head and neck may preclude closure. At the time of incisional biopsy, flaps should not be considered because they can contaminate multiple compartments. Meticulous hemostasis is mandatory and, if necessary, closed drains should be placed and brought out immediately adjacent to the most dependent area and in line within the incision. Should a hematoma develop, the entire area of the hematoma must be re-excised at the time of subsequent surgery. Most important, children with these lesions should only be evaluated, biopsied, and treated at institutions with appropriate surgical expertise, including limb-salvage techniques and pathologic support.

The exact margin required for local control remains to be determined. Based on the planes of dissection of the original sarcoma, there are four possible surgical margins.[75,79,80 and 81] An *intralesional margin* of resection is defined by the plane of dissection violating the pseudocapsule, and only a portion of the tumor is removed and obvious macroscopic tumor is left behind. Regrowth of the tumor is a certainty unless additional measures are taken. A *marginal margin* is defined by the pseudocapsule being the plane of dissection. When there are marginal margins, local recurrence rates range from 60% to 70%. A *wide resection* includes tumor, its pseudocapsule, and a margin of normal tissue removed in all directions *en bloc*. Quantitative measurements in centimeters are not implied in the definition of wide margins. Recurrence rates are 5% to 10% after this type of resection margin. *Radical margins* by definition are extracompartmental resection or resection of the whole soft tissue compartment. Recurrence rates are less than 5% when resections with radical margins are performed.

The amount of normal margin required to minimize the risk of local failure is unknown; however, a 1- to 2-cm margin after resection is usually preferred. For large, high-grade, and deep-seated tumors, the potential for local recurrence is high. The extent of normal tissue margin may become an important factor in preventing recurrence and the determining factor in deciding whether adjuvant therapy is delivered in these cases. Importantly, local recurrence is most often associated with inadequate treatment of the primary tumor with inadequate surgical margins.

Should diagnostic imaging studies, review of intraoperative sites, or pathologic examinations reveal that there is residual tumor or that the margins are close, it is recommended that the patient undergo reexcision of the primary site. In patients undergoing reexcision, residual disease is present in 30% to 40% of cases.

### Surgery for Extremity Tumors

Amputation is infrequently required in the current management of NRSTS of the extremity. [74,75,82,83,84 and 85] This is due to better surgical techniques and the low rate of recurrence when RT is used to treat marginal surgical margins. Further, amputation does not offer a clear survival benefit when compared to less extensive surgery followed by radiation. Nevertheless, amputation may be the only choice in a skeletally immature child or when there is obvious neurovascular involvement.

As previously mentioned, the primary goal of surgery is to achieve a wide local resection with adequate margins, which are considered to be approximately 2 cm. To ensure this 2-cm margin, careful palpation to gauge the extent of the tumor is done as the dissection proceeds. The previous biopsy site is excised with at least a 1-cm margin. Flaps are developed and complete resection obtained by either a wide or a compartmental resection. Although wide margins are obtained in most directions, in certain situations, especially around vessels and nerves, it may be possible to achieve a marginal margin of only a few millimeters. Subsequent RT is required in these cases for adequate local control. The adventitial sheath along the vessels or the perineural sheath adjacent to the tumor may be removed along with the specimen to obtain additional margin. If the vessel is grossly involved, resection and interposition of a prosthetic or venous graft may be considered. Here it is to be understood that the risk of infection poses the main threat to the graft. When tumor abuts bone, stripping the periosteum or marginal resection of the bone can be performed. The resultant defect can be bridged by allograft or vascularized fibula graft.

Sarcomas of the antecubital and the popliteal fossae present special problems. The complex neurovascular anatomy and loose connective tissue preclude wide resection of the tumor and close margins virtually always result. [82] Because of this, RT in the form of brachyradiotherapy (BRT), external beam RT (EBRT), or both are required for local control. Amputation for tumors in these sites is considered for treatment of local recurrence or when there is gross neurovascular involvement. In the skeletally immature child, successful local control with surgery, radiation, or both likely has a poorer functional outcome than when the tumor arises in a skeletally mature individual.[85]

When NRSTSs arise in the hand or foot, the close confines and tight compartments make resection marginal at best. Ray amputation of one or more digits may result in wider margins. RT is often necessary for optimal local control. Amputation of the foot may be required for large invasive tumors and local recurrences or when a poor functional outcome is anticipated. Amputation of the foot may also be necessary for adequate pain control. The recommended approach to tumors of the hand and foot is to achieve minimal surgical margins combined with subsequent RT. This approach maximizes local control and functional outcome without jeopardizing

overall survival.[85]

The incidence of nodal involvement in NRSTS is low.[86,87] In a collective review of more than 2,500 cases it was noted to be 3.9%. The incidence was dependent on the grade of the lesion, with an incidence of 0% for grade 1 lesions and only 2% for grade 2 tumors; however, the incidence rose to 12% for grade 3 tumors. Angiosarcoma and epithelioid sarcoma are the histologies most commonly associated with lymphatic metastases. Nodal metastasis of NRSTS in adults has been recognized to be associated with a poor outcome and is commonly treated with radical surgery. At St. Jude, 80 of 230 patients underwent lymph node dissection or biopsy of suspicious nodes defined as greater than 1.5 cm by imaging studies.[81,85] The nodes were positive in only ten patients, of whom eight had high-grade lesions. In light of these data, routine lymph node sampling is not recommended, but lymph nodes greater than 1.5 cm that are associated with large, high-grade primary lesions should be biopsied. Furthermore, any other large or suspicious node should also be reasonably considered for biopsy.

After conservative surgery in combination with RT, it is essential to maintain function using vigorous postoperative rehabilitation therapy supervised by a musculoskeletal oncology team. This is even more important in the skeletally immature child, where associated long-term complications, such as fibrosis and a painful or shortened extremity, should be avoided. Good to excellent results have been reported in 75% to 80% of adults, with more than 75% returning to full employment. At St. Jude, long-term complications include shortening, flexion deformity, chronic edema, fracture, and secondary malignancy noted in 7 of 50 patients with extremity NRSTS.[81,85]

### Surgery for Trunk Primaries

The primary incisional biopsy of trunk NRSTS is of paramount importance.[88,89 and 90] In most instances, biopsies should be in the longitudinal axis or parallel to the ribs. In the paravertebral area a vertical incision is preferred. Preoperative imaging studies determine the course and extent of resection needed to obtain satisfactory margins. It is important to recognize that the crucial aspect is the deep margin. If there is infiltration of the muscles or intrathoracic extension, a formal chest wall resection is performed. The anterior and posterior extent of rib resection is usually approximately 2.5 cm beyond the margin of the tumor. The superior and inferior extent is generally assumed to be one rib above or below the extent of primary lesion. The resultant deficit is usually closed with a prosthetic mesh or by regional muscle flaps. In young children and in situations in which extensive chest wall resection may predispose to severe scoliosis, consideration can be given to resection along the periosteum and placement of afterloading catheters for BRT.

### Surgery for Abdominal Wall Tumors

The abdominal wall is an unusual site for primary NRSTS. Accurate preoperative imaging studies are necessary to determine the extent of resection.[74,89] The entire thickness of the abdominal wall including the peritoneum, if necessary, can be resected. The major problem after resection of the peritoneum is that direct contact between intestine and nonabsorbable mesh used to close the defect has been noted to increase the risk of fistulization. To prevent this, an omental patch or placement of absorbable mesh is preferred. Local and regional rotation flaps may also be used to cover the defect. When margins are close, RT is considered for adequate local control. To minimize the effect of RT on the small bowel, polyglactin 910 (Vicryl) mesh is used to displace the bowel away from the radiation field.

### Surgery for Visceral Sarcomas

Visceral sarcomas are extremely rare. The most common variant is the gastrointestinal stromal tumor (formerly called *leiomyosarcoma*). The common sites include the large bowel and the stomach. Wide resection is the treatment of choice.[91] Failures, either local or metastatic, particularly to the liver, are associated with grade 3 tumor histology.

### Surgery for Retroperitoneal Tumors

Retroperitoneal sarcomas also are uncommon in children. Primary resection is the treatment of choice. In adult series, resection of the viscera including the kidney has been associated with a lower recurrence rate. Unfortunately, no large series are available in the pediatric age group. The morbidity of aggressive resection has to be weighed against the long-term risk of RT on viscera and bowel.

### Surgery for Head and Neck Sarcomas

Aggressive surgical resection is the mainstay for local control of head and neck sarcomas.[92] Modern reconstructive techniques, including locoregional rotation flaps, vascularized flaps, or free composite grafts have greatly assisted in the surgical resection. Local recurrences have been resected from the base of the skull or from the anterior skull using craniofacial exposure.

## RADIATION THERAPY

RT is an integral component of the treatment of NRSTS in children. The indications for RT vary according to tumor histiotype, pathologic grade, tumor size, location, extent of resection, and other clinical factors, including the overall treatment plan.[59]

After the indications for RT have been established, the best RT treatment modality must be selected. EBRT delivered by using a linear accelerator is the most commonly used RT modality. A variety of recently developed EBRT techniques are available for treating the pediatric patient. These techniques may be broadly described as *conformal RT*, in which three-dimensional imaging and treatment planning are used to minimize the risk to normal tissue structures that might be vulnerable to radiation.[93] BRT is the interstitial, intracavity, or superficial application of radioisotopes in a temporary or permanent fashion. Most commonly, iridium-192 and iodine-125 are used in the form of a low-dose-rate temporary interstitial implant that delivers approximately 35 to 40 cGy per min. BRT involves additional logistical considerations and requires a team with expertise in the treatment of NRSTS.[94] Newer forms of BRT that are available include the use of high-dose-rate sources that deliver treatment in a pulse fashion not unlike that of a linear accelerator.[95] Moreover, EBRT and BRT may be combined in a manner that optimizes the probability of local control and decreases the acute and late effects of therapy. When RT is indicated, decisions regarding the timing of RT, the total dose, the fractionated dose, and the treatment volume must be considered. All of these factors greatly influence the risk of side effects. At the center of this discussion is the selection of the appropriate treatment volume. Treatment volume critically influences local tumor control and treatment-related side effects. The use of established radiation delivery techniques such as BRT and the evaluation of new modalities such as conformal RT can improve the therapeutic value of RT for children.

### Historical Perspective

Suit and colleagues[96,97,98 and 99] showed in a series of reports that local control of NRSTS could be achieved with a high rate of success by combining surgery and RT. The reports outlined many of the technical and radiotherapeutic aspects of sarcoma management that remain in use to this day, including the use and necessity of conventionally fractionated RT (180 to 200 cGy per day) at a relatively high total dose (greater than 64 Gy) and a more formal definition of the treatment volume. Using the “shrinking field” technique, they treated a larger volume to a lower dose (50 Gy) and used a boost dose to deliver the highest or final prescription dose to a smaller volume. They carefully studied the planned use of EBRT or BRT as the boost modality, the sequencing of surgery and RT, including preoperative RT, and measures that could be used to minimize side effects and improve functional outcome.

Since the performance of this pioneering work, more wide local excision followed by RT has been a standard therapy in many cases for local control of NRSTS amenable to resection. Treatment approaches to adult NRSTS of the extremity have continued to change over the last 20 years. Modern limb-sparing surgery combined with RT has been shown to yield local control rates ranging from 85% to 95% while preserving limb function. Many treatment approaches that integrate limb-sparing surgery and RT include preoperative or postoperative EBRT with or without the use of BRT or intraoperative RT. The use of these methods in children and adolescents requires careful planning with an experienced pediatric radiation oncologist. To date, no clinical trial has compared these combined-modality approaches with respect to treatment results and functional outcome. Further, the data describing functional outcome in adults and children are limited.[100,101 and 102]

### Current Management Principles and Controversies

Early involvement of the radiation oncologist is important to the appropriate management of known or suspected NRSTS. If tumor control requires RT, the radiation

oncologist can assist the multidisciplinary team by defining the region to be treated and by considering function-sparing treatment using special BRT or EBRT modalities. Taking measures to delineate the extent of disease and to limit the irradiated volume can significantly reduce potential side effects. In an effort to standardize treatment and integrate the efforts of all members of the sarcoma team, consensus guidelines have been developed for the management of soft tissue sarcomas in adults.[103] Most of these guidelines are also applicable to children. Consensus guidelines have also been developed by the American Brachytherapy Society for the use of BRT in the treatment of adults and children with soft tissue sarcoma.[104]

Tumor location has important implications for both surgery and RT and plays an important role in the potential morbidity of RT. The need for maximal surgical resection and adjuvant RT for certain low-grade, most high-grade, and selected recurrent tumors is well accepted. Regardless of the extent of resection, however, the dose of radiation required to achieve local control (greater than 64 Gy) is relatively high when compared to doses used for the treatment of other pediatric sarcomas, rhabdomyosarcoma, and Ewing's sarcoma family tumors.

Surgical technique plays an important role in defining the treatment volume. When biopsy or resection of a soft tissue lesion is being planned, the radiation oncologist should be consulted by the surgeons to help plan an approach that avoids disruption of normal tissues and places the scar over the tumor. Placement of radiopaque clips to define the tumor bed or regions at highest risk will help with RT treatment planning. When resection is attempted, it should be performed with the objective of achieving negative margins, good hemostasis, and a good functional outcome. Incisional biopsy should be considered when resection is likely to be incomplete. However, children are often referred for evaluation and treatment after the incomplete resection of an NRSTS that was thought to be a benign lesion. Although there is poorer outcome for patients treated without a comprehensive multidisciplinary plan, high-dose RT can be used in such cases in an adult to achieve local control. When resection is not possible, advanced RT techniques are beneficial; however, the local failure rate and local morbidity are higher.

RT may be avoided for selected patients with high-grade NRSTS who have undergone wide local excision with the removal of a large cuff of normal tissue and documented negative biopsies of the surgical cavity. It would also be reasonable to identify subsets of patients who do not require irradiation and who should not be subjected to its long-term morbidity.[105] The following presentations may not require radiation: histologic margins of resection of greater than 1 cm, and a local recurrence in a site that does not preclude function-sparing surgery. Although we have found that the tumors in children are relatively smaller than those found in adults, the type of wide local excision that is likely to obviate the need for RT is also likely to cause substantial surgical morbidity. Furthermore, a generous wide local excision is often impossible in children because of their lack of subcutaneous tissue. Many NRSTSs have satellite nodules within the tumor bed, even when the inked margins are negative. When a non-oncologic surgical procedure is performed, RT is virtually always required. There are limited data on the indication for radiation based on the extent of the surgical margin in children with NRSTS. In one small study of high-grade tumors with resection margins less than 1 cm, successful local control was achieved in five of seven patients not treated with RT and in seven of seven patients when RT was given postoperatively. Of 20 high-grade tumors that were completely resected with margins greater than 1 cm and were not treated with adjuvant RT, 15 were locally controlled for an extended period.[106] More data are required to define clearly the role of RT based on resection margin. Despite this, high-grade tumors that are completely resected with close margins often are treated with EBRT or BRT to enhance local control. BRT may be combined with EBRT for high-grade and intermediate-grade tumors with positive, inadequate, or indeterminate margins, without regard to tumor size or anatomic location.[94] Low-grade tumors are treated with EBRT or BRT only when the risk of recurrence and reresection morbidity is high, or when there has been a recurrence. RT may be avoided for small, superficial tumors in very young patients when resection can be performed with adequate margins, generally greater than 5 mm. Aggressive multimodality therapy including RT may enhance local control and quality of survival in patients with metastatic disease, as well.

### Importance of Local Control

Despite the high rate of success in achieving local control, optimal disease-free survival and survival for pediatric NRSTS has not yet been achieved.[10] Distant metastases are most likely a reflection of aggressive tumor biology rather than local treatment approaches. Thus, improved systemic strategies are required to improve survival; however, because long-term survival cannot be achieved without local tumor control and because tumor recurrence and second surgery cause substantial morbidity, every effort should be made to achieve local control with the least morbidity and smallest impact on quality of life. Unfortunately, insufficient numbers of children have been studied to determine the effect of local control measures on survival.

### Differences between Adults and Children with Soft Tissue Sarcoma

The treatment of soft tissue sarcomas in children requires sophisticated methods of RT treatment planning and delivery to improve the therapeutic ratio of RT. Indeed, children have the most to gain from advances in RT that reduce late effects. Because high doses of radiation are necessary to achieve local control of NRSTS and because many patients with NRSTS are at an age that makes them especially susceptible to devastating side effects, children with NRSTS should be referred to treatment centers equipped with advanced treatment delivery techniques and experience in treating children. However, there is no evidence that these tumors are more sensitive to RT in children than when they occur in adults. Thus, the use of lower doses in an effort to limit side effects cannot be recommended outside of carefully constructed and controlled clinical trials.

### Radiation Therapy Planning

Advanced methods of EBRT treatment planning and delivery have been developed to ensure that the prescribed radiation dose conforms to well-defined targets and spares normal tissues from high doses of irradiation. These methods have been adopted to increase the accuracy of RT, decrease the potential for late effects, and improve local control through improved targeting and dose escalation. These two methods, conformal RT and BRT, may be used alone or in combination when indicated for local control.[93]

RT for NRSTS requires experience and precision. A planning computed tomography (CT) scan of the extremity is mandatory, and treatment facilities should have the capability to use both CT and MRI for the planning process. Correlating the tumor volume as defined by the preoperative MRI study and the studies used in the RT planning process is necessary. A preoperative dose of 45 to 50 Gy or a postoperative dose of 60 to 65 Gy (conventional fractionation) is commonly prescribed and is administered by using a shrinking field technique. The initial field should encompass all areas of gross disease, as defined by preoperative MRI, or the tumor bed, as defined by the surgical clips. When possible, the initial field is usually treated with 5-cm margins; however, treatment of the entire cross section of the extremity is avoided to prevent edema and loss of function. Immobilization of the extremity with customized molds is an important component of radiation treatment planning.

Advanced methods of treatment planning and delivery may offer great potential benefits to children with NRSTS. It has become increasingly apparent that wide treatment margins (greater than 5 to 10 cm) and inclusion of the scar and drain sites, formerly advocated for all patients, are not necessary when strict surgical oncology practices are applied and intraoperative assessment of the tumor is performed.[107] Indeed, the results of a prospective randomized trial of adjuvant BRT for extremity and truncal soft tissue sarcomas in adults suggest that margins of 2 cm are adequate.[102] In that study, the target area for BRT was defined by adding a 2-cm margin beyond the superior and inferior extent of the tumor bed and 1.5 to 2.0 cm laterally. The rate of local control was 82% for adult patients with high-grade sarcomas treated in this manner without EBRT.[108]

A simplified prescription for RT includes a stated dose and volume. The two are melded into a physical representation of the treatment. *Three-dimensional conformal RT* is any method that is capable of conforming (shaping) the isodose distribution to the target in three dimensions. The value of a particular conformal treatment plan is determined by its reproducibility, the percentage of the planning target volume that receives the prescription dose, and the nominal dose to normal or critical structures. Such a treatment plan is currently accomplished by immobilizing the patient in a manner that is reproducible for daily treatment. Immobilization plays an important role in realizing a conformal treatment plan. Once a patient is adequately and reproducibly immobilized, CT or MRI data are obtained with the patient in the treatment position. The image data are then transferred to a planning computer, after which specific targets are defined and dose-limiting structures or normal tissues are identified within the image data. Most institutions adhere to the International Commission on Radiation Units definitions of the tumor volumes.[109] These include the gross tumor volume, clinical target volume, and planning target volume. The gross tumor volume includes any gross tumor or the tumor bed. The clinical target volume generally includes the gross tumor volume with an anatomically defined margin meant to treat subclinical microscopic disease; the margin is selected according to tumor type, anatomic site, and pertinent clinical-pathologic information relevant to the patient's overall treatment plan. A geometric margin is added to the clinical target volume to create the planning target volume. This additional margin is meant to consider all possible geometric variations and daily variability in localization. With the above-mentioned targets defined, the radiation beams are oriented to achieve trajectories that minimize the dose delivered to normal tissues; this process results in a conformal treatment plan. Expert judgment is required to balance the desire to achieve a conformal isodose distribution that decreases sharply outside of the planning target volume with the possibility of irradiating larger volumes of normal tissue with low doses of radiation. When developing a conformal treatment plan, one should not limit the orientation of the beams to a single plane (coplanar), which will substantially limit the ability of the treatment to conform to the target volume. The beams should be allowed to approach the target volume from any orientation (noncoplanar) and should preferably traverse the least amount of normal tissue or traverse normal tissues that are least susceptible to radiation effects. The entrance and exit characteristics of the radiation beams greatly influence the irradiated

volume. Finally, the orientation and number of radiation beams should be chosen to obtain a treatment plan that adheres to institutional definitions of conformality and safety. Under certain circumstances, the beam arrangement may resemble that used in a conventional treatment plan. [93]

### Preoperative Radiation Therapy

RT given before surgical resection has a number of therapeutic and functional advantages for all types of NRSTS. Therapeutically, preoperative RT treats a nonhypoxic tumor bed, allows limited-volume irradiation, improves resectability, and lessens the likelihood of intraoperative contamination. Functionally, preoperative RT can preserve organs or neurovascular structures, epiphyseal plates, and physiologic function either through limited-volume RT using conformal techniques or by permitting limited resection. There is a good radiobiologic rationale for preoperative RT. Even with a large tumor mass, preoperative RT to a dose of 45 to 50 Gy may inactivate more than 99% of the tumor cells. This may decrease the likelihood of tumor implantation during surgery. Tumor cells that are shed into the circulation at the time of surgery are also hypothetically less likely to be viable or able to establish distant metastases. With preoperative RT, the radiation oncologist need treat only tissues thought to be at risk for tumor involvement; the radiation fields need not encompass areas to be manipulated by the surgeon, as is the case in postoperative therapy. The greatest advantage to the use of preoperative RT may be that it allows some patients to undergo limb-salvage procedures rather than amputation. Even if the tumor mass does not decrease in size after RT, the lesion may consist of necrotic debris with little viable tumor. A potential difficulty with preoperative RT is delayed healing of the surgical wound, although if good surgical and radiotherapeutic techniques are used, primary healing should occur. There are several series that demonstrate that planned preoperative RT in patients with high-grade sarcoma can yield excellent results, with 5-year disease-free survival rates of 56% to 74% and local control rates of 83% to 95%. [97,110,111] Wound complication rates of 6.5% to 30%, similar to or exceeding those that would be expected with postoperative RT, have been reported with conventional methods of treatment planning and appear to be the only negative aspect of preoperative RT. [100,112] The greatest gains with preoperative treatment have been shown in the treatment of large tumors [99,113] and in studies combining preoperative RT with preoperative chemotherapy. [114] The general guidelines for preoperative RT of NRSTS include EBRT to 50 Gy; resection 3 to 4 weeks later; and a boost to 64 to 68 Gy using intra- or postoperative EBRT, intraoperative high-dose BRT (Ir-192), or low-dose BRT (I-125 or Ir-192).

The experience of preoperative RT for pediatric NRSTS is limited. Because it may be possible to use lower doses of radiation when RT is combined with surgical excision in this manner, studies that define the optimal sequencing of RT and surgery are needed. The National Cancer Institute of Canada is conducting a phase III trial of preoperative versus postoperative EBRT in curable adult NRSTS of the extremity. [115]

### Postoperative Radiotherapy

There are several theoretical advantages of postoperative RT. These include the institution of immediate surgery, avoidance of radiation-induced delays in wound healing, and the availability of a large specimen for histopathologic investigation with definitive interpretation of tumor size and extension. With this approach, the initial postoperative treatment volume should include the entire wound, which usually is larger than the volume that would have been treated preoperatively. Several retrospective, single-institution series have assessed this approach. The 5-year results include a disease-free survival rate of 60% to 68% and a local control rate of 78% to 92%. [116,117 and 118] In the late 1970s and early 1980s, the NCI conducted a small randomized, prospective trial to compare the results of limb-sparing surgery with postoperative RT to amputation in patients with high-grade sarcomas of the extremity. [65] Although the local control rate was slightly better with amputation, the groups had similar disease-free and overall survival rates. In the limb-sparing group, 85% of patients retained a functional limb. Clearly, the functional preservation of the extremity is an important theoretical advantage of conservative surgery and postoperative RT as compared with radical resection or amputation. Little objective information has been available, however. Some small, retrospective studies have found no quality of life advantage in limb salvage as compared with radical treatments. [119,120] These results are difficult to understand and are counterintuitive. In 1991, Stinson and colleagues [101] from the NCI reported the long-term effects of conservative surgery and irradiation on functional outcome in 145 adult patients with sarcoma of the extremity who were treated between 1975 and 1986. Overall, 84% of patients were ambulating without an assistive device and with mild or no pain. As more precise RT methods evolved at the NCI over the 11-year period, the complication rate decreased. Although the extent of surgery clearly influenced functional outcome, the concomitant use of adjuvant chemotherapy, including doxorubicin, did not.

Two more recent NCI trials have assessed the role of postoperative RT for adult soft tissue sarcomas of the extremity. Ninety adults with high-grade (histologic grade 2 or 3 on a scale of 1 to 3) lesions were randomly assigned to receive either adjuvant postoperative irradiation (45 Gy for 5 weeks to the wide surgical bed, with an 18-Gy boost over 2 weeks) and adjuvant postoperative chemotherapy or adjuvant postoperative chemotherapy alone. [121] With a median follow-up of 5 years, none (0%) of 44 patients in the RT group had local treatment failure, whereas 9 (20%) of 46 patients had local failure after surgery and postoperative adjuvant chemotherapy alone ($p = .002$). However, there was no difference between the two groups in the rate of 5-year survival (80%). In the second trial, [60] patients with low-grade (grade 1) NRSTS of the extremity were randomly assigned either to receive postoperative irradiation (doses similar to those used in the previous trial) or to be observed after wide resection. [122] With a median follow-up of 8 years, there have been six (21%) local failures among 29 patients under observation and one local failure among 28 patients receiving postoperative RT ( $p = .06$). The single local recurrence in the adjuvant RT group occurred at the margin of the radiation field. Overall, eight patients on the observation arm have developed recurrent tumor, as compared to three patients who received RT ( $p2 = .08$). Although these groups may have been too small to allow the detection of a statistically significant difference in the rate of recurrence, postoperative RT appears to be indicated even for patients with low-grade sarcomas. [122]

### Brachytherapy

BRT is the intracavitary, interstitial, or surface application of radioisotopes or radiation-generating devices; they may be permanent or temporary. BRT is an excellent alternative or adjunct to EBRT. It has inherent tissue-sparing properties and dosimetric advantages that can be used to deliver RT in a conformal manner. [123] The technique relies heavily on preimplant assessment of tumor extent, including biopsy of the surgical field, diagnostic imaging, and the extent of resection. In general, the implant volume is limited to the tissues exposed at the time of surgery, although with careful technique, catheters may be placed approximately 2 to 3 cm beyond the wound. Temporary implants, the most commonly used form of BRT for pediatric patients, are readily placed in most head and neck, truncal, extremity, and intracavitary sites. In the administration of low-dose BRT, for which there is a reasonable pediatric experience, catheters or guiding devices are placed at the time of surgery and are loaded with radioactive sources 5 to 6 days after the operation. These sources remain in place for a prescribed interval of time and are removed together with the catheters or guiding devices. Permanent implants are not commonly used in the primary management of pediatric sarcomas. They are reserved for situations in which normal tissue tolerance has been exceeded with EBRT and high doses of localized RT may be effective.

BRT is an excellent treatment option for pediatric patients with NRSTS. Disease control may be achieved with a high rate of success when BRT is used alone or in combination with EBRT. This treatment approach offers several advantages over EBRT for pediatric patients with NRSTS reducing the dose of radiation to normal tissues and shortening the overall treatment time while maintaining a comparable rate of local control. The reduction of radiation doses delivered to normal tissues decreases the probability of growth deformity, adiochemotherapy interactions, and hypothetically, the risk of second tumor formation.

The value of BRT for NRSTS has been consistently demonstrated in adults. [108,124,125 and 126] An initial series of 33 patients with locally advanced sarcomas, many of which would have required amputation, resulted in an 88% local control rate. [100] The rate of local control was 70% for patients with high-risk tumors that abutted or actually invaded a major neurovascular bundle, which had been dissected and preserved. Subsequently, a prospective randomized trial at Memorial Sloan-Kettering Cancer Center confirmed the highly significant effect of BRT in preventing local recurrence after limb salvage surgery. [108,127] Local failures occurred in 2 of 52 patients randomly assigned to receive BRT and in 9 of 65 patients who did not receive BRT ( $p = .06$). The results were more significant in an analysis of patients with high-grade lesions, in which none of the 41 patients who received BRT had local failure, but 5 of 47 patients who did not receive BRT ( $p = .03$) had local failure. The most common major complication of BRT was poor wound healing. Improvements in surgical technique and standardization of the radiation treatment planning, including a planned delay of loading for at least 5 days after surgery, have reduced the rate of wound complications. There is also evidence that adult patients with involved surgical margins have a higher probability of local control of local disease when treated with combined BRT and EBRT than when treated with implants alone. [124] In children, the data are more limited; the reported series include relatively small numbers of patients with different tumor types. [94,128,129,130,131 and 132] The advantage of BRT over wide local excision alone for local control was conclusively demonstrated in adults with high-grade tumors. [108] Because assessments of BRT in children include patients with rhabdomyosarcoma and Ewing's sarcoma family tumors, there are limited data specific to NRSTS in children. Thirty-one children with NRSTS who were treated with BRT were reviewed at St. Jude Children's Research Hospital. Twenty-seven patients were initially managed with BRT; ten of these patients had BRT alone, and the remainder were treated with a combination of BRT and EBRT. There was no local or regional treatment failure in the group treated with BRT alone. Eight patients were alive with no evidence of disease 9 to135 months after diagnosis. There was one local failure in the BRT plus EBRT group. [94]

Although BRT considerably shortens the overall treatment time and has local control rates that approach those reported for conventional preoperative or postoperative EBRT, we recommend its application only at major cancer centers with active BRT services. Prospective trials of BRT for children with soft tissue

sarcomas are needed.

### Intraoperative High-Dose Rate or Electron Beam Radiation Therapy

Intraoperative high-dose rate (IOHDR) RT or electron beam RT (IORT) is the application of BRT or EBRT at the time of operative exposure of the treatment volume.[133,134] The major advantage of IOHDR and IORT is the opportunity to remove, reposition, or shield critical structures such that high-dose, single-fraction RT can be precisely delivered to the tumor bed with minimal toxicity. These advantages improve the therapeutic ratio of the treatment and often allow RT to be given in a location in which normal tissues would be damaged if they were traversed by EBRT. This is especially true for previously irradiated locations. IOHDR or IORT can be given instead of or as a boost treatment before or after EBRT. In this technique, a tissue-equivalent material containing patent catheters is positioned in the operative bed. To irradiate the target, the catheters are connected to a remote afterloader and the source is then conveyed from the afterloader into the catheters, in which it dwells at defined positions for prescribed time intervals. Sites that are difficult to reach are treated by this method. A specially shielded operating room is required, and the patient is remotely monitored during the treatment. The use of 1,200-cGy single-fraction IOHDR in 16 pediatric patients with solid tumors, 11 of whom had bone or soft tissue sarcomas in abdominal, thoracic, or pelvic sites, resulted in actuarial rates of local control, metastasis-free survival, and overall survival of 61%, 51%, and 54%, respectively, with a median follow-up of 18 months.[134] These patients' tumors would be classified as high risk on the basis of their clinical presentation. The outcomes we observed in this small cohort suggest that IOHDR is a safe method for delivering RT and for escalating the total dose of RT.

### Nonextremity Soft Tissue Sarcomas and Special Sites

Approximately 40% of soft tissue sarcomas occur in nonextremity sites such as the retroperitoneum. The surgical approach to these tumors is constrained by the lack of feasibility of wide local resection. Adjacent vital structures often limit surgery to local excision with, at best, limited margins of resection. Because of the difficulty of obtaining wide, negative margins, postoperative RT is usually recommended. Intraoperative RT and dose escalation has been tested most commonly in the retroperitoneum.[135,136 and 137] Sarcomas as a group are not common tumors, and NRSTSs arising in the hand and foot are very rare. Unlike alveolar rhabdomyosarcoma, most patients with NRSTS of the hand or foot, excluding epithelioid sarcoma, have localized disease at presentation and may be at lower risk for developing metastases, probably because the tumors are smaller and are detected earlier. Given the functional complexity of the hand and foot and the better prognosis for this patient group, the issue of how best to establish local control and maintain function is important. Previously, it was assumed that the high doses of radiation required to control even microscopic sarcoma would result in such poor function of the hand or foot that amputation was considered the treatment of choice. It is now apparent that this assumption was wrong; two series have documented excellent tumor control with preservation of function. [138,139]

### Acute and Long-Term Sequelae of Radiation Therapy

The most common side effects of EBRT or BRT—radiation dermatitis, cellulitis, fibrosis, and telangiectasia—are reported to occur in 10% to 50% of cases. Radiation osteitis may be seen.[140] Second malignant neoplasms may also be induced by RT.[93] The effects on the musculoskeletal system in young and growing children require careful treatment planning by experienced pediatric radiation oncologists. These effects include limitation of growth of bones and soft tissues. This may lead to leg length inequity and gait disturbances. Joint dysfunction with decrease in range of motion may also contribute to gait disturbance. Reduction of muscle mass with the radiation field may result in weakness. Bone fracture may occur as a consequence of RT, especially when the surrounding musculature is reduced due to surgery, radiation, or both. Circulatory complications and resulting edema may also be seen.

### Conclusions

RT remains one of the most effective primary and adjuvant treatments for pediatric sarcomas. When RT is indicated, treatment is usually focal, and attempts are made to spare normal tissues as much as possible without reducing the probability of local control. Because of this consideration, BRT and conformal methods of RT treatment planning and delivery should be considered for pediatric patients with NRSTS.

## CHEMOTHERAPY

### Adjuvant Therapy—Adult Trials

The role of adjuvant chemotherapy in the treatment of adult NRSTS continues to be controversial. To date, only 3 of 15 randomized adjuvant chemotherapy trials in adults have shown a significant survival advantage for the adjuvant chemotherapy group. [141,142] The first study randomized 59 patients (36 with extremity primary tumors) to receive 8 to 11 courses of cyclophosphamide, vincristine, dacarbazine (DTIC), and doxorubicin (CYVADIC) versus observation. Five-year metastasis-free survival and overall survival were significantly better for the chemotherapy group: 65% versus 34% ( $p = .003$) and 83% versus 43% ($p = .002$), respectively. A second study randomized 77 patients with high-grade extremity NRSTS to observation versus single-agent doxorubicin and found a significant survival and disease-free survival advantage for patients who received adjuvant chemotherapy.[141] A third study randomized 104 patients with high-grade, large, primary extremity soft tissue sarcomas to chemotherapy using the combination of epirubicin and ifosfamide versus observation. At a median follow-up of 36 months, patients randomized to the chemotherapy arm had significantly higher overall and disease-free survival estimates. [142] All of the remaining randomized studies of adults showed no benefit of adjuvant chemotherapy. Thus, the benefit of adjuvant chemotherapy has not been clearly established.

Several additional adult trials have shown improved disease-free survival when adjuvant chemotherapy is used. The first, a small randomized study of adjuvant chemotherapy in 65 adults with NRSTS of the extremities at the NCI showed a disease-free survival benefit for patients who received adjuvant chemotherapy with cyclophosphamide and doxorubicin.[65] With a median follow-up of 7.1 years, the 5-year disease-free survival was 75% for those treated with chemotherapy and 54% for those receiving no chemotherapy.[65,143] This result was not duplicated in the NCI series for patients with sarcomas of the trunk. The second series of adult patients observed for more than 10 years at M. D. Anderson Hospital showed the disease-free survival rate of those patients treated with vincristine, Adriamycin, cyclophosphamide, dactinomycin, and irradiation was 55%, compared with 35% ($p = .05$) for patients treated with surgery and irradiation alone. [144] The third study conducted by the European Organization for Research on the Treatment of Cancer (EORTC) demonstrated higher relapse-free survival rates in patients who received adjuvant chemotherapy; however, no survival advantage for the chemotherapy arm was evident.[145] In contrast, four randomized trials evaluating the role of Adriamycin in the adjuvant treatment of NRSTS did not reveal any clear benefit. [146,147,148 and 149]

Of interest, meta-analysis of 14 randomized trials of adjuvant chemotherapy comprising 1,568 adult patients with NRSTS demonstrates a reduction in the risk of local failures and distant failures at 10 years with a 10% recurrence-free survival and 4% survival advantage for those receiving adjuvant chemotherapy with doxorubicin-based regimens.[145a] Extremities have the clearest evidence of treatment effect. These data show only a minimal benefit in adult patients with NRSTS.

### Adjuvant Therapy—Pediatric Trials

The role of adjuvant chemotherapy in the treatment of pediatric rhabdomyosarcoma has been well established; however, its role in the treatment of NRSTS remains controversial. In children, there has only been one prospective randomized trial of adjuvant chemotherapy for NRSTS. From June 1986 through May 1991, the POG evaluated the benefit of adjuvant chemotherapy (vincristine, Adriamycin, cyclophosphamide, and dactinomycin) compared to observation in surgically resected pediatric NRSTS.[61] Of the 81 eligible patients, only 30 accepted randomization and no evidence of improved outcome could be seen in the subgroup that received adjuvant chemotherapy. Five-year survival and event-free survival estimates were significantly worse for patients who received adjuvant chemotherapy; however, this is likely the result of an imbalance in the number of patients with high-grade lesions who received adjuvant chemotherapy. Because an adult study suggests that ifosfamide may be more effective than cyclophosphamide against these sarcomas, future randomized trials of adjuvant chemotherapy in pediatrics will likely use this agent in combination with anthracyclines.[150,151 and 152]

Based on existing data in children, the role for adjuvant chemotherapy for surgically resected NRSTS has not been established. Its use should continue to be investigated in the context of multi-institutional trials. Patients with extremity primaries and close margins may benefit from adjuvant chemotherapy to reduce the risk of local recurrence; however, this will require careful evaluation.

### Therapy for Advanced Disease—Adult Trials

There are a number of active regimens in the treatment of advanced NRSTS: MAID (mesna, Adriamycin, ifosfamide, and DTIC),[153] MAP (mitomycin C, Adriamycin,

and cisplatin),[154] CYVADIC,[155] Adriamycin,and cyclophosphamide with or without vincristine, [64] and ifosfamide with etoposide.[156,157] All of these regimens have a significant response rate in advanced disease.

In a series of trials of adults with advanced soft tissue sarcomas, the EORTC has demonstrated the following: that (a) DTIC as part of CYVADIC did not add to the outcome seen with Adriamycin plus cyclophosphamide; (b) ifosfamide is preferable to cyclophosphamide because it results in a higher response rate, equivalent survival, and less toxicity when given as a single agent; (c) ifosfamide is active in some cyclophosphamide-resistant tumors; (d) addition of ifosfamide to an Adriamycin regimen results in a higher response rate; (e) on the basis of sequential trials, the dose of Adriamycin is apparently directly related to the response rate; and (f) higher doses of Adriamycin are associated with a prolonged disease-free interval. [158]

One of the trials, an Intergroup Phase III randomized study of doxorubicin and dacarbazine with or without ifosfamide and mesna in 340 adults with advanced soft tissue and bone sarcomas demonstrated a longer time to progression, but more myelosuppression after ifosfamide and mesna were seen. In this study and in two additional randomized trials of doxorubicin (Eastern Cooperative Oncology Group and EORTC) with and without ifosfamide, the response rate was higher in the ifosfamide-containing arms.[159] Another recent EORTC trial randomized 294 eligible patients to receive standard-dose doxorubicin (50 mg per $m^2$ on day 1) and ifosfamide (5 g per $m^2$ on day 1) versus an intensified regimen combining doxorubicin (75 mg per $m^2$ on day 1), with the same ifosfamide dose followed by granulocyte-macrophage colony-stimulating factor.[145] Objective responses were observed in 21% of patients in the standard arm and in 23% of patients in the intensified arm. Progression-free survival was significantly longer in the intensive arm, but there was no difference in overall survival between the two therapeutic arms.

### Therapy for Advanced Disease—Pediatric Trials

Pediatric studies in advanced NRSTS are limited. A recently reported POG study evaluated the role of DTIC in the context of multi-agent chemotherapy with vincristine, Adriamycin, cyclophosphamide, and dactinomycin for patients with unresected or metastatic NRSTS. [61] The addition of DTIC did not improve outcome, and the overall results were similar to those reported in adults: overall survival and event-free survival at 4 years were 30% and 18%, respectively. The POG has recently completed a pilot study of vincristine, ifosfamide, and doxorubicin for similar patients. The results of this trial are not yet available. Although many chemotherapy regimens have activity in advanced NRSTS in both children and adults, significant improvement in survival for children has not been achieved with the current regimens. Based on adult trials from the EORTC, more intensive chemotherapy regimens that use higher doses of ifosfamide and Adriamycin may be beneficial in the treatment of advanced NRSTS. Few data exist as yet in the treatment of children, however. The described pilot POG trial will contribute to our understanding.

### Conclusions

The most important issues to address in the chemotherapy of children with NRSTS are the following: (a) to discover very effective therapy for children with NRSTS; (b) to define the role of adjuvant chemotherapy in children with surgically excised tumors; (c) to evaluate the impact of chemotherapy on children who present with metastatic disease or with unresectable nonmetastatic tumors; (d) to determine the role of ifosfamide in combination with Adriamycin or etoposide in the treatment of children with NRSTS, especially those with advanced disease; (e) to evaluate the optimal dose intensity of the chemotherapy agents and regimens used to treat NRSTS.

## CONGENITAL FIBROSARCOMA

### Epidemiology, Biology, and Genetics

Although rare, fibrosarcoma is one of the most common NRSTSs in children and adolescents.[160] It is the most common soft tissue sarcoma occurring in children younger than 1 year.[1,40,160] Historical series of patients with congenital fibrosarcomas suggest that there is a predominance of boys [40,41]; however, another report and review of the literature reveal no significant gender predominance. [42] There appear to be two peaks in incidence of fibrosarcoma according to age: in infants and children younger than 5 years, and in patients 10 to 15 years of age. Although some authors believe that the biology of these tumors is similar in the two age groups, most think that the tumors in infant congenital fibrosarcomas usually have a more benign course. [40,41,161] Despite its name, this is not a fibrosarcoma in the conventional sense, and it does not commonly metastasize despite repeated local recurrences. [40] The Armed Forces Institute of Pathology (AFIP) series document a low metastatic rate of 10%. In fact, this low level of metastatic potential, combined with biologic observations such as a failure of xenograft tumor formation in mice and a near-diploid karyotype on flow cytometry have led some to question the terminology “fibrosarcoma.” [162,163] However, careful karyotypic studies have clearly documented a recurring t(12;15) translocation, which has been cloned recently, revealing a novel fusion gene formed by ETV6 (or TEL) with the high-affinity nerve growth factor NTRK3 (TRKC). This abnormality is not found in infantile myofibromatosis or other early childhood fibromatosis, nor is it found in adult-type fibrosarcomas occurring in older children. [164,165] This unique abnormality clearly distinguishes this tumor from other, similar tumors such as infantile myofibromatosis and congenital hemangiopericytoma, with which it is sometimes confused.[166]

### Pathology

Histologically these tumors are composed of a uniform population of fibroblasts or myofibroblasts. Little stroma is present; when it is, it is often loose or poorly formed collagen, best seen on reticulin stain as opposed to trichrome stain. The mitotic rate is generally low but can be quite high, a finding of no prognostic significance. Retroperitoneal and head and neck lesions generally fare worse than extremity lesions despite an identical histology.

### Clinical Presentation

In a review of the literature detailing the experience with 52 cases of congenital fibrosarcoma, 37 were found to have occurred on an extremity and 15 on the trunk. [42] The presentation is usually with a localized mass with no systemic symptoms.

### Principles and Recommendations for Treatment

The usual treatment strategy for infants with congenital fibrosarcoma is surgical extirpation by wide local excision without additional radiation or chemotherapy. Of the patients with extremity primaries described above, 92% were free of metastatic disease and 95% were alive despite a 32% local recurrence rate; only six have died (11.5%).[42] Two children who died of recurrent congenital fibrosarcoma were reported to have had a pathologic pattern in the tumors that was typical for MFH at the time of local relapse.[167] This finding suggests a relation between fibrosarcoma and MFH that is not well recognized or understood. Because late local recurrences do not appear to affect overall survival of patients with congenital fibrosarcoma, conservative surgical management aimed at maintaining as much function as possible and avoiding amputation is often the preferred approach. Moreover, because of the known long-term consequences of RT and the potential late effects of chemotherapy, the use of these modalities in the local management of congenital fibrosarcoma is generally not advised unless surgical removal is not possible initially. A number of investigators have reported a dramatic reduction in size of large masses with the use of preoperative chemotherapy. [168] This approach has allowed more conservative surgical approaches without amputation. Chemotherapeutic regimens that have been used include ifosfamide, vincristine, and dactinomycin; vincristine, dactinomycin, and cyclophosphamide; and vincristine and dactinomycin without an alkylating agent. [169,170 and 171] Vincristineand dactinomycin are preferred initial agents because of their relative lack of long-term side effects and lack of leukemogenesis. There is no established role for adjuvant chemotherapy after a surgical procedure in the management of congenital fibrosarcoma.

For congenital fibrosarcomas that arise in axial locations, the local recurrence rate is similar to that for extremity tumors (33%); however, the metastatic rate and mortality rate are higher, 26%, compared with 10% or less for extremity primaries.[42,43]

## FIBROSARCOMA

### Epidemiology, Biology, and Genetics

Unlike congenital fibrosarcoma, conventional fibrosarcoma is a full-fledged malignancy with very real potential to metastasize, particularly when it occurs in older, especially postpubertal, patients. Although this diagnosis is infrequently made in adults, in the pediatric age group, this is a well-recognized tumor. Histologically, it is not different from fibrosarcomas in adults. The behavior is similar as well. Because virtually all of these tumors occur in postpubertal adolescents, age is a strong

predictor of both histology and prognosis among fibrous tumors in this age. Clonal translations t(X;18), t(2;5) and t(7;22) have been reported in adult-type fibrosarcoma.[172]

Laboratory studies of many malignancies have revealed characteristic cytogenetic and molecular genetic alterations that are useful in diagnosis or for prediction of clinical behavior (i.e., metastasis and treatment responsiveness). Recurrent genetic abnormalities have been noted in fibrosarcoma, [173] but a reliable method of distinguishing between high- and low-grade lesions is so far unknown. Because mutations in the p53 oncogene have been observed at high frequency in many soft tissue sarcomas,[174],[175],[176],[177],[178],[179] and [180] and because p53 mutations have been associated with poor prognosis within groups of similar tumors, [181],[182],[183] and [184] it may be suspected that p53 mutations could be used to discriminate true fibrosarcoma from other fibrous tumors. [185] However, this has not proved to be the case in larger series of tumors subjected to DNA sequence confirmation of p53 mutations. [186]

### Pathology

Fibrosarcoma is a spindle cell tumor with a characteristic herringbone pattern made up of regularly interweaving fascicles of parallel arrays of tumor cells ( Fig. 34-4A). Important features include evidence of abnormal mitoses, nuclear pleomorphism, and increased basophilia of individual, sometimes anaplastic, tumor cells. Cells are densely packed, but reticulin stain reveals a regular pattern of stromal collagen fibers not easily appreciated by light microscopy. The most important entities to distinguish are aggressive fibromatosis (which can be exceedingly aggressive locally but does not metastasize), nodular fascitis, myositis ossificans, and inflammatory pseudotumor among nonmalignant conditions, and neurofibrosarcoma, MPNST, poorly differentiated embryonal rhabdomyosarcoma, and monophasic (spindle cell) synoviosarcoma among malignant tumors (Table 34-10). It is not always possible to differentiate congenital fibrosarcoma from fibromatosis [41] and other fibrous tumors. Individual tumors must be evaluated in light of clinical information such as age, site, history, and duration of the lesion. In particular, fibrosarcoma in the first year of life is a serious but rarely metastasizing tumor; the apparently same tumor in an adolescent frequently develops metastases. [163] Therefore, age must be considered when making the diagnosis. Intermediate ages present challenges to pathologists and oncologists alike. Confusion with benign fibrous lesions such as myositis ossificans (a posttraumatic lesion) and nodular fascitis has occasionally led to overtreatment.

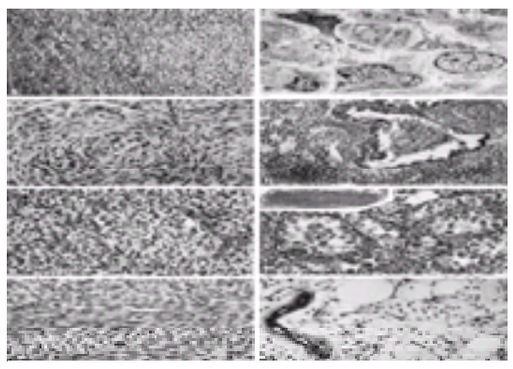

**FIGURE 34-4.** Differentiated soft tissue sarcomas other than rhabdomyosarcoma. **A:** Fibrosarcoma. This tumor is rare in adults and uncommon in older children, but it is one of the most common nonmyogenous soft tissue sarcomas in the first decade. Interlacing fascicles of spindle cells appear either elongate ( *left*) or round (*right*), depending on plane of section. The cells are closely packed and homogeneous, and resemble normal fibroblasts. Mitoses, pleomorphism, and nuclear hyperchromatism are rare [hematoxylin and eosin (H&E) stain, ×250]. **B:** Neurofibrosarcoma. The light microscopic appearance of this tumor may be indistinguishable from that of fibrosarcoma. Electron microscopy (EM) reveals evidence of nerve sheath differentiation, although not often as well developed as seen here, in which some tumor cells envelop neurites (*upper center*), mimicking Schwann cells. More often, only fragmented basal lamina and slender cell processes are present (EM, ×2,000). **C:** Malignant fibrous histiocytoma (MFH). The most common soft tissue sarcoma of adults, MFH is uncommon in children. The angiomatoid variant, seen here, is frequently seen in children. The propensity for tumor cells to form vascular structures ( *center*) accounts for the name (H&E, ×250). **D:** Synovial sarcoma. Classic biphasic synovial sarcoma is an unmistakable entity. Distinct epithelial, glandular differentiation ( *center*) alternates with fibrosarcomatous stroma (*right*). Islands of tumor cells separated by hyaline stroma are sometimes seen (*left*), and staghorn vasculature (not illustrated) is often conspicuous (H&E, ×100). **E:** Hemangiopericytoma. Thought to recapitulate normal pericytes, this tumor varies from Ewing's-like (as here) to a spindle cell variety resembling smooth muscle. In all cases, reticulin stains outline individual tumor cells and nests. EM demonstrates evidence of pericytic differentiation. Tumor cells do not form vascular spaces but surround them (*center*) (H&E, ×250). **F:** Alveolar soft part sarcoma. This problematic tumor is easily differentiated from all other sarcomas. The glandular or alveolar pattern is always prominent; tumor cells appear to rest on a basement membrane. Spaces within are variably present, as here. The tumor cells possess abundant pink cytoplasm that by light microscopy resembles muscle. However, periodic acid–Schiff–positive, diastase-resistant cytoplasmic crystalloids ( *center*) are present in tumor cells. By EM, these crystals are diagnostic (*inset*). Evidence favors a myogenous origin of this tumor, although myogenous differentiation has never been identified using EM (H&E, ×250). **G:** Leiomyosarcoma. Smooth muscle tumors in children are rare but do occur. Leiomyosarcoma in children and adults is characterized by spindle cells that resemble fibroblasts but stain intensely with eosin because of their content of smooth muscle actin-myosin bundles. Some degree of pleomorphism (*bottom center*) and mitosis (*upper center*) are often found (H&E, ×250). **H:** Liposarcoma. All liposarcomas are rare in children, and of the four types commonly seen in adults, only the myxoid type is common in children. This relatively low-grade sarcoma resembles fetal lipoblasts, often interspersed among more differentiated adipocytes (large clear cells). The vasculature ( *left*) is routinely prominent in liposarcomas and helps to differentiate this tumor from lipoblastoma and related benign fatty tumors (H&E, ×400).

| Tumor | MIC2 | Keratin | Epithelial membrane antigen | S100 | Neurofilament/ tubular protein | Vimentin |
|---|---|---|---|---|---|---|
| Fibrosarcoma | - | - | - | - | - | + |
| Synoviosarcoma | - | + | + | - | - | ± |
| Malignant peripheral nerve sheath tumor | - | ± | ± | + | ± | + |
| Ewing's sarcoma/primitive neuroectodermal tumor | + | ± | ± | - | - | ± |
| Desmoplastic small round cell tumor | - | ± | ± | - | - | + |

**TABLE 34-10. THE IMMUNOHISTOCHEMICAL PROFILE OF NONRHABDOMYOSARCOMA SOFT TISSUE SARCOMA**

### Clinical Presentation

Fibrosarcomas occur most frequently on the extremity, often in the distal segments; 70% of the reported cases of congenital fibrosarcoma occur at this site. [40],[41] and [42] In a review of 182 children with fibrosarcoma, the extent of disease was defined: 80% had localized disease, 8% had regional dissemination, and 12% had widespread disseminated disease.[187]

### Principles and Recommendations for Treatment

The overall approach to treatment of the older child with fibrosarcoma is different from the approach to an infant with congenital fibrosarcoma but similar to that for other NRSTSs. In contrast to congenital fibrosarcoma, the 5-year survival rate of fibrosarcoma in older patients is approximately 60%. [5] The most common site of metastasis in these older patients is the lung. The treatment principles are those outlined in the general discussion of treatment of NRSTS in children.

## MALIGNANT PERIPHERAL NERVE SHEATH TUMOR

### Epidemiology, Genetics, and Biology

MPNSTs account for approximately 5% to 10% of all NRSTSs in children.[29,30,31 and 32] MPNSTs occur in association with NF1, which is characterized by café au lait spots, axillary freckling, neurofibromas, skeletal dysplasia, learning disabilities, and a variety of neoplasms.[27] Approximately 5% to 16% of patients with NF1 develop MPNST. NF1 is a common autosomal dominant disorder that has been mapped to 17q11.2.[27] The gene has been cloned. Although its function remains unknown, the NF1 gene probably acts as a recessive tumor suppressor gene. An evaluation of two malignant tumors from NF1 patients revealed allele loss at informative loci on both the long and short arms of chromosome 17.[27]

In addition, reports of somatic deletion of the NF1 gene in a neurofibrosarcoma further suggest the hypothesis that the lack of a tumor suppressor gene is important in the pathogenesis of this tumor. Another study of ten patients with MPNST, of whom nine had NF1, found recurrent abnormalities of chromosomes 1, 11, 12, 14, 17, and 22. These data suggest that inactivation of the NF1 gene and loss of tumor suppression genes on 17p and 22q may be associated with neoplastic transformation. A point mutation at the p53 locus at 17p13 has also been demonstrated in an MPNST, further supporting a role for the p53 gene or other genes on the short arm of chromosome 17 in some of the malignancies seen in conjunction with NF1.[27] Additional reports have demonstrated multiple cytogenetic aberrations characterized by loss of chromosomes and multiple structural anomalies of diverse types.[188,189]

The increased incidence and earlier occurrence of neurofibrosarcomas in children and young adults with NF1 provide strong clinical evidence for the hypothesis that these tumors are caused in part by the LOH of a tumor suppressor gene.

### Pathology

The variety of histologic appearances of this tumor is rivaled only by the many variants of MFH in adult soft tissue sarcomas.[190,191,192,193,194,195,196,197 and 198] No one description does justice to this entity, in which in addition to expected fibrosarcoma-like elements, a wide variety of other histologies can be found, notably epithelial, glandular, and even cartilaginous or other heterotopic elements. No other pediatric soft tissue tumor is as variable in its appearance, raising questions as to whether it is a single entity. Nonetheless, current thinking groups all of these disparate tumors as one: MPNST.

Although superficially similar in appearance, MPNST must be differentiated from fibrosarcoma. The cells are usually more variable in size and shape, a herringbone pattern is usually absent, and often typical features of adult MPNST can be found in some areas of the tumor: a myxoid stroma, palisading of nuclei, and occasionally well-defined organoid arrays of nuclei (so-called Verocay bodies).[199] These features, common in benign schwannomas, are far less conspicuous in the malignant counterpart but can be diagnostic if present. Electron microscopy is by far the most useful method of establishing a specific diagnosis; Schwann cell differentiation, lacking only neurites within cytoplasmic concavities (mesaxons), is usually conspicuous ( Fig. 34-4B). Alternatively, immunocytochemistry with S-100 antibodies is often useful[200] (Table 34-10). Some tumors are exceedingly complex and contain additional elements—for example, muscle elements in malignant triton tumor, glandular elements resembling synovial sarcoma, cartilage, bone, and melanocytic elements (pigmented malignant nerve sheath tumor, clear cell sarcoma, melanoma of soft parts)—yet are, broadly speaking, still within this general category of MPNST.

MPNST may be unique among childhood sarcomas. First, it is well known that neurofibromatosis patients are at increased risk for development of MPNST. Second, the gene for NF1 has been cloned.[201,202] Finally, it has been shown that NF1 is deleted in cases of neurofibrosarcoma.[28] These initial observations suggest that NF1 abnormalities may be relevant to the genesis of MPNST in non-NF1 patients as well. They have already been identified in other neural tumors in children and adults.[203]

### Clinical Presentation

In a report of 24 children with MPNST, 16 had the associated neurofibromatosis syndrome. The most common primary sites were extremity (42%), retroperitoneum (25%), and trunk (21%); three tumors occurred in other sites. A second report of 25 patients had similar findings, with six patients having stage I tumors, five stage II, ten stage III, and four stage IV.[204] Of the 49 patients, only six (12%) had metastases at diagnosis.

### Principles and Recommendations for Treatment

Surgery plays a key role in the management of MPNST in children. Of the 24 patients in the first series described in the previous paragraph, 12 underwent gross total removal of the tumor, and nine of these were tumor-free survivors at 3 years.[204] In contrast, none of the 12 patients who could not have their tumors grossly removed were alive without disease at 3 years. In the second series of children, 8 of 11 patients with gross total resections were free of disease. In contrast, of the 14 patients with incomplete removal of tumor, only five achieved complete remission.[205] In these two small groups of patients, it appears that patients treated by complete removal with adequate margins and those treated by gross resection and irradiation to microscopic residual disease had similar and good outcomes. Irradiation therefore contributes to local control of MPNST in patients with microscopic disease after initial surgery.[204,205] This result is consistent with the experience in adult patients. As with other NRSTSs, the role of adjuvant chemotherapy is not established for MPNSTs.

Although chemotherapy can produce tumor regression in patients with unresectable and metastatic disease, no chemotherapy regimen has emerged that can produce an adequate disease-free survival rate in patients with advanced disease. The most commonly used regimens include vincristine, cyclophosphamide, dactinomycin, and doxorubicin.[204] None of the patients with gross residual disease after surgery in the series reported survived disease-free, despite the use of this chemotherapy in 10 of the 12 cases.[204] Although the optimal regimen has not been defined, the combination of ifosfamide and etoposide, a regimen highly active in the treatment of recurrent small round cell tumors of neural origin, produced partial or complete tumor regression in seven of the eight patients in a small series of patients with recurrent MPNSTs.[156] Treatment with the combination of ifosfamide and etoposide is now being explored in this tumor. For patients with advanced disease, the combinations of ifosfamide with Adriamycin and ifosfamide with etoposide are the most promising.

## MALIGNANT FIBROUS HISTIOCYTOMA

### Epidemiology, Biology, and Genetics

Although MFH was the most common histologic diagnosis in the NCI series of adult patients with extremity sarcomas (accounting for 25% of the series, or 53 of 211 patients), it is much less common in children.[6,65,206] In the St. Jude series in children, 5 (8%) of the 62 cases of NRSTS were diagnosed as MFH.[207] In the Societe Internationaled'Oncology Pediatrique (SIOP) mesenchymal malignancy trials (MMT84 and MMT89), MFH was the second most common NRSTS, accounting for 10% of the cases.[208] MFH rarely occurs in the neonatal period or during the first year of life.[209,210]

Cytogenetic analysis of short-term cultures has revealed chromosomal abnormalities in MFH ( Table 34-2).[211] It has been observed that tumors with 19p+ have a pronounced tendency to recur both locally and systemically.[211] Ring chromosomes have also been noted in MFH tumor cells.[212]

### Pathology

Stout[213] popularized the notion that many soft tissue sarcomas in adults were not simply fibrous lesions but rather possessed more than one tissue element (e.g., fat, fibrous tissue, tissue macrophages). This concept has been widely adopted, and the diagnosis of MFH is now more common than in the past. Not surprisingly, MFH is now also more commonly diagnosed in children as well.[214,215] The typical microscopic appearance resembles fibrosarcoma but is distinct therefrom by the absence of a herringbone pattern, the presence of marked cellular pleomorphism, the presence of multiple cell types (especially lipid-laden tumor cells), and an overall more malignant appearance (Fig. 34-4C). A storiform pattern of tumor cells (described as radiating fascicles of tumor cells at right angles to one another) is virtually diagnostic of the tumor.[216,217]

Two caveats regarding MFH in children must be noted. First, fibrosarcoma and even recurrent aggressive fibromatoses may develop the appearance of MFH on

recurrence.[167] Whether this represents bona fide MFH is unclear, but the association with an aggressive clinical course is clear. Second, angiomatoid MFH, the only common form of recognized MFH occurring as a primary tumor in young children (especially in those younger than 15 years), may not be true MFH after all. [218] Work on a large series of cases of angiomatoid MFH has documented numerous differences in phenotypic expression by immunocytochemistry, including the expression of myogenic markers.[218,219] This, combined with the distinctive histology (Fig. 34-4C) and unusually favorable prognosis, strongly suggests that this lesion is a unique soft tissue lesion in children and young adults and should be differentiated from the adult-type MFH. Grossly, this tumor is distinctly nodular. Although a prominent vascular pattern is often present within the central nodular region of these tumors, there is a disagreement as to whether this tumor can express myoid or vascular markers.[220,221] Overall, the tumor often appears myofibroblastic and benign. It is far less malignant in behavior as well. An estimated 1% of these tumors develops metastases, less than any other form of so-called MFH. Angiomatoid MFH still possesses metastatic potential in rare circumstances, however.

### Clinical Presentation

In a series of ten children with MFH aged 2 to 18 years, two tumors occurred on the trunk, three in the lower limbs, and one each in upper limb, scalp, and kidney [220]; two additional cases occurred near the orbit in a field irradiated for retinoblastoma. [220] MFH is one of the most common radiation-induced sarcomas, and this may provide a clue to its pathogenesis.[34] The most common site of metastasis is the lung, although metastases to the brain and other sites are also seen. As previously noted, the pulmonary metastases and local recurrences of infantile fibrosarcoma have been reported in some cases to have the pathologic pattern of MFH. [167]

### Principles and Recommendations for Treatment

Because of the rarity of this tumor in childhood, the approach to treatment of MFH is based primarily on the experience with adults. In a recent series of 107 adult patients with MFH, the 3-year survival rate was 72%. Patients with tumors located in the extremities had a better 3-year survival rate than those with tumors of the trunk or head and neck (81% vs. 54%, respectively).[221] The accepted initial management is wide local excision of the tumor. If the tumor arises in the extremity, limb-sparing operations with irradiation to the tumor bed have been as successful as amputations. The tumor must be small and appropriately placed to allow such an approach, however. Although some experience in adults suggests that adjuvant chemotherapy is of benefit, the role of adjuvant chemotherapy has not yet been established in children with this tumor.[61] In data from two small reports, wide local excision was associated with long-term survival in all 14 patients. [220,221] and [222] Onlya minority received chemotherapy. Thus, the role of extirpative surgery is the accepted approach to MFH in children; however, the role of adjuvant chemotherapy is not established.

MFH is a chemoresponsive tumor. In an adult series, 31% of the 38 patients evaluated responded to preoperative chemotherapy and radiotherapy. Chemotherapy with vincristine, dactinomycin, and cyclophosphamide with or without doxorubicin has produced objective tumor regressions in children with advanced disease; however, the optimal chemotherapy regimen for children with advanced disease has not yet been determined. [223,224,225,226,227] and [228] Four of five children treated by Raney and coworkers with group III or IV disease had complete (three patients) or partial (one patient) tumor regressions, and two remained disease-free at 4.6 and 5.4 years, respectively.[223] Responses to the combination of ifosfamide and etoposide have also been seen. [156] As with other children with advanced NRSTS, the combination of ifosfamide and Adriamycin is promising and requires evaluation in children.

The approach to treatment of angiomatoid MFH is different from that for classic adult-type MFH. Because the risk of metastasis is very low, adjuvant chemotherapy is not indicated. This tumor does occasionally metastasize, however. A recent report of a single patient with metastatic disease suggests that this lesion may be chemoresponsive, as well.[228]

## SYNOVIAL SARCOMA

### Epidemiology, Biology, and Genetics

Synovial sarcoma is one of the most common soft tissue tumors in adults.[64] In the AFIP series of 345 cases, the median age was 26.5 years; 72% of patients were younger than 40 years.[229] In adolescents and young adults, synovial sarcoma is the most common NRSTS.[6,229] In a series of 154 patients with NRSTS, synovial sarcoma accounted for 23% of the cases seen at St. Jude Hospital over a 29-year period.[230] In a POG prospective trial of adjuvant chemotherapy, synovial sarcoma accounted for 26% of the cases,[61] and in the SIOP mesenchymal malignancy trials (MMT84 and MMT89), synovial sarcoma accounted for 17% of the tumors.[207,208]

Synovial sarcoma is characterized cytogenetically by the translocation t(X;18)(q11;Xp11), which results in the fusion of the *SYT* gene located on chromosome 18q11 and one of three closely related genes *SSX1*, *SSX2*, or *SSX4* located on the Xp11 breakpoint.[14,15] and [16,231,232] The fusion of these genes creates a chimeric fusion transcript *SYT-SSX,* which results in an altered transcription pattern through SSX-mediated binding sites. The SYT-SSX1 and SYT-SSX2 transcripts can readily be detected using reverse transcriptase-polymerase chain reaction. In one study, the SYT-SSX1 transcript was detected in 42 of 77 cases (54%) of synovial sarcoma and the SYT/SSX2 in the remaining cases.[14,16] Biphasic synovial sarcomas are almost exclusively associated with SYT/SSX1 transcript. For patients with localized disease, the SYT/SSX2 predicted improved overall metastases-free survival and survival. [233] A strong association between SYT-SSX1 fusion transcript and a high (greater than 10%) Ki-67 index was noted in one series.[16]

### Pathology

This peculiar soft tissue sarcoma of older children and young adults is unique for its propensity to differentiate into two distinct elements: a spindle cell fibrous stroma virtually indistinguishable from fibrosarcoma and a distinct glandular component with absolute epithelial differentiation (Fig. 34-4D). No other sarcoma in children does this, with the exception of rare nerve sheath tumors also containing glands. Epithelial differentiation can also be encountered in epithelioid sarcoma, a superficial soft tissue sarcoma with a granulomatous appearance.[234] Mesothelioma is typically recognized for a similar biphasic appearance, but it is rarely seen in children. [235]

The usual tumor is biphasic; it is this unique characteristic that sets it apart from other soft tissue sarcomas, especially fibrosarcoma. The absence of the glandular epithelial component renders the diagnosis extremely difficult unless immunocytochemistry with keratin antibodies is used. In that case, the spindle cells in synovial sarcoma are positive, unlike those in fibrosarcoma or any other soft tissue sarcoma except epithelioid sarcoma. [236] As noted above, the characteristic cytogenetic abnormality t(X;18) is present in the vast majority of both tumors, biphasic and monophasic. [15,16,231,232] and [233,237]

It is important to compare the histology of the monophasic or poorly differentiated variants of synovial sarcoma to fibrosarcoma, as this is a common differential diagnostic dilemma. Histologically, there may be great similarity on superficial inspection between the two; however, common features of synovial sarcoma such as “staghorn” vascularity, compared to the interlacing bundles of tumor cells giving a “herringbone” pattern in fibrosarcoma, are helpful diagnostically. Certainly, any evidence of divergent cellular differentiation strongly suggests that the tumor is more than a fibrosarcoma and warrants serious consideration of synovial sarcoma. Ultimately, the distinction is far more reliably made using immunohistochemistry. The presence of keratins and epithelial membrane antigen in clusters, or even single cells, within the tumor virtually excludes fibrosarcoma.[238,239,240,241] and [242] The most reliable method of diagnosing monophasic synovial sarcoma is the use of cytogenetics as described above.[243]

### Clinical Presentation

The median age in most series of patients is in the third decade of life, with approximately 31% of cases occurring in patients younger than 20 years, with a median age of 13 years in one large series.[244,245,246,247,248,249] and [250] The male to female ratio is usually approximately 1.2:1.0 in most large series, suggesting a slight difference in incidence related to gender. The most common anatomic location in which the tumor arises is the lower extremity, often in the region of the thigh and knee. Seventy-four percent of the tumors presented in the lower extremity in one report and 60% in another. [244] The next most common site is the upper extremity. Approximately 15% to 20% occur on the head, neck, and trunk.[244,245,246,247,248,249] and [250] CTand MRI scans usually reveal a particular heterogeneous septate mass with calcification.[251,252] As with most NRSTSs, the most common site of metastatic disease is the lung, which comprised 94% of the sites of metastases in the AFIP series.[229] Unlike most other NRSTSs, synovial sarcoma more frequently spreads to regional lymph nodes. This occurred in 21% of the patients with metastases in the AFIP series; only 2 of 37 pediatric cases had lymphatic metastases, however.[229]

### Principles and Recommendations for Treatment

The factors reported to be of adverse prognostic significance are the presence of metastases, large tumor size (diameter greater than 5 cm), tumor invasiveness, grade 3 histology, older age, tumor with poor histologic differentiation, and bone or neurovascular invasion. [249,250,253,254] and [255] The disease-free survival for adult patients with localized tumors of the extremity has been reported to be approximately 70% in a prospectively treated group. [64,65] Eighty percent of the patients treated at St. Jude over a 30-year period with group I or II disease were alive at 5 years, compared with only 17% of the patients with group III or IV disease. [253] Of 16 children with synovial sarcoma treated on the SIOP MMT84 trial, 68% were alive and disease-free in long-term follow-up. [206] For 26 patients enrolled in the Cooperative Soft Tissue Sarcoma Study of the German Society of Pediatric Oncology, the 5-year event-free survival estimate was 72% when a multimodality treatment approach that incorporated ifosfamide, doxorubicin, and irradiation was used. [256] These results are similar to those reported by the same group on a previous trial in which 31 patients with synovial sarcoma had an overall event-free survival rate of 74% at 5 years using multi-agent chemotherapy and irradiation after initial tumor excision or biopsy.[244]

Because this tumor is relatively rare in children, the guidelines for its optimal treatment have not yet been established. Wide local excision is the treatment of choice to control the primary tumor. Analysis of the adult series suggests that limb-sparing procedures with limited surgical margins followed by RT to the tumor bed produce an overall outcome that is similar to the outcome of patients treated with amputation. [64] Because most children are growing rapidly, the optimal approach to these tumors in young patients is usually surgery alone, to avoid the effects of ionizing irradiation of growing bones and soft tissues. RT is often required to control microscopic disease, however. The effectiveness of irradiation in the permanent control of large-bulk disease has not been established.

Although synovial sarcoma is a chemoresponsive tumor, the role of adjuvant chemotherapy has not been established. Although the results of a subsequent German study using multi-agent chemotherapy and irradiation appear superior to those in the earlier German experience using radical surgery alone, data from a randomized trial have not confirmed this apparent benefit. [257] Tumor regressionsin patients with advanced disease have been documented with a number of chemotherapy regimens.[258,259,260] and [261] Furthermore, synovial sarcoma is among the most chemosensitive NRSTSs and often responds to ifosfamide- or doxorubicin-based regimens.[145,261,262,263,264,265] and [266] Of 14 patients with nonmetastatic synovial sarcoma treated with preoperative chemotherapy consisting of high-dose cisplatin and doxorubicin or high-dose ifosfamide (14 g per $m^2$) plus cisplatin and doxorubicin, 13 of 14 patients remained disease-free at a median follow-up of 37 months (range, 6 to 85 months).[267] Objective tumor regressions have also been seen with the combination conventional regimen of ifosfamide and etoposide. [156] Because the lungs are often the only site of metastatic disease, aggressive resection of pulmonary lesions has been of benefit. [64,268] The role of adjuvant RT in completely resected lung lesions remains controversial.

## HEMANGIOPERICYTOMA

### Epidemiology, Biology, and Genetics

Hemangiopericytoma is rare in children and accounts for approximately 3% of all soft tissue sarcomas in this age group. [6,7,8] and [9,160] In the St. Jude series of NRSTS, only 5 of the 62 patients had hemangiopericytoma.[6] Cytogenetic abnormalities have been found in some hemangiopericytomas. The simple translocations t(12;19)(q13;q13.3) and t(13;22)(q22;q11) have been noted, as have complex, multiple chromosomal abnormalities. [269,270] These tumors occur most commonly in infants and typically arise in the subcutis and oral cavity. Although these tumors often exhibit histologic features (e.g., increased mitotic activity and necrosis) that would indicate a poor prognosis in adults, the prognosis for infants with this tumor is usually excellent. [271,272] and [273] Aggressive metastatic and multifocal lesions do occur in infants, however. Hemangiopericytomas in older children are usually more aggressive and carry a higher incidence of metastatic disease. [272,273]

### Pathology

This soft tissue neoplasm, also first described by Stout, [213] can be benign or malignant. It was thought to be derived from vascular pericytes, the first layer of support cells adjacent to endothelial cells in normal vessels, but biologic evidence of this origin in most cases has not been forthcoming. A more likely explanation is that individual cells of this mesenchymally derived neoplasm may occasionally exhibit pericytic differentiation. Whether such differentiation is unique to this tumor remains to be seen, especially because hemangiopericytic pattern may be observed in many spindle cell tumors.

The ultrastructural appearance of these tumors occasionally supports pericytic differentiation. [274] Such cells can be detected in putative cases of hemangiopericytoma (Fig. 34-4E); however, this is the exception, not the rule. Rather, it is the tissue pattern of a uniform tumor with a staghorn vascular pattern and reticulin positivity around each tumor cell that characterizes the diagnosis. Whether these tumors are truly pericytic is open to question.

### Clinical Presentation

The most common primary site of disease is an extremity, especially the lower extremity. The retroperitoneum is the second most common site of disease, followed by the head and neck region and then the trunk. In infants, these tumors frequently arise in the tongue and sublingual region. The most common sites of secondary disease are the lungs and bone. Patients with hemangiopericytoma may present with hypoglycemia or hypophosphatemic rickets that resolve with removal of the tumor.[49,50]

### Principles and Recommendations for Treatment

The behavior of hemangiopericytoma in older children is similar to that in adult patients. [275,276,277] and [278] The overall 5-year survival rate in most adult series varies from 30% to 70%.[275,276,277] and [278] The most widely accepted therapeutic approach is wide local excision. [275,276] and [277] As with other soft tissue sarcomas, RT is used if complete surgical removal of the tumor cannot be accomplished.[64] Local control has been achieved in this fashion with both microscopic and macroscopic disease remaining after surgery.[279] Three reports have documented the benefit of radiation in local control of these tumors even if there is gross residual disease remaining after chemotherapy.[280,281] and [282] In one small series, all four patients initially treated with surgery and postoperative RT remained alive with no evidence of disease even though three had gross residual disease at the time of irradiation. [283] The role of adjuvant chemotherapy has not been established; however, the high incidence of metastatic disease and the relative chemoresponsiveness of this tumor have led many investigators to treat these patients with adjuvant chemotherapy after extirpation of the primary tumor. Responses to chemotherapy with advanced disease have been reported with the use of vincristine, cyclophosphamide, doxorubicin, dactinomycin, methotrexate, mitoxantrone, and other alkylating agents.[47,284]

Hemangiopericytoma in infants, although similar in histologic appearance to the adult form, usually follows a more benign course. [45] The treatment of choice for infantile hemangiopericytoma is surgery alone if the tumor is localized.

## ALVEOLAR SOFT PART SARCOMA

### Epidemiology, Biology, and Genetics

Alveolar soft part sarcoma (ASPS) is a rare sarcoma that usually arises in persons aged between 15 and 35 years. [285,286] and [287] In most adult series, it accounts for less than 1% of the cases.[64,288] Although 6 of the 62 patients in the St. Jude series had ASPS,[6] the actual incidence in children and adolescents is probably lower. [7,8] and [9] In the SIOP mesenchymal malignancy trials, 5 of 122 children had ASPS.[207]

The prognosis of this tumor is related to the presence of metastases, the extent of local disease, and the location of the tumor. Primary sites common in children, the orbit and the head and neck, are associated with a more favorable outcome compared with ASPS in adults. Chromosomal analysis of several cases has shown an abnormality at 17q25; the ASPL-TFE3 gene fusion has recently been cloned. [289,290]

### Pathology

ASPS is of uncertain histogenesis.[291] By far the most distinctive feature of this sarcoma is the presence of periodic acid–Schiff–positive, diastase-resistant inclusions in the cytoplasm by light microscopy (Fig. 34-4F). By electron microscopy, they show a regular crystalline structure (Fig. 34-4F, inset). Their biochemical nature is

unknown, although adenosine triphosphatase has been found in the tumors by some, suggesting myogenic differentiation. [292] No biologically active secretory product has been detected in a tumor or patient. The finding that some inclusions closely resemble neurosecretory granules has provoked suspicion that the tumor may be neuroepithelial, although other researchers have found seemingly identical inclusions in muscle. [292,293] Immunocytochemical data have overwhelmingly supported a myogenic phenotype for this tumor despite the lack of any known normal tissue counterpart. [294,295,296,297,298,299,300,301 and 302] Nonetheless, in light of its unusual clinical behavior, this tumor should not be grouped with alveolar rhabdomyosarcoma clinically or therapeutically.

### Clinical Presentation

ASPS usually presents as a slow-growing, asymptomatic mass. The tumor usually occurs in the skeletal muscle of the extremities [285,286,287 and 288]; however, in children, the head and neck region is a common site. The most frequent sites of occurrences in the head and neck are orbit and tongue. [303] The clinical course of ASPS is often indolent. Despite the fact that more than 80% of children and young adults with ASPS are alive 2 years after diagnosis, most patients die of this disease, sometimes as long as 20 years after the diagnosis is made. [304,305] The most common metastatic site is the lung, followed by brain, bone, and lymph node. [304,305]

### Principles and Recommendations for Treatment

Because of the indolent clinical course, the initial therapeutic approach is usually complete local excision alone, with irradiation and chemotherapy reserved for treatment of recurrent disease. [305,306 and 307] With this standard approach, however, most patients eventually relapse and subsequently die of disease. This ominous fact strongly suggests that new approaches to the prevention of relapses are needed to treat this disorder. Younger patients may have a better prognosis; however, younger age is associated with more favorable primary sites. Improved disease-free intervals exist for orbital ASPS compared to nonorbital ASPS, and for head and neck ASPS compared to extremity ASPS. Aggressive attempts to surgically remove metastatic disease should be made in light of the indolent course. This may be especially true for brain metastases. [308] RT may be beneficial for patients when complete extirpation of the tumor is not achievable. All 12 patients with metastatic disease in one series had meaningful palliation of extraskeletal disease with radiotherapy; six patients without metastatic disease but with large local tumors had prolonged local control with RT. [309] Responses to chemotherapy have been reported, primarily with anthracycline-based regimens. In a more recent report of the St. Jude series, 9 of 11 patients survived long term even though chemotherapy did not produce responses. [309a]

## LEIOMYOSARCOMA

### Epidemiology, Biology, and Genetics

Although leiomyosarcomas account for approximately 7% of all soft tissue sarcomas in adults, this tumor is rare in childhood, accounting for fewer than 2% of cases. [310,311 and 312] Only three leiomyosarcomas were reported in a large series of 135 soft tissue tumors in infants and children from the Mayo Clinic. [313]

The role of irradiation as a predisposing factor for leiomyosarcoma is disputed; however, the occurrence of leiomyosarcoma in skin, subcutaneous tissue, and other soft tissues after irradiation has been reported. [314,315,316,317,318 and 319] They are much less common as secondary tumors than MFH, fibrosarcoma, or osteosarcoma. Leiomyosarcomas have also been reported in individuals with bilateral retinoblastoma, [314,315] occurring both within and outside the radiation field. This suggests that the genetic abnormality at the RB1 locus may be important in the pathogenesis in this tumor. Adding more evidence to support this hypothesis is a recent report that mutations at the RB1 locus occur in some sporadic leiomyosarcomas. [320]

Although smooth muscle tumors have been rare in children, the appearance of HIV infection in adult and pediatric populations has altered the normal incidence of both smooth muscle and vascular tumors in both age groups in some populations. [35,36 and 37] Previously unreported tumors with such differentiation are increasingly being reported, sometimes multifocal and with varying phenotypes, including apparently benign and malignant smooth muscle tumors. Of interest is the report of EBV linked to leiomyomas and leiomyosarcomas in children with acquired immunodeficiency syndrome. [37] This is the first example of EBV associated with a soft tissue sarcoma, although it is well known to be associated with Hodgkin's disease and lymphoproliferative syndromes. There are now 12 such cases of leiomyosarcoma in patients who are HIV-positive. EBV genomes have been identified in the leiomyoma and leiomyosarcoma cells of HIV-infected patients. These tumors have also been reported after treatment for acute lymphocytic leukemia [38] and during immunosuppression to prevent renal allograft rejection. [39] In addition, leiomyosarcomas have been reported in patients with Hodgkin's disease in irradiated fields and in the urinary bladder after cyclophosphamide treatment. [321] These reports raise the question of whether the immune defect associated with the underlying disease somehow interacts with the therapy to predispose the tissue to development of this tumor. A t(12;14) translocation has been reported in a leiomyosarcoma arising in a child. The same translocation has been found in leiomyosarcomas arising in adults and in uterine leiomyosarcomas. This suggests that genes arising near the breakpoint of t(12;14)(q 14-15;q23-24) are probably important in the pathogenesis of benign and malignant smooth muscle tumors. [322,323] Other authors have suggested three patterns of cytogenetic abnormalities: (a) hypodiploid; (b) pseudodiploid, associated with reciprocal translocations; and (c) heterogeneous karyotypic findings. [324]

### Pathology

Leiomyosarcoma is normally an exceedingly uncommon soft tissue sarcoma in children but has been documented in one large series only recently. [325,326] Most smooth muscle–appearing tumors are in fact variants of embryonal rhabdomyosarcoma (type A, or leiomyomatous rhabdomyosarcoma) and carry an excellent prognosis. [327] Nonetheless, occasional tumors with bona fide smooth muscle differentiation, indistinguishable from the adult counterpart, are encountered. The tumor cells are elongated, with cigar-shaped nuclei and brightly eosinophilic cytoplasm (because of the content of myofilaments); they are closely packed in parallel arrays ( Fig. 34-4G). The appearance is superficially similar to fibrosarcoma, but the eosinophilic cytoplasm, the nuclei resembling smooth muscle in normal tissues, and the usual monotonous regularity of tumor cells are clearly distinct therefrom. Rarely, tumors with combined phenotypic characteristics, such as adipocyte and smooth muscle differentiation, have been reported. [328]

### Clinical Presentation

The most common primary sites in adults are the retroperitoneum, peripheral soft tissue, and gastrointestinal tract. [310,311,312 and 313,329,330 and 331] Otherless common sites are vascular sites and the subcutaneous region. In contrast, the most common primary site in children is the gastrointestinal tract, especially the stomach. [329] Leiomyosarcoma arises less commonly in the retroperitoneum, in the peripheral soft tissue, and in the genitourinary tract. This tumor has also been reported to arise in the orbit, perineum, saphenous vein, bladder, cecum, colon, and ovary of children. It is clear that they may arise in almost any soft tissue or vascular structure. [332,333,334,335,336,337 and 338]

A particularly important clinical presentation to recognize is the gastric epithelioid leiomyosarcoma, which may be associated with extra-adrenal or adrenal paraganglioma and pulmonary chondroma: Carney's triad. [339,340] This syndrome may present with the full triad but commonly does not. It typically presents in younger individuals, more commonly young women, usually with symptoms related to the gastric tumor. [339,340] The patients must then be monitored closely for the occurrence of the other lesions. This gastric sarcoma may progress very slowly even with the presence of metastatic disease, unlike the conventional gastric leiomyosarcoma.

### Principles and Recommendations for Treatment

The most common approach to the treatment of these tumors has been wide local excision alone. [310,311 and 312,329,330 and 331] The roles of chemotherapy and RT in the treatment of leiomyosarcoma in children is not yet known. If complete extirpation of the tumor can be achieved, the prognosis is usually good for tumors arising outside the gastrointestinal tract; however, patients with tumors arising in the gastrointestinal site usually have a poor prognosis. [310,331,341] Leiomyosarcomas of the colorectal region in children, although extremely rare, appear to have a relatively good prognosis if the tumor can be completely excised. [330]

In children with advanced leiomyosarcoma, there is limited experience with chemotherapy. Responses have been seen with MAID, CYVADIC, and other combination chemotherapy regimens. [153,342,343] Adriamycin and DTIC appear to have the best activity against this disease. In contrast, ifosfamide with or without etoposide does not appear to have any significant activity against leiomyosarcoma. [156]

Epithelioid leiomyosarcoma of the stomach is a benign-acting lesion that must be differentiated from true leiomyosarcoma. Although this tumor may rarely

metastasize, it can almost always be cured with local excision. Long-term survival has been reported in the face of metastatic spread, further supporting the conclusion that this tumor has benign behavior. [344,345,346,347 and 348]

## LIPOSARCOMA

### Epidemiology, Biology, and Genetics

Liposarcoma is one of the most common soft tissue sarcomas in adults; it accounts for 5% to 18% of cases in most series. [64,349,350] Although it is primarily a disease of adults, with a peak age incidence of 40 to 60 years, this tumor may occur in children, most often in the early part of the second decade of life. [351,352 and 353] The tumor may rarely affect infants and young children, in whom its behavior is almost always benign if complete removal can be achieved. [351] As is the case with many of the sarcomas discussed in this chapter, recent laboratory studies have identified a recurrent genetic abnormality that is probably of both etiologic and diagnostic value. The consistent cytogenetic findings in myxoid liposarcoma of a t(12;16)(q13;p11) translocation strongly suggests that a gene in the region of 12q13 plays an important role in the pathogenesis of this tumor. [322,354,355,356 and 357] Specifically, fusion of a transcription factor (CHOP), essential for adipocytic differentiation to another gene (TLS or EWS), has been documented in myxoid liposarcoma. [17,18 and 19] This observation has been extended to round cell liposarcoma as well. [358] No such recurring molecular genetic abnormality has yet been described in the other two major forms of liposarcoma (i.e., well differentiated and pleomorphic), nor has the incidence of this abnormality within round cell and myxoid liposarcoma yet been documented. Lipomas also have structural changes in chromosome 12q13-q14, suggesting that the degree of abnormality at this locus may be related to the growth of lipogenic tumors. [322,355]

### Pathology

To many, liposarcoma is not a tumor of childhood. Most pathologists have been loath to diagnose malignancy in a soft tissue neoplasm with lipoblastic differentiation, preferring instead to diagnose lipoblastomatosis or lipoma. This prejudice is unwarranted in view of the documented examples of liposarcoma in children. [359,360,361 and 362] As in adults, the tumor may be well differentiated, myxoid, round cell, or pleomorphic, in increasing degrees of malignancy and with decreasing rates of survival. Myxoid liposarcoma is the most common histologic subtype in adults, accounting for 45% to 55% of all liposarcomas. [363] The myxoid subtype is also the most common in children: in one series, 13 of the 18 tumors were the myxoid subtype. [362] A typical liposarcoma myxoid type is illustrated in Figure 34-4H. Most tumor cells are fibroblastic; only rare cells show conspicuous lipoblastic differentiation. The distinction between liposarcoma and MFH can be difficult, but the presence of a myxoid stroma, conspicuous small blood vessels, and scant mitotic activity are all typical of liposarcoma, unlike MFH or even fibrosarcoma.

### Clinical Presentation

The two most common primary sites are the lower extremity and trunk. The most common lower extremity site is the thigh-knee region; the most common truncal site is the retroperitoneum. Although metastases are uncommon, the most frequent site is the lung in most series; however, a recent review of 60 adult patients with liposarcoma found that isolated extrapulmonary disease was the site of initial metastasis in 59% of patients with metastases. [364] This suggests that in comparison with other soft tissue sarcomas there is a higher tendency toward extrapulmonary sites. [364] In addition, these investigators observed that these patients in this small series had a longer disease-free interval compared with other patients with pulmonary disease.

### Principles and Recommendations for Treatment

Because these tumors rarely metastasize but can be locally invasive, the treatment of choice for localized liposarcoma is wide local excision alone. [351,352 and 353] For retroperitoneal tumors, this strategy may not be possible, however. Local recurrences may ultimately result in death of the patient by extension of the tumor into vital structures despite the absence of metastatic disease. A recent series of patients younger than 23 years demonstrated the importance of completely resecting this tumor. [362] Irradiation appears to be effective in the control of microscopic disease in adult series [64]; however, its role in the treatment of children has not yet been determined. Irradiation should be strongly considered for retroperitoneal liposarcomas in children.

The role of adjuvant chemotherapy in the treatment of liposarcomas of childhood has not yet been defined; nevertheless, the long-term prognosis for children with this rare tumor is very good with surgery alone as long as the tumor can be removed with adequate surgical margins. [351,352 and 353]

A small series of children with liposarcoma with microscopic residual disease treated with EBRT has been reported; two of three children remained disease-free at 2 and 11.8 years after diagnosis. [362] The effectiveness of irradiation and chemotherapy in the treatment of gross residual disease has also not yet been established, but there are reports of responsiveness to chemotherapy.

# OSTEOSARCOMA

MICHAEL P. LINK
MARK C. GEBHARDT
PAUL A. MEYERS

## INTRODUCTION

In the 1920s, a celebrated surgeon of international repute summarized a scientific meeting on bone sarcomas by acknowledging, “If you do not operate, they die; if you do operate, they die just the same. Gentlemen, this meeting should be concluded with prayers.”[1] One might have drawn a similarly disheartening conclusion from meetings on osteosarcoma conducted in the 1960s and early 1970s: Few therapeutic advances had occurred during the preceding half century, and the outlook for patients with osteosarcoma was indeed dismal. Despite aggressive surgery, more than 80% of children presenting without evidence of metastases developed tumor recurrences and died of their disease within 5 years of diagnosis.

In the last three decades, remarkable progress has been made in our understanding of the biology and etiology of osteosarcoma and in the treatment of affected patients. As a result of the development of effective adjuvant therapy and advances in surgical and diagnostic imaging techniques, the majority of patients who have limb primary tumors and present without metastases can now be cured. Advances in surgical techniques also have permitted improvements in the quality of life of survivors through the use of limb-sparing surgical procedures to control the primary tumor. Explosive advances in genetics and molecular biology have provided new insights into mechanisms of tumorigenesis and have suggested novel avenues of research.

## EPIDEMIOLOGY

Osteosarcoma is a primary malignant tumor of bone, deriving from primitive bone-forming mesenchyme and characterized by the production of osteoid tissue or immature bone by the malignant proliferating spindle cell stroma.[2,3] and [4] Although rare in childhood (metastatic lesions to the skeleton are more common), primary bone tumors are the sixth most common group of malignant neoplasms in children[5]; in adolescents[6] and young adults, they are the third most frequent neoplasms, exceeded in older children only by leukemias and lymphomas. Malignant bone tumors have been reported to occur in the United States at an annual rate of approximately 8.7 cases per million children and adolescents younger than 20 years. [5] Only one-half the bone tumors in childhood are malignant[6]; of these, osteosarcoma is the most frequent,[2,6,7] accounting for 35% of all primary sarcomas of bone and 56% of the malignant bone tumors in the first two decades of life. [6] (Ewing'ssarcoma, the second most frequent primary bone cancer, actually is more common than osteosarcoma in children younger than 10 years.) Each year in the United States, osteosarcoma is diagnosed in approximately 400 children and adolescents younger than 20 years. [5] Most series show boys to be affected more frequently, and the incidence in black children is higher than that in whites. [2,5,8,9]

The peak incidence of osteosarcoma occurs in the second decade of life during the adolescent growth spurt ( Fig. 35-1), a feature that suggests a relationship between rapid bone growth and the development of this malignancy. Several lines of evidence have been cited to support this relationship. First, patients with osteosarcoma are taller than their like-aged peers. [10] Similarly, the risk of developing osteosarcoma in breeds of large dogs (e.g., the Great Dane and the St. Bernard) has been reported to be nearly 185 times that for small breeds. [11] Second, osteosarcomas occur at an earlier age in girls than in boys, corresponding to the more advanced skeletal age and earlier adolescent growth spurt of girls, [12] whereas the increased risk for osteosarcoma among boys may result from the larger volume of bone formed during a longer growth period. Third, osteosarcoma has a predilection for the metaphyseal portions of the most rapidly growing bones in adolescents (the distal femur, proximal tibia, and proximal humerus), and tumors of the humerus tend to occur at a younger age than do tumors of the femur and tibia, corresponding to the earlier growth spurt of the humerus. [12] Thus, the tumor appears to occur most frequently at sites where the greatest increase in length and size of bone occurs. This has led to the speculation that bone tumors arise from an aberration of the normal process of bone growth in length and remodeling [12,13]; rapidly proliferating cells might be particularly susceptible to oncogenic agents, mitotic errors, or other events leading to neoplastic transformation. [10]

## ETIOLOGY AND GENETICS

The etiology of osteosarcoma is unknown. A viral etiology was suggested by evidence that bone sarcomas can be induced in select animals by viruses [14,15] or cell-free extracts of human osteosarcoma.[16] Support for an association of an infectious agent with osteosarcoma also derives from studies demonstrating anti-sarcoma-specific antibodies in patients and in close relatives of patients with sarcomas. [17,18] and [19] In addition, lymphocytes cytotoxic to osteosarcoma cells have been found in the peripheral blood of both patients with osteosarcoma and their parents. [20] However, no convincing data have emerged from the laboratory to demonstrate a causative

infectious agent, and such speculation has been discarded. Antecedent trauma often has been associated with the development of bone tumors, but little evidence exists to support a causal relationship. Rather, injury (particularly pathologic fracture) often brings the patient to medical attention, and radiographs reveal the underlying neoplasm.

The only environmental agent known to produce bone sarcomas in human beings is ionizing radiation. Radiation is implicated in approximately 3% of osteosarcomas,[8,9] although the incidence of postirradiation sarcoma is low in view of the extent to which therapeutic irradiation has been used. [2,21] An increased incidence is likely to be seen as more patients survive long enough after primary irradiation to develop this complication. Osteosarcomas resulting from therapeutic irradiation initially were seen after high orthovoltage radiation doses to bone (see Chapter 13).[22] More recently, osteosarcomas have been reported also as a complication of megavoltage irradiation,[23] although the incidence after megavoltage irradiation may be lower because absorbed bone doses are reduced considerably with this technique.[23,24] The interval between irradiation and the appearance of osteosarcoma has ranged from 4 to more than 40 years (median, 12 to 16 years), [2,25] and bone sarcoma has occurred after irradiation for both benign and malignant conditions. Noteworthy is that osteosarcomas have been associated also with the use of bone-seeking radioisotopes,[26] such as intravenous radium 224 for the treatment of ankylosing spondylitis and tuberculosis, [26,27] and the use of Thorotrast as a diagnostic radiocontrast agent.[28]

Treatment with alkylating agents also may be linked to the subsequent development of bone cancer independent of the administration of radiotherapy. The risk of subsequent bone cancer appears to rise with increasing drug exposure, and the administration of alkylating agent chemotherapy may potentiate the effect of radiation in the development of secondary osteosarcomas.[29] Treatment with anthracyclines appears to shorten the interval to the development of secondary bone sarcomas. [30]

Osteosarcoma has been reported in patients with Paget disease, and cases of osteosarcoma in patients older than 40 years are associated almost exclusively with this premalignant condition.[2] Approximately 2% of patients with Paget disease develop osteosarcoma, and the occurrence of osteosarcoma is not necessarily related to the extent of involvement of the skeleton by Paget disease.[2] Histologically, osteosarcomas in patients with Paget disease are indistinguishable from conventional osteosarcoma, although multiple bone involvement is frequent, [2] and the prognosis for such patients is poor. [9] Other benign bone lesions also are associated with an increased risk of the development of osteosarcoma. Lesions predisposed to such malignant degeneration include solitary or multiple osteochondroma, solitary enchondroma or enchondromatosis (Ollier disease), multiple hereditary exostoses, fibrous dysplasia, chronic osteomyelitis, sites of bone infarcts, and sites of metallic implants for benign conditions.[2,9,31,32]

Several families have been described in which multiple members have developed osteosarcoma,[2,33,34] suggesting that a genetic predisposition to this tumor exists. By far the strongest genetic predisposition to osteosarcoma is found in patients with hereditary retinoblastoma (see Chapter 28). The subsequent development of second nonocular tumors in patients who survive retinoblastoma has been reported in many case reports and series. The majority of second malignancies are sarcomas, and almost 50% are osteosarcomas.[35,36] The actuarial risk for the development of a secondary tumor among patients with hereditary retinoblastoma has been estimated to be between 8% and 90% at 30 years.[37,38,39 and 40] Although the occurrence of secondary osteosarcoma in survivors of retinoblastoma was initially thought to represent a complication of radiotherapy,[35] it is now apparent that a relationship between osteosarcoma and hereditary (bilateral) retinoblastoma exists that is independent of therapy, since the secondary cancers virtually always occur in patients with hereditary retinoblastoma with germ line deletion [37] (although the sporadic form of retinoblastoma is more common), occur in sites far distant from irradiated tissue (e.g., in the extremities), and occur in patients who did not receive irradiation as part of therapy for retinoblastoma. In hereditary retinoblastoma, osteosarcomas occur 2,000 times more frequently in the skull after radiotherapy and 500 times more frequently in the extremities than would be expected in the general population. [37,41] The available evidence suggests that retinoblastoma is one of several childhood tumors that arise as a result of recessive mutations[41,42 and 43]; several studies confirm that the specific locus involved in the generation of retinoblastoma (mapped to band q14 of chromosome 13 and termed the *RB susceptibility locus*) is implicated in the generation of osteosarcoma as well,[44,45,46,47 and 48] even in patients without a prior history of retinoblastoma. Tumor cells from some osteosarcomas and osteosarcoma cell lines (from patients without retinoblastoma) were found to demonstrate specific loss of constitutional heterozygosity for loci scattered on chromosome 13 [46,47 and 48] or to demonstrate complete chromosome 13 homozygosity,[44,47] although analysis of constitutional (nontumor) DNA from the same patients indicated heterozygosity at these same loci. Further studies have found deletions or rearrangements of the *RB* gene, absence of RNA transcripts corresponding to the retinoblastoma locus, [45] or altered expression of the *RB* gene product in osteosarcomas and osteosarcoma cell lines.[46] The RB protein is a 105-kd nuclear phosphoprotein, which binds to DNA and is phosphorylated by cyclin-dependent kinases during the S and $G_2$/M phases of the cell cycle, but its exact function remains to be determined. The experimental introduction (by retrovirus-mediated gene transfer) of a cloned *RB* gene into osteosarcoma cells that lack the *RB* gene product results in restoration of the expression of the RB protein in such tumor cells and a change in cell morphology, significant inhibition of tumor cell growth in culture, inhibition of the formation of tumor colonies on soft agar, and suppression of tumor formation in nude mice.[49] Apparently, a common mechanism for tumorigenesis in retinoblastoma and some osteosarcomas involves the unmasking of recessive mutations at a locus exerting pleiotropic tissue effects.[47] Thus, defects in both retinoblastoma alleles occurring in an appropriate *bone* cell may lead to osteosarcoma much in the same way that defects in both alleles of the *RB* gene in a retinoblast leads to the generation of retinoblastoma. [44] Rapidly proliferating regions of bone may be particularly susceptible to mitotic errors, which might result in homozygosity of a defective retinoblastoma allele and tumor formation. Recent studies indicate that the initial mutations of the *RB* gene in sporadic osteosarcomas occur predominantly in the paternal gene,[50] suggesting the involvement of germinal imprinting in producing the differential susceptibility of the two genes to mutation.

Many osteosarcomas and osteosarcoma cell lines apparently express normal-sized RB protein and have normal RB alleles, implying that for some osteosarcomas, alternative pathways of tumorigenesis exist independent of *RB* gene inactivation.[49] Further investigations have implicated a second recessive oncogene, p53, in the etiology or progression of osteosarcoma. The gene, which has been mapped to the chromosome region 17p13.1, encodes a 53-kd nuclear phosphoprotein that binds DNA and is believed to be involved in regulation of DNA replication and, thus, to be involved in control of the cell cycle. [51] The p53 gene product appears to be critical in maintaining the integrity of the genome. In normal cells, the presence of DNA damage results in accumulation of p53, which switches off replication to allow time for DNA repair. If repair of DNA damage is unsuccessful, p53 may trigger apoptosis, thus inducing cellular suicide. Cells with mutant or inactivated p53 cannot respond appropriately to DNA-damaging agents and accumulate mutations at an increased rate, leading to malignant transformation. [52]

Several lines of evidence implicate an important role for p53 in malignant transformation in osteosarcoma. First, the chromosome region 17p12-17p13.3 has shown frequent losses of heterozygosity in a variety of tumors, notably osteosarcoma,[53] and this region is a frequent locus of karyotypic change (particularly deletion of the short arm of chromosome 17) in osteosarcomas. Further, transgenic mice containing a highly expressed mutated p53 gene [54] and transgenic mice with both p53 alleles destroyed by an insertion mutation [55] have an increased incidence of many cancers, particularly osteosarcomas. Studies of osteosarcomas and osteosarcoma cell lines have demonstrated a substantial proportion that exhibit detectable alterations in p53, including homozygous deletions of the p53 locus, loss of heterozygosity at loci flanking p53, or failure of expression of p53 protein or expression of p53 proteins of aberrant size. [51,56,57,58 and 59] Mutations of the p53 gene are detectable in almost 25% of cases of osteosarcoma,[60] and such mutations prove to be fairly heterogeneous in their distribution in the gene and the type of genetic alteration that results. Inactivation of the p53 gene product appears to be important for the growth of many osteosarcomas, presumably as a result of loss of a growth regulator that normally constrains cellular proliferation. [51,57] Moreover, transfection of single copies of wild-type p53 are sufficient to suppress the neoplastic phenotype of human osteosarcoma cells lacking p53 expression and of cells expressing a mutated p53 allele. [61]

The p53 gene product normally interacts with other cellular proteins so that mutations in genes coding for proteins required for p53 functions may affect p53 activity indirectly and thus facilitate malignant transformation. A cellular phosphoprotein, MDM2—the product of the murine double minute 2 gene that binds to both wild-type and mutant forms of the p53 gene product—appears to be involved in transcriptional regulation and may regulate some aspects of p53 activity [62] or may functionally inactivate p53.[63] The human MDM2 gene has been localized to chromosome 12q13-14,[63] a region that has been found to be amplified in approximately 20% of osteosarcoma tumor specimens.[64] Preliminary results indicate that in tumors demonstrating MDM2 amplification, no mutations in p53 are found. Thus, high levels of MDM2 may inactivate the tumor suppressor activity of p53 by complexing with it through mechanisms analogous to those employed by viral oncoproteins, such as SV40 T antigen and adenovirus E1B.[52,63] Amplification of MDM2 production thus may have the same functional effect as mutations of the p53 gene. Notably, in one study, amplification of MDM2 was detected in metastatic and recurrent osteosarcomas but not in primary tumor specimens,[65] suggesting that the MDM2 gene product may be involved in tumor progression rather than primary tumorigenesis. Likely, other partners of p53 capable of binding p53 may be important in tumorigenesis as well.[52]

In addition to its appearance in retinoblastoma kindreds, osteosarcoma occurs also as part of another familial cancer syndrome in which affected families are afflicted with a spectrum of cancers, including carcinoma of the breast, soft tissue sarcomas, brain tumors, leukemia, adrenal cortical carcinoma, and osteosarcoma. [66,67] Affected members of such families with the so-called Li-Fraumeni syndrome have a projected risk of developing invasive cancer of 50% by age 30 and more than 90% by age 70.[68] The p53 gene has been found to play a pivotal role in the Li-Fraumeni syndrome, because affected kindreds have been found to inherit germline mutations of this gene.[68] Screening of large series of children with osteosarcoma reveals that approximately 3% to 4% carry constitutional germline mutations in p53.

The majority of these cases with germline p53 mutations occurred in patients with a strong family history of cancer, with family histories suggestive of the Li-Fraumeni syndrome, or in patients with multiple cancers.[69,70] Thus, osteosarcoma may appear as the initial or subsequent malignant neoplasm in cancer-prone individuals, although likely such patients represent only a small proportion of children with osteosarcoma.

Two recessive oncogenes—p53 and RB—thus have major roles in tumorigenesis in osteosarcoma. Both RB and p53 are involved in cell cycle regulation, and both pathways are inactivated in the majority of human cancers. Other genes almost certainly are involved in these processes. Analysis of DNA from primary tumors and corresponding normal cells from patients with osteosarcoma demonstrates a high frequency of allele loss at loci on chromosomes 3q and 18q (in addition to 13q and 17p, the known loci of RB and p53, respectively), suggesting that at least two additional tumor suppressor genes are involved in the development of osteosarcoma.[71,72] and [73]

## PATHOLOGY

The diagnosis of osteosarcoma is based on histopathologic criteria and correlation with a confirmatory radiologic appearance. The histologic diagnosis of osteosarcoma depends on the presence of a frankly malignant sarcomatous stroma associated with the production of tumor osteoid and bone ( Fig. 35-2). Great variability exists in the histologic patterns seen in this tumor and in the degree of osteoid production, so that extensive review of the pathologic material and, rarely, electron microscopy may be required to demonstrate tumor osteoid.

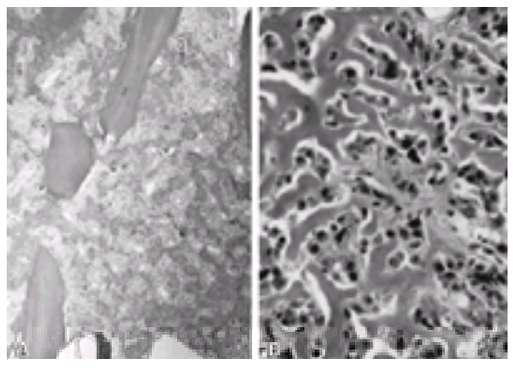

**FIGURE 35-2. A:** Photomicrograph of a field of an osteosarcoma demonstrating extensive osteoid formation intimately associated with a sarcomatous stroma (×100). **B:** High-power view demonstrating cellular atypia and other features of the malignant cellular stroma (×400).

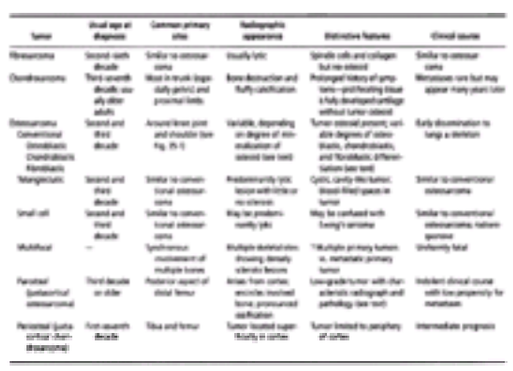
Because osteosarcomas are thought to arise from a mesenchymal stem cell capable of differentiating toward fibrous tissue, cartilage, or bone, [74] osteosarcoma shares many features with chondrosarcoma and fibrosarcoma, tumors of the same family (generically termed *osteogenicsarcomas*) with which osteosarcoma is easily confused (see Chapter 8 and Chapter 38).[4] However, chondrosarcomas and fibrosarcomas are distinguished from osteosarcoma by their lack of production of osteoid substance, the *sine qua non* for the diagnosis of osteosarcoma. Features that distinguish chondrosarcoma and fibrosarcoma from osteosarcoma are summarized in Table 35-1. A number of distinct clinicopathologic variants of osteosarcoma have been defined based on clinical, roentgenographic, and histologic features ( Table 35-1). The largest group of osteosarcomas are the conventional osteosarcomas ( Fig. 35-2, Fig. 35-3), the variants of which are seen predominantly in children and adolescents. In conventional osteosarcoma, the connective tissue stroma variably appears as a mixture of large, atypical, spindle-shaped cells that are cytologically highly malignant, with large irregular nuclei and abnormal mitotic figures. The stroma may be largely anaplastic. Large numbers of benign-appearing giant cells may be evident in up to 25% of cases. Interspersed in the pleomorphic stroma are areas of osteoid production and calcification intimately associated with the malignant cells.



| Tumor | Usual age at diagnosis | Common primary site | Radiographic appearance | Distinctive features | Clinical course |
|---|---|---|---|---|---|
| Fibrosarcoma | Second–sixth decade | Similar to osteosarcoma | Usually lytic | Spindle cells and collagen but no osteoid | Similar to osteosarcoma |
| Chondrosarcoma | Third–seventh decade; usually older adults | Most in trunk (especially pelvis) and proximal limbs | Bone destruction and fluffy calcification | Prolonged history of symptoms—and healthy tissue is fully developed cartilage without tumor osteoid | Metastases rare but may appear many years later |
| Osteosarcoma<br>Conventional (osteoblastic, chondroblastic, fibroblastic)<br>Telangiectatic | Second and third decade | Around knee joint and shoulder (see Fig. 35-1) | Variable, depending on degree of mineralization of osteoid (see text) | Tumor osteoid present; variable degrees of osteoblastic, chondroblastic, and fibroblastic differentiation (see text) | Early dissemination to lungs a skeleton |
| Telangiectatic | Second and third decade | Similar to conventional osteosarcoma | Predominantly lytic lesion with little or no sclerosis | Cystic, cavity-like tumor; blood-filled spaces in tumor | Similar to conventional osteosarcoma |
| Small cell | Second and third decade | Similar to conventional osteosarcoma | May be predominantly lytic | May be confused with Ewing's sarcoma | Similar to conventional osteosarcoma; radiosensitive |
| Multifocal | — | Synchronous involvement of multiple bones | Multiple skeletal sites showing densely sclerotic lesions | "Multiple primary tumors vs. metastatic primary tumor | Uniformly fatal |
| Parosteal (juxtacortical osteosarcoma) | Third decade or older | Posterior aspect of distal femur | Arises from cortex; encircles involved bone; pronounced ossification | Low-grade tumor with characteristic radiograph and pathology (see text) | Indolent clinical course with low propensity for metastasis |
| Periosteal (juxtacortical chondrosarcoma) | Fifth–seventh decade | Tibia and femur | Tumor located superficially in cortex | Tumor limited to periphery of cortex | Intermediate prognosis |

**TABLE 35-1. THE FAMILY OF OSTEOGENIC SARCOMAS**

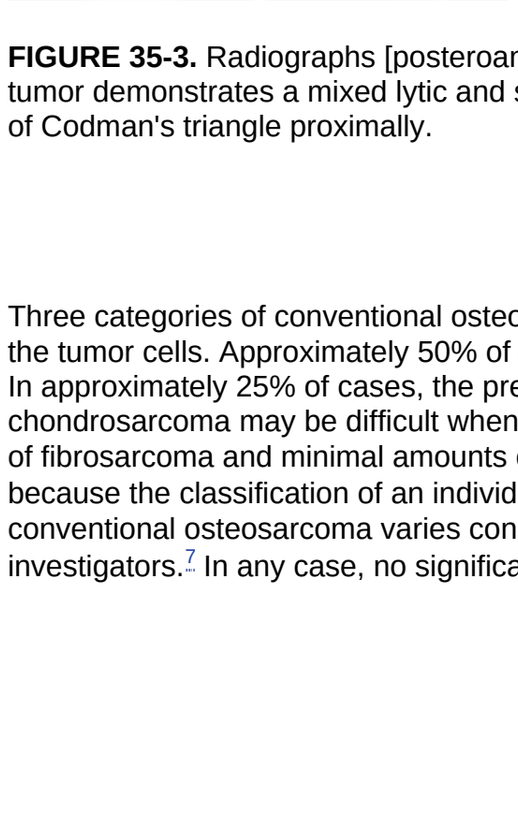


**FIGURE 35-3.** Radiographs [posteroanterior **(A)** and lateral **(B)** projections] of a conventional osteosarcoma involving the distal femur and extending up the shaft. The tumor demonstrates a mixed lytic and sclerotic appearance, a soft tissue mass with ossification apparent in the soft tissue, and periosteal reaction and the formation of Codman's triangle proximally.

Three categories of conventional osteosarcoma have been defined by Dahlin and Coventry [6,8] and Dahlin and Unni[9] on the basis of the predominant differentiation of the tumor cells. Approximately 50% of cases of osteosarcoma are characterized by abundant production of osteoid and are classified as osteoblastic osteosarcoma. In approximately 25% of cases, the predominant differentiation is toward cartilage (chondroblastic osteosarcoma), and distinguishing these tumors from pure chondrosarcoma may be difficult when osteoid production is minimal. The remaining cases demonstrate a spindle-cell stroma, with a herringbone pattern reminiscent of fibrosarcoma and minimal amounts of osteoid (fibroblastic osteosarcoma). The value of this subclassification of conventional osteosarcomas is not well established because the classification of an individual tumor is necessarily arbitrary and subject to errors of sampling. [9] The fact that the distribution of these subtypes of conventional osteosarcoma varies considerably in other series suggests that the criteria for distinguishing among these subtypes are not accepted by all investigators.[7] In any case, no significant differences in behavior or outcome can be determined among these subclasses. [8] Grading of osteosarcomas is difficult, but

the majority is judged to be high-grade.

Several variants of osteosarcoma that have been described appear to behave clinically like conventional osteosarcoma and should be treated as such. Telangiectatic osteosarcoma is an unusual variant (approximately 3% of all osteosarcomas) that characteristically appears as a purely lytic lesion on plain radiographs, with little calcification or bone formation.[2,6] The radiographic appearance is reminiscent of aneurysmal bone cyst[75] and giant-cell tumor, with which it often is confused. These tumors are grossly cystic and histologically demonstrate dilated spaces filled with blood and necrotic tissue, with viable tumor confined to the periphery of the lesion. Although sometimes reported to be associated with a particularly unfavorable outcome,[9,76] telangiectatic osteosarcoma is best approached as a conventional osteosarcoma, because recent results fail to demonstrate any difference in prognosis for patients with this histologic variant.[77,78 and 79] Small-cell osteosarcoma[80,81,82,83,84 and 85] is a variant that histologically is confused easily with Ewing's sarcoma. The production of malignant osteoid matrix distinguishes the tumor from Ewing's sarcoma, a critical distinction because the therapeutic approaches to the two tumors are quite different. Confusion with Ewing's sarcoma is particularly likely when tumor osteoid is not evident in the histologic sections from a small biopsy. In these cases, radiographic features—particularly the presence of tumor new bone—may reveal the true nature of the lesion and exclude the diagnosis of Ewing's sarcoma.[82] Immunocytochemical studies may be necessary to make the distinction, and recently described antibodies to the MIC2 gene product uniformly expressed by the cells of Ewing's sarcomas may be useful for this purpose.[86] Whether small-cell osteosarcoma is responsive to radiotherapy has been debated,[80,81] so that specific recommendations regarding the management of the primary tumor remain uncertain. The natural history of small-cell osteosarcoma has not been defined clearly, but little evidence suggests that this variant behaves differently from other varieties of conventional osteosarcoma.[80,81,82,83,84 and 85] An aggressive approach with systemic chemotherapy seems advised. The malignant fibrous histiocytoma (MFH) subtype of osteosarcoma[87] is distinguished from primary MFH of bone[9] on the basis of the finding of tumor osteoid and woven bone in the osseous component (but not the extraosseous component) of the tumor.[87] Although a rare variant of osteosarcoma, the MFH subtype accounts for one-third of osteosarcomas in patients older than 60.[88] Both the MFH variant of osteosarcoma and primary MFH of bone appear to behave clinically as high-grade sarcomas, and the distinction may be academic.[87]

Certain variants of osteosarcoma have been distinguished from conventional osteosarcoma because of their unique clinicopathologic features and characteristic clinical behavior. The most important of these clinicopathologic variants is the parosteal osteosarcoma (juxtacortical osteosarcoma), which constitutes fewer than 5% of all osteosarcomas.[4,9,89,90 and 91]The posterior aspect of the distal femur is the site most commonly involved, but other long bones may be affected. Clinically, these lesions occur in older patients with a relatively long history of symptoms (sometimes longer than 1 year). Parosteal osteosarcoma also presents a characteristic radiographic appearance (Fig. 35-4A,Fig. 35-4B); the tumor appears to arise from the cortex from a broad base without invasion of the medullary cavity, a finding that can be confirmed by computed tomography (CT) or magnetic resonance imaging (MRI), and the lesion encircles the involved bone. Intense ossification is typical and, histologically, these lesions appear to be low-grade. In contrast to classic osteosarcoma, parosteal osteosarcomas are clinically indolent and are characterized by local recurrence rather than by distant metastatic spread after inadequate surgical excision. The outcome in patients who undergo radical excision of the primary tumor usually is favorable.[4,9,89,90] A substantial proportion of parosteal osteosarcomas are found to have undergone dedifferentiation (i.e., a high-grade spindle-cell sarcoma coexists with a lower-grade, more typical parosteal sarcoma).[91] Dedifferentiation is seen more often at the time of a recurrence but is observed in more than 50% of cases at initial diagnosis.[91] Rarely, lesions appearing to be parosteal osteosarcomas have been encountered that are high-grade or appear to invade the medullary cavity. Medullary cavity invasion is more common in those tumors that exhibit dedifferentiation.[91] Although such features may not be anticipated from the clinical or plain radiographic features, medullary invasion sometimes is demonstrable by MRI or CT. Such lesions are much more ominous and behave aggressively, in the manner of classic high-grade osteosarcomas, with a high propensity for metastatic spread.

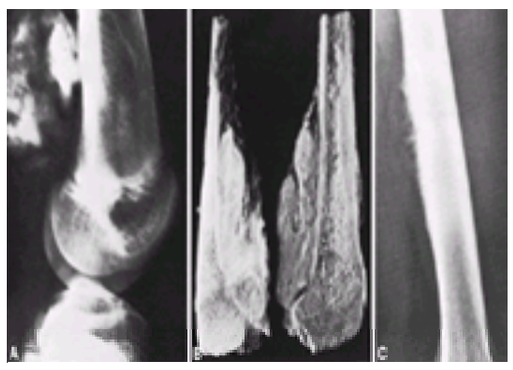

**FIGURE 35-4. A:** Radiograph of a typical parosteal osteosarcoma involving the posterior aspect of the distal femur. Intramedullary involvement is not evident. **B:** Sagittal section of gross specimen from a parosteal osteosarcoma (not the same case as in **A**). The bony mass is adherent to the underlying cortex and is situated entirely on the surface of the bone. **C:** Radiograph of a typical periosteal osteosarcoma. Tumor involving the midshaft of the femur is radiolucent, does not involve the marrow, and shows perpendicular spiculation. (Reproduced with permission from DC Dahlin, KK Unni. Osteosarcoma of bone and its important recognizable varieties. Am J Surg Pathol 1977;1:61–71.)

Another rare variant is the periosteal osteosarcoma[92,93] that, like parosteal osteosarcoma, arises on the surface of bone without involvement of the marrow cavity. The lesion occurs frequently in the second decade of life and has a propensity for involvement of the upper tibial metaphysis, appearing as an ill-defined radiolucent lesion on the surface (Fig. 35-4C). Histologically, the tumors are relatively high-grade, predominantly chondroblastic osteosarcomas and must be distinguished from periosteal chondrosarcoma, a lower-grade tumor that does not have tumor osteoid and follows a more indolent course. The prognosis for patients with periosteal osteosarcoma is worse than that for those with parosteal osteosarcoma; the tumors tend to recur locally unless radical resection is performed.[9,92,93] Lesions of the femur are more likely to recur, even after approaches that accomplish wide (but not radical) surgical margins.[93] Some authorities contend that periosteal osteosarcomas may, indeed, represent high-grade surface lesions presenting early in their clinical course.[2] This theory might explain the intermediate prognosis for patients with periosteal osteosarcomas and the higher rate of systemic spread observed. In this view, systemic chemotherapy (as for children with conventional high-grade osteosarcoma) is indicated for patients with periosteal osteosarcomas as well, but this area remains controversial because such lesions are rare. It should be noted that conventional high-grade osteosarcomas may develop on the surface of bone and may be confused with parosteal or periosteal osteosarcoma.[94,95] However, high-grade osteosarcoma of the surface of bone resembles conventional osteosarcoma histologically and in its clinical behavior. Low-grade intraosseous tumors also occur,[96] although they are rare. Intraosseous low-grade osteosarcomas are well-differentiated, with minimal cytologic atypia, and can be mistaken for benign conditions, particularly fibrous dysplasia. A tendency to local recurrence, especially after inadequate surgery, is the rule, and distant metastases are unusual.[9,96] Critical considerations are the grade of the lesion and its anatomic location. High-grade tumors require systemic chemotherapy, whether they arise in the conventional medullary location or on the surface of a bone. Low-grade lesions should be treated by wide surgical resection without adjuvant chemotherapy.

Several additional variants of osteosarcoma are distinguished from classic osteosarcoma because of differences in biologic behavior. Primary osteosarcoma of the jaw occurs most often in older patients, tends to demonstrate prominent chondroid differentiation, and is associated with a more indolent course, having a tendency to local recurrence rather than to distant metastases, especially if the tumors are low-grade.[97,98] A recent review of published series of osteosarcoma of the head and face suggests that osteosarcoma patients benefit from the addition of systemic chemotherapy.[99] By contrast, osteosarcoma occurring in patients with Paget disease is associated with a very aggressive clinical course and few survivors.[9] Histologically, however, the tumors are identical to conventional osteosarcoma, as are osteosarcomas occurring in irradiated bones. Extraosseous osteosarcoma is an uncommon variant that arises outside of bone and occurs most frequently in the soft tissues of the lower extremity in middle-aged adults.[100,101] Extraosseous osteosarcomas are seen (although not exclusively) as a late complication of radiotherapy. Local excision of these lesions is inadequate treatment because local recurrences and distant metastases invariably follow limited surgery.[100,101] Finally, multifocal osteosarcoma is a rare entity in which multiple synchronous skeletal tumors are present at diagnosis and in which each lesion resembles a primary tumor radiographically, suggesting a multicentric origin of the sarcoma. Not clear is whether such sarcomas arise in multiple sites or whether one of the lesions is the true primary tumor that has spread rapidly to other skeletal sites in the absence of lung metastases.[9,102,103] Interestingly, a study of four patients with multifocal osteosarcoma revealed germline mutations of the p53 gene in two cases.[104]

## CLINICAL PRESENTATION, NATURAL HISTORY, AND PATTERNS OF SPREAD

The majority of patients with osteosarcoma present with pain over the involved area, with or without an associated soft tissue mass. The average duration of symptoms is 3 months, although a history of 6 months or longer is not uncommon. Parosteal osteosarcomas, in particular, can be associated with painful symptoms of several years' duration, reflecting the relatively indolent behavior of this variant. Osteosarcoma characteristically involves the long tubular bones, especially adjacent to the knee joint. The distal femur and proximal tibia are the sites involved most frequently, followed in decreasing frequency by the proximal humerus and middle and proximal femur (Fig. 35-1).[2,6] Involvement of the flat bones of the axial skeleton, notably the pelvis, occurs in approximately 15% to 20% of cases but accounts for fewer than 10% of cases in the pediatric age group. Osteosarcoma of the jaw is a peculiar entity that accounts for fewer than 7% of all osteosarcomas and follows a more indolent course, as noted.

Approximately 15% to 20% of patients with osteosarcoma present with visible macrometastatic disease. The majority of these metastatic lesions are found in the lungs, although a small fraction of patients present with bone metastases with or without concomitant pulmonary metastases. Presentations with multiple bone metastases may reflect multifocal primary tumors (multifocal sclerosing osteosarcoma) and carry an extremely grave prognosis. [9,102,103]

Because osteosarcoma has been demonstrated to be relatively unresponsive to radiotherapy, surgical removal of the primary tumor is necessary for durable local control (as discussed in the section Treatment). Fortunately, the majority of patients with osteosarcoma present with primary tumors of the extremities, and local control can be achieved readily by amputation (see Chapter 12). In historical series (before 1970), the outlook for children with osteosarcoma was dismal, despite adequate surgical control of the primary tumor by amputation.[105,106,107,108 and 109] The overwhelming majority of patients presenting without evidence of metastases and treated only with surgery of the primary tumor ultimately developed distant metastases; 50% of patients developed metastases—virtually always in the lung—within 6 months of amputation and, overall, more than 80% ultimately developed recurrent disease. This discouraging natural history was documented at a number of centers and was summarized in a literature review in 1972.[109] Eleven studies conducted between 1946 and 1971 reporting data from 1,337 patients were reviewed. Of 1,286 patients with adequate follow-up treated with surgical ablation of the primary tumor (almost all amputations), only 253 patients (19.7%) survived 5 years. The 10-year survival dropped only slightly, to 16%, indicating that the majority of 5-year survivors were cured.

The appearance of metastatic disease was an ominous sign in historical series because few patients survived beyond 1 year after detection of tumor recurrence. The majority of patients developed multiple bilateral pulmonary metastases as the first evidence of recurrence, [4,110] and more than 95% of patients who died of metastatic disease had lung involvement at the time of death. Metastases to bones of the skeleton occur in 15% to 30% of patients. Less common sites of metastases occurring preterminally or discovered at autopsy include pleura, pericardium, kidney, adrenal gland, and brain. [108] Involvement of lymph nodes is unusual but is a poor prognostic sign. Death from metastatic disease results from pulmonary failure due to widespread lung metastases, pulmonary hemorrhage, pneumothorax, and superior vena cava obstruction.

Although variability in overall outcome of patients with osteosarcoma was noted in historical series, the expectation that fewer than 20% of patients would survive beyond 5 years (based on data from multiple centers) served as the background for trials of adjuvant chemotherapy conducted in the 1970s and 1980s. The inescapable conclusion from those historical studies was that 80% of patients presenting without overt metastatic disease in fact had microscopic subclinical metastases at the time of diagnosis that were undetectable by techniques then available.

By the late 1970s, the prognosis for children with osteosarcoma clearly was improving, an improvement largely attributed to the application of adjuvant therapies. However, data from the Mayo Clinic[111,112 and 113] suggested that the natural history of osteosarcoma had changed since the late 1960s and that the prognosis for patients had improved independently of the administration of adjuvant therapy. Data from other small studies, [114,115 and 116] particularly from a randomized controlled trial of adjuvant chemotherapy with single agent high-dose methotrexate conducted at the Mayo Clinic, [117] appeared to confirm this change in the natural history of osteosarcoma. Thus, at the beginning of the 1980s, the true natural history of osteosarcoma was controversial, and assessing the efficacy of adjuvant therapy was difficult. In the 1970s, trials of adjuvant chemotherapy for osteosarcoma were conducted without concurrent control groups, and benefits were inferred by comparison to historical controls and to the expectation that fewer than 20% of patients treated only with surgery would survive relapse-free. The controversy surrounding the apparent change in the natural history of osteosarcoma and its impact on the interpretation of adjuvant therapy trial results cast doubt on the apparent benefits of adjuvant chemotherapy demonstrated in numerous uncontrolled trials of the 1970s. [118,119 and 120]

Two trials conducted in the 1980s were designed to address the natural history of surgically treated osteosarcoma of the extremity. [121,122 and 123] The outcome of patients in these trials, who were treated only with surgery of the primary tumor, recapitulated the historical experience prior to 1970: More than one-half of these patients developed metastases within 6 months of diagnosis and, overall, more than 80% developed recurrent disease within 2 years of diagnosis. Thus, the natural history of osteosarcoma apparently has not changed over time, and fewer than 20% of patients treated only with surgery of the primary tumor can be expected to survive relapse-free. The bleak historical experience that had served as the background for numerous uncontrolled adjuvant trials of the 1970s appears to be an equally valid control for studies of the 1980s, 1990s, and beyond.

## CLINICAL EVALUATION AND DIAGNOSTIC STUDIES

The evaluation of suspected osteosarcoma begins with history recording, physical examination, and plain radiographs. The duration of symptoms is variable and may have prognostic significance (see the section Prognostic Factors). Pain in other bony sites may represent metastatic involvement, but metastases are most likely to occur in the lungs and do not produce respiratory symptoms in the absence of extensive lung involvement. Systemic symptoms, such as fever and weight loss, occur rarely in the absence of very advanced disease. [4,8] Physical examination typically is remarkable only for the soft tissue mass usually evident at the primary site; regional and distant lymph node metastases rarely are observed.

Laboratory evaluation seldom is revealing. Elevation of the serum alkaline phosphatase level is observed in more than 40% of patients but does not correlate reliably with disease extent,[4,124] although the serum alkaline phosphatase level may have prognostic significance (see the section Prognostic Factors). The serum lactate dehydrogenase (LDH) level may be elevated in approximately 30% of patients presenting without metastases. [122]

### Radiologic Evaluation

Radiographic examination of the involved bone is extremely useful in the evaluation of patients with a suspected malignant bone tumor (see Chapter 9). Plain films of malignant bone tumors usually reveal permeative destruction of the normal trabecular pattern, with indistinct margins and no endosteal bone response. Intense periosteal new bone formation and lifting of the cortex with formation of a Codman triangle are common (Fig. 35-3).[125] A soft tissue mass frequently is observed as the tumor erodes from the medullary cavity through the cortex and into the adjacent soft tissue. Characteristic radiographic features, along with clinical information and tumor location, permit prediction of the histologic diagnosis from the plain radiographs in more than two-thirds of cases of osteosarcoma. [125]

Osteosarcomas of the long bones invariably involve the metaphyseal portion of the bone; involvement of the diaphysis of the long bones occurs in fewer than 10% of the cases.[126] Thus, the eccentric location of the tumor in the metaphyseal portion of the long bone is characteristic of osteosarcoma, whereas Ewing's sarcoma (the most frequent consideration in the differential diagnosis) tends to occur in the flat bones or in the diaphyseal portions of the long bones of the skeleton and more frequently appears as a predominantly lytic lesion on plain radiographs. Ossification in the soft tissue in a radial or “sunburst” pattern is classic for osteosarcoma but is neither a reliable nor a specific feature. None of the radiographic features is pathognomonic, however, and biopsy always is required to confirm the diagnosis. Radiographically, osteosarcomas may appear to be osteosclerotic in approximately 45% of cases, purely osteolytic in 30%, and mixed sclerotic and lytic in the remaining 25%.[125] Such radiographic findings reflect the degree of ossification and mineralization rather than the amount of osteoid found in the tumor, because uncalcified osteoid substance produces no radiopacity even if present in large amounts. [9]

Although plain radiographs are extremely useful in evaluating malignant bone tumors, the extent of the primary lesion often is underestimated seriously by such studies. Further radiographic evaluation of the primary tumor thus is essential in planning the definitive surgery. Both CT and MRI contribute substantially to the accurate estimation of local tumor extent before surgery. MRI is particularly suitable for assessing bone tumors and has largely supplanted the CT scan for this purpose (Fig. 35-5).[127,128,129,130 and 131] Tumor extent as defined by MRI has been found to be an accurate estimate of tumor boundaries determined at the time of definitive surgery.[128] MRI has been particularly accurate in assessing the intraosseous extent of tumor and tumor extent with respect to muscle groups, subcutaneous fat, joints, and major neurovascular structures around the tumor.[131] Such information is critical in planning the level of amputation or for planning limb salvage resections. The use of gadolinium-diethylenetriamine penta-acetic acid (Gd-DTPA) as an agent for the purpose of enhancing the contrast of bone tumors on MRI presents some theoretic advantages, but preliminary data are disappointing, and Gd-DTPA enhancement does not contribute significantly to the assessment of tumor

extent.[131]

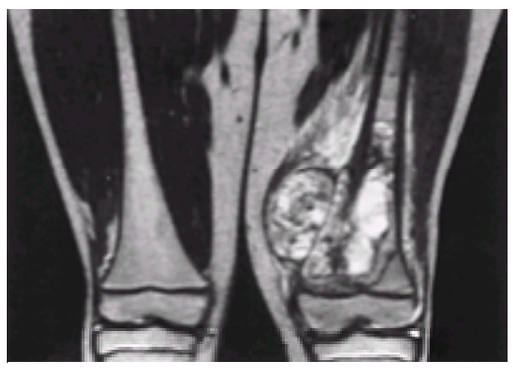

**FIGURE 35-5.** T2-weighted coronal magnetic resonance image through both distal femurs of the patient whose plain radiographs are shown in Figure 35-3 demonstrates the large distal femoral osteosarcoma with extensive soft tissue invasion. The proximal extent of tumor in the marrow cavity is clearly demonstrated.

The radionuclide bone scan also is indicated in the initial diagnostic evaluation to define the extent of the primary tumor. Because uptake of the radiopharmaceutical will extend slightly beyond the limits of tumor, it defines a safe margin to use in planning surgery of the primary lesion. [132,133] The sensitivity of radionuclide bone scanning is useful also in the detection of "skip lesions," which are seen infrequently in patients with osteosarcoma. [134] Increased uptake of a radiopharmaceutical in a site separate from the primary tumor but in the involved bone should alert the surgeon to the possible existence of skip lesions, information that should be considered in planning the surgical approach to the tumor.

In the past, arteriography was believed to be useful for evaluating the primary tumor for consideration of limb salvage procedures. However, with the advent of MRI, most investigators find that angiograms contribute little in determining local operability (see Chapter 9). Arteriograms performed in only the anteroposterior plane provide little definitive information on the relationship of the extramedullary tumor extent to the primary vascular structures. Arteriograms also provide poor visualization of veins, which may be a more significant surgical problem than arteries.

The presence of metastases at diagnosis is an extremely important prognostic variable with a major impact on management, so appropriate surveillance must precede the definitive approach to the primary tumor. The lung is the first site of metastasis in 90% of children with osteosarcoma, and routine posteroanterior and lateral radiographs of the chest allow detection of metastases in the majority of cases. Linear tomography and CT of the chest are more sensitive in detecting pulmonary metastases: In as many as 10% to 20% of patients, metastatic nodules found on linear tomography or CT of the chest are undetectable on conventional chest radiographs.[135] Because CT is more sensitive than linear tomography, especially for the detection of pleural-based lesions, [125,136,137 and 138] the CT scan probably is the choice for screening osteosarcoma patients for metastatic disease, although false-positive results have been a problem with this technique. If on CT scan a lesion cannot be defined unequivocally as metastatic disease, histologic confirmation is indicated, especially if the lesion does not appear on plain radiographs.

Because metastases to other bones of the skeleton are seen in approximately 10% of patients with osteosarcoma, a radionuclide bone scan also is indicated in screening for metastatic disease. Scanning with methylene diphosphonate labeled with technetium $^{99m}$TC has been found to be very sensitive for the detection of metastatic bony sites and, in the majority of cases, is more sensitive than are plain radiographs. [132,139]

**Follow-Up Studies**

With the increasing use of chemotherapy administered before definitive surgery to facilitate limb-sparing operations, radiographic evaluations have assumed increasing importance for early assessment of responsiveness of the primary tumor to chemotherapy and for predicting the histologic response (discussed in the sections Limb Salvage Surgery and Presurgical Chemotherapy). Several techniques have been proposed for this purpose, but none has been reported thus far to be sufficiently sensitive or reliable. Assessment by conventional radiographs, CT, and MRI show definite changes in response to presurgical chemotherapy, but the changes do not correlate reliably with histologic response, and the radiographic assessment is necessarily subjective and nonquantitative. [131] Investigators in the German Society for Pediatric Oncology (GPO) have used scintigraphic evaluation with $^{99m}$Tc–methylene diphosphonate parametric imaging of the tumor blood pool and labeled methylene diphosphonate plasma clearance by the tumor bone. Presurgical scintigraphic evaluation of tumor response to presurgical chemotherapy correlated highly with the degree of tumor regression as graded histologically after surgery. [140] Studies have indicated that response in the primary tumor measured by thallium 201 scintigraphy more reliably predicts the histologic tumor response. [141] Arteriography has been recommended by some investigators (particularly those who favor the administration of repeated courses of intra-arterial chemotherapy), because areas of tumor vascularity and tumor stain can be assessed repeatedly with each course of chemotherapy. However, results of angiography have not been fully reliable for distinction between responders and nonresponders. [142] Assessment by static MRI has been disappointing. However, dynamic MRI using bolus injections of Gd-DTPA may prove to be a promising technique for following responsiveness of primary tumors.[143] Positron emission spectroscopy would appear to be ideally suited, but the technique is not yet available at all centers.

Radiographic evaluations also are a critical component of the longer-term follow-up of patients treated with surgery and chemotherapy as surveillance for metastatic disease and local recurrence. Patients with osteosarcoma should be followed up frequently with radiographic studies for metastatic surveillance for at least 5 years from the completion of therapy. Because the overwhelming majority of first recurrences appear asymptomatically in the lungs, plain chest radiographs should be performed monthly for at least 2 years from diagnosis and with decreasing frequency thereafter. The importance of detecting metastases early cannot be overemphasized (see the section Treatment of Metastases). Thus, any abnormality detected on plain chest radiographs should be followed up diligently. CT of the chest is a useful adjunct to plain radiographs for this purpose and should be performed routinely every 4 to 6 months for the first 2 years from diagnosis and whenever a persistent suspicious abnormality appears on plain films. Radionuclide bone scans also should be obtained every 4 to 6 months for the first 2 years. Although bone metastases are likely to produce symptoms, occasional asymptomatic metastases in the skeleton may be detected by bone scan, and any abnormality should be confirmed by plain radiographs. Evaluation of the stump after amputation and of the affected limb after tumor resection can be difficult because of bone scan and radiographic abnormalities resulting from unequal weight bearing and callus formation. However, evaluation of the primary site should not be overlooked because of the possibility of local recurrence, especially after limb salvage procedures.

**Biopsy**

Although the radiographic findings in a patient with a suspected malignant bone tumor may be highly suggestive, a biopsy is always required to confirm the diagnosis. The timing of the biopsy in relation to the other diagnostic procedures has been debated; many investigators claim that interpretation of the bone scan and MRI (in terms of the extent of the primary tumor) may be unreliable if these investigations are undertaken after biopsy. [125,131,144] The tissue disturbance caused by the biopsy in most instances should be minimal, especially if a needle biopsy is performed, and should not have a major impact on information from radiographic studies. A major advantage of obtaining the imaging studies prior to the biopsy, however, is that the surgical approach to resection of the primary tumor can be considered, and the biopsy incision can be placed in a location that allows excision of the site en bloc with the tumor specimen. Because many biopsies in children are performed with general anesthesia, obtaining the chest CT scan prior to the biopsy reduces the likelihood that postoperative atelectasis will be confused with a pulmonary metastasis.

The biopsy should be performed or directed by an orthopedic surgeon familiar with the management of malignant bone tumors and experienced in the required techniques,[145] preferably by the surgeon who ultimately will perform the definitive surgical procedure. Fine-needle aspiration and core-needle biopsy have been recommended at a number of centers,[146,147,148,149 and 150] but most patients require open biopsy to be certain that a generous sample of adequate and representative tissue is obtained. Many pathologists are reluctant to render a definitive diagnosis when only small fragments of tissue are available. Moreover, if additional tumor tissue is obtained, it may be submitted for other biologic studies, some of which (e.g., DNA content, genetic studies, and MDR determination) may have important prognostic significance (see the section Prognostic Factors).[151,152,153,154,155,156,157 and 158] The surgeon should plan the biopsy carefully, with consideration of subsequent definitive surgery (or radiotherapy), because a poorly conceived and poorly placed biopsy may jeopardize the subsequent treatment, especially a limb salvage procedure.[159,160 and 161]

The incision should be made longitudinally in a fashion that disturbs as little of the normal anatomy as possible. Having both plain radiographs and the MRI available is helpful to determine the most direct route between the skin and the primary tumor. In general, the incision is made over the soft tissue mass. Making a surgical defect in the bone is not necessary if tissue can be obtained from the soft tissue mass. Avoiding a bone defect renders subsequent fracture less likely, and the least mineralized tissue is at the periphery of the tumor. A frozen section taken at the time of biopsy ensures that adequate tissue has been obtained for diagnosis. Several studies have indicated that the frequency of tumor seeding of biopsy sites is high, and so, even if it is a needle biopsy, the biopsy site must be excised en bloc with the tumor during the definitive surgical procedure. [162,163] Placement of the biopsy site with a view to the eventual definitive surgical procedure is essential (especially if limb salvage surgery is a consideration) to allow excision of the biopsy site in continuity with the definitive bony resection. Meticulous hemostasis after the biopsy also is essential. Placement of absorbable gelatin sponges or methyl methacrylate in the bone defect is useful to control bleeding, and efforts to control muscular vessels with external compression for 1 to 2 days may reduce the incidence of hematomas and subsequent wound infection in the biopsy site. [159,160,164] The use of a tourniquet is optional, whereas obtaining adequate hemostasis and using drains brought out near or through the incision prior to closure to prevent a large hematoma are important.

In the past, showering of tumor cells at the time of biopsy was believed to result from surgical manipulation and to account for the poor prognosis for patients with osteosarcoma. Reducing the dissemination of tumor cells was thought possible by performing the definitive surgical procedure at the same time as the initial biopsy. However, this strategy of biopsy and definitive surgery during one operation has become less popular for a number of reasons: Immediate definitive surgery after the biopsy does not lead to a superior outcome; the difficulties of making the histologic diagnosis from the frozen section alone are significant; psychological advantages accrue in preparing the patient for definitive surgery; the surgeon may benefit from a longer interval to plan the definitive surgery (particularly if a limb salvage is undertaken); and the administration of chemotherapy before definitive surgery for osteosarcoma has gained support. In most cases, the biopsy is performed to confirm the diagnosis, and definitive surgery of the primary tumor is undertaken at a later date, in a separate surgical procedure.

## Staging

Because of the unsuitability of standard staging systems when applied to skeletal tumors, Enneking et al. [165,166] at theUniversity of Florida established a staging system for malignant skeletal tumors based on a retrospective review of cases of primary malignant tumors of bone treated by primary surgical resection. This system categorizes nonmetastatic malignant bone tumors by grade—low-grade (stage I) or high-grade (stage II)—and further subdivides by the local anatomic extent: intracompartmental (A) or extracompartmental (B). The compartmental status is determined by whether the tumor extends through the cortex of the bone. Patients with distant metastases are categorized as stage III. The classification was designed primarily for determining surgical treatment and comparing results between institutions and surgeons. High-grade intramedullary lesions (i.e., stage IIA) are very rare, because most high-grade tumors (including osteosarcomas) break through the cortex into the extramedullary tissues early in their natural history and present as stage IIB lesions. The American Joint ommittee on Cancer has a similar staging system for bone tumors; it constitutes four instead of three stages, but stage III is undefined. It is similar to the tumor-node-metastasis (TNM) system used for other cancers but is essentially the same as the Musculoskeletal Tumor Society system. Neither staging system has been subjected to tests of validity. [167] Nevertheless, the Enneking staging system remains the only one that is widely accepted for skeletal tumors, and its use facilitates comparison of outcomes of different therapeutic regimens.

## Prognostic Factors

Several clinical characteristics are thought to be of prognostic significance for patients with osteosarcoma, independent of therapy. [168] Such factors may become less powerful prognostically as the outcome for patients with osteosarcoma continues to improve. The most important prognostic factor appears to be extent of disease at diagnosis, in that patients with overt metastatic disease have an unfavorable outcome. Although aggressive approaches to disease in patients presenting with metastases have improved their prognosis somewhat (discussed in the section Treatment of Metastases), the majority of such patients ultimately die of their disease.

Histology exerts an important influence on outcome. Parosteal and intraosseous well-differentiated osteosarcomas, in particular, are associated with a favorable prognosis, and periosteal osteosarcomas have an intermediate outlook. [89,90,91,92 and 93] Among the variants of conventional osteosarcoma, there appears to be no significant relation between histologic subtype (osteoblastic, fibroblastic, and chondroblastic) and overall survival. [8] Telangiectatic osteosarcomas have been associated with a particularly poor prognosis in some series, [9,76] but the behavior of this variant in the era of chemotherapy appears to be similar to that of other conventional osteosarcomas. [77,78 and 79]

Osteosarcomas arising in preexistent lesions or from radiation exposure behave clinically as de novo lesions, except those in patients with Paget disease, which are associated with an adverse prognosis. [9] Histologic grading likewise has not correlated reliably with outcome, in large part because most classic osteosarcomas are high-grade lesions. DNA content of tumor cells has been investigated in patients who had conventional osteosarcoma and received adjuvant chemotherapy, and it has been found to correlate significantly with outcome. [156] Patients with near-diploid tumor cell lines fare significantly better than do those with hyperdiploid tumor cell lines. Therefore, measurement of tumor DNA content may be extremely useful in identifying high- and low-risk cases.

The primary site of disease also is an important variable. A review of survival figures from several large series [169,170] suggests that patients with axial skeleton primary tumors have a poor prognosis. Because complete surgical excision with clean margins is a prerequisite for long-term disease control, tumors arising in certain axial skeleton sites (e.g., skull, vertebrae) are not amenable to curative surgery. Now, more innovative surgical strategies are used for tumors in some axial skeleton sites (particularly primary tumors in the pelvis), and tumors once considered unresectable can be approached with curative intent. Less intuitive is the association of tibial primary lesions with a more favorable prognosis in most, [122,169,171] but not all, [4] series. Tumors of the proximal humerus have been associated variably with a favorable or unfavorable prognosis. In general, more distal primary tumors have been associated with a more favorable prognosis.

Tumor size also has been cited as a powerful prognostic factor. In the prechemotherapy era, small tumors (less than 5 cm) were associated with a favorable prognosis and large tumors (greater than 15 cm) with a dismal prognosis. [4] This relation has not been confirmed in all series, and the effect of tumor size may result from a correlation of size and primary site. [170] In studies from the GPO, tumor involvement of more than one-third of the affected bone was associated with adverse outcome. [172] Data from an other study indicate that the local extent of tumor predicts outcome more reliably than does tumor size alone. [173] Among patients with clinical stage IIB lesions, those with tumors that penetrated the periosteum and invaded two or more structures adjacent to the bone were much more likely to suffer treatment failure than were patients with less extensive tumors. Intramedullary extent of tumor (as evaluated by CT scan) also correlates with the risk of subsequent development of metastatic disease. [174] Skip metastases, although rare, are an ominous sign: Almost all patients with skip metastases in one series had either local recurrence or distant metastases, [175] despite treatment with adjuvant chemotherapy. These data suggest that skip lesions from osteosarcoma are best considered to be metastatic lesions and to be associated with a poor outcome.

Duration of symptoms before treatment may be an indirect measure of tumor growth rate and has prognostic value. Patients with longer durations of symptoms have a superior outcome. [4] In addition, patients with long intervals between the onset of symptoms and diagnosis are likely to have an indolent variant of osteosarcoma (particularly parosteal osteosarcoma).

Additional patient characteristics reported to be of prognostic value include age (children younger than 10 years fare worse; patients older than 20 years have a more favorable outlook); gender (female patients have a more favorable outcome) [176,177]; and serum and tumor tissue alkaline phosphatase (elevated levels are associated with a greater risk of subsequent metastatic disease). [124,178] The level of serum LDH also has been found to be an important prognostic factor in patients treated with adjuvant chemotherapy. [122] In the Multi-Institutional Osteosarcoma Study, elevated serum LDH at diagnosis was found to be the most powerful, single, adverse prognostic factor for patients with nonmetastatic osteosarcoma of the extremity treated with adjuvant chemotherapy. In studies from the Memorial Sloan-Kettering Cancer Center, [171] a steady increase in risk of relapse or death was associated with increased serum LDH activity at diagnosis. These findings parallel results of studies of non-Hodgkin's lymphoma, in which serum LDH has been found to correlate with both tumor burden and prognosis. [179]

Recently, attention has been directed at molecular markers of prognosis. A study [180] of a small number of patients with osteosarcoma examined loss of heterozygosity (LOH) at the *RB* gene locus and found that patients whose tumors demonstrated no LOH at *RB* were less likely to present with metastatic disease and that all such patients were projected to survive without recurrence at 5 years. The prognosis for patients with LOH at *RB* was significantly worse, even if only patients without evidence of metastasis at diagnosis were considered. Expression of the human epidermal growth factor receptor 2 (HER2/erbB-2) has been shown to have prognostic significance in a number of human cancers. In patients with osteosarcoma, overexpression of HER2 has been associated with an inferior outcome. [181,182]

Response to preoperative chemotherapy is another powerful prognostic indicator [168,183,184 and 185]; however, tumor response is not known prospectively (i.e., before the institution of therapy). When an experienced pathologist carefully evaluates the resected specimen, the proportion of viable tumor cells surviving after presurgical chemotherapy can be determined. Several classification schemes have been developed but in general patients who demonstrate fewer than 2% residual viable tumor cells in the resection specimen have a prognosis better than those patients with higher proportions of viable tumor cells remaining. In theory, more aggressive therapy can be administered to those with a poor histologic response; however, to date no studies have demonstrated the efficacy of this approach.

Resistance to chemotherapy probably is responsible for poor outcome in some patients with osteosarcoma. The MDR1 gene encodes a glycoprotein that transgresses the cell membrane. Termed *p-glycoprotein*, this active pump mechanism actively excludes certain classes of drugs from the tumor cell and can be reversed by certain agents. Recent studies have shown that the overexpression of p-glycoprotein is associated with an unfavorable outcome in patients with osteosarcoma treated with multi-agent chemotherapy and is more predictive of event-free survival than is histologic assessment of the primary tumor after presurgical chemotherapy. [151,153] These results remain to be confirmed. Studies have been performed also to investigate mechanisms by which osteosarcoma may develop resistance to methotrexate. Osteosarcoma cells develop loss of the reduced folate carrier, and this loss is associated with a lower probability of favorable histologic response in the primary tumor after treatment with multi-agent chemotherapy, which includes high-dose methotrexate. [186]

## TREATMENT

### Surgical Management of the Primary Tumor

Because osteosarcoma usually is unresponsive to conventional-dose radiotherapy, management of the primary tumor in extremity lesions is surgical. Removal of all gross and microscopic tumor with a cuff of normal tissue completely surrounding the tumor is required to prevent local recurrence. Primary surgical procedures fall into two major categories: amputation and limb salvage procedures. Both approaches incorporate the basic principle of en bloc excision of the tumor and biopsy site through normal tissue planes. Other procedures, such as intralesional curettage or marginal resection, which often are successful for benign tumors of bone (e.g., giant-cell tumor, chondroblastoma, aneurysmal bone cyst), are inadequate for local control of osteosarcoma. Malignant tumors must be removed en bloc with a margin of normal, uninvolved tissue. Local extension of malignant bone tumors occurs primarily by intramedullary and extramedullary extension. After the tumor breaks through the cortex, it infiltrates normal muscle. However, direct invasion of adjacent arteries or nerves is rare, and involvement of veins usually is by tumor thrombus rather than by direct invasion of the vein wall. Osteosarcomas may cross the growth plate to enter the epiphysis of the bone but seldom cross the articular cartilage.[187,188,189 and 190] The adjacent joint may be involved, however, in the event of a fracture of the articular cartilage or if the tumor travels along the capsular structures or cruciate ligaments to enter the joint. [191] This observation has been used as a rationale to perform extra-articular resections in all osteosarcomas, but the advent of MRI has rendered possible the accurate assessment of the joint for tumor involvement. Because osteosarcomas seldom actually penetrate the joint, intra-articular resections are possible in the majority of extremity osteosarcomas. [192]

The selection of surgical procedure involves consideration of several interrelated factors, including tumor location, size, or extramedullary extent; presence or absence of distant metastatic disease; and such patient factors as age, skeletal development, and lifestyle preference, which may dictate the suitability of limb salvage or amputation.

### Amputation

The traditional surgical approach to local control of osteosarcoma of the extremity is amputation, which permits removal of all gross and microscopic tumor with clean margins and provides durable local control in most cases. However, amputation, even with a wide margin of normal tissue, has not prevented stump recurrence in all cases. Stump recurrence has been attributed to the extensive intramedullary spread and to the existence of skip lesions. Skip lesions—tumor deposits in the affected bone that are separated from the primary tumor by several centimeters of normal bone—have been reported to occur in up to 20% of cases of osteosarcoma. [134] This high incidence of skip lesions led some surgeons to recommend removal of the entire affected bone at the next proximal joint to ensure clean surgical margins and to avoid the problem of residual tumor in the stump. Such radical amputations result in considerable aesthetic and functional morbidity and seriously diminish the functional rehabilitation available with prostheses. Furthermore, such radical surgery has been demonstrated not to translate into better overall survival of patients. [193] The advent of more sensitive imaging techniques, such as MRI, renders possible the accurate definition of the intramedullary extent of tumor and the detection of skip lesions. This capability has enabled orthopedic surgeons to proceed confidently with cross-bone amputations to treat the primary tumor, allowing a safety margin of normal marrow above the most proximal medullary extent of tumor as defined by the MRI.[194,195,196 and 197] The local recurrence rate has been acceptably low (less than 5%), indicating that skip lesions are indeed rare. [198] A preoperative MRI of the entire involved bone should be scrutinized carefully for marrow extent and skip metastases, and the pathologist should bisect the amputated bone specimen immediately after it has been removed to ensure complete excision of the tumor. Although used in common practice, frozen sections of marrow margins have not been shown to be of much value. [199]

The treating team must have detailed discussions with affected children and parents regarding the choice between amputation and limb salvage. No clear advantage derives from either approach, although they are vastly different. The choice will depend on the age of the patient, the location of the tumor, the presence or absence of a pathologic fracture, and the desires of the patient and family. For lesions of the foot or ankle, a below-knee amputation probably is more functional than any limb salvage resection. For lesions above the knee, the advantage of amputation is less clear, and patients with high-thigh amputations or hip disarticulations and hemipelvectomies have difficulties in wearing prostheses. Very young patients may do better with amputation because of the avoidance of major limb length inequality, but this is a relative indication. Despite the development of myoelectric prostheses, no prosthesis comes close to duplicating normal hand function, so attempts to avoid amputation in the upper extremity are worthwhile. Amputees may have long-term complications of pressure sores from the prosthesis, phantom sensations, and phantom limb pain. Stump overgrowth in children with cross-bone amputations may be a difficult problem. [200,201,202 and 203] The vast majority of patients will chose limb salvage if given the option, but they must know that modern prosthetics, especially in the lower extremity, provide for excellent ability to walk and participate in a variety of sports activities. [204,205,206 and 207] The limb salvage patient will be advised to avoid most of these athletic activities.

If amputation is performed, early rehabilitation is important to restore the patient to a functional lifestyle (see Chapter 45 and Chapter 46). Improvements in the prostheses available for amputees have enhanced the functional results for these patients. [204] The functional results are excellent for patients who have had below-knee amputations, with very little measurable functional disability. Low above-knee amputations also have successful functional outcome. Studies of gait mechanics and oxygen consumption in lower-extremity amputees and in patients treated with limb salvage and rotationplasty have yielded conflicting results. Some studies show a higher energy consumption in amputees, whereas others show no difference in the groups studied. [207,208,209,210 and 211] The consensus is that energy consumption during gait is highest in above-knee amputees, intermediate in rotationplasty or arthrodesis, and lowest in mobile knee reconstructions. [203] Patients with tumors in more proximal segments of an extremity are likely to suffer more severe functional and cosmetic disability. Surprisingly, in several studies, no differences can be demonstrated in outcome vis-à-vis acceptance of their surgical procedure, ability to walk, pain, or psychosocial adjustment for patients undergoing amputation as compared to those treated with limb-sparing resection for tumors of the lower extremity. Most studies have shown that amputees adjust to their loss, although their concerns differ from those of patients who undergo limb salvage procedures; amputees are concerned primarily with body image and ability to afford a new prosthesis.[193,212,213 and 214]

### Limb Salvage Surgery

Improvements in survival of patients with osteosarcoma coupled with better imaging techniques, especially MRI, have led most centers to offer patients limb-sparing procedures for lesions about the knee, shoulder, and hip. In view of the close margins used in some limb salvage procedures, higher rates of local recurrence might be anticipated as compared to those associated with amputation, but this has not been the case. Some had feared that patients undergoing limb salvage would have an outcome worse than that in patients treated by amputation. Indeed, investigators of the GPO found the distant failure rate for patients treated by en bloc resection to be significantly higher than that for those undergoing amputation. [172,215] Although no randomized studies have been performed, carefully selected patients treated by experienced surgeons with limb-preserving operations do not appear to have a survival disadvantage. [193,203,216,217 and 218] The role of preoperative chemotherapy in rendering limb salvage surgery safer is unclear, although the administration of chemotherapy before resection seems to render the procedure easier by reducing the edema around the tumor and, on occasion, shrinking the tumor. One center has shown that patients with a less than wide margin and poor histologic response to presurgical chemotherapy have a higher risk of local recurrence than those with a wide margin and a good histological response. [219,220 and 221] However, the local recurrence rate was not high in a large multi-institutional study in which patients did not receive preoperative chemotherapy before either amputation or local resection (MP Link, unpublished data). [122] If the possibility of accomplishing complete excision is in doubt, amputation is the indicated procedure; local recurrence is intolerable,

because metastatic spread of tumor invariably follows.[219,222] The administration of chemotherapy cannot compensate for inadequate surgery.

The longevity of endoprosthetic devices used in limb reconstruction remains problematic, and late infections and graft failure may result in delayed amputations for patients treated by limb resection. Recent reviews suggest that limb-sparing surgery is associated with a higher rate of reoperation for complications, but a better functional outcome is achieved.[193] As young patients with osteosarcoma survive normal life spans, possibly they will outlive their endoprosthetic devices and allograft replacements, and pessimism about the *ultimate* longevity of these replacements may be warranted. However, late mechanical failures likely will be reparable with further surgery.

Screening candidates for limb salvage requires a careful staging workup, including a high-quality MRI of the entire involved bone. The decision to perform a limb-sparing procedure as opposed to amputation is based on the extent of tumor within the medullary cavity, the relationship of the soft tissue mass to the surrounding nerves and blood vessels, the extent of muscle involvement, and invasion of the adjacent joint. In most instances, the joint is not involved. MRI is the most important tool in making this assessment and has replaced the need for angiograms and CT scans.[187,194,195,223]

On the basis of reports from previous studies (discussed in the section Presurgical Chemotherapy), the degree of primary tumor response to presurgical chemotherapy also might be important in deciding whether to proceed with limb-sparing resection. The response to preoperative chemotherapy can be assessed by dynamic MRI, although thallium scans and positron emission tomography scans also have been proposed as accurate modalities.[224,225,226,227,228,229] and [230] Patients presenting with a pathologic fracture may be poor candidates for limb-sparing surgery.[222] Although some investigators have reported healing of pathologic fractures during presurgical chemotherapy, allowing for limb salvage surgery to be undertaken safely,[231] most surgeons recommend amputation rather than limb salvage surgery because of an unacceptably high local recurrence rate when more conservative surgical techniques are used.[222] The definitive answer to the question of whether patients with pathologic fractures should undergo limb salvage surgery is unknown, but clearly such patients are at an increased risk for local recurrence and should be selected for limb salvage with great care. The age of the patient, location of the primary tumor, and functional desires of the patient also are important considerations. A reasonable estimate is that 80% or more of patients with nonmetastatic extremity osteosarcoma are being treated with limb-preserving surgery but, in each case, the decision to perform such a procedure should weigh the risks and benefits as compared to amputation.

Once a tumor is resected, a variety of options are available for reconstruction of an affected limb. In the upper extremity, osteosarcomas most frequently involve the proximal humerus. In most cases, resecting the proximal humerus and some surrounding muscle is possible with or without a portion of the scapula, preserving the neurovascular supply to the arm and hand (the so-called *Tikhoff-Linberg resection*).[232] Options of bony reconstruction include osteoarticular allografts, metallic prostheses, composites of allograft and prosthesis, and vascularized or nonvascularized fibular grafts. If the entire deltoid and rotator cuff are resected, performing a shoulder arthrodesis may be preferable. Even if no reconstruction is performed, preserving the hand is superior to any currently available upper-extremity prosthesis. Tumors of the radius and ulna are rare and, depending on their size and location, can be reconstructed with allografts or autografts (fibula).

In the lower extremity, osteosarcomas are located most frequently in the distal femur, proximal tibia or, less commonly, proximal femur. In these sites, the reconstruction options include osteoarticular allografts, metallic prostheses, arthrodeses (achieved either by allograft or autografts), or allograft-prosthetic composites. Each of these alternatives has advantages and disadvantages, and no carefully controlled studies have documented superiority of one technique as compared to the others. Deciding which specific reconstruction to use is complex and involves a number of factors, but probably the most important is the experience and preference of the surgeon. Finally, some primary tumors can be resected without the need for bone reconstruction. Such sites include the proximal fibula, rib, clavicle, scapula, and parts of the pelvis (Fig. 35-6). Lesions of the distal tibia are best treated by below-knee amputation, and for tumors in the hands and feet, ray amputations usually are possible.

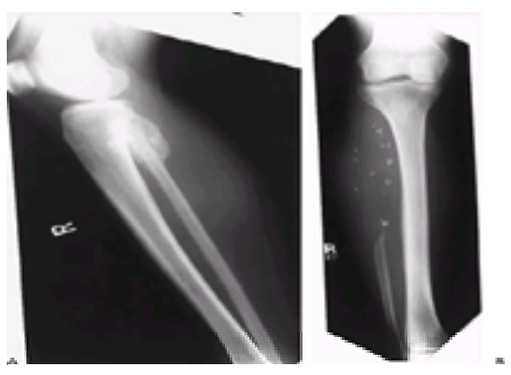

**FIGURE 35-6. A:** Lateral radiograph of an osteosarcoma of the right proximal fibula after presurgical chemotherapy. **B:** Postoperative radiograph demonstrating the surgical defect from resection of the proximal fibula without reconstruction. The peroneal nerve was preserved, although frequently, sacrificing it is necessary. The patient has essentially normal function. If the peroneal nerve is resected, the functional loss is minimal and can be accommodated by an ankle-foot orthosis or a posterior tibial tendon transfer.

The pelvis presents a most challenging site. If the lesion is in the ilium, pubis, or ischium, resection of the tumor with no need for reconstruction may be possible. Lesions involving the acetabulum are more complicated. Although hemipelvectomy (hind-quarter amputations) previously were the only surgical option for such lesions, en bloc excision of the hemipelvis with preservation of the extremity now can be performed in most instances with equal local tumor control. Reconstruction of the resultant defect has been difficult, and metallic endoprostheses have had limited success (80% failure) because of difficulties with the fixation of the prosthesis to the remaining pelvis. The large lever arms and forces applied to the fixation have resulted in frequent loosening and migration of the endoprosthesis. Other methods of obtaining structural integrity have included the use of allografts, fusion of the proximal femur to the ilium or sacrum, attempting a reconstruction with an allograft or a custom metallic prosthesis, and internal hemipelvectomy with no replacement at all (Fig. 35-7).[233,234,235,236,237] and [238] When no replacement is used, a gap between the femur and pelvis is bridged by scar tissue from the adjacent soft tissue, and this fibrous union allows the patient to bear approximately 80% of the body weight.[233] Approximately 2 to 4 inches of limb shortening occurs, which requires additional shoe lifts, and most patients use a cane or crutch. However, even with these limitations, this procedure appears to be a useful alternative to amputative hemipelvectomy, with superior functional results.[233] Whatever reconstruction is chosen, the complication rate is very high as compared to other sites, and achieving negative margins is difficult.[235,237,239,240,241,242,243] and [244]

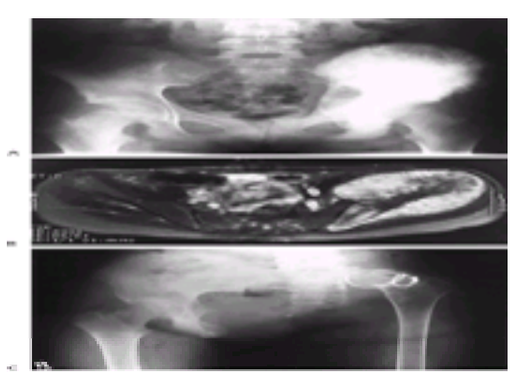

**FIGURE 35-7. A:** Radiograph of an osteosarcoma of the left ilium after presurgical chemotherapy. **B:** Magnetic resonance imaging demonstrates the extent of the lesion throughout the ilium with extension into the iliacus muscle and gluteal muscles. It abuts the sacroiliac joint. **C:** Postoperative radiograph 4 years after internal hemipelvectomy. Because of the extent of the bony and soft tissue resection, no formal reconstruction was carried out. The femoral head was wired provisionally to the sacrum, where it has remained. The patient is able to ambulate with a lift in the shoe and a brace for a partial foot drop.

Osteosarcomas of the spine and sacrum are rare, and treatment must be individualized. Resections are possible at times, but achieving tumor-free margins while retaining neurologic function is very difficult. Multimodality therapy combining limited surgery with irradiation is used frequently. Rarely, osteosarcomas in the spine and sacrum are treated by chemotherapy and irradiation alone.[245,246,247 and 248]

The various alternatives for limb salvage for extremity osteosarcomas are similar in adults and children but, in children, the added factor of remaining growth renders reconstructions more complicated. Specifics of the various reconstruction techniques are detailed here.

### *Osteoarticular Allografts*

Osteoarticular allografting is one alternative for reconstruction of tumor defects of the proximal tibia, distal femur, or proximal humerus.[249,250,251,252,253,254,255,256 and 257] Grafts are procured according to the guidelines of the American Association of Tissue Banks and are stored in a fresh frozen state at –80°C until needed. They are size-matched to specific patients using radiographs of the involved bone and allograft, and they have been shown to be safe from the standpoint of transmission of viral and bacterial disease, owing to the rigor of the procurement protocols.[258,259] Allografts are immunogenic, but the immune response is minimized by fact that they are nonvascularized, and freezing reduces their antigenicity.[260,261,262 and 263] These grafts initially were thought to be resorbed slowly and replaced by host bone but, in practice, host invasion occurs primarily at the allograft-host junction and along the surface of the bone.[264]

Osteoarticular allografts in young people offer certain advantages for reconstruction not available with metallic prostheses.[256] They provide articular surfaces for the involved bone and obviate the need to resect the adjacent articular surface and growth plate. Allografts provide ligaments for joint reconstruction, including cruciate ligaments, and sites for attachment of host tendons (Fig. 35-8, Fig. 35-9). Once the osteosynthesis heals, the longevity of the allograft is anticipated to be superior to that of metallic implants, because they are not subject to loosening, particulate wear debris, and mechanical breakage. If the joint surface deteriorates, the joint can be revised employing a standard total knee prosthesis, and they are not subject to stress shielding and loss of bone stock, as are metallic replacements.

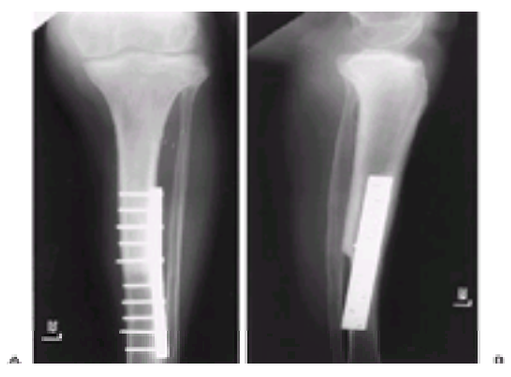

**FIGURE 35-8.** Anteroposterior **(A)** and lateral **(B)** radiographs 5 years after limb-sparing resection of an osteosarcoma of the proximal tibia and reconstruction with osteoarticular replacement of the proximal tibia. The osteosynthesis was achieved with a plate, and the bones have united.

**FIGURE 35-9.** Anteroposterior **(A)** and lateral **(B)** radiographs 4 years after limb-sparing resection of an osteosarcoma of the distal femur and reconstruction with osteoarticular replacement.

Allografts have obvious potential problems and are subject to fracture, nonunion, joint instability, and infection.[256,265,266,267,268,269 and 270] The procedure is technically challenging, and the rehabilitation process is prolonged. Allografts are not meant to allow the patient to return to athletic activities (a drawback in young children), but most limb salvage reconstructions are associated with this limitation.

An MRI after presurgical chemotherapy is used to make the final assessment of resectability. A T1-weighted coronal image is the best study to determine the medullary extent of the lesion and the presence of skip metastases.[194] Sufficient bone must remain after resection of the tumor (usually with 3 to 5 cm of adjacent uninvolved marrow) to achieve osteosynthesis. The size of the patient is a definite issue: It is unlikely that a child younger than 8 to 10 years of age will be large enough to make it possible to find an osteoarticular graft of appropriate size. Practitioners must understand that in girls younger than 12 and in boys younger than 14, other procedures, such as contralateral epiphysiodesis or ipsilateral lengthening, may be necessary at a future time to prevent leg length inequality.[271,272] Usually, gaining 1 to 2 cm of length in older children is possible at the time of the operation by using a graft that is longer than the length of bone resected.

The technical aspects of the procedure are similar to those in adults.[250,256,257,273] A wide, intra-articular resection is performed. If tumor involvement of the joint is a concern, the joint can be inspected through a small arthrotomy at the beginning of the procedure. If the joint is found to be involved, the wound is closed and an extra-articular resection or amputation can be performed. Otherwise, a longitudinal incision is made anteromedially or anterolaterally, and a cuff of uninvolved muscle is retained around the tumor. The neurovascular structures are identified and preserved, and the bone is divided with an oscillating saw 3 to 5 cm above the level of involvement predicted by the MRI. The joint ligaments and cruciate ligaments are divided, leaving as much length as possible on the remaining host bone without violating the tumor. The specimen is examined by an experienced pathologist to assess the margins of resection. An osteoarticular allograft then is thawed, cultured for aerobic and anaerobic organisms, and cut to fit the length of the defect. If the patient is skeletally immature, the allograft bone is fashioned 1 to 2 cm longer than the length of bone resected, depending on the integrity of the soft tissues. The osteosynthesis can be achieved with broad DC plates or intramedullary rods. The former appear to achieve osteosynthesis more reliably because of more rigid fixation, whereas the latter are associated with a lower fracture rate.[274,275] Cruciate ligaments are primarily repaired using heavy, nonresorbable sutures, and then the capsular structures are repaired primarily adjusting for appropriate length. Host menisci are preserved unless resected for tumor considerations. The patellar ligament is repaired in a pants-over-vest fashion to the graft ligament in proximal tibial lesions. The joint should be stable at the completion of the repair. The soft tissues are closed with the aim of achieving a complete muscle closure over the graft. Depending on the extent of muscle resection, this closing may require local rotational (gastrocnemius) flaps or, at times, free vascularized transfers.

Osteosarcomas of the proximal humerus can also be resected with wide margins preserving the vasculature and nerves to the upper extremity (Fig. 35-10). The deltoid muscle (and frequently parts of the rotator cuff) are resected, and the axillary nerve and glenoid may have to be sacrificed. The biologic reconstruction options include an osteoarticular allograft or an allograft-prosthetic composite or a shoulder arthrodesis.[255,270,276,277,278,279,280,281 and 282] Even leaving the shoulder flail offers function superior to that of an amputation. The complication rate with osteoarticular allografts is high,[255,270,277] leading some surgeons to prefer allograft-prosthetic composites to reduce the incidence of fracture.[277,283,284] The overall function is good in approximately 70% of patients, but abduction above the horizon seldom is achieved. An arthrodesis allows more powerful abduction and may be appropriate in people interested in manual occupations, but achieving an arthrodesis is difficult. Combinations of allografts and vascularized fibulae increase the likelihood of a successful arthrodesis. Motion—especially rotation—is sacrificed for power of

abduction.[249,256,277,278,285]

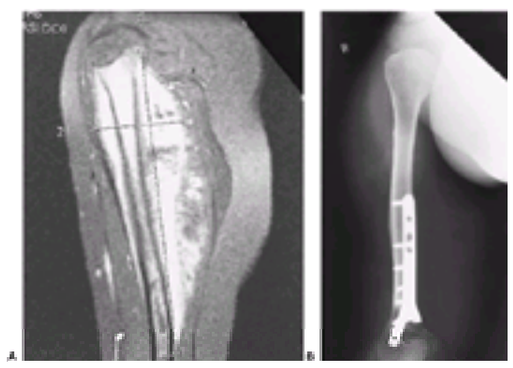

**FIGURE 35-10. A:** Magnetic resonance imaging of a 12-year-old with osteosarcoma of the proximal humerus. The soft tissue extent of the mass is extensive, and it involves the majority of the humeral shaft. **B:** Radiograph 1 year after limb-sparing resection and reconstruction with an osteoarticular allograft. Reasonable range of motion of the shoulder and elbow is present.

Postoperatively, the extremity is immobilized in a cast or brace for 6 to 8 weeks, and motion is begun in a protective brace at that time. In the lower extremity, weight bearing is restricted to touchdown status but, when early signs of bony union are visible, partial weight bearing in a brace can begin. Osteosynthesis in patients receiving chemotherapy usually occurs between 9 and 12 months.[257] The early complications include wound healing problems that are less frequent with experience of the surgeon and the liberal use of rotational and free flaps and skin grafts. [250,252,256,265,267,268] and [269] When wound dehiscence occurs, it should be treated aggressively with débridement, closure, and soft tissue transfers, if necessary. Nonunion occurs in 10% to 25% of allografts in children, and the incidence appears to be greater in patients receiving chemotherapy.[250,256,257] This complication usually is managed easily by revision of the fixation and autogenous bone grafting. Fracture usually is a late complication, occurring between 3 and 8 years from the procedure. The incidence is approximately 20% of allografts in children. [257] Fractures can be treated by standard management techniques but, on occasion, a fracture will result in failure of the implant and will require removal of the graft and reconstruction with a second graft, a metallic prosthesis, or amputation. Also possible may be salvaging the graft by augmenting it with a vascularized fibular graft (either as a free transfer or a pedicle graft for tibial sites) if the joint is functional. [286,287,288] and [289]

Infection occurs in 10% to 15% of pediatric allografts [249,252,256,266,267,270] and is a more devastating complication. A deep infection almost always results in failure of the graft.[266] In perhaps one-half of such cases, removal of the graft, insertion of an antibiotic-impregnated polymethyl methacrylate cement spacer, and intravenous antibiotics followed by a second allograft in 3 months will achieve a successful result. [290]

The functional results are satisfactory in approximately 60% to 70% of children with high-grade sarcomas requiring adjuvant chemotherapy. [250,252,255,270,291,292] Running, jumping, and contact sports are not encouraged but sometimes are performed by these young patients. For growing children, attention must be paid to limb length. [272] For children nearing skeletal maturity (the majority of patients), this is seldom a problem, because the limb can be lengthened 1 to 2 cm at the time of the reconstruction. If further growth of the contralateral side leads to an ultimate discrepancy of 2 cm or less, no correction is necessary. For girls in the 10- to 12-year age group or boys in the 12- to 14-year age group, a contralateral epiphysiodesis may be necessary. An alternative is to delay equalization until after skeletal maturity; if the discrepancy is significant (5 cm or more), consideration is given to closed femoral shortening of the uninvolved side or limb lengthening of the involved side.

Children younger than 8 years seldom are candidates for an osteoarticular allograft about the knee. An amputation, rotationplasty, or the use of an “expandable” prosthesis is preferable, although a prosthesis is less likely to be successful in children younger than 8 years.

### *Intercalary Allografts*

In some instances, an osteosarcoma is located in the diaphysis of the bone, such that the adjacent joints and metaphyses can be spared. In young patients in whom a margin of bone can be obtained while preserving the proximal and distal femoral metaphyses, an intercalary allograft can be employed to reconstruct the diaphysis.[249,250,277,293,294] Fixation can be achieved with plates so that the growth plate can be spared or, if the epiphysis is needed for fixation, the fixation devices (screws) in the epiphysis can be removed to allow growth once the osteosynthesis has healed. Some surgeons employ vascularized fibular grafts with or without allografts to achieve a similar reconstruction. [286,287,288] and [289] Good function has resulted from intercalary allografts alone. [249,293]

Some lesions of the distal diaphysis of the femur extend close to the growth plate but not into the epiphysis. Such a situation may afford the possibility of preserving the epiphysis but not the growth plate and still achieving a negative bony margin. To do so requires careful analysis of a good-quality MRI with a radiologist who has expertise in judging tumor extent. If the epiphysis can be spared, doing so seems preferable, so that an affected child's own joint surface can be preserved. This provides a durable reconstruction and excellent function if sufficient quadriceps function can be preserved. Limb length equality may have to be achieved by other means if such a child is very young. A similar situation may occur (but less commonly) in the proximal tibia.

### *Metallic Prostheses*

Metallic prostheses have been employed successfully to reconstruct tumor defects in adults, and similar approaches have been applied to children.[295,296,297,298,299,300,301,302] and [303] These devices are manufactured as casts of cobalt, chrome, or steel, or they are machined from titanium. The advantages of endoprostheses are the immediate stability allowing weight bearing, freedom from postoperative immobilization, and a low incidence of early complications. The infection rate has been reported to be between 0% and 35% and varies with the site of the reconstruction. [304,305,306,307,308] and [309] Fatigue fracture of the metal and loosening of the prosthesis are other potential problems. Fatigue fracture of the metal is a design and stress problem that potentially can be improved by changes in casting methods, use of stronger metals, or improvements in stress-relieving joint designs. Loosening of the endoprosthesis at the cemented bone-prosthesis interface is a problem that is not resolved as easily, but it is minimized by the use of meticulous cement technique and stress-reducing total joint mechanics, such as a rotating-hinge knee design. Recent design modifications that allow for bony ingrowth at the stem-host junction and uncemented designs also may prove useful.[305,310,311] These improvements encourage extramedullary ingrowth of the host's own bone along the metallic endoprosthesis shaft, thereby providing a biologic fixation of the prosthesis.

As with allografts, limb length is an issue, especially because the adjacent proximal tibial or distal femoral growth plate may have to be either resected or crossed by the implant to accommodate the prosthetic knee joint. In one series,[312] the operative extremity limb length was 79% that of the normal limb after treatment. Also, the tibial growth plate has been demonstrated to continue to grow after cementing a stemmed prosthesis across it. [313]

Several different types of “expandable” prosthesis that have been devised can be lengthened as the child grows. [291,295,297,298,302,304,314,315,316,317] and [318] These constructs provide immediate stability and early return to function but present the caveat of poor longevity in young active children. Problems include fixation and stress shielding in the growing child, mechanical failure of these more complex implants, and debate regarding the optimal fixation to the host bone. All these concerns are shared with prostheses in adults but, in the child, issues include a longer life span (if the tumor treatment is successful) and greater activity than that in adults. A “growing prosthesis” implanted in children almost certainly will loosen or mechanically fail with time or simply may be too small when such children reach adulthood and so may need to be replaced with another prosthesis.[314] Several centers have reported a steadily declining survival curve for metallic prostheses in children. [302,304,314,316] Most often, these prostheses can be revised to another prosthesis. The need for future revisions of the prosthesis if an affected child survives an entire life span should be expected. One concern is that over time, the bone stock remaining will render the revision of a prosthesis difficult, if not impossible.

Metallic prostheses are used most commonly for lesions about the knee and employ rotating- or pure-hinge knee implants. Prostheses for the proximal femur are similar to those in adults, and growth is not as much an issue in this location. The indications are similar to those for allografts (a resectable lesion in a child older

than 8 years), although limbs in patients requiring extra-articular resections can be reconstructed by prostheses as well. The technique of resection is similar to that for an allograft. Achieving a wide resection and preserving sufficient muscles, nerves, and vessels are desirable. Careful preoperative planning is necessary to ensure that a suitable implant is available. Several types of prostheses designed for children have a mechanism for serial lengthening of the implant. These prostheses are complex, and their mechanical failure rate is fairly high. Recent design features have improved the ability to expand the prostheses as the child grows. In most cases, the prosthesis will have to be revised to a standard prosthesis after skeletal maturity.

Recently, modular tumor prostheses have been available in North America and Europe [299,308,309,319,320] but, in smaller children, a custom implant may be necessary. The development of modular prosthetic systems for segmental bone and joint replacement after tumor resection increases the options for surgeons in planning tumor resections (Fig. 35-11). Such prostheses are available for the distal and proximal femur, proximal tibia, and proximal humerus. Each consists of components appropriate for the segment to be replaced (usually an intramedullary stem, a body segment, and a joint component), and each component comes in various segmental lengths and stem dimensions. Such modular systems permit almost immediate availability and choice of sizes suitable for most tumor sites for most patients and for reconstructions of almost any length, so that individualized, customized devices need not be ordered for each patient. The advantages of modular prostheses include the simpler design, ready availability, flexibility with regard to the length of resection at the time of operation, and lesser cost than that of custom prostheses. For distal femoral lesions, the length of the implant is constructed by combining various-length body segments with the distal femoral component to match the resected length. The articular surface of the proximal tibia is resected (preserving the physis), and a smooth-stemmed tibial component is employed using cement on the tibial surface and in the medullary canal. Studies have indicated that the growth plate has sufficient strength to break the cement mantle over time and allow for growth of the proximal tibia.[313] Alternatively, an uncemented smooth-stemmed tibial component can be employed and revised after skeletal maturity. Lengthening is accomplished by replacing the body segment of the prosthesis by a new segment that is longer (usually 1 to 2 cm per lengthening) than the initial one. This requires dislocation of the knee and a special device to loosen the Morse tapers. Lengthening can be a difficult procedure, because an unforgiving fibrous capsule develops around the prosthesis. In most instances, it must be resected completely to gain length. Nerves and vessels embedded in scar must be protected carefully. Young children require two to three lengthening procedures to compensate for growth discrepancies of 1 to 9 cm. There are limited data on the number of children in the 8- to 10-year age group who have reconstructions with expandable prostheses around the knee and reach skeletal maturity with equal limb lengths.

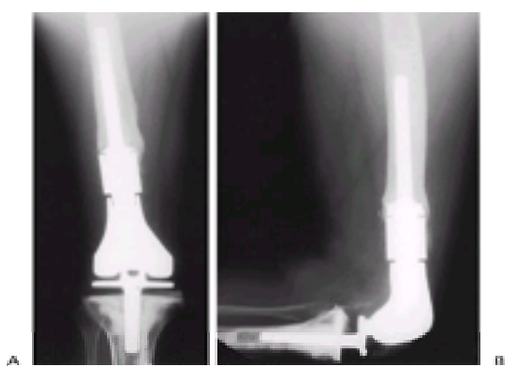

**FIGURE 35-11.** Anteroposterior **(A)** and lateral **(B)** radiographs of an osteosarcoma of the distal femur after resection and reconstruction with a commonly used modular, rotating-hinge prosthesis. The precise length of this prosthesis can be designed at the time of operation by combining segments of different lengths. The rotating-hinge knee joint compensates for ligamentous loss.

Prosthetic reconstruction of the proximal tibia is complicated by the need to reattach the patellar tendon to the prosthesis to gain active knee extension. Much research has gone into developing tissue ingrowth into the prosthesis to achieve this extension, but most surgeons rely on synthetic materials to attach the tendon to a loop or pad on the prosthesis and augment this with a medial gastrocnemius flap to gain tissue to which to attach the tendon. This approach seems to be moderately successful in restoring the extensor mechanism.

The complications of endoprostheses include metallic wear debris in the soft tissues (100% of titanium implants), expansion failures (approximately 30%), loosening of the prosthesis, and mechanical failure.[298] The reported infection rates vary with the series but appear to be much higher in the tibia than in the femur.[304] Careful soft tissue closure and use of gastrocnemius rotation flaps (when necessary) are critical to reducing the infection rate. Complications of lengthening include dislocation, joint contracture, and nerve palsies. The 5-year revision-free survival of the prosthesis in one series was 15% for an expandable prosthesis and 72% for the modular prosthesis.[298] Reported results of recent series of children with osteosarcoma treated with endoprosthetic replacement are encouraging. The local recurrence rate is acceptably low (5% to 11%), but the complication rate remains high (55% to 80%).[216,297,304,314,315,321] Mechanical failure or loosening is almost inevitable in young children receiving these prostheses, but usually such prostheses can be revised when the children reach skeletal maturity.

Similar prostheses are available for use after resection of proximal humerus osteosarcomas. They work well for restoring bony integrity, but achieving muscle attachments to the prosthesis is difficult. Heavy suture or arterial graft materials have been used to accomplish this with varying success. Stability of the shoulder joint may be a problem, and affected patients likely will not achieve good active shoulder mobility.

### *Allograft-Prosthetic Composites*

Another alternative to limb reconstruction is to combine a standard knee or proximal humerus prosthesis with an allograft for lesions about the knee or shoulder.[250,256,277,283,284,291,322,323,324,325] and [326] This combination offers the advantage of joint reconstruction employing a more standard arthroplasty and of restoring bone stock with allograft bone. In the shoulder, the composites offer the advantages of protecting the allograft with a metallic stem and avoiding periarticular fractures seen in osteoarticular grafts. In addition, the allograft provides attachment sites for the rotator cuff and other muscles. Similarly, in the proximal tibia, the allograft provides a site for attachment of the patellar tendon, and the prosthesis provides a stable joint reconstruction. At all sites, the composites allow for modularity and, in theory, may provide a reconstruction more durable than that of osteoarticular allografts or metallic prostheses.

### *Arthrodesis*

Although arthrodesis was a popular reconstruction in the early days of limb salvage ( Fig. 35-12), especially about the knee, the availability of mobile joint reconstructions has largely replaced this as an option. In the knee, the major advantage is durability. Once the construct heals, the long-term outcome is good and provides a reconstruction that can be used safely in some sports and heavy labor.[249,278,281,327,328] The major disadvantage is the inability to flex the knee, which is problematic while sitting in tight spaces, such as theaters and airplanes.

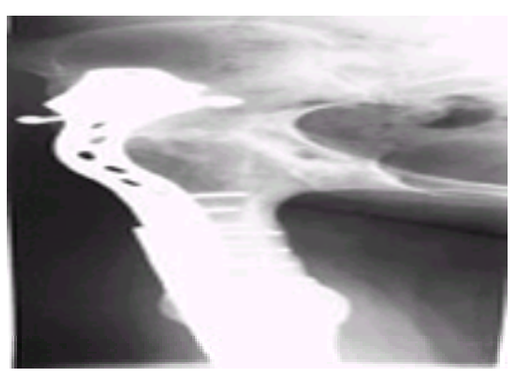

**FIGURE 35-12.** Radiograph 10 years after extra-articular resection of an osteosarcoma of the femoral neck, with a pathologic fracture and contamination of the hip joint. Reconstruction was accomplished with an intercalary allograft to create a hip arthrodesis. The patient walks with a nearly normal gait and can sit without

difficulty because of the flexibility of the lumbar spine.

In the shoulder, it is perhaps a more acceptable option. It allows for powerful positioning of the shoulder and arm in space and is useful in an athletic person or a heavy laborer. The benefit of power to abduction and forward flexion is at the cost of limitation of rotation of the shoulder. Achieving an arthrodesis of the shoulder is difficult after resection of a tumor, and combinations of allografts and vascularized or nonvascularized fibular grafts and special fixation devices are necessary to achieve solid union.

***Rotationplasty***

Young children with high-grade sarcomas of the knee area have limited options for reconstruction after resection of the tumor. Limb-sparing procedures have the drawbacks of activity restrictions, high complication rate, limb length inequality, and complexity. An above-knee amputation for a distal femoral osteosarcoma in very young patients leaves such children with a very short lever arm to power a prosthesis, and it becomes relatively shorter as the child grows (i.e., the child's opposite limb grows, but the femoral stump does not).

The operation described by Borggreve and adapted for congenital defects (e.g., proximal femoral focal deficiency) by Van Nes has been applied to the tumor setting by Salzer and provides a reconstruction option for certain situations. [329,330,331,332,333,334,335,336,337,338,339] and [340] It can be thought of as an intercalary amputation of the distal femur (or proximal tibia). The reconstruction employs the distal leg that is rotated 160 to 180 degrees, and this provides the advantage of a longer lever arm and an active “knee” joint provided by the ankle and foot ( Fig. 35-13).

**FIGURE 35-13. A:** Rotationplasty performed for a distal femur osteosarcoma with foot inverted and ankle functioning as a knee. **B:** With the below-the-knee external prosthesis in place, the patient has excellent lower-extremity function. (See Figure 45-3 and Figure 45-4.)

The indications for rotationplasty include a distal femoral or a proximal tibial osteosarcoma in skeletally immature patients or in those who want to continue sporting activities, or as a salvage procedure for a failed distal femoral reconstruction. It must be possible to preserve the sciatic nerve and its branches, although the vessels may be divided and anastomosed to increase the margin if necessary. The advantages are the wide margin that includes the skin, adjacent knee joint, and thigh muscles; the avoidance of phantom pain; rapid healing of the osteosynthesis site; and a relatively low complication rate. The obvious drawback is the appearance, which is repulsive to some. At times, the patient may be more in favor of this option than are the parents or the physicians. Interestingly, young children usually do not view the procedure as an amputation because the foot remains and, with a good prosthesis, they are able to function better than other amputees. [341,342,343] and [344] Follow-up studies have not demonstrated any adverse psychological outcomes, [330,334,345,346] and carefully selected patients who have undergone the procedure usually are content.[335] Preoperative discussions must be honest and complete, so that both patient and family are aware of the nature of the procedure and the expected outcome. A helpful approach is for them to meet with a physical therapist who is familiar with this procedure, to view videotapes of patients who have undergone the procedure and, ideally, to meet a patient with a rotationplasty. All these techniques are necessary in addition to considerable time spent explaining the rationale and the relative advantages and disadvantages of this and the other options, such as amputation and limb-sparing procedures. Recently, the number of patients willing to undergo this procedure has diminished; many prefer to try a limb-sparing procedure and to reserve rotationplasty until or unless limb sparing fails.

The procedure itself is well described in the literature. The tendency is to make the thigh long, so that the rotated “knee” appears to be distal to the contralateral knee. Unless the femoral resection is fairly high, the rotationplasty knee will be distal to the contralateral normal knee. Accurately predicting remaining growth is difficult because the distal tibial physis and the tarsal bones become analogous to the contralateral distal femoral growth plate.

In general, a boy older than 14 and a girl older than 12 probably should have the rotationplasty knee placed opposite the contralateral knee. For younger patients, placing it 2 to 4 cm more caudal is appropriate. [335,347] The vessels may be resected with the specimen to increase the amount of normal tissue margin. An anastomosis of the vein and artery can be completed after achieving osteosynthesis. Flushing the leg with a perfusate of heparin and cool Ringer's lactate solution is helpful in decreasing the effects of the ischemia time, which should be less than 1 hour. At times, the small vessels will spasm and necessitate revision of the anastomosis, but this does not lead to loss of the leg or a compartment syndrome. An alternative is to dissect the vessels free from the tumor and loop them carefully back on themselves with the nerves. Postoperatively, the wound is observed for healing and perfusion of the foot. The patient is placed in a spica cast or brace for 6 weeks to allow early healing of the osteosynthesis site and to allow mobilization. A prosthesis can be provided at 6 to 8 weeks, and partial weight bearing can be continued until the osteosynthesis site has healed. Stressing range of motion of the ankle (especially full plantar flexion) is important early in the postoperative course; if a patient loses motion, the ankle should be splinted in full plantar extension while at rest. [335]

This procedure has been described also for tumors of the proximal tibia, with successful results. [345,348] Modifications of this procedure have been described for lesions about the hip or those involving a large portion of the proximal femur. [216,349,350] The ilium and distal femur must be preserved for this procedure to provide a “hip” and a “knee.” A similar procedure has been reported for lesions about the shoulder. [351]

A rotationplasty offers a durable and functional, albeit cosmetically unpleasant, reconstruction option for selected patients with a sarcoma. For very young patients with a distal femoral or proximal tibial lesion, it avoids the repeated surgical procedures necessary to achieve limb length equality and allows affected children to run and play exceedingly well. The other useful indications include a failed limb salvage procedure or a pathologic fracture when amputation would be the only alternative.

**Radiotherapy in the Management of the Primary Tumor**

In the past, radiotherapy was recommended to treat the primary tumor in osteosarcoma. However, osteosarcoma has been found to be a highly radioresistant lesion. Radiation doses of less than 6,000 cGy have been associated with only transient tumor control, [352] and viable tumor has been observed in amputation specimens after doses of 8,000 cGy or more.[353,354] The failure of conventional radiotherapeutic fractionation techniques to provide durable local control of osteosarcoma may be explained by the presence of a relatively high percentage of hypoxic tumor cells and *in vitro* evidence that osteosarcoma cells may have increased capacity to repair sublethal radiation injury.[355]

Before the 1970s, when osteosarcoma was almost uniformly fatal, a strategy of primary radiotherapy followed by delayed amputation evolved in an effort to avoid mutilating surgery in patients destined to die of their disease. [1,353] High-dose radiotherapy was administered initially, and ablative surgery was used only for those patients remaining free of disease 4 to 6 months after the completion of radiotherapy. However, in a subsequent assessment, primary radiotherapy was found to result in few responses; local recurrences appeared in virtually all cases, and palliation (the ostensible goal of delayed surgery) was poor. [352]

With improvements in the control of micrometastatic disease by systemic chemotherapy, the majority of patients should now be approached with curative intent, so

local recurrence is intolerable. Apparently, the overall control rate of the primary tumor with radiotherapy is significantly less than with ablative surgery, so radiotherapy has little role in the management of primary osteosarcomas that are controllable by surgery. The use of hypofractionated radiotherapy or other novel radiation fractionation techniques, with or without radiosensitizers to overcome the capacity of osteosarcoma cells to repair sublethal damage, may result in more durable control of primary osteosarcoma, although the increased soft tissue injury that results may limit this approach. [355]

The increased normal tissue injury associated with large dose-per-fraction radiation argues for multiple small fractions (hyperfractionation) in an effort to spare normal tissues. Because of the substantial risk of local recurrence in osteosarcomas treated primarily with irradiation, primary radiotherapy or radiotherapy as an adjunct to debulking surgery should be reserved for patients with unresectable tumors and patients with axial skeleton tumors that cannot be excised completely. Such patients have fared poorly in the past because durable local control has been difficult to achieve.

## Adjuvant Treatment

### *Chemotherapy*

Although control of the primary tumor is accomplished reliably by surgery, data from historical studies and recent controlled trials indicate that more than 80% of patients with osteosarcoma treated with surgery only will develop metastatic disease. Microscopic, subclinical metastatic disease is thus present at the time of diagnosis in the majority of patients without overt metastases. Evidence from animal models supports the notion that subclinical metastases can be eradicated by chemotherapy if the treatment is initiated when the total burden of metastatic tumor is sufficiently low [356,357 and 358] and provides the rationale for adjuvant chemotherapy in osteosarcoma. However, osteosarcoma is a notoriously drug-resistant neoplasm, and the list of drugs active against macroscopic disease and thus applicable in the adjuvant setting is disappointingly short. Before 1970, none of the drugs tested had produced responses in more than 15% of patients, and most of the responses in phase II studies were partial rather than complete. More promising results were observed in the 1970s and early 1980s in phase II trials of doxorubicin, [359] high-dose methotrexate (HDMTX) with leucovorin rescue,[360,361 and 362] cisplatin,[363,364,365 and 366] and ifosfamide.[367] The hopeless prognosis of patients with osteosarcoma in the 1970s led to the enthusiastic application of these agents singly or in combination as adjuvant therapy after amputation or resection of the primary tumor. An apparent improvement in outcome as compared to the historical experience was demonstrated in a number of uncontrolled trials of adjuvant therapy conducted in the 1970s and early 1980s. Two randomized, controlled trials conducted in the mid-1980s confirmed both the validity of the historical experience as a control for these studies and the favorable impact of adjuvant chemotherapy in the treatment of osteosarcoma. [121,122 and 123]

Reported results of some of the important adjuvant chemotherapy trials of the 1970s and 1980s are summarized in Table 35-2. Concerns have been raised that the favorable results achieved in patients treated with adjuvant chemotherapy might not be sustained with longer follow-up, as late relapses occur, and that adjuvant chemotherapy for osteosarcoma might delay but not prevent relapse. However, results of many of the adjuvant studies reported in Table 35-2 (some with follow-up beyond 20 years) suggest that life tables for relapse-free survival have stable plateaus beyond 4 years and that relapses after 3 years are infrequent. The majority of patients surviving 3 years without evidence of recurrence thus are likely to be cured.

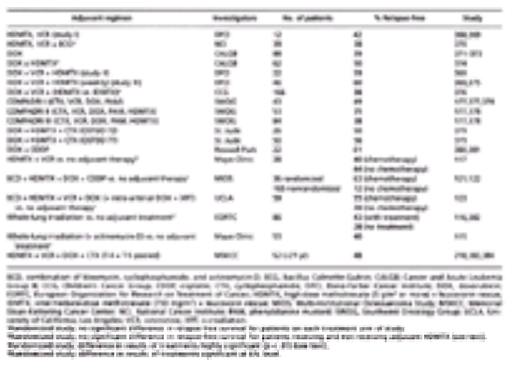

**TABLE 35-2. REPORTED RESULTS OF REPRESENTATIVE TRIALS OF ADJUVANT THERAPY FOR OSTEOSARCOMA**

Examination of the results of adjuvant trials reveals a trend in the direction of improved outcome for patients treated on more recent protocols. Considering that so few drugs have demonstrable activity against macroscopic osteosarcoma, the results reported in adjuvant trials are remarkable. With currently available regimens, approximately 60% to 70% of patients with nonmetastatic osteosarcoma of the extremity will survive without evidence of recurrence. The development of adjuvant regimens has been largely empirical, and newer, more intensive regimens have resulted in further improvements in outcome. The majority of regimens currently in use incorporate doxorubicin, cisplatin, and HDMTX. The role of HDMTX in the treatment of osteosarcoma has been questioned, [385] because a randomized study conducted by the Children's Cancer Study Group[376] comparing HDMTX and intermediate-dose methotrexate in combination with doxorubicin as adjuvant therapy failed to show any benefit for patients receiving HDMTX. The overall outcome was not better than that achieved in studies using doxorubicin alone. In contrast, a more recent study from the Instituto Rizzoli[386] demonstrated superior responses in the primary tumor and a superior outcome for patients receiving HDMTX as compared to those receiving intermediate-dose methotrexate in the context of a multi-agent chemotherapeutic regimen. Other trials also have concluded that serum methotrexate levels achieved in patients may correlate with tumor responses observed and with patient outcome.[387,388 and 389] A peak methotrexate level of 1,000 μM appears to be a "threshold" that must be exceeded to observe a therapeutic effect in osteosarcoma. [387,388]

A trial conducted by the European Osteosarcoma Intergroup compared the combination of doxorubicin and cisplatin alone or doxorubicin and cisplatin alternating with HDMTX as pre- and postsurgical chemotherapy for patients with osteosarcoma.[390] The disease-free survival for patients receiving the two-drug regimen (without HDMTX) was significantly superior to that of patients treated with all three drugs. However, in this study, the intensity of administration of HDMTX was compromised by the design of the study, and the overall outcome of patients in this report is inferior to that observed in other recent studies. Thus, the role of HDMTX in chemotherapy of osteosarcoma requires further study.

The combination of bleomycin, cyclophosphamide, and actinomycin-D[391] was pioneered in early trials from Memorial Sloan-Kettering Cancer Center (Memorial Hospital) and was incorporated into trials conducted by other investigators as well. A subsequent phase II trial at the St. Jude Children's Research Hospital failed to show any benefit,[392] and the regimen of bleomycin, cyclophosphamide, and actinomycin-D no longer is recommended for the treatment of osteosarcoma.

The activity of ifosfamide was demonstrated more recently, and this promising agent is included in some newer regimens currently under study. The Children's Cancer Group (CCG) and the Pediatric Oncology Group (POG) have completed a randomized trial to evaluate the addition of ifosfamide to the treatment of osteosarcoma. Patients were randomly assigned to treatment with cisplatin, doxorubicin, and HDMTX, with or without the addition of ifosfamide. The preliminary results of this trial did not demonstrate a benefit for the patients who were treated with the addition of ifosfamide. [457]

### *Whole-Lung Irradiation*

Prophylactic irradiation of the lungs as an adjuvant to surgical treatment of the primary tumor was evaluated in several trials. Osteosarcoma is not considered to be a radioresponsive tumor; these trials were justified by theoretic estimates of tumor burden in pulmonary micrometastases in patients with subclinical disease and radiobiologic considerations of the "curability" by radiotherapy of patients presenting with fewer than $10^5$ tumor cells in micrometastases.[116,382] Results have demonstrated only marginal (if any) benefit for irradiated patients, [115,116,382] and adjuvant whole-lung irradiation is not incorporated into modern treatment regimens for osteosarcoma.

### *Presurgical Chemotherapy*

The administration of chemotherapy before definitive surgery of the primary tumor (in addition to postoperative adjuvant chemotherapy) has been used with increasing frequency in recent years. The strategy initially evolved from early attempts at limb salvage surgery at the Memorial Sloan-Kettering Cancer Center, where customized

endoprosthetic devices were used for limb reconstruction. As fabrication of these devices required 2 to 3 months, patients were treated with chemotherapy after biopsy while awaiting definitive surgery.[218] Tumor shrinkage in response to chemotherapy facilitated limb salvage, and patients treated with presurgical chemotherapy appeared to fare better than did concurrent patients treated with immediate surgery and postoperative adjuvant therapy. Moreover, histologic evaluation of the excised tumor after treatment with chemotherapy was found to be a powerful prognostic factor for tumor recurrence; patients demonstrating extensive residual viable tumor cells were more likely to develop distant metastases despite continuation of chemotherapy adjuvantly after surgery.[393] The prognostic value of residual viable tumor after presurgical chemotherapy has been confirmed in several trials.[168,172,218,383,384,386,390,394,395 and 396]

To provide uniformity in the assessment of residual viable tumor after chemotherapy, several systems for grading the effect of presurgical chemotherapy have been proposed on the basis of the histologic assessment of cellularity and necrosis in the excised specimen. The grading system developed at the Memorial Hospital by Huvos[393] has been used widely and has served as a model for other systems for grading residual viable tumor ( Table 35-3).[394,397,398] In the Huvos system, complete or near-complete absence of residual viable tumor (grade III or grade IV effect, less than 10% residual viable tumor) is associated with a better prognosis. Lesser effect (grade I or grade II) with more than 10% residual viable tumor is associated with an inferior prognosis. Such grading systems are necessarily imprecise and subject to sampling errors. However, with meticulous attention to adequate sectioning from multiple sites of the surgical specimen, the effect of chemotherapy and an estimate of residual viable tumor can be assessed reliably. In most studies, patients with favorable chemotherapy effect (grade III or grade IV with less than 10% residual viable tumor) fare extremely well, whereas those with more than 10% residual viable tumor after presurgical chemotherapy (grade I or grade II effect) are likely to develop distant metastases. Thus, patients at high risk for the development of recurrent disease apparently can be identified early in treatment on the basis of the poor histologic response of the primary tumor to presurgical chemotherapy. Noteworthy is that in all studies, patients with grade I and grade II chemotherapy effect and residual viable tumor at the time of resection of the primary tumor still have outcomes significantly superior to that of patients who do not receive adjuvant chemotherapy. Thus, patients with grade I and grade II chemotherapy effect and residual viable tumor after initial chemotherapy still can be expected to benefit from the administration of chemotherapy.

| Grade | Effect |
|---|---|
| I | Little or no effect identified |
| II | Areas of acellular tumor osteoid, necrotic, or fibrotic material attributable to the effect of chemotherapy, with other areas of histologically viable tumor |
| III | Predominant areas of acellular tumor osteoid, necrotic, or fibrotic material attributable to the effect of chemotherapy, with only scattered foci of histologically viable tumor cells identified |
| IV | No histologic evidence of viable tumor identified within the entire specimen |

From G Rosen et al. Primary osteogenic sarcoma: eight year experience with adjuvant chemotherapy. J Cancer Res Clin Oncol 1983;106 [Suppl]:55–67.

**TABLE 35-3. HISTOLOGIC GRADING OF THE EFFECT OF PREOPERATIVE CHEMOTHERAPY ON PRIMARY OSTEOSARCOMA**

Although the predictive value of histologic assessment after presurgical chemotherapy is now indisputable, a number of problems have surfaced in the application of grading chemotherapy effect to patient management. Unfortunately, different criteria for the definition of favorable and unfavorable chemotherapy effect are used in different grading systems, rendering comparisons among studies difficult. Especially noteworthy is that in a recent update of the Memorial Hospital experience with presurgical chemotherapy, the implications of “favorable” and “unfavorable” chemotherapy effect have changed somewhat. Apparently, grade IV chemotherapy effect is predictive of favorable outcome. However, the outcome of patients with grade III chemotherapy effect is not significantly superior to that for patients with grade II chemotherapy effect.[171] Thus, only patients who experience a grade IV chemotherapy effect after presurgical chemotherapy might be considered in the most favorable prognostic group.

Perhaps most problematic are the differences among studies conducted to date in the timing of surgery relative to the initiation of chemotherapy, and especially the variable duration of exposure to chemotherapy prior to definitive surgery and histologic evaluation of chemotherapy effect in the primary tumor. Apparently, presurgical chemotherapy regimens of longer duration are associated with a higher proportion of patients achieving favorable chemotherapy effect.[171,399] However, as the duration of presurgical chemotherapy increases, the predictive value of chemotherapy effect for outcome may be lost; longer, more intensive presurgical regimens may produce a greater proportion of patients achieving favorable chemotherapy effect, but the favorable effect obtained from such regimens may not translate into more favorable outcome. An analysis from the Memorial Hospital suggests that this is indeed the case.[171] Thus, as the proportion of patients achieving a favorable chemotherapy effect increases with the administration of longer, more intensive presurgical regimens, the value of this prognostic factor may be lost.

In addition to the value of identifying responsive and nonresponsive tumors, the strategy of presurgical chemotherapy is attractive because of other theoretic considerations.[383] Because chemotherapy is administered very soon after biopsy and diagnosis, treatment of micrometastases known to be present in the majority of patients can be instituted early. This represents a significant advantage over the traditional adjuvant approach, wherein the administration of systemic chemotherapy is delayed by a month (approximately one tumor doubling time for osteosarcoma) or more by surgery and the time necessary for wound healing. Such a delay is likely to be most critical early in treatment, when the burden of micrometastatic disease is high. Earlier treatment might reduce the chance of spontaneous emergence of drug-resistant clones of tumor cells in the micrometastases.[400,401]

One of the most compelling rationales for presurgical chemotherapy is its use as an *in vivo* drug trial to determine the drug sensitivity of an individual tumor and to customize postoperative chemotherapy. Results of studies from the Memorial Hospital and elsewhere suggest that patients whose tumors demonstrate near-complete absence of viable tumor cells in the resection specimen after presurgical therapy are destined to do well when the same therapy is continued postoperatively. Patients whose tumors demonstrate 10% or more residual viable tumor cells after the presurgical regimen have a much less favorable outlook and might benefit from a change in chemotherapeutic agents. Although this is an attractive hypothesis, several objections can be raised on theoretic grounds. Considerations of cell kinetics predict that responsiveness (or lack thereof) of a bulky tumor may not predict responsiveness of micrometastases.[402] Data from leukemia trials indicate that drugs active in the adjuvant (maintenance) setting may not be those that are most active against bulky macroscopic disease. Similarly, experimental data indicate that drugs with only modest activity against macroscopic tumor still may be active in the adjuvant setting. Finally, prolonged exposure to presurgical chemotherapy might select for drug-resistant tumor cells that might metastasize before definitive surgery.

The strategy of individualizing therapy on the basis of tumor response was pioneered at the Memorial Hospital in the T-10 trial.[185,384] Patients whose tumors demonstrated less than 10% residual viable tumor cells were continued on the same therapy as used preoperatively; patients with more than 10% residual viable tumor cells in the primary tumor were treated with a change in the postoperative chemotherapy. In preliminary reports of results of this study, almost all the patients demonstrating *favorable* chemotherapy effect were projected to survive free of recurrence. Nearly 85% of patients who demonstrated an *unfavorable* chemotherapy effect were projected to remain relapse-free at 3 years with the change in postoperative chemotherapy. The preliminary projected 3-year relapse-free survival rate for all patients in the T-10 study was 90%, with individualized therapy based on histologic assessment of residual viable tumor cells after presurgical chemotherapy. Because of these very favorable preliminary results, the T-10 protocol served as a model for many of the osteosarcoma treatment studies launched in the 1980s, virtually all of which featured the use of presurgical chemotherapy and individualization of therapy based on chemotherapy effect in the primary tumor.

Results reported from representative trials using presurgical chemotherapy are summarized in Table 35-4. Responses in the primary tumor have been variable, with favorable chemotherapy effect in 30% to 85% of patients. The overall results are excellent but comparable to adjuvant studies that used regimens of equal intensity without any presurgical chemotherapy (Table 35-2). Further, the importance of “custom tailoring” of therapy (whereby postoperative chemotherapy is individualized on the basis of assessment of chemotherapy effect in the primary tumor) in this strategy remains to be defined. Several trials are pertinent in this regard. The CCG attempted to duplicate the T-10 regimen in a multi-institutional setting (CCG 782).[394] Whereas patients achieving favorable chemotherapy effect in the primary tumor (28% of the patients) fared extremely well (projected 5-year event-free survival of 87%), the remaining patients with unfavorable chemotherapy effect did not benefit from a change in therapy postoperatively and had a less favorable outcome (projected 5-year event-free survival of 49%). Overall, only 56% of patients in the CCG study were projected to remain free of recurrent disease at 5 years—a disappointing result when compared to the initial results reported from Memorial Hospital.

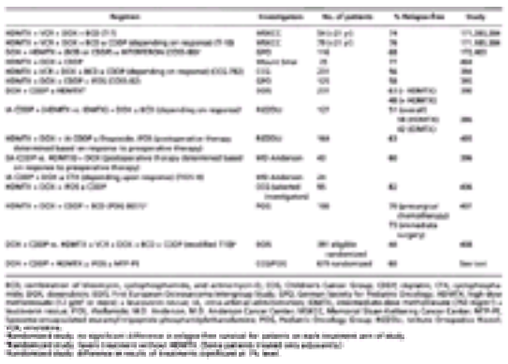

**TABLE 35-4. REPORTED RESULTS OF REPRESENTATIVE TRIALS INCORPORATING PRESURGICAL CHEMOTHERAPY FOR OSTEOSARCOMA**

Other studies conducted in the 1980s attempted to reproduce the remarkable results of the T-10 regimen, but all reported less promising results, particularly among patients achieving an unfavorable chemotherapy effect after presurgical chemotherapy. [389,408] In the COSS-82trial of the GPO,[395] which also tested the strategy of individualized therapy, results suggested that patients demonstrating unfavorable chemotherapy effect in the primary tumor are destined to do poorly and that treatment of poor responders with “salvage regimens” (as in the T-10 protocol) is inadequate to improve their prognosis. Investigators of the GPO concluded that active agents should not be withheld from the initial therapy of patients with newly diagnosed disease. At the Instituto Rizzoli, [396,409] overall results have improved over time, concurrent with the adoption of the strategy of presurgical chemotherapy. However, the Rizzoli investigators concluded that the improvement in prognosis more likely reflects improved effectiveness of the agents used rather than the use of presurgical chemotherapy per se, because a group of patients treated concurrently at the same institution without the benefits of presurgical chemotherapy fared just as well as did patients treated with presurgical chemotherapy. [409]

As in most trials of presurgical chemotherapy, an early trial of presurgical chemotherapy reported from the Rizzoli Institute demonstrated that patients achieving favorable chemotherapy effect in their primary tumors had a better overall outcome; however, change in the postoperative chemotherapy for those with unfavorable chemotherapy effect did not alter their adverse prognosis. However, in a more recent Rizzoli trial [405] conducted between 1986 and 1990, patients were treated initially with HDMTX, doxorubicin, and intra-arterial cisplatin preoperatively. Patients with favorable chemotherapy effect (less than 10% residual viable cells in their primary tumors) were treated postoperatively with 21 additional weeks of the same agents, whereas those with unfavorable chemotherapy effect received 30 weeks of chemotherapy, including ifosfamide and etoposide in addition to doxorubicin, cisplatin, and HDMTX. Seventy-one percent of patients in this study achieved a favorable chemotherapy effect after presurgical therapy, and 71% of those patients were projected to be disease-free survivors at 5 years. Of note, the patients with unfavorable chemotherapy effect had a projected disease-free survival equal to that of good responders if only patients receiving adequate therapy are considered. This Rizzoli trial represents one of the few studies in which the strategy of salvage chemotherapy for poorly responding patients has been shown to be of benefit.

Perhaps of greatest significance is that mature results from the Memorial Hospital studies [171,184] indicate that the very promising preliminary results were not sustained with further follow-up. Moreover, no difference in overall disease-free survival is apparent, regardless of whether patients received presurgical chemotherapy as part of their management. Although histologic evaluation of the primary tumor after presurgical chemotherapy strongly predicted subsequent disease-free survival and overall survival, with longer follow-up the Memorial investigators were unable to demonstrate an improvement in disease-free survival for patients who had unfavorable chemotherapy effect and received a modification of their postoperative chemotherapy as compared to a similar group of patients treated without such individualization of therapy. [171] In support of these findings, members of the Pediatric Oncology Group (POG) reported results of a randomized trial designed to test the impact of presurgical chemotherapy on outcome of patients with extremity osteosarcoma.[407] The overall event-free survival was identical regardless of whether patients were treated with chemotherapy prior to definitive surgery of the primary tumor. Moreover, the overall results of this study were identical to those achieved in a predecessor study wherein all patients were treated with immediate surgery followed by conventional adjuvant chemotherapy. Thus, the administration of presurgical chemotherapy (with or without individualized therapy on the basis of tumor response) per se does not appear to have led to an improvement in the outcome of children with osteosarcoma, at least in terms of rate of cure. Rather, recent improvements in outcome probably reflect the increasing intensity of the chemotherapeutic regimens used.

Although histologic evaluation of chemotherapy effect in the primary tumor after presurgical therapy is a powerful predictor of outcome, the likelihood that an individual patient will respond favorably cannot be predicted at the time of diagnosis. Because it is apparent that the majority of patients achieving a poor chemotherapy effect will relapse and modifications of postsurgical chemotherapy fail to have an impact on this unfavorable outcome, strategies are needed to predict favorably and poorly responding patients prior to the initiation of therapy so that more aggressive approaches can be used earlier in therapy for patients with a poor prognosis. The availability of reliable prognostic factors would permit stratification of patients to achieve two important goals: (a) selection of patients with an inferior prognosis who might benefit from novel or more intensive therapy, and (b) selection of patients with a superior prognosis who could be spared the acute and delayed toxicity of intensified therapy. Molecular markers that might accurately predict the response to presurgical chemotherapy and overall outcome currently are under study but cannot yet be recommended.[151,153,180]

The use of presurgical chemotherapy has been advocated also to increase the proportion of patients who are suitable candidates for limb salvage surgery and to facilitate limb-sparing procedures by tumor shrinkage in response to chemotherapy [410] and by provision of a window of time to fabricate customized endoprosthetic devices if needed for limb reconstruction. As noted, the largest proportion of limb-sparing procedures is performed at institutions using presurgical chemotherapy, but this finding may reflect the preference of institutional surgeons committed to limb-sparing surgery in any case, rather than reflecting any measurable benefit attributable to the use of presurgical chemotherapy per se. Little question remains that the number of patients believed to be suitable candidates for limb-sparing surgery is increasing concomitant with the increasing use of presurgical chemotherapy. This finding may reflect improvements in reconstructive techniques available and the increased experience and confidence of tumor surgeons. This trend has raised concern that selection criteria may be stretched by inexperienced surgeons to accommodate inappropriate candidates who might be better treated by amputation.[411] Presurgical chemotherapy (or for that matter, postoperative adjuvant chemotherapy) cannot reliably serve as a substitute for use of sound surgical principles.

Presurgical chemotherapy has been administered also via the intra-arterial route directly into the arterial supply of the tumor to maximize drug delivery to the tumor vasculature and drug extraction by the tumor.[386,397,412,413] Doxorubicin and cisplatin, in particular, have been delivered by prolonged intra-arterial infusion into vessels of the extremity. High local drug concentrations have been documented by pharmacokinetic studies, [397] and dramatic responses in primary tumors have been observed. The technique appropriately has been limited to centers with excellent angiographic support and facilities to administer repeated courses of intra-arterial therapy preoperatively. The rationale for the use of intra-arterial therapy is not self-evident for several reasons. Even in the prechemotherapy era, control of the primary tumor was rarely a problem. Rather, micrometastatic disease present in the lung ultimately killed the patient. Improvements in the outcome of patients with osteosarcoma have resulted directly from improvements in systemic chemotherapy for micrometastatic disease rather than from better local control measures. Thus, strategies that improve drug delivery to the primary tumor at the expense of drug delivery to micrometastatic disease are counterintuitive. Further, most intra-arterial regimens use single-agent chemotherapy for the first 2 to 3 months of treatment, whereas improvements in outcome for patients with osteosarcoma have resulted from the application of multi-agent chemotherapy.

Data from the COSS-86 study of the GPO challenge the notion that intra-arterial administration leads to superior response in the primary tumor [414] as compared to the same treatment given intravenously. Also unclear is whether the administration of intra-arterial chemotherapy translates into superior overall outcome for patients as determined by improvement in relapse-free survival. An update of studies from the M. D. Anderson Cancer Center, where intra-arterial chemotherapy was pioneered,[396] indicates that the overall disease-free survival for patients treated with intra-arterial cisplatin, definitive surgery, and postoperative adjuvant chemotherapy is projected to be 60%, a disappointing result from a single-institution trial when compared to results achieved in other multi-institutional trials with or without presurgical chemotherapy (see Table 35-2, Table 35-4). Even if the administration of intra-arterial chemotherapy does not improve the overall outcome for patients with osteosarcoma, intra-arterial administration of presurgical chemotherapy has been suggested possibly to maximize response in the primary tumor, thus facilitating limb-sparing surgical procedures, and to maximize the number of patients suitable for such procedures. A study conducted at the Rizzoli Institute [415] addressed this issue directly by randomly assigning patients with osteosarcoma to receive presurgical chemotherapy (HDMTX, doxorubicin, and cisplatin) intravenously or to receive the same presurgical chemotherapy with intra-arterial administration of cisplatin. Although the proportion of patients achieving favorable responses in the resected tumor specimens was significantly higher among patients treated with intra-arterial therapy, the proportion of patients treated with limb-sparing surgery was the same in the two treatment groups (intravenous and intra-arterial therapy). Thus, from the perspectives of overall cure rate and rate of

limb-sparing surgery, the administration of intra-arterial chemotherapy does not seem justified, and the popularity of this strategy has waned in recent years.

### *Use of Biologic Response Modifiers*

Therapeutic trials based on immunologic approaches to osteosarcoma have been stimulated by documentation of tumor-specific humoral [17,19] and cellular [20] immune responses in patients and animals with osteosarcoma. The presence in osteosarcoma patients of tumor-specific cytotoxic lymphocytes that are inhibited by a concomitant population of "inhibitor lymphocytes" [20] suggestsa role for specific and nonspecific immune stimulation in the treatment of osteosarcoma. Early trials using the injection of inactivated osteosarcoma cells [416] or tumor cell lysates [417] induced evidence of cellular immune response in patients but produced no definitive therapeutic advantage. Similarly, cross-transplantation of biopsy specimens as a means of antitumor immunization resulted in no significant reduction in the incidence of metastatic disease. [416,418] Nonspecific immune stimulation with bacille Calmette-Guérin vaccine was not effective therapeutically, [416] even when administered in conjunction with adjuvant chemotherapy. [370] Interferon has been demonstrated to inhibit the growth of osteosarcoma cell lines *in vitro* [419] and was used as an adjuvant to surgery in an uncontrolled trial from the Karolinska Hospital in Sweden. A significant improvement over historical results was observed, but this improvement was less dramatic when compared to a concurrent group of patients treated only with surgery in other Swedish hospitals. [114,420] In the COSS-80 trial (Table 35-4), patients were treated with presurgical and postsurgical adjuvant chemotherapy and were assigned randomly to receive or not to receive interferon in addition to chemotherapy. No benefit in relapse-free survival could be demonstrated for patients treated with interferon. [172]

Liposome-encapsulated muramyl tripeptide-phosphatidylethanolamine (liposomal MTP-PE), a derivative of bacille Calmette-Guérin, is a promising biologic agent for the treatment of osteosarcoma. [421,422] and [423] Liposomal MTP-PE activates monocytes *in vitro* to a tumoricidal state against osteosarcoma and other tumors. When it is injected intravenously in animals, similar macrophage activation can be demonstrated, resulting in the complete eradication of established pulmonary metastases in a rodent model. In dogs with spontaneously occurring osteosarcoma, the administration of MTP-PE prolonged median survival after amputation as compared to untreated controls, [424] and the combination of cisplatin and liposomal MTP-PE resulted in superior survival of dogs with osteosarcoma as compared to those treated with cisplatin alone. [425,426] Studies to date indicate that liposomal MTP-PE can be administered safely to human beings, [422,423] but the efficacy of the compound in the treatment of osteosarcoma awaits further study. Likely, liposomal MTP-PE will be most useful in patients with minimal residual disease, probably in combination with standard chemotherapy. A randomized trial testing this hypothesis recently was conducted in the United States and Canada jointly by the CCG and the POG, with promising preliminary results. [457]

Hybridoma technology and advances in the technology for cloning T cells and expanding such clones for therapeutic purposes [427] provide interesting possibilities for future trials. Monoclonal antibodies specific for the ganglioside $G_{D2}$—a cell-surface antigen expressed by human neuroblastomas—also recognize human osteosarcomas. [428] These antibodies already have been used for imaging and treatment of patients with neuroblastoma and may prove useful in treatment of patients with osteosarcoma as well. Clinical trials of such antibodies now are under way. Similarly, T-cell clones that have been isolated from the peripheral blood of patients with osteosarcoma [429] are cytotoxic to autologous tumors and can be expanded *in vitro* for reinfusion into patients. Possibly, lymphocytes with enhanced antitumor reactivity may be cloned directly from tumor specimens [427] and may provide a more potent source of immunoreactive cells for therapy of osteosarcoma.

### *Treatment of Metastases*

Historically, patients who had osteosarcoma and developed metastases had a poor prognosis and were treated palliatively. Most of such patients died within 1 year of developing metastatic disease. Although attempts at surgical resection of metastatic pulmonary nodules were undertaken as early as 1940, [430] the first systematic aggressive surgical approaches to these patients were initiated in the mid-1960s. Little doubt remains that the development in the last 20 years of more effective salvage therapies for patients who develop metastases has contributed substantially to the improved survival of children with osteosarcoma. [430,431,432,433,434,435,436,437,438,439,440,441,442,443,444] and [445]

The biology of osteosarcoma offers the unique opportunity to cure patients who have developed metastases. More than 85% of recurrences are in the lung, where complete surgical resection of tumor nodules with wide margins can be accomplished relatively easily (and repeatedly). With frequent thoracic CT scanning, metastatic nodules can be detected when fairly small and more easily resectable, although in most cases the surgeon will discover at thoracotomy more lesions than anticipated from the CT scan. [446] Not all lesions detected on CT scan represent metastases, [447] and histologic confirmation should be undertaken (at least for a first relapse) before committing affected patients to intensive salvage therapy. In a significant proportion of patients, the lungs are likely to be the *only* site of metastases, especially when recurrences appear relatively late (i.e., more than 1 year after diagnosis) and when the metastatic lesion is solitary. In such cases, the recurrent tumors are likely to have a more indolent behavior and may not themselves further metastasize. Such patients have been cured by thoracotomy alone (discussed later). [448]

Complete surgical resection of all overt metastatic disease is a prerequisite for long-term salvage after relapse. Patients not treated by thoracotomy have little hope for cure. [436,437,443,444] The majority of pulmonary lesions can be resected successfully by wedge resection without risk of local recurrence [432] while preserving the maximum lung tissue and allowing for the possibility of future pulmonary resections. Rarely, segmentectomy, lobectomy, or even pneumonectomy may be required to control more extensive lesions. Bilateral lung metastases can be approached by staged lateral thoracotomies performed 1 to 2 weeks apart, a program that is tolerated well by otherwise healthy young adults and adolescents.

Some surgeons have advocated an approach by median sternotomy. Although metastases can be removed from both lungs in one procedure using this approach, surgical exposure is not as complete (especially in the retrocardiac area and left lower lobe), and subsequent repeat thoracotomy is more difficult.

The completeness of surgical resection is an important determinant of outcome in that patients left with measurable or microscopic disease at the resection margins are unlikely to be cured. [436,449] Evidence of disruption of the visceral pleura by tumor has been found to be associated with an adverse prognosis and is thought to carry the same implications as incomplete resection. [437,441] In one series, 9 of 11 (82%) patients who had complete resections without evidence of pleural disruption became long-term survivors, as compared to only 2 of 15 (13%) who had incomplete resection or pleural disruption by tumor. More stringent criteria for complete resection, which include attention to the status of the pleura, are valuable prognostically but, even with an aggressive surgical approach, only 42% of patients (11 of 26) could be rendered disease-free surgically in one series when these stringent criteria were applied. [437]

Several other prognostic factors have been examined in patients treated for metastases. Variables that appear to have significant prognostic value include the number of nodules detected on the prethoracotomy CT scan and the disease-free interval between initial diagnosis and the development of metastases. In general, patients with late-appearing solitary pulmonary nodules (more than 1 year after surgery for the primary tumor) are most likely to be cured, whereas those with more than three nodules that appear within 6 months of surgery have a less favorable outcome. [432,436,437,443,445,448,449] Although an initial disease-free interval of less than 6 months indicates a less favorable prognosis, this finding should not exclude affected patients from consideration for salvage surgery [436]; the poor prognosis for patients who experience relapse within 1 year of initial diagnosis reported in some series may reflect the use of a less aggressive approach for such patients. [437] The number of nodules also has not been prognostically important in all series, although patients presenting with more than 16 nodules on preoperative tomography are unlikely to have successful complete resection. [436] Several reports indicate that adjuvant chemotherapy for primary osteosarcoma may reduce the number of metastatic nodules in patients destined to relapse, thus increasing the chance that these metastases will be resectable. [110,450] However, that this translates into an improved cure rate for patients developing recurrent disease after adjuvant chemotherapy is unclear. [450]

Many investigators have advocated the use of postthoracotomy adjuvant chemotherapy (and even lung irradiation) [438,440,443,444] and [445] to destroy presumed residual microscopic deposits after surgical treatment of overt metastases. The contribution of such adjuvant therapy has not been examined in a controlled study. In small series, long-term survival has been reported without the use of further chemotherapy, [436,437,441,448] although survivors treated with only surgery were more likely to be those who had suffered late relapse with solitary pulmonary nodules. The likelihood that a patient will benefit from the administration of chemotherapy to treat relapse is highly dependent on the chemotherapy experience of such a patient prior to relapse. Tumors recurring after exposure to multi-agent intensive regimens are less likely to respond to salvage regimens (assuming that active drugs can even be identified that have not already been used in the previous treatment of the patient).

Thus, when overt metastatic disease is discovered, a systematic approach is recommended. A careful search for all metastatic lesions by thoracic CT scan and radionuclide bone scan is essential; other investigations to search for metastases to other sites should be performed if clinically indicated. The discovery of unresectable extrathoracic metastases or of obviously unresectable pulmonary disease (because of hilar involvement, malignant pleural effusion, massive disease or, perhaps, the presence of more than 16 nodules) is a contraindication to aggressive thoracotomy, and the patient should be treated palliatively. Radiotherapy may be

particularly useful in palliative treatment. In selected patients with unresectable disease (especially those with no previous exposure to chemotherapy), an aggressive approach with curative intent still may be indicated. The use of chemotherapy (with or without radiotherapy) rarely produces complete response of all metastatic disease, but some patients with inoperable metastases may respond sufficiently to permit complete resection of disease at a later date, with a chance for long-term disease control. Rare patients with isolated bony metastases also have been cured by such an aggressive approach.

Patients with resectable lung disease should undergo thoracotomy to remove all evidence of disease. Bilateral disease is not a contraindication and can be approached by staged bilateral thoracotomies or median sternotomy. The role of adjuvant chemotherapy after thoracotomy remains to be defined, but such treatment probably is indicated, at least for patients with multiple lesions (more than three) appearing within 6 months to 1 year of initial surgery and for patients who have incomplete resection of metastatic disease or evidence of pleural disruption by tumor. Repeat thoracotomies may be required for subsequent recurrence and should be recommended as long as all evidence of disease can be resected.

Several approaches incorporating chemotherapy and radiotherapy administered before or after thoracotomy have been used to treat patients with metastases. Survival after relapse doubtless has been enhanced by approaches designed with curative intent that incorporate repeated aggressive surgery to remove overt disease. With such treatment, 30% to 40% of patients have been reported to survive beyond 5 years after relapse, [435,436] and [437,440,441,443,444] and [445] although not all these patients ultimately will be cured. Many of these reports include patients who did not receive adjuvant chemotherapy as part of their initial treatment or whose adjuvant chemotherapy did not include all agents with demonstrable activity. Patients who relapse after multi-agent chemotherapy and surgery have a significantly lower probability for survival. Such considerations emphasize the value of close follow-up, with frequent chest radiographs and thoracic CT scans to detect recurrent disease when it still is resectable. Thus, for patients with osteosarcoma, presentation with or development of metastases is not a hopeless situation; aggressive systematic treatment of metastases offers prolonged survival for many patients and the possibility of cure for a significant fraction. Ironically, as adjuvant regimens used in frontline therapy of patients are intensified and the number of patients surviving without ever developing recurrence increases, the proportion who are likely to be salvageable after relapse may decrease, because patients who experience relapse are more likely to have drug-resistant recurrences.

Management of patients with clinically detectable metastatic disease at initial presentation incorporates some of the same principles that guide the management of recurrent disease.[451,452] and [453] Such patients have no previous exposure to chemotherapy, and their tumors thus are more likely to be chemosensitive than are those tumors recurring after initial adjuvant therapy. As in the treatment of recurrent disease, resection of all measurable disease (at the primary and metastatic sites) is a prerequisite for cure, and patients with extrathoracic metastases are unlikely to be cured. Timing of the surgery of the primary tumor and metastatic sites has been variable, but most modern approaches prescribe a strategy of alternating chemotherapy and surgery. The initial treatment usually is a course of chemotherapy, followed by surgical resection of the primary tumor, followed by a second course of chemotherapy and surgical ablation of metastatic sites, followed by the remaining courses of chemotherapy. Patients with tumors that are responsive to presurgical chemotherapy are more likely to be cured. Although improving, the outlook for patients presenting with metastatic disease is poor.

## CONCLUSIONS AND FUTURE CONSIDERATIONS

In the last three decades, the prognosis for children with osteosarcoma has improved dramatically. The benefit of adjuvant chemotherapy that prevents recurrence in almost two-thirds of patients with limb primaries is indisputable. Aggressive, systematic approaches with thoracotomy have improved the outlook for patients presenting with or developing metastases after therapy. Nevertheless, refinements in therapy are needed. More than one-third of children presenting without metastases will experience relapse after current therapy. The strategy of presurgical chemotherapy has not lived up to the initial promise of improving the disease-free survival for patients with osteosarcoma, although this strategy may facilitate limb-sparing surgery.

The morbidity related to therapy is considerable because many patients still require amputation to control the primary tumor; advances in surgical techniques for limb reconstruction may allow for limb-sparing surgery for an increasing proportion of patients. The toxicity and expense of current chemotherapeutic regimens are substantial, and the late effects of such therapy have not yet been assessed completely. The late cardiac injury resulting from therapy with anthracyclines already has emerged as a significant price of cure for survivors of osteosarcoma. [454] Despite promising new approaches, patients with axial skeleton primaries continue to fare poorly because local control cannot be achieved in the majority of cases. The outcome for patients presenting with metastatic disease remains unsatisfactory.

Limb salvage has been adopted enthusiastically by orthopedic surgeons. Although the safety of this approach appears to have been demonstrated and the functional results appear to be superior to amputation, late complications occur in many patients, and the psychological outcome for patients undergoing limb salvage is not clearly superior to that of amputees.[193,213] Limb-sparing surgery thus may not be the appropriate approach for all patients. Strategies to sterilize the primary tumor site by administering intensive intra-arterial chemotherapy in the hope of avoiding surgery for the primary tumor altogether have been attempted, but results to date indicate an unacceptable local recurrence rate, [396] and this approach cannot be recommended.

New active drugs promise to add further to the armamentarium of chemotherapeutic agents available for use against osteosarcoma. Ifosfamide already has been incorporated into frontline treatment regimens, although the benefit of this addition remains to be confirmed. Primary drug resistance and treatment failure in osteosarcoma may be associated with the multi-drug-resistant phenotype mediated by p-glycoprotein. Strategies to reverse the multi-drug-resistant phenotype with cyclosporine and its less toxic analogs may prove useful in the management of recurrent disease and, ultimately, in frontline treatment.

Although immunotherapy of osteosarcoma has not yet proved successful, advances in technology have provided immunotherapists with more active and more specific reagents. Monoclonal antibodies against osteosarcoma may prove useful for delivering drugs or radiopharmaceuticals directly to tumor. Antibodies with exquisite specificity will be required for this purpose. Cloned cytotoxic T cells may also provide more specific antitumor therapy and may prove most useful in the adjuvant setting.

Finally, studies of osteosarcoma have elucidated some of the growth factors and receptors that play critical roles in tumor cell proliferation. Insulin-like growth factor-1 has been found to be a potent mitogen for osteosarcoma cells, suggesting possible intriguing endocrine therapies of this disease. [455] Osteocalcin is expressed in high levels by tumor cells of osteosarcoma, suggesting the use of the osteocalcin promoter as a relatively tissue-specific target for delivery of therapeutic toxic genes (e.g., the herpes simplex thymidine kinase gene that activates acyclovir to produce cytotoxicity in dividing cells). [456] Overexpression of HER2 in a subset of patients with osteosarcoma with adverse prognosis[181,182] suggests a strategy to target this receptor therapeutically. A “humanized” antibody directed against the extracellular domain of the HER2 receptor (Herceptin) already has proven to be effective in women with advanced breast cancer and currently is under study in a trial for patients with metastatic osteosarcoma.

The prospects for understanding the biology of osteosarcoma and improving therapy for affected children thus appear bright. Although numerous problems remain to be addressed, the current state of therapy—with more than two-thirds of patients who have nonmetastatic osteosarcoma of the extremity being cured of their disease—represents an exceptional advance, achieved in less than three decades. The celebrated surgeon of the 1920s who exhorted his colleagues to pray for children with osteosarcoma might well be gratified by the remarkable advances in treatment over the last 30 years.

# GERM CELL TUMORS

BARBARA CUSHING
ELIZABETH J. PERLMAN
NEYSSA M. MARINA
ROBERT P. CASTLEBERRY

## INTRODUCTION

Gonadal and extragonadal germ cell tumors are infrequent in childhood, occurring at a rate of 2.4 cases per million children and representing approximately 1% of cancers diagnosed in persons younger than 15 years.[1] Until recently, the myriad of histologic subtypes and sites of origin and the paucity of cases hindered the standardization of care for such children. The challenge presented by these neoplasms to pediatric oncologists and pediatric surgeons is to control the tumor while maintaining future fertility. With the advent of effective chemotherapy and the recognition that many of these tumors respond in a similar manner, the management of germ cell tumors is being clarified. However, because of the low incidence of these tumors, cooperative group studies will be necessary to extend future therapeutic advances.

## EMBRYOGENESIS AND HISTOGENESIS OF GONADAL TUMORS

Germ cell tumors are presumed to share a common cell of origin, the primordial germ cell, yet they remain a heterogeneous group of tumors. Variations regarding age, sites of presentation, histopathology, and malignant potential stem from differences in the stage of germ cell development at tumorigenesis, differences in the tumor environment secondary to the gender of the patient and location of the clone, and specific genetic aberrations. Therefore, understanding the development of embryonic germ cells is critical to an appreciation of these issues.

The primordial germ cells first become evident in the extraembryonic yolk sac by the fourth week of gestation. By the fifth week, the germ cells migrate through the mesentery to the gonadal ridge.[2] This migration appears to be mediated by the c-kit receptor and its ligand, stem-cell factor, or steel factor. Primordial germ cells express c-kit. Stem-cell factor is expressed with an increasing gradient from yolk sac to gonadal ridge, guiding germ cells to the gonadal ridge. [3,4] and [5] In animal models, primordial germ cells not expressing c-kit are unable either to migrate to the gonad or to proliferate during this migration. Extragonadal germ cell tumors are presumed to arise from germ cells that have migrated aberrantly.[6]

The fate of the germ cells, after their arrival at the gonadal ridge, depends on the sex genotype of the individual. During a narrow window of opportunity in the sixth to seventh week, a gene on the Y chromosome (the SRY gene) initiates male sex determination. Ovarian differentiation commences either in the absence of a Y chromosome or if the window of opportunity is missed.[7] Testicular differentiation manifests itself by the abrupt development of cellular cords (sex cords) in the seventh week. Primordial germ cells populate these sex cords; then, within a few days, they undergo mitotic arrest and remain until puberty. The ovary does not demonstrate the defined sex cords seen in the testis. Instead, primordial germ cells populate the mesenchyme of the primitive gonad while continuing to divide and proliferate. At approximately 16 to 18 weeks' gestation, the germ cells gradually enter into meiosis I, then arrest in the prophase of meiosis I as oocytes. Simultaneously, the follicular cells surround the oocytes. Primordial germ cells are not associated with follicular cells prior to entry into meiosis. The entry into meiosis of primordial germ cells is a gradual process that continues until birth.

The gonads contain three cell types having neoplastic potential. Germ cells give rise to germ cell tumors. The cells of the sex cords rarely may develop into stromal tumors, such as testicular Sertoli or Leydig cell tumors, ovarian granulosa cell tumors, or mixtures of these components. Last, coelomic epithelium covering the ovary may evolve into epithelial neoplasms, found most often in adults.[8,9]

## GENETICS AND MOLECULAR BIOLOGY

The heterogeneity of the pediatric germ cell tumors is evident also in studies investigating their genetic and molecular properties. Four biologically distinct subcategories are noted: tumors of the adolescent testis, tumors of infancy, extragonadal tumors of adolescents, and tumors of the adolescent ovary.

### Genetic Characteristics of Adolescent Testicular Tumors

Adolescent testicular germ cell tumors most commonly become clinically evident several years after puberty, suggesting that a critical genetic event occurs with, or is unmasked at, puberty. However, because these tumors have been shown to arise in premeiotic germ cells, some observers believe the critical event occurs in the embryonic gonad.[10] Despite their histologic heterogeneity, tumors of the adolescent and adult testis are relatively homogeneous genetically, demonstrating an aneuploid DNA content and the isochromosome 12p or i(12p).[11,12,13 and 14]

The i(12p) is composed of two copies of 12p (Fig. 36-1), both from the same parental origin.[15] Testicular tumors lacking i(12p) often show gain of 12p material within marker chromosomes.[16] The i(12p) has been documented by fluorescent *in situ* hybridization in intratubular germ cell neoplasia, a precursor lesion of testicular germ cell tumors. This finding provides further evidence that this genetic alteration occurs early in germ cell tumor pathogenesis.[17] Whether the critical genetic event is gain of 12p, loss of 12q, or both is not fully understood. Murty et al.[18] noted loss of heterozygosity at the 12q13 and 12q22 regions in 41% and 47% of tumors, respectively. Genes implicated in the pathogenesis of other solid tumors that map to the 12q13 region, including INT1, GLI, and MDM2, are not altered in testicular germ cell tumors.[18] Testicular germ cell tumors also have exhibited loss of chromosome 13 (38%), gain of chromosome 21 (45%), gain of chromosome 8 (45%), gain of chromosome 1q (36%), and high-level gain of 12p11.2-12.1, suggesting amplification.[19,20] Other less frequent genetic changes include loss of 1p,[21,22] K-ras, and N-ras mutations[23]; high N-*myc* expression without amplification[24]; absence of p53 mutation[25]; loss of heterozygosity for 11p13 and 11p15 with preferential loss of the paternal allele[26]; loss of 3p[27]; deletion of DCC[28,29]; and biallelic expression of H19 and insulin-like growth factor-2.[30]

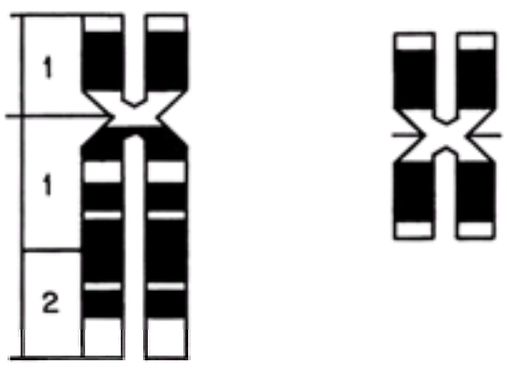

**FIGURE 36-1.** Normal chromosome 12 (*left*) and isochromosome 12p (*right*).

### Genetic Characteristics of Adolescent Ovarian Tumors

The genetic biology of ovarian germ cell tumors is more complex than that of testicular germ cell tumors and is considered separately for mature teratomas, immature teratomas, and malignant ovarian germ cell tumors.

#### *Mature Teratomas*

Cytogenetic assessment of more than 325 ovarian mature teratomas demonstrates that 95% are karyotypically normal, with only 5% showing gains of single whole chromosomes, the identity of which differs from case to case.[31,32,33 and 34] Studies of molecular loci have shown that the majority of mature ovarian teratomas have entered but not completed meiosis.[31,35,36] These diploid tumors are genetically unique in that the majority of their genome is isodisomic.[37]

#### *Immature Teratomas*

Ovarian immature teratomas are heterogeneous. Some show evidence of a meiotic stem-cell origin, and others show mitotic origins, suggesting failure of early meiotic arrest.[38] The frequency of chromosomal abnormalities in immature teratoma is higher than in mature teratoma, but no consistent abnormalities, including the i(12p), have been described. All except one of the patients with cytogenetically abnormal immature teratomas reported to date have experienced multiple recurrences. The exception was a tumor showing a 47,XXX karyotype. In contrast, all patients previously described with karyotypically normal immature teratomas have remained disease free.[38,39,40,41,42,43 and 44]

Apparently a correlation exists between the histologic grade of immature teratoma and DNA content. Grades 1 and 2 are diploid, and grade 3 tumors are aneuploid.[45] King et al.[39] reported that diploid, grade 3 immature teratomas may have a better prognosis as compared to aneuploid tumors.

#### *Malignant Ovarian Germ Cell Tumors*

As are germ cell tumors of the adolescent testis, most malignant ovarian germ cell tumors are aneuploid. Approximately 75% contain i(12p), 42% and 32% have gains of chromosomes 21 and 1q, respectively, and 25% and 42% have loss of chromosomes 13 and 8, respectively.[44,46,47,48,49,50 and 51] DNA fingerprinting of four patients with dysgerminoma suggested an origin from premeiotic germ cells or germ cells at the beginning of the first meiotic division.[35] Also described was the development of a malignant endodermal sinus tumor with i(12p) and aneuploidy within an immature teratoma that had no i(12p) and was diploid. Such an event supports a genetic clonal evolution in this process.[46,47]

In summary, although malignant ovarian germ cell tumors appear to be equivalent to their adolescent testicular counterparts, immature and mature ovarian teratoma remain unique subcategories of germ cell tumors likely to have a different mechanism of origin.

### Genetic Characteristics of Extragonadal Germ Cell Tumors of Older Children

Aberrant or incomplete migration of primordial germ cells is one explanation for the origin of extragonadal germ cell tumors. Another hypothesis is that these tumors arise from totipotent embryonal cells that have escaped the influence of embryonic organizers controlling normal differentiation. This latter proposal is supported by a number of observations, the foremost being that ectopic germ cells only rarely have been reported to exist in human embryos, most having disappeared by 18 weeks' gestation.[52,53 and 54] Although data from animal models predict these tumors to be postmeiotic in origin,[55] other studies have shown extragonadal germ cell tumors in older children to be postmitotic in origin.[48,56,57 and 58]

The two most common sites for extragonadal germ cell tumors in older children are mediastinum and brain. Cytogenetic analysis of central nervous system teratoma has shown a high frequency of sex chromosome abnormalities, most commonly increased copies of the X chromosome.[59,60] The i(12p) has been described in some, but not all, pineal germinomas, but it has not been seen in pineal teratoma.[60,61 and 62] Ploidy analyses of mediastinal germ cell tumors suggest that most are diploid or tetraploid,[63] and some contain i(12p).[64] The extragonadal germ cell tumors in adolescents and adults are associated with hematopoietic malignancies of various cell lineages that present soon after the initial presentation of the germ cell tumors. The malignant hematopoietic clone commonly demonstrates i(12p), unlike hematopoietic malignancies that arise secondary to therapy.[65,66 and 67]

### Genetic Characteristics of Extragonadal and Testicular Germ Cell Tumors of Young Children

In children younger than 4 years, germ cell tumors arising in gonadal and extragonadal sites are histologically, clinically, and genetically similar. Most teratomas in this age group are diploid, have normal karyotypes and, if completely resected, behave in a benign fashion regardless of degree of immaturity and site of origin.[48,56,57,68,69] Malignant germ cell tumors in these young children are almost exclusively yolk sac tumors, arise from a preexisting teratoma, and most often are diploid or tetraploid.[45,70] Recurrent cytogenetic abnormalities involve chromosomes 1, 3, and 6, among others, but only rarely the 12p.[45,69,70 and 71] *In situ* hybridization studies have demonstrated deletion of 1p36 in 80% to 100% of infantile malignant germ cell tumors arising from testicular and extragonadal sites.[72,73] Genetic surveys of regions of gain or loss in these infantile yolk sac tumors document recurrent loss of 6q24-qter, gain of 20q and 1q, and loss of 1p. A small minority of tumors show evidence for c-myc or n-myc amplification.[74] The clinical significance for these markers is entirely unknown. Patterns of genetic expression have not been reported in these tumors.

## PATHOLOGY

Germ cell tumors show numerous histologic subtypes. Although the histologic features of each subtype are independent of presenting clinical characteristics, tumor biology and clinical behavior vary with site of origin, stage, and age of the patient.[75,76] For example, mature teratoma in infants and in the ovary almost invariably are diploid and benign, whereas those in the adult testis are aneuploid and potentially malignant.[77] The histologic classification of these tumors is shown in Table 36-1. The pathologic features of each histologic subtype are discussed separately.

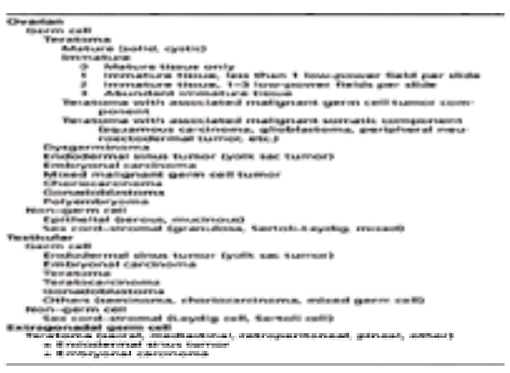

**TABLE 36-1. HISTOLOGIC CLASSIFICATION OF PEDIATRIC GONADAL AND EXTRAGONADAL TUMORS**

### Mature Teratoma

Teratomas are the most common histologic subtype of childhood germ cell tumor arising in ovary and extragonadal locations.[75,78,79 and 80] Mature teratomas of the gonads are encapsulated, multicystic, or solid tumors.[75,78,79 and 80] Extragonadal teratomas differ from those arising from the gonads only in the absence of a clearly defined external capsule. This characteristic in sacrococcygeal teratoma requires that the coccyx be removed during surgery to reduce the risk of recurrence.

The mature teratoma is composed of mature representative tissues from all three germ cell layers: ectoderm, mesoderm, and endoderm. Although any tissue type may be seen, the most common are skin and skin appendages, adipose tissue, mature brain, intestinal epithelium, and cystic structures lined by squamous, cuboidal, or flattened epithelium. Some tissue types are site-specific. For example, hematopoietic, pancreatic, or pituitary tissue frequently is found in mediastinal tumors and rarely in teratoma at other sites.[81] Components of the mature teratoma occasionally may be biologically active, with secretion of enzymes or hormones, including insulin, growth hormone, prolactin, and vasopressin.[82,83 and 84]

### Immature Teratoma

Immature teratomas have a gross appearance similar to that of mature teratoma and likewise are composed of representative tissues from all three germ layers. Unique to these tumors is the presence of various immature tissues, usually neuroepithelium, although immature ectodermal, mesodermal, and endodermal elements also may be observed. A number of grading systems have been established for immature teratoma, all of which systems are variations of the system originally devised by Thurlbeck and Scully.[85] All quantify the degree of immaturity in the lesion (Table 36-1). Only in immature teratoma of the adult ovary has grading of immature elements had potential prognostic significance. Even so, most of these studies predated the full appreciation of the range of histologic appearance of endodermal sinus tumor. Immature teratomas in children behave in a malignant fashion only if foci of malignant germ cell elements (usually yolk sac tumor) and specific clinical characteristics (usually advanced stage) are present. Because clusters of yolk sac tumor may be very small or associated intimately with the immature neural tissue, or both, and because they frequently do not stain positively for a-fetoprotein (AFP), they are easily overlooked ( Fig. 36-2). Tumors containing such foci likely are responsible for the reports that immature teratoma may metastasize.

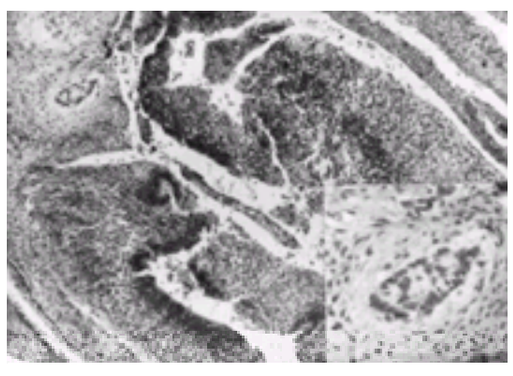

**FIGURE 36-2.** A small focus of glandular yolk sac tumor is present in a loose myxoid background (*upper left*), closely associated with a large area of immature neural tissue. In the inset, the large, vesicular nuclei and prominent nucleoli of the yolk sac tumor cells are seen at higher magnification.

### Yolk Sac Tumor (Endodermal Sinus Tumor)

Yolk sac tumors are the most common pure malignant germ cell tumor in young children and are the most common germ cell tumors, benign or malignant, in the testes of infants and young boys.[77] Yolk sac tumor is the only malignant germ cell tumor type occurring in the sacrococcygeal region.[75,80,86] Yolk sac tumors rarely occur in pure form in extragonadal sites of adolescents but more frequently are a component of the mixed malignant germ cell tumors occurring in these locations.[81,87,88] Grossly, these tumors consist of friable, pale gray, mucoid tissue in which variable amounts of hemorrhage and necrosis are present. The microscopic features are varied and have been characterized fully only in the last two decades.[89,90] Individual cells may be small and pale, with scant cytoplasm, round to oval nuclei, and inapparent nucleoli, or they may be medium-sized to large with clear vesicular nuclei and prominent nucleoli, resembling cells of an embryonal carcinoma or germinoma. Mitoses range from few to many. Four general patterns and a number of variations have been recognized. These patterns are useful in the recognition of endodermal sinus tumor but have no other known clinical relevance.

The pseudopapillary or festoon pattern and the microcystic or reticular pattern are the most common and widely recognized. Both contain Schiller-Duval bodies, structures formed by a central small blood vessel closely invested by two layers of tumor cells ( Fig. 36-3). The microcystic or reticular pattern is associated most often

with eosinophilic globules and strands that only occasionally stain positively for AFP or a $_1$-antitrypsin. The pseudopapillary and parietal patterns often are observed after chemotherapy.[91] The solid pattern usually is found only focally and may resemble embryonal carcinoma, but the cells are smaller and less pleomorphic than those of embryonal carcinoma and tend to have nucleoli less prominent than those of either embryonal carcinoma or germinoma. A variant of the solid pattern is the hepatoid pattern, which closely resembles fetal liver.[92] A fourth pattern is the polyvesicular vitelline pattern, characterized by small, empty cystic structures lined by a single layer of malignant cells that merge from cuboidal to flat. The cells often are embedded in a loose, frequently myxoid stroma. Two other patterns have been described. The enteric pattern resembles the fetal human gastrointestinal tract and typically stains positively for AFP and chorionic embryonic antigen.[90,93,94] The mesenchyme-like pattern stains positively for cytokeratin and vimentin but not for AFP and has been implicated as the source of the sarcomas that occasionally occur in patients who have had a yolk sac tumor.[92]

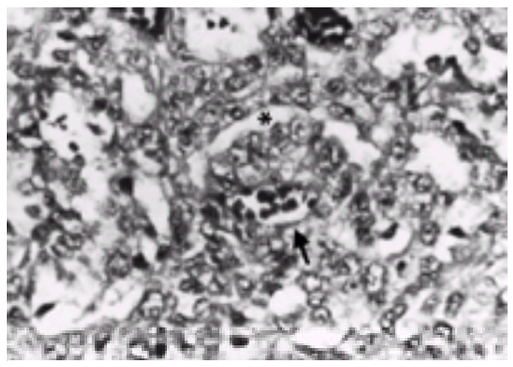

**FIGURE 36-3.** Schiller-Duval body seen here in the microcystic pattern of yolk sac tumor is characterized by a central blood vessel ( *arrow*) closely invested by a layer of tumor cells and separated from a second layer of tumor cells by a space (*star*), likened by some to Bowman's space in the glomerulus.

### Germinoma

Germinomas, also termed *dysgerminomas* or *seminomas*, depending on tumor location, are the most common pure malignant germ cell tumors that occur in the ovary (dysgerminomas) and central nervous system in children.[86,87,95] Pure seminomas represent the most common malignant germ cell tumor in men older than 20 years. However, pure seminomas are distinctly unusual in men younger than 20 years.[77] This distinction likely is due to the slower growth rate of seminomas and hence the later age of presentation. Grossly, germinomas are encapsulated, solid, gray-pink tumors with a rubbery consistency and occasional small foci of hemorrhage and necrosis. Microscopically, the tumor cells are arranged in nests separated by bands of fibrous tissue in which variable numbers of lymphocytes are identified ( Fig. 36-4). The cells are large, with clear cytoplasm, distinct cell membranes, and large round nuclei having one or two prominent nucleoli. Granulomas with giant cells frequently are present. Syncytiotrophoblasts also may be present, but they do not alter the prognosis of the tumor unless they are associated with cytotrophoblasts in foci of choriocarcinoma. Immunohistochemically, the germinoma cells have strong staining for placental alkaline phosphatase (PLAP), whereas the syncytiotrophoblasts stain for human chorionic gonadotropin beta-subunit (b-HCG). The primary differential diagnosis of germinomas, particularly in small biopsies of extragonadal sites and at the time of frozen section analysis, includes a hematopoietic disorder such as lymphoma and the solid variant of endodermal sinus tumor, as these merit different therapeutic approaches.

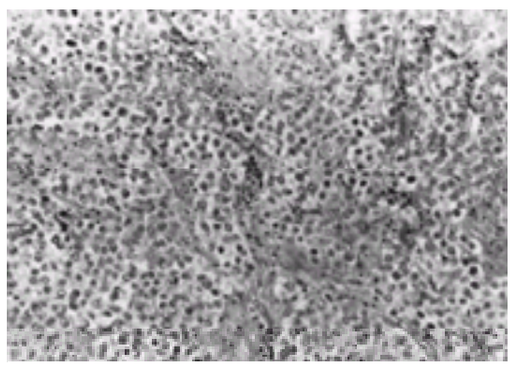

**FIGURE 36-4.** In this germinoma, nests of monomorphic cells with abundant clear cytoplasm and round to oval vesicular nuclei with prominent nucleoli are separated by delicate bands of connective tissue in which a few lymphocytes can be identified.

### Embryonal Carcinoma

Embryonal carcinoma rarely occurs in a pure form in children, being more often a component of a mixed malignant germ cell tumor.[75,77] These carcinomas are characterized by large cells with large, overlapping nuclei and very large, round nucleoli ( Fig. 36-5). The major pattern is epithelial and consists of large nests of cells with varying amounts of central necrosis. Pseudotubular and papillary patterns that may be confused with those of yolk sac tumor are frequent, but the cells are AFP-negative, and the tumors typically lack the eosinophilic hyaline globules characteristic of yolk sac tumors. Unlike other germ cell tumors, embryonal carcinoma is positive for CD30 by immunohistochemical staining.

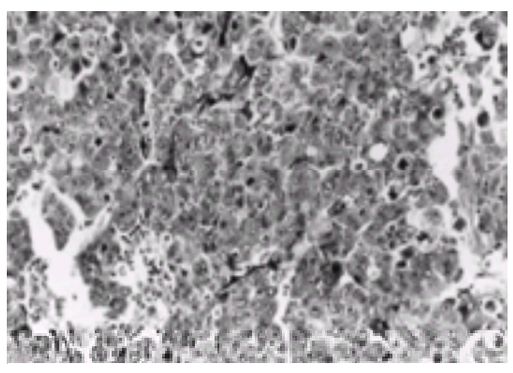

**FIGURE 36-5.** The embryonal carcinoma has large, vesicular, overlapping nuclei with extremely large, prominent nucleoli and moderate amounts of eosinophilic cytoplasm. A number of individually necrotic cells characteristic of this tumor are present.

### Choriocarcinoma

Like embryonal carcinoma, choriocarcinoma rarely occurs outside the context of malignant mixed cell tumors in adolescents.[75,77] The rare case of pure choriocarcinoma detected in infants almost always represents metastasis from maternal or placental gestational trophoblastic primary tumor.[96,97] These tumors characteristically are very hemorrhagic and friable. Microscopically, two types of cells must be present to confirm the diagnosis: *cytotrophoblasts*, which classically

appear as closely packed nests of relatively uniform, medium-sized cells having clear cytoplasm, distinct cell margins, and vesicular nuclei, and *syncytiotrophoblasts*, which represent multinucleate syncytial trophoblastic cells ( Fig. 36-6). The syncytiotrophoblastic elements stain positively for b-HCG, accounting for the associated high concentrations of serum b-HCG in these patients.

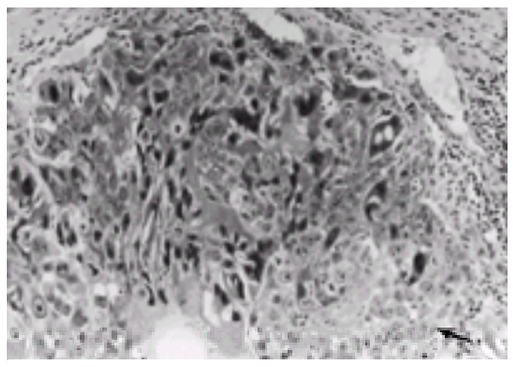

**FIGURE 36-6.** The choriocarcinoma is characterized by nests of small cells (*arrow*) with clear cytoplasm, round vesicular nuclei, and prominent nucleoli (cytotrophoblasts), intimately associated with large, giant syncytiotrophoblasts ( *arrowhead*). Some of these latter cells are multinucleate.

### Gonadoblastoma

Gonadoblastoma is a benign tumor found in dysgenetic gonads of phenotypic female subjects who have at least a portion of the Y chromosome. The tumors usually are small (1 to 3 cm in diameter), soft to firm, gray-tan to brown, and slightly lobulated. They often have a gritty feel on cut sections because of the presence of multifocal calcification. Microscopic features include the proliferation of both germ cells and gonadal sex cord cells. The germ cells show positivity for PLAP. [75] Germinoma frequently develops with gonadoblastoma.[98] In addition, because gonadal dysgenesis may not come to clinical attention until adolescence, the presence of calcifications within a dysgerminoma of an otherwise normal female patient suggests the prior presence of gonadoblastoma and hence merits evaluation of the patient for gonadal dysgenesis.

### Associated Pathologic Findings

#### *Intratubular Germ Cell Neoplasia*

Seminiferous tubules adjacent to testicular malignant germ cell tumors in adolescents and adults may show increased numbers of enlarged, atypical germ cells with abundant clear cytoplasm and prominent nucleoli. These cells show positivity for PLAP and c-kit, similar to the cells of seminomas. [10,99] Such foci have been termed *intratubular germ cell neoplasias* and are thought to represent neoplasia *in situ*.[99,100] and [101] The germ cells in the seminiferous tubules adjacent to infantile testicular malignant germ cell tumors also may be somewhat increased in number and slightly enlarged, with abundant, clear cytoplasm. [102] These cells are negative for the markers of intratubular neoplasia, both PLAP and c-kit, and therefore do not qualify as neoplastic precursor lesions. [10,75]

### Gliomatosis peritonei

A significant number of ovarian teratomas are associated with nodules of mature glial tissue implanted throughout the peritoneum or in lymph nodes. [103,104] Mature glial nodules also have been described in cervical lymph nodes in association with teratomas of the head and neck. [105,106] As long as these tissues are mature and composed only of glial tissue, this process is termed *gliomatosis peritonei*, and neither tumor stage nor prognosis is affected. Unclear is whether implants of immature neural or other mature or immature nonneural tissues are associated with the same benign prognosis.

## CLINICAL MARKERS

The role of clinical markers in the diagnosis of germ cell tumors is well established. In current clinical studies, their usefulness in predicting response or indicating the presence of residual or progressive disease is being examined. [107] These clinically applicable tools in the management of germ cell tumors have been categorized as follows: (a) oncofetoproteins (AFP and b-HCG); (b) cellular enzymes (lactate dehydrogenase [LDH] and PLAP); and (c) cytogenetic and molecular markers (see the section Genetics and Molecular Biology).

### a-Fetoprotein

AFP, an $a_1$-globulin, is the earliest and predominant serum-binding protein in the fetus, reaching its peak concentration at 12 to 14 weeks' gestation and gradually falling to reach an adult normal level of less than 10 ng per dL at approximately age 1 year. [108] As AFP levels begin to decline in fetal development, albumin becomes the principal serum-binding protein. In early embryogenesis, AFP is produced in the yolk sac and later by hepatocytes and the gastrointestinal tract. [108] In 1974, the association between serum elevation of AFP and the natural history of adult germ cell tumors was described. Elevated serum levels or positive immunohistochemical staining of germ cell tumors for AFP indicates the presence of malignant components, specifically yolk sac or embryonal carcinoma. The serum half-life ( $t_{1/2}$) of AFP is 5 to 7 days.[109] Because of the wide variation in levels at birth, especially with infants of less than 40 weeks' gestational age, and the wide variability in $t_{1/2}$ at different ages within the first year of life, [110] difficulties arise in interpreting decay of serum AFP as an indication of residual or recurrent germ cell tumor in infants younger than 8 months.[111,112] Normal ranges have been established to address these problems (Table 36-2).[110,113]

| Age | No. of patients | Mean ± SD (ng/mL) |
|---|---|---|
| Premature | 11 | 134,734 ± 41,446 |
| Newborn | 55 | 48,406 ± 34,718 |
| Newborn–2 wk | 16 | 33,113 ± 32,503 |
| 2 wk–1 mo | 12 | 9,452 ± 12,610 |
| 2 mo | 40 | 323 ± 278 |
| 3 mo | 5 | 88 ± 87 |
| 4 mo | 31 | 74 ± 56 |
| 5 mo | 6 | 46.5 ± 19.0 |
| 6 mo | 9 | 12.5 ± 9.8 |
| 7 mo | 5 | 9.7 ± 7.1 |
| 8 mo | 3 | 8.5 ± 5.5 |

From JT Wu, K Sudar. Serum AFP levels in normal infants. Pediatr Res 1981;15:58, with permission.

**TABLE 36-2. NORMAL RANGES OF SERUM a-FETOPROTEIN IN INFANTS**

Increasing levels of serum AFP, however, are not necessarily indicative of tumor progression. For example, abrupt escalation in serum AFP can occur after chemotherapy-induced tumor lysis.[114] Spurious persistence of elevated serum AFP may reflect an alteration in hepatic function from such conditions as viral hepatitis (hepatitis B, hepatitis C, and human immunodeficiency virus–associated hepatitis), cholestasis secondary to anesthesia, or exposure to phenytoin or methotrexate.[114,115] Marrink et al.[116] reported that measurement of the ratio of concanavalin A to nonbound AFP can be useful in discerning AFP production from tumor

cells (ratio, 12% to 43%) versus production from liver (ratio, <10%). These possible explanations should be considered in interpreting elevations of serum AFP.

Other conditions associated with elevated serum AFP include hepatoblastoma, pancreatic and gastrointestinal malignancies, lung cancers, and benign liver conditions, including hepatic dysfunction and cirrhosis. [117,118]

### b-Subunit of Human Chorionic Gonadotropin

Human chorionic gonadotropin is a glycoprotein comprised of a- and b-peptide subunits and normally is synthesized during pregnancy by syncytiotrophoblasts of the placenta to maintain viability of the corpus luteum. The a-subunit is similar to a-peptides of other hormones, such as luteinizing hormone, follicle-stimulating hormone, and thyroid-stimulating hormone; the b-subunit is antigenically distinct, serving as the basis for the method of serum assay. [119] Minute amounts, less than 5 mIU/mL, are detected in serum of healthy adults.[120] The serum $t_{1/2}$ of b-HCG is 24 to 36 hours.[120]

Elevation of serum b-HCG in patients with germ cell tumors implies the presence of clones of syncytiotrophoblasts, such as choriocarcinoma, or of syncytiotrophoblastic giant cells, found frequently in germinomas (pure seminomas or dysgerminomas) and occasionally in adult embryonal carcinoma. Immunoperoxidase staining of tumor for b-HCG detects these hormone-containing elements.[121]

Like serum AFP, sudden elevation of serum b-HCG occurs after cell lysis secondary to chemotherapy. [114] Iatrogenic hypogonadism secondary to bilateral orchiectomy, oophorectomy, or chemotherapy also may be associated with rising levels of serum b-HCG because of an increase in luteinizing hormone that results in immunologic cross-reactivity.[115] Other conditions in which modest elevations of serum b-HCG have been reported include multiple myeloma and other malignancies of liver, pancreas, gastrointestinal tract, breast, lung, and bladder. [117] Simultaneous elevation of serum AFP and b-HCG has been described in ovarian embryonal carcinoma in an 11-year-old and in patients with polyembryoma.[122]

### Other Markers

Because some germ cell tumors with identifiable malignant elements do not produce measurable amounts of serum AFP or b-HCG, other markers with potential prognostic value have been investigated. Serum LDH, a glycolytic enzyme that appears to correlate with growth and regression of various solid neoplasms, has not shown specificity for a specific histologic subtype of germ cell tumors. In patients with dysgerminoma, serum levels of the LDH isoenzyme 1, the gene for which resides on 12p,[120] correlate with the tumor burden and aid in the planning and assessment of surgical management. [123] PLAP is a fetal isoenzyme of alkaline phosphatase that is elevated in the sera of up to 30% of patients with stage I disease and of almost 100% of cases with advanced seminoma. [124,125] As with AFP and b-HCG, immunohistochemical staining for PLAP sometimes is useful in determining the origin of histologically undifferentiated tumors. [120]

Although elevated serum levels of carcinoembryonic antigen are reported in patients with ovarian tumors, the usefulness of this antigen has been hampered by lack of tumor specificity and correlation to disease natural history. [126] The carbohydrate antigen CA-125, which is related to the tissues of the coelomic epithelium and müllerian ducts, has been assessed in ovarian cancers of germ cell and epithelial origin. CA-125 has been reported to have some correlation with other tumor markers and to be of value in monitoring patients with ovarian tumors of germ cell, epithelial, and stromal origin, [127,128] although its utility in these patients remains to be defined because of the limited numbers of patients studied to date. [126] Extreme elevation of serum levels of CA-19-9, an antigen in the Lewis A blood group system, has been reported at recurrence of ovarian immature and mature teratoma with yolk sac elements [129]; however, the role of CA-19-9 is even less clear than that of CA-125.[126]

## TREATMENT OVERVIEW

The heterogeneity of pediatric germ cell tumors relative to histologic type, site of origin, age, and stage demands an individualized, multimodality treatment plan. In recent years, the timing and aggressiveness of surgery have been refined with the development of a variety of effective chemotherapeutic agents. The role of radiotherapy is yet to be established completely in the treatment of pediatric germ cell tumors.

### Principles of Surgery

Surgical resection is the therapy of choice in benign tumors, such as teratomas. With malignant lesions, removal is indicated, if possible. However, given the availability of effective chemotherapy, resection should not be undertaken to the point of sacrificing vital structures. In this situation, only debulking or biopsy is appropriate. After initial chemotherapy, second-look surgery serves to assist in achieving complete response in selected patients. Surgical considerations that are unique to the various germ cell tumors are addressed in the following sections.

### Principles of Chemotherapy for Germ Cell Tumors

In the last two decades, substantial improvements in the cure rates for pediatric germ cell tumors have occurred, stemming in large part from the evolution of effective chemotherapeutic strategies, most of which were developed for and investigated in the larger adult population with these neoplasms. Although available data from children are more limited, the adult experience appears to hold true for most childhood germ cell tumors as well. In both populations, the advent of effective combination chemotherapy has attenuated the natural history differences noted in germ cell tumors of different histopathologic subtypes and sites of origin.

As single agents, actinomycin-D, vinblastine, bleomycin, doxorubicin, cisplatin, and etoposide have proved efficacious in treating various tumors of germ cell origin, with objective response rates (complete plus partial responses) ranging from 28% to 100%. [130,131,132,133,134] and [135] Combinations of these agents demonstrating synergistic activity have served as the basis for numerous multidrug regimens ( Table 36-3).

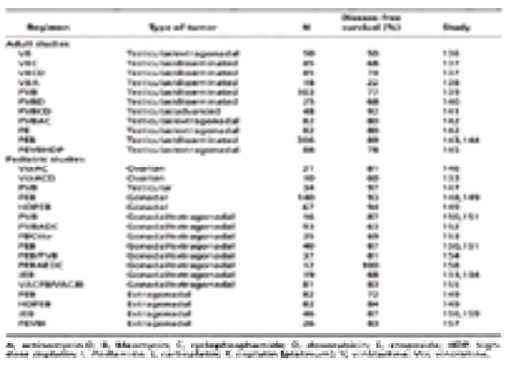

**TABLE 36-3. EVOLUTION OF COMBINATION CHEMOTHERAPY IN GERM CELL TUMORS**

Most adult studies have been conducted in patients with testicular and extragonadal tumors, primarily with advanced or disseminated disease. Before platinum, disease-free survival (DFS) ranged from 22% to 74%, with steady increases related to the addition of agents to the vinblastine-bleomycin backbone. [136,137] and [138] The advent of cisplatin and its incorporation into combination regimens resulted in a substantial increase in DFS, to between 68% and 92%. [139,140,141,142,143,144] and [145] Use of the platinum-based combinations may obviate the need for four- and five-agent regimens and their associated side effects. Bosl et al. [142] compared a regimen of vinblastine, bleomycin, cyclophosphamide, cisplatin, and actinomycin-D with one of cisplatin plus etoposide and reported almost identical rates of complete response (96% vs. 93%, respectively) and DFS (80% in both groups). Moreover, the two-drug regimen was associated with far less toxicity. Einhorn and Williams [140] could not demonstrate additional benefit after the addition of doxorubicin to a regimen of cisplatin (platinum), vinblastine, and bleomycin (PVB) in the treatment of disseminated testicular cancer in adults and suggested that, with the improvement in outcome in these patients, the goal of future trials should be to reduce toxicity. In a randomized

study of 184 patients with favorable-prognosis testicular tumors comparing outcome after three versus four courses of PVB, the rates of complete response and survival were almost identical, and less toxicity was observed in the short-course arm.[144] Administration of cisplatin in higher doses (40 mg per $m^2$ per day × 5 as compared with 20 mg per $m^2$ per day × 5) with saline and mannitol diuresis has proved superior to conventional-dose cisplatin and appears to overcome platinum resistance.[145] Although more toxicity is associated with the higher doses of platinum, toxicity still is tolerable.

The pediatric record, although not as extensive, has mirrored the adult experience in that combination chemotherapy has been found to be superior to single or dual agents and the addition of platinum has further boosted the efficacy of these regimens.[133,134,146,147,148,149,150,151,152,153,154,155,156,157] and [158] The dosages and methods of administration of current regimens employed in pediatric germ cell tumors [PVB; cisplatin (platinum), etoposide, and bleomycin (PEB); and carboplatin, etoposide, and bleomycin (JEB)] are given in Table 36-4. PEB was the standard treatment used in intergroup studies by the Pediatric Oncology Group (POG) and the Children's Cancer Group (CCG). For high-risk germ cell tumors, PEB was compared to a combination of high-dose cisplatin plus etoposide and bleomycin.[148,149] The preliminary experience of Pinkerton et al.[159] in the United Kingdom with carboplatin in pediatric germ cell tumors provides the basis for future studies comparing regimens containing cisplatin or carboplatin with the goal of reducing permanent toxicity. In a more recent report from the United Kingdom Children's Cancer Study Group's Germ Cell Tumour Studies, carboplatin (600 mg per $M^2$) with etoposide and bleomycin (JEB) demonstrated efficacy over standard-dose cisplatin [100 mg per $M^2$ (PEB)]. These data must be interpreted with caution, as comparisons were not made with high-dose cisplatin, the study was retrospective, and the standard platinum group was made up of small patient numbers (N = 21).[156] Marrow-ablative doses of carboplatin and etoposide followed by autologous marrow reinfusion may provide a method of salvaging patients who experience relapse or whose disease proves refractory to treatment.[160]

| Regimen | Components | Administration | Study |
|---|---|---|---|
| PVB | Cisplatin [platinum] | 20 mg/m² i.v. days 1–5 | 139 |
| | Vinblastine | 0.2 mg/kg i.v. days 1 & 2 | |
| | Bleomycin | 15 U/m² i.v. days 2, 9, 16 | |
| PEB | Cisplatin [platinum] | 100 mg/m² i.v. day 1 | 222 |
| | Etoposide | 120 mg/m² i.v. days 1–3 | |
| | Bleomycin | 15 U/m² i.v. day 2 | |
| JEB | Carboplatin | 600 mg/m² i.v. day 1 | 159 |
| | Etoposide | 120 mg/m² i.v. days 1–3 | |
| | Bleomycin | 15 U/m² i.v. day 2 | |

B, bleomycin; E, etoposide; J, carboplatin; P, cisplatin; V, vinblastine.

**TABLE 36-4. CHEMOTHERAPEUTIC REGIMENS FOR PEDIATRIC GERM CELL TUMORS**

Specific recommendations for incorporating chemotherapy into the management of pediatric germ cell tumors are discussed separately for each tumor. Generally, in low-risk disease (stage I testicular and ovarian tumors), no chemotherapy is indicated if careful observation is possible. Patients with moderate-risk gonadal tumors or progression of disease in untreated tumors may be managed adequately with three to four courses of a platinum-containing regimen. For higher-risk patients (higher-stage testicular or ovarian tumors and extragonadal tumors), 6 months of a platinum-based chemotherapeutic regimen is indicated.

## OVARIAN TUMORS

Ovarian tumors are rare, accounting for only some 1% of childhood malignancies.[161,162] Although ovarian tumors may occur at any age, the incidence increases at 8 to 9 years and peaks at 19 years.[161] For children younger than 15 years, these tumors are most common between the ages of 10 and 14.[163,164] As it does with testicular tumors, the frequency of ovarian germ cell tumors parallels gonadotropin release, implicating hormonal factors in their etiology.[163,165,166] In contrast to adult ovarian tumors, two-thirds of pediatric ovarian tumors are of germ cell origin, with tumors of epithelial and stromal origin occurring less frequently.[161,164,167,168] The types of malignant ovarian germ cell tumors are detailed in Table 36-1. In order of decreasing frequency, the categories are dysgerminoma, endodermal sinus tumor (yolk sac carcinoma), immature teratoma, mixed germ cell tumor, and embryonal carcinoma.[169]

Abdominal pain is the presenting symptom in up to 80% of patients.[163,164,170] The pain can be chronic in nature but, in up to one-third of patients, mimics an acute abdomen.[163] Most of these latter patients have associated ovarian torsion[163,164] and often undergo exploratory surgery for presumed acute appendicitis.[163,164] Other presenting signs and symptoms include a palpable abdominal mass, fever, constipation, amenorrhea, vaginal bleeding and, rarely, urinary frequency and dysuria.[164,171] Precocious puberty, more often associated with ovarian stromal tumors, has been described in endodermal sinus tumor, choriocarcinoma, and mixed teratoma with sarcomatous and non–germ cell carcinomatous elements.[171]

Ultrasonography is used most often for the initial evaluation of patients with abdominal or pelvic masses and will differentiate cystic from solid masses.[172,173] Although the presence of a solid ovarian mass raises the suspicion of malignancy, the majority will be benign teratoma.[163] Even the use of color and Doppler ultrasonography techniques will not distinguish benign from malignant lesions.[174] Computed tomography (CT) of the abdomen and pelvis is helpful in identifying the site of origin, the extent of tumor, the presence of calcifications or fat, and metastatic disease. In a pediatric study evaluating the use of CT for patients with ovarian masses, Jabra et al.[175] noted that only 55% of children with teratomas had radiologic evidence of fat as compared to 94% of adult patients in similar circumstances.[176] CT appears useful also in monitoring tumor response and, as reported by Moskovic et al.,[177] may detect features suggestive of transformation of malignant disease to benign disease after chemotherapy (retroconversion). In that report, tumor maturation, characterized radiographically by increased density, more circumscribed margins, and the presence of internal calcification with fatty areas and cystic changes, was observed and followed up in seven patients with immature teratomas. At second-look surgery, all seven patients had mature teratoma without malignant elements and remained well from 1 to 6 years after treatment.

Because patients can develop metastatic disease to the thoracic lymph nodes, lung and, rarely, bone,[169,178,179,180] and [181] staging evaluation should include chest CT and $^{99m}$TC-pertechnetate–enhanced scintigraphy. Assessment of serum tumor markers AFP and b-HCG is essential, as the majority of pediatric patients with ovarian germ cell tumors have an endodermal sinus tumor component.[150,182]

The staging system designed by the International Federation of Gynecology and Obstetrics and shown in Table 36-5 creates a framework for staging pediatric tumors.[183] Based on clinical, surgical, and pathologic findings, this system includes cytologic examination of any thoracic or peritoneal fluid. A modification of this staging system (Table 36-6) was devised by the POG and the CCG for use in intergroup studies. This surgicopathologic system refines the International Federation of Gynecology and Obstetrics system by accounting for (a) the higher risk of tumor recurrence in patients who have positive peritoneal washing and are therefore up-staged, (b) the utility of tumor markers for prediction of outcome, and (c) the lack of negative prognostic impact of gliomatosis peritonei if only mature glial tissue is present. The clinical features of the various ovarian tumors are summarized in Table 36-7 and detailed here.

| Stage | Extent of disease |
|---|---|
| I | Tumor limited to the ovaries |
| Ia | Limited to one ovary; no ascites. No tumor on external surface; capsule intact |
| Ib | Limited to both ovaries; no ascites. No tumor on external surfaces; capsule intact |
| Ic | Limited to one or both ovaries but with tumor on surface of one or both ovaries; or with capsule ruptured; or with positive ascites or positive peritoneal washings |
| II | Tumor involving one or both ovaries with pelvic extension |
| IIa | Extension and/or metastases to uterus and/or tubes only |
| IIb | Extension to other pelvic tissues |
| IIc | As in IIa or IIb but with positive ascites or positive peritoneal washings; or with capsule ruptured |
| III | Tumor involving one or both ovaries with peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal lymph nodes; extension to small bowel or omentum; superficial liver metastases |
| IIIa | Limited to true pelvis grossly with negative nodes but histologically confirmed microscopic seeding of abdominal peritoneal surfaces |
| IIIb | Limited to one or both ovaries with negative nodes but histologically confirmed implants of abdominal peritoneal surfaces, none >2 cm diameter |
| IIIc | Abdominal implants >2 cm diameter and/or positive retroperitoneal or inguinal nodes |
| IV | Tumor of one or both ovaries with distant metastases outside of peritoneal cavity; parenchyma liver metastases; pleural effusion, if present, must have positive cytology |

From III, Sommer, Dissection and staging of malignant tumors in the female pelvis. Int J Gynaec Obstet 1971;9:312, with permission.

**TABLE 36-5. INTERNATIONAL FEDERATION OF GYNECOLOGY AND OBSTETRICS STAGING FOR OVARIAN TUMORS**

| Stage | Extent of disease |
|---|---|
| I | Limited to ovary or ovaries; peritoneal washings negative for malignant cells<br>No clinical, radiographic, or histologic evidence of disease beyond the ovaries<br>Tumor markers normal after appropriate postsurgical half-life decline<br>The presence of gliomatosis peritonei[a] does not up-stage patient |
| II | Microscopic residual or positive lymph nodes (≤2 cm as measured by pathologist)<br>Peritoneal washings negative for malignant cells<br>Tumor markers positive or negative<br>The presence of gliomatosis peritonei[a] does up-stage patient |
| III | Lymph node with malignant metastatic nodule (>2 cm as measured by pathologist)<br>Gross residual or biopsy only<br>Contiguous visceral involvement (omentum, intestine, bladder)<br>Peritoneal washings positive for malignant cells<br>Tumor markers positive or negative |
| IV | Distant metastases, including liver |

[a]Peritoneal nodules composed entirely of mature glial tissue and having no malignant elements.

**TABLE 36-6. CHILDREN'S ONCOLOGY GROUP STAGING OF OVARIAN GERM CELL TUMORS**

| Tumor type | Median age (yr) | Relative frequency (%) | Features |
|---|---|---|---|
| Dysgerminoma | 15 | 34 | Rapidly developing; 14–25% with other germ cell elements; very radiosensitive |
| Endodermal sinus tumor (yolk sac) | 18 | 16 | ↑AFP; 75% stage I; all patients require chemotherapy because of high risk for relapse, even in low-stage disease |
| Teratoma | | | |
| Mature (solid, cystic) | 10–15 | 33 | Neuroglial implants may occur with cystic or solid teratomas but do not affect prognosis; surgery is mainstay of treatment |
| Immature | 11–14 | 10 | Grading system based on amount of neuroepithelium present; prognosis inversely related to stage and grade; 35% with ↑AFP |
| Embryonal carcinoma | 14 | 6 | 47% prepubertal; ↑HCG and precocious puberty common; chemotherapy indicated |
| Mixed malignant germ cell tumor | 16 | 11 | 40% premenarchal; 30% sexually precocious; AFP/HCG may be increased |
| Gonadoblastoma | 8–18 | 1 | Associated with dysgenetic gonads and sexual maldevelopment; removal of both gonads is treatment of choice |
| Other (polyembryoma, choriocarcinoma) | NA | <1 | Rare in children |

AFP, α-fetoprotein; HCG, human chorionic gonadotropin; NA, not available; ↑, increased.

**TABLE 36-7. CLINICAL FEATURES OF PEDIATRIC OVARIAN TUMORS**

### Teratoma

Teratomas are composed of well-differentiated tissues arising from the three germ cell layers (endoderm, ectoderm, and mesoderm) and usually contain tissues foreign to the anatomic site of origin.[184] Teratomas occasionally can be monodermal or composed of a single germ cell layer, which typically includes thyroid, carcinoid, or neuroectodermal tissue.[184,185] On the basis of their imaging findings, teratomas can be classified as either cystic or solid. Teratomas can be classified also according to their histologic composition as follows: mature, containing well-differentiated tissues; immature, containing varying degrees of immature fetal tissue, most often neuroectodermal; or malignant, containing at least one of the malignant germ cell elements. The management of mature and immature teratomas is based on the most malignant element present. Recent reports suggest that monodermal teratomas composed of neuroectodermal tissue do not respond as well to germ cell tumor–directed therapy.[186,187]

The mature cystic teratoma is the most common type of germ cell tumor and, like all ovarian tumors, is most common during the second decade of life. Approximately 10% of patients with teratomas have bilateral tumors[185] and, in this instance, every effort should be made to preserve fertility.[188] Although rare, between 1% and 3% of mature cystic teratomas present with ovarian torsion, and an additional 1% to 3% can rupture spontaneously, which can be fatal.[185,189] Rupture of the teratoma may be associated with two clinical pictures: acute peritonitis (sudden rupture of contents) or a granulomatous peritonitis, resulting from a chronically leaking tumor, which typically presents with multiple small peritoneal implants and adhesions.[189] The solid teratoma also is most frequently benign, although it can be associated with peritoneal implants and lymphatic spread.[190,191] The treatment of choice for patients with mature teratomas is surgical resection.

Immature teratomas are pathologically distinct from the benign and malignant teratomas. As discussed in the section Pathology, they are graded (from 1 to 3) by the amount of immature tissue present, using the system of Norris et al.[192] and later modified by Robboy and Scully.[193] In adult series, including some pediatric patients, the median age at diagnosis is between 17 and 21 years.[192,194,195,196,197 and 198] However, a recent intergroup pediatric study of completely resected ovarian immature teratomas reported a median age of 10 years.[199] Thus, up to 50% of pediatric patients with ovarian immature teratomas might be premenarcheal. As with other ovarian tumors, the most frequent complaint is abdominal pain, occurring in 75% to 95% of patients,[192,195,197] and a palpable abdominal mass in 44% to 88%.[192,195] At laparotomy, the majority of tumors are unilateral, but spread beyond the ovary is documented in from 31% to 50%.[192,195,197] Common metastatic sites include lymph nodes, liver, peritoneal surfaces and, rarely, the lung.[192,195]

Much controversy surrounds the management of immature teratomas in children. Norris et al.[192] described 58 patients with ovarian immature teratomas and reported that 70% of those with grade 3 tumors underwent relapse. On the basis of this experience, the recommendations for treatment of ovarian immature teratomas have been to proceed with chemotherapy in patients with grades 2 and 3 tumors.[194,195,196,197 and 198] In contrast, a similar relationship of histologic grade to outcome has not been reported in pediatric patients with testicular and extragonadal immature teratomas.[200,201,202,203 and 204] Thus, some have suggested that the clinical behavior of immature teratomas in the pediatric population might be different from their adult counterparts.[203,204] This hypothesis was tested in a prospective study conducted by the POG and the CCG. In that intergroup trial, the 44 patients with ovarian immature teratomas were treated with complete surgical resection followed with observation only.[199] The 4-year event-free survival of this subset was 98%, with only one patient developing recurrent tumor. On central pathologic review, 30% of these patients had microscopic foci of malignant elements, which did not appear to affect outcome adversely. As in other studies,[195] approximately 30% of patients had elevated serum AFP, but in not all of those were microscopic foci of endodermal sinus tumor detected.[199]

The prognostic significance of mature peritoneal implants (gliomatosis peritonei)[193,205] in patients with immature teratomas is uncertain. Although having peritoneal implants does not up-stage the patient's disease, reports have cited malignant transformation of these elements[206] and growth during and after chemotherapy.[177,207,208]

The experience with immature teratomas in the recent intergroup study from the POG and the CCG[187,199] strongly supports using complete resection only, followed by close observation of serum tumor markers and diagnostic imaging. Those patients unable to undergo complete resection should be offered chemotherapy similar to that used for other germ cell tumors (i.e., PEB). Although ample adult data report using these regimens,3[194,195 and 196,198] the pediatric experience is limited to a recent German trial in which the recurrence rate approached 18% and appeared related to the degree of resection.[209]

### Dysgerminoma

Dysgerminoma represents the female counterpart of testicular seminoma and is the most common ovarian germ cell tumor of childhood and adolescence.[210,211 and 212] Although it can occur at any age during childhood, it occurs most frequently during adolescence, with a peak age at 19 years.[166] The most common presenting signs and symptoms include the development of an abdominal mass in 50% of patients[181,213] and abdominal pain in 36% to 48%.[181,213,214] The majority of patients present with stage I disease,[181,213,214 and 215] but the tumor can spread via the lymphatic system to the left kidney and para-aortic region, and it can disseminate to the liver, lung, or supradiaphragmatic lymph nodes.[181] Dysgerminoma can be bilateral in up to 20% of cases.[212,215] When dysgerminoma occurs as a component of a mixed germ cell

tumor, therapy should be directed against the most malignant element present.

Unlike other ovarian germ cell tumors, dysgerminomas were curable even before the advent of effective chemotherapy, with survival rates ranging from 86% to 94% after surgery and radiotherapy.[181,212,213 and 214] Although radiotherapy produces very high cure rates, it has significant late sequelae that can be particularly severe in children who have not achieved their final adult height.[214,216] In addition, because the majority of patients with dysgerminoma present during their reproductive years and the use of radiotherapy has the potential to cause infertility, an increasing emphasis has been placed on attempts to treat patients with chemotherapy instead of radiotherapy. The adult experience with this strategy confirms the chemosensitivity of this tumor.[217,218 and 219] On the basis of these data, the present recommendations are that patients with stage I dysgerminomas be observed after surgical resection. However, some authors would recommend the use of cisplatin-based therapy even in stage I patients, to reduce the 20% risk of recurrent disease.[217] Patients with more advanced disease will require four to six cycles of cisplatin-based therapy for cure.[217,219] Following this approach, sustained remissions in 90% of patients can be anticipated,[219,220] and up to 70% of patients will have normal menstrual function.[210]

### Yolk Sac Tumor

Yolk sac tumor, also known as *endodermal sinus tumor*, is the most aggressive of the ovarian malignant germ cell tumors[180,221] and the most common ovarian malignant germ cell tumor in pediatric patients.[150,152,182,222] The median age at the time of diagnosis is approximately 19 years,[180,221] and most patients have elevated levels of AFP.[150,182] The tumor can spread to lymphatics and peritoneal structures quickly, accounting for the acute onset of symptoms.[180,221] Abdominal pain occurs in up to 80% of patients; 75% of patients have abdominal masses.[180,221] Distant metastases are seen in liver, lungs, lymph nodes and, rarely, in bone.[180] Historically, the prognosis for these tumors was poor with surgery and radiotherapy.[180,221] With the advent of cisplatin-based therapy, outcomes have improved dramatically, and DFS for all stages presently exceeds 80%.[143,148,151,155,217,223]

### Embryonal Carcinoma

In contrast to adult testicular tumors, embryonal carcinoma is a rare component of ovarian germ cell tumors.[184] The median age at diagnosis is 14 years, and the most common presentation is an abdominal mass (80%) or abdominal pain (53%) or both.[180] Because the tumor has multinucleate giant cells similar to those in syncytiotrophoblasts, which can produce HCG, patients often present with precocious puberty, amenorrhea, or hirsutism.[180] Although morphologically similar to endodermal sinus tumor, embryonal carcinoma can be readily distinguished pathologically. Approximately one-half of the patients present with stage I tumors and undergo unilateral salpingo-oophorectomy only. However, the tumor may extend into peritoneal surfaces or metastasize to lymph nodes, lung, and liver.[180] After surgical resection, survival is only 50%, suggesting the presence of micrometastases. As this tumor is rare, the data regarding the impact of chemotherapy on natural history are scant. However, on the basis of the adult experience with testicular tumors,[224] the recommended treatment course is cisplatin-based therapy.[152,182]

### Mixed Malignant Germ Cell Tumor

Mixed malignant germ cell tumors comprise a subset of germ cell tumors containing more than one malignant component. Various reports suggest that 10% to 40% of patients with malignant germ cell tumors have mixed histology.[150,152,169,182,211] The median age at diagnosis is 16 years,[169,211] and 40% of patients are prepubertal.[169] Most patients present with abdominal pain or an abdominal mass (or both).[169,211] Approximately 30% of prepubertal patients have precocious puberty.[169]

The most common histologic component is dysgerminoma, but immature teratoma, endodermal sinus tumor, and embryonal carcinoma also can be detected in varying proportions. As with the other germ cell tumors, evaluation of tumor markers at the time of diagnosis is essential, as patients with mixed germ cell tumors having endodermal sinus tumor, embryonal carcinoma, or dysgerminoma may have elevated markers that are useful for diagnosis and follow-up. In general, these patients are managed on the basis of the most malignant element present in the specimen, usually with the use of cisplatin-based chemotherapy.

### Choriocarcinoma

Pure ovarian choriocarcinomas are rare and most commonly are components of mixed ovarian germ cell tumors.[184,225,226] The tumor typically produces HCG that can produce false-positive pregnancy test results and, in prepubertal patients, precocious puberty.[225] Choriocarcinomas can be either gestational or nongestational, but the diagnosis of nongestational choriocarcinoma is difficult in women of childbearing age and can be confirmed only in prepubertal patients.[225,226 and 227]

Choriocarcinoma is an aggressive subtype of germ cell tumor with a propensity for early metastases to lung, liver, and brain. Gestational choriocarcinomas are exquisitely sensitive to methotrexate[228] and are highly curable even in the presence of widespread metastases.[229,230,231 and 232] In contrast, the small number of patients analyzed with nongestational choriocarcinomas may have a less favorable prognosis.[226,227,233] Such patients usually are managed as for other ovarian germ cell tumors.[233]

### Polyembryoma

Polyembryomas are rare tumors of the ovary, often reported in combination with other neoplastic components.[234,235] Their presenting signs and symptoms are similar to those of other ovarian germ cell tumors. A report has cited precocious puberty secondary to HCG production by this tumor.[236] Polyembryomas are very malignant tumors and, although not radiosensitive, have been reported to respond to chemotherapy similar to that used for other malignant germ cell tumors of the ovary.[236]

### Gonadoblastoma

Gonadoblastomas are tumors composed of germ cells intermixed with stromal cells (usually Sertoli or granulosa cells with or without Leydig cells).[237,238 and 239] These neoplasms develop during the teenage years, most frequently in patients with XY gonadal dysgenesis, although a small number might occur in patients with 45 XO/46, –XY mosaicism.[238,239 and 240] Most often, such patients present to their physicians for evaluation of amenorrhea,[238] eading to chromosomal analysis. Patients may have a eunuchoid body habitus, lack of secondary sexual characteristics, elevated gonadotropin levels, and the presence of streak gonads.[238,241,242] Because of the 30% risk for malignancy,[239] the management of patients with this condition should include prophylactic removal of their streak gonads.[238,239]

Most gonadoblastomas are small to medium-sized and behave in a benign fashion unless overgrowth of a malignant germ cell element is present. Although most tumors are unilateral, up to 36% are bilateral. Dysgerminoma is the most common malignant element occurring in approximately 50% of cases.[237,239] Although data are limited, chemotherapy used for other malignant germ cell tumors should be considered, depending on the malignant germ cell tumor element present and the stage of the disease.[243]

## TESTICULAR TUMORS

Pediatric testicular tumors are rare, accounting for 2% of solid malignant neoplasms in boys.[201,244] The annual incidence in the United States for white and black boys younger than 15 years of age is 1.1 and 0.9 per 100,000 population, respectively.[1] Although adolescent tumors resemble those seen in adults, prepubertal tumors differ with respect to incidence, clinical manifestations, histopathology, and prognosis.[201,244] The major risk factor for development of testicular tumors during childhood is the presence of an undescended testicle[245,246] (see the section Cryptorchid Testis).

Approximately 75% of childhood testicular tumors are of germ cell origin (Table 36-8), as compared with more than 90% of those found in the adult population.[201,247] Two-thirds of the germ cell tumors are endodermal sinus tumors, and a smaller portion are teratomas. Rarely, a mixture of germ cell and stromal components (gonadoblastoma) is noted in a phenotypic female patient with dysgenetic gonads and male karyotype.

| Tumor type | Median age (yr) | Relative frequency (%) | Features |
|---|---|---|---|
| Endodermal sinus tumor (yolk sac) | 2 | 26 | Most common of malignant germ cell tumors of the testes; ↑ AFP; as compared to adult cases, pediatric tumors are pure histologically. 85% stage I. Chemotherapy reserved for higher stage or recurrent disease |
| Teratoma | 3 | 24 | Poorly differentiated histologic features do not impart a malignant course in children. Surgery alone usually is sufficient treatment. |
| Embryonal carcinoma | Late teens | 20 | Uncommon in young children; ↑AFP a HCG; managed as for adults, with retroperitoneal lymphadenectomy ± chemotherapy ± irradiation based on stage. |
| Teratocarcinoma | Late teens | 13 | 80% stage I with 75% survival after surgery alone. More advanced disease requires multimodality therapy. |
| Gonadoblastoma | 5–10 | <1 | Associated with sexual maldevelopment syndromes, bilateral involvement in 30%. Bilateral removal of gonads is treatment of choice. |
| Others (seminoma, mixed germ cell tumor, choriocarcinoma) | NA | 16 | Rare in children. |

AFP, α-fetoprotein; HCG, human chorionic gonadotropin; NA, not applicable; ↑, increased.

**TABLE 36-8. CLINICAL FEATURES OF PEDIATRIC TESTICULAR TUMORS**

Almost all testicular tumors are identified as irregular, nontender scrotal masses. [248] The paucity of associated signs or symptoms may lead to delays in evaluation for up to 6 months for germ cell tumors and 24 months for non–germ cell tumors.[201] Although testicular tumors do not transilluminate, 20% may be associated with reactive hydroceles at the time of diagnosis. [249,250] Li and Fraumeni[251] reported a 21% incidence of concomitant inguinal hernias. Approximately 90% of pediatric tumors are localized, as compared with 39% in adults. [250] Metastatic disease typically spreads to the lymph nodes of the retroperitoneum and chest.

Preoperative assessment of serum markers (e.g., AFP, b-HCG) is essential because it serves as the basis for staging and patient monitoring. Ultrasonography is instrumental in localizing the scrotal mass with respect to the testicle and for distinguishing a simple hydrocele from a reactive hydrocele associated with the testicular tumor. Metastatic evaluation should include ultrasonography and CT of the abdomen and pelvis, in addition to chest radiography and CT and bone scintigraphy with $^{99m}$Tc-pertechnetate. Because focal atelectasis after general anesthesia can mimic metastatic pulmonary lesions, CT scan of the chest before surgery is recommended. Lymphangiography no longer is an acceptable method of evaluating the retroperitoneum in children. [244,252]

Previously, the only staging system used consistently for prepubertal patients with testicular tumors was that proposed by Evans et al., [253] which defined disease according to whether it was confined to scrotum, metastatic to regional lymph nodes (within the abdomen), or metastatic to distant sites. Recently, investigators from the POG and the CCG developed staging criteria (Table 36-9) that also account for tumor marker status and less-than-ideal transscrotal surgery to these tumors. Features unique to the various histologic subtypes of testicular tumors are summarized in Table 36-8 and are detailed later.

| Stage | Extent of disease |
|---|---|
| I | Limited to testes<br>Completely resected by high inguinal orchiectomy or transscrotal orchiectomy with no spill<br>No clinical, radiographic, or histologic evidence of disease beyond the testes<br>Tumor markers normal after appropriate postsurgical half-life decline; patients with normal or unknown markers at diagnosis must have a negative ipsilateral retroperitoneal node dissection to confirm stage I |
| II | Trans-scrotal orchiectomy with gross spill of tumor<br>Microscopic disease in scrotum or high in spermatic cord (<5 cm from proximal end)<br>Retroperitoneal lymph node involvement (≤2 cm)<br>Increased tumor marker after appropriate half-life |
| III | Retroperitoneal lymph node involvement (>2 cm)<br>No visceral or extra-abdominal involvement |
| IV | Distant metastases, including liver |

**TABLE 36-9. PEDIATRIC ONCOLOGY GROUP/ CHILDREN'S CANCER GROUP STAGING OF TESTICULAR TUMORS**

The classic surgical approach for both diagnosis and treatment of testicular tumors is radical inguinal orchiectomy, with *en bloc* excision of spermatic cord structures and testicle. In adults, Giguere et al.[254] reported recurrence of tumor in inguinal and retroperitoneal sites in association with surgical procedures that violate the scrotum, tunica vaginalis, and tunica albuginea. This adverse outcome was attenuated by subsequent radical orchiectomy with partial scrotectomy, which excised the previous incision site, combined with retroperitoneal node dissection and chemotherapy. The low risk in pediatric tumors, assuming the transscrotal approach is not associated with tumor spillage, and the excellent response of pediatric tumors to modern chemotherapy obviate the need for up-staging disease in these otherwise low-risk patients or for performing a modified retroperitoneal lymphadenectomy in this situation.

### Cryptorchid Testis

The cryptorchid testicle is the most significant risk factor for the development of testicular carcinoma. Considering that 10% of patients with testicular cancers are found to have undescended testicles and that the prevalence of undescended testicle is estimated at 0.23%, the theoretic risk for testicular cancer has been estimated to be 10- to 50-fold higher in boys and men with undescended testicles. [245,255,256]

Histologic abnormalities of germinal, tubular, or Sertoli tissue occur in 85% of undescended testicles, although only a few (fewer than 1%) are truly dysgenetic. [256,257] Because surgical relocation of the testes decreases the incidence of histologic anomalies, extrascrotal location appears more important than pathologic factors regarding malignant potential. The specific locale of the cryptorchid testicle does influence the risk of malignancy: The 8% to 22% of undescended testicles situated in the abdomen[255,257,258] account for approximately 45% of malignancies.[258,259] and [260] Typically, the histologic tumor types related to the cryptorchid testicle are seminoma and embryonal carcinoma, and presentation is typically in the fourth decade of life. [101,245,257]

Hormonal therapy with HCG has been reported to induce descent of the testicle into the scrotum in 15% of patients aged 2 to 5 years and in 44% aged 10 to 14 years. [261] Hadziselimovic[262] noted that 60% of cases responded to gonadotropin-releasing hormone (GnRH) but did not account for retractile testes in the study. In a double-blind randomized study of GnRH by nasal insufflation in which retractile testes were excluded, GnRH performed no better than placebo. [263]

Orchidopexy is advised on the undescended testicle after 6 months and before 18 months. [256] This earlier intervention, however, may not prevent the subsequent development of testicular carcinoma.[255,256] Although extensive data from children undergoing orchidopexy before age 5 are unavailable, reduction in the risk of cancer with decreasing age of orchidopexy has been reported. [264] The prepubescent child with an intra-abdominal testicle undergoing orchidopexy should have a testicular biopsy performed in search of carcinoma *in situ*. The pubertal male patient with an undescended testicle should undergo inguinal exploration and orchiectomy if a normally placed contralateral testicle is present. In the absence of a contralateral testicle, orchidopexy may be performed, but a biopsy of the testicle is mandatory, as is close follow-up. Parents and older patients should be advised of the importance of extended periodic medical examination and frequent self-examination throughout such a patient's life.

### Yolk Sac Tumor

Yolk sac tumor is the malignant testicular tumor that occurs most frequently in children [77,78,79] and [80]; its myriad synonyms include *endodermal sinus tumor, infantile embryonal carcinoma, orchidoblastoma, Teilum's tumor,* and *clear-cell adenoma*.

From the perspectives of histopathology and natural history, yolk sac tumor of childhood is distinct from its adult counterpart. [77] In children, yolk sac tumor is characteristically pure, whereas adult tumors contain other malignant components. Pediatric testicular yolk sac tumor is localized (stage I) in up to 85% of cases, and the overall survival rate is higher than 70%. [150,265,266] and [267] Weissbach et al.[247] reported survival to be correlated with age (i.e., younger than 2 years vs. 2 years and

older). However, with modern chemotherapy, Mann et al.[150] reported survival of 96% in all prepubertal patients.

Several earlier reports documented increased survival from 60% to 90% in children who had radical orchiectomy and retroperitoneal lymphadenectomy, as compared with those who had orchiectomy alone.[268,269] These series were reported before the improvement of clinical staging with serum markers and CT. Considering that retroperitoneal lymphadenectomy identifies disease in 0% to 20% of cases,[201,252,267] that a significant risk of postoperative ejaculatory dysfunction is present, that serum AFP is elevated in 90% of patients,[265,266] and that two-thirds of patients are cured by orchiectomy alone,[150] the routine use of retroperitoneal lymphadenectomy in stage I patients has been questioned in favor of a more conservative approach.[249,266,269]

After radical orchiectomy, patients are monitored by measurement of serum AFP and periodic evaluation of the chest and abdomen. This process permits early identification of relapses and timely initiation of effective chemotherapy. This conservative approach is being evaluated prospectively in the POG/CCG intergroup study. Even with normalization of AFP, patients with stage I disease must be observed cautiously, because 20% to 40% of false-negative measurements have been identified and retroperitoneal nodal disease has occurred before elevation of AFP.[270,271]

For more advanced disease (stage II or stage III), initial chemotherapy followed by debulking surgery and, possibly, retroperitoneal lymphadenectomy has been suggested in older patients and adults.[272,273] A nerve-sparing modification of retroperitoneal node dissection recently was shown to preserve ejaculation in more than 90% of patients.[269] Because chemotherapy has proven very effective in younger children with this disease, the need for subsequent retroperitoneal lymphadenectomy has been challenged.[249,269,274]

Children with higher-stage disease require postoperative chemotherapy. Regimens containing cisplatin, vinblastine, and bleomycin have improved survival dramatically, even in patients with disseminated disease.[139,140,151,275,276] The addition of ifosfamide and teniposide to these regimens also is promising.[139,277,278] The duration of chemotherapy remains to be determined. Griffin et al.[267] suggested 1 year of treatment, but Einhorn et al.[137] could notdemonstrate the efficacy of extended treatment with vinblastine in advanced disease. Children with residual tumor may benefit from second-look surgery or irradiation.

### Embryonal Carcinoma

The adult-type embryonal carcinoma occurs rarely in young male individuals, usually in late adolescence or early adulthood.[79,80] Reports from the POG[222] and the Pediatric Tumor Registry of Germany[80] documented a 7% incidence among 42 pediatric testicular malignant germ cell tumors. No embryonal carcinomas were noted among 61 cases of testicular cancer in the United Kingdom Children's Cancer Study Group study.[150] The presenting symptoms include an enlarging scrotal mass, metastatic abdominal or mediastinal disease, or localized peripheral lymphadenopathy. Serum AFP or b-HCG (or both) may be elevated, and measurements should be obtained preoperatively.

Initial treatment consists of radical inguinal orchiectomy. On the basis of stage, various combinations of retroperitoneal lymphadenectomy, irradiation, and platinum-containing chemotherapy have been employed. The efficacy of surveillance in stage I tumors and of platinum-containing chemotherapeutic regimens in others is being evaluated in the POG/CCG intergroup trials.

### Teratoma

Teratomas represent 10% of testicular neoplasms in children and occur most frequently before the age of 4 years.[11,102] Approximately15% of these tumors have poorly differentiated elements or immature neuroectodermal components. In prepubescent patients, these features do not impart an adverse prognosis, and essentially all such patients follow a benign clinical course after radical inguinal orchiectomy.[200,201] In contrast, postpubescent testicular teratomas are considered malignant even if these histologic features are not seen. In the postpubertal male person in whom stage II and stage III disease may be observed, the apparently appropriate approach is to perform retroperitoneal lymphadenectomy with nerve sparing and to employ chemotherapy and, possibly, radiotherapy. The use of cisplatin, vinblastine, and bleomycin is associated with a 50% rate of complete response in disseminated disease,[139] with others achieving complete response with chemotherapy plus second-look surgery.

## EXTRAGONADAL TUMORS

Extragonadal germ cell tumors usually occur in midline sites as evidence of *in vivo* alteration in the complex migratory patterns of the embryonal gonads. In order of frequency, the most common locations are sacrococcygeal, mediastinal (including pericardium, heart, and lung), intracranial, retroperitoneal, and uterine. Symptoms relate to the site and histology of the tumor. The POG/CCG intergroup study reported 80% event-free survival and 100% survival with complete resection alone in immature teratomas even when microscopic foci of yolk sac tumor were present.[187] A conservative approach for nonintracranial tumors, similar to that for low-stage gonadal germ cell tumors, also has been reported by the German cooperative study.[279]

### Sacrococcygeal Tumors

Sacrococcygeal teratomas are the most common germ cell tumors of childhood, accounting for 40% of all the germ cell tumors and up to 78% of extragonadal germ cell tumors.[76,78] They also are the most frequently recognized neoplasm of fetuses.[280,281] The histogenesis of these tumors is thought to be related to incomplete migration of germ cells from yolk sac endoderm to the urogenital ridge in presacral tumors or to multipotential embryonic cells associated with the primitive streak (Hensen's node) in postsacral presentations.[282]

Approximately 75% of patients are female.[76,283,284] Congenital anomalies are observed in up to 18% of patients,[76] with musculoskeletal and central nervous system defects being the most common (24% and 26%, respectively).[284] Altmann et al.[76] reviewed the natural history data from 398 cases of sacrococcygeal teratoma and developed a means of classification (Fig. 36-7). Because most of these neoplasms are exophytic and visible to external examination (Fig. 36-8), approximately 80% are diagnosed within the first month of life. These exophytic tumors are less likely to be associated with malignant components.

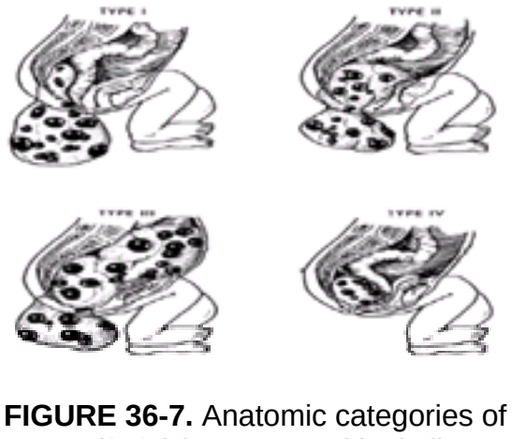

**FIGURE 36-7.** Anatomic categories of sacrococcygeal teratomas. Type I (47%) is a tumor predominantly externalized with limited extension into the sacral region; type II (34%) is a tumor with similar external component and intrapelvic extension; type III (9%) is a tumor with a minimal external component and significant intra-abdominal extension; type IV (10%) is an internalized presacral tumor without external evidence of disease.[76]

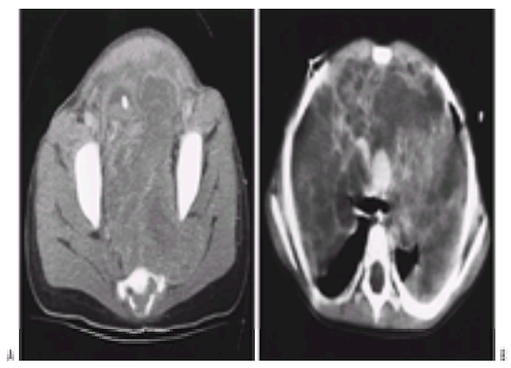

**FIGURE 36-8. A:** Abdominal computed tomographic scan in a 24-month-old girl with a presacral endodermal sinus tumor that fills the pelvis and demonstrates inhomogeneous enhancement after intravenous contrast. Note Foley catheter in compressed bladder and the tumor extending through left sacrosciatic notch. **B:** Chest computed tomographic scan in a 15-month-old girl demonstrating a mediastinal endodermal sinus tumor filling the thorax and showing mixed attenuation at the level of carina.

Approximately 17% of sacrococcygeal teratomas exhibit malignant features.[76,283] The incidence of malignant components is related to surgical type (38% in type IV vs. 8% in type I), age at diagnosis, and gender, but not to the size of the tumor.[76,222] The most common malignant elements identified within the sacrococcygeal lesions are yolk sac tumor and embryonal carcinoma.[75] A histologic grading system similar to that used for immature teratomas has been attempted in extragonadal tumors, but the predictive value of this exercise is not as clear as that in ovarian immature teratoma.[202,204]

Early and complete excision of the presacral germ cell tumor has been the mainstay of successful management.[76] Preoperative establishment of the anatomic boundaries of the tumors, evaluation for evidence of metastatic spread, and assessment of markers (i.e., AFP and b-HCG) for malignancy help to individualize treatment planning. Principles of operative excision that lead to the most successful procedure include (a) sacral incision with removal of the coccyx, (b) early ligation of middle sacral arteries and veins, and (c) circumferential preparation of the torso and lower extremities should intraoperative changes be necessary.[285] The sacrifice of vital organs is not indicated for benign neoplasms, and exenteration of untreated malignant lesions has not proven beneficial.

The cure rate of infants or children with a benign presacral germ cell tumor is more than 95%.[222,285] Cautious monitoring of such patients is required, because malignant germ cell tumors are well recognized to recur either from missed malignant elements in the original tumor or from malignant conversion of residual tissue.[86,282,285,286] Until recently, only a 10% salvage rate for malignant lesions was expected.[274,285,287] With the recognition that excision of primary malignant lesions alone has cured few patients, the addition of chemotherapy, particularly platinum-containing regimens addressing the specific malignant element, has improved survival.[168,222,288,289 and 290]

### Mediastinal Tumors

Thoracic germ cell tumors usually (although not exclusively) are located in the anterior mediastinum.[291,292,293,294 and 295] They are more common in male individuals.[296,297,298,299 and 300] Adolescents typically present relatively asymptomatically, in contrast to infants and toddlers, who more often exhibit severe respiratory symptoms, including hemoptysis.[301,302 and 303] Teratoma subtypes (mature, immature, or malignant) comprise the bulk of the histologic subtypes seen, but yolk sac tumor and choriocarcinoma occasionally may be detected.[293,294 and 295,297,301] Mediastinal teratomas occasionally have sarcomatous foci resembling rhabdomyosarcoma, angiosarcoma, or undifferentiated sarcoma.[81] These foci are extremely aggressive, tend to overgrow the remaining teratoma, and create difficulty in treatment. Therefore, appropriate metastatic surveys for these tumors and assessment of serum markers (AFP, b-HCG, LDH, and PLAP) are recommended. Mediastinal germ cell tumors frequently are associated with Klinefelter's syndrome (47,XXY).[304]

Malignant germ cell tumors, usually with a yolk sac tumor component, are associated also with hematopoietic malignancies.[305,306 and 307] The source of these malignancies is controversial, but studies have shown that the cells in the hematopoietic malignancy have cytogenetic and molecular genetic identity and are immunohistochemically similar to pluripotential cells within the germ cell tumor rather than the host's own bone marrow cells. This evidence supports the contention that the germ cell tumor cells—and not the patient's host marrow—are the source of the second malignancy.[67,108,305,308,309] Very rarely, such malignancies have been associated with gonadal tumors as well[75]; in most such cases, affected patients have been shown to have some form of XY gonadal dysgenesis. More recent pediatric studies reporting outcome specifically for mediastinal subsets of children and adolescents with malignant germ cell tumors treated with platinum-based regimens suggested that although this site is considered less favorable, event-free survival of 57% to 88% was achieved.[155,156 and 157]

### Intracranial Tumors

Primary intracranial germ cell tumors may be located in the pineal gland (62%) or suprasellar region (31%), or they may span both areas (7%).[310,311] Symptomatology depends on the growth pattern and histology of the tumor and may include visual disturbances, diabetes insipidus, hypopituitarism, Parinaud's syndrome (convergence nystagmus), anorexia, and precocious puberty.[312,313] Histologically, two-thirds of the tumors are germinomas, and the rest are nongerminomatous, some mixed with yolk sac tumor, choriocarcinoma, or teratocarcinoma.[311,313] Drop metastases to the spine and extracranial spread to lung and bone have been reported.[310,314] Serum levels of AFP and b-HCG should be measured, because they are elevated in some patients.[311]

Initial management should include attempts to obtain a biopsy and to resect the primary tumor so that appropriate subsequent therapy may be planned. Germinomas traditionally have been treated with radiotherapy. More recently, studies by Finlay et al.[315] reported that many of these tumors can be managed with a carboplatin-based chemotherapeutic regimen.

### Tumors at Other Sites

Other extragonadal sites of origin of germ cell tumors include retroperitoneum, pelvis, cervix or uterus, vagina, prostate, abdominal wall, bile duct, omentum, hernia sac, and lip.[150,152,222,316,317,318,319 and 320] Vaginal lesions must be differentiated from vaginal rhabdomyosarcoma. Although metastatic bone disease is infrequent, it is reported in 3% of adult patients with newly diagnosed disease and in 9% of those with relapses.[321]

## FUTURE CONSIDERATIONS

During the last decade, the progress in understanding and managing germ cell tumors of children has been substantial. The intergroup (POG/CCG) studies in the United States and the evolving trials in Europe and the United Kingdom demonstrate clearly that the next challenge will be to refine further our comprehension of these diverse tumors through the development of risk groupings. As with acute lymphocytic leukemia and neuroblastoma, the continued focus on the molecular and genetic facets of pediatric germ cell tumors promises to yield data that will explain and predict the diverse behavior of these tumors and perhaps lead to the development of unique treatment strategies. Further trials are being proposed to investigate the role of chemoprotective agents, such as amifostine, to reduce ototoxicity in young children receiving higher doses of cisplatin. The development of less toxic chemotherapeutic combinations is a high priority for all patients but certainly for lower-risk patients who require some postoperative treatment. For high-risk disease, dose-intensive therapy with autologous marrow re-infusion requires further assessment. Newer agents, such as ifosfamide, carboplatin, and perhaps topotecan, will be investigated further in patients with relapses and should furnish the basis of future combination regimens.

# ENDOCRINE TUMORS

CHRISTIAN A. KOCH
KAREL PACAK
GEORGE P. CHROUSOS

## INTRODUCTION

Endocrine tumors are those neoplasms arising from endocrine organs, regardless of whether they secrete hormones, and those tumors secreting hormones, regardless of the tissue of origin. The secretion of hormones by neoplasms of nonendocrine origin or by neoplasms arising from glands that normally secrete different hormones is called *ectopic production*.[1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20 and 21] Endocrine tumors represent approximately 4% to 5% of all neoplasms observed in children.[22,23,24 and 25] Most of these tumors do not secrete hormones.

Approximately 40% to 45% of childhood endocrine tumors arise from the gonads (e.g., germ cell, testicular, and ovarian tumors), 30% arise from the thyroid gland, and 20% arise from the pituitary gland. The others arise from the parathyroid glands, the adrenal cortex and medulla, the gastroenteropancreatic system, and nonendocrine tissues, such as the thymus.

Most endocrine tumors in childhood are clinically benign or low-grade malignancies. A small percentage of gonadal and germ cell tumors, thyroid neoplasms, and adrenocortical tumors are high-grade malignancies. Malignant carcinomas of the parathyroids, the adrenal medulla, and the gastroenteropancreatic system are rare.

Some endocrine tumors in childhood are of embryonic origin (e.g., germ cell tumors, craniopharyngiomas). Although most neoplasms that occur in children are sporadic, a small portion of certain endocrine tumors are familial, with some transmitted in a mendelian fashion. For instance, medullary carcinomas of the thyroid gland and pheochromocytomas can occur in a familial syndrome called *multiple endocrine neoplasia type II* (MEN II). MEN II is transmitted in an autosomal dominant fashion with high penetrance.[26] MEN type I (MEN I) is also a familial endocrine cancer syndrome. Patients with MEN I commonly have tumors of the parathyroid glands and pituitary gland.[4,5 and 6,27] The association of skin or heart myxomas, spotty skin pigmentations (e.g., lentigines), and multiple endocrine tumors is known as *Carney complex*, a condition that is inherited in an autosomal dominant manner.[28] Other genetic disorders, such as neurofibromatosis type 1 (NF-1) and von Hippel-Lindau (VHL) disease, frequently are associated with endocrine tumors, most commonly pheochromocytoma.[29]

This chapter discusses the endocrine tumors of the hypothalamic-pituitary unit, the thyroid gland, the parathyroid glands, the adrenal cortex and medulla, the adrenergic ganglia, and the gastroenteropancreatic system (e.g., insulinomas, gastrinomas, glucagonomas, VIPomas, and somatostatinomas). Also reviewed are ectopic hormone–secreting tumors and the MEN syndromes. Several features of these tumors are summarized in Table 37-1. Gonadal and germ cell tumors and carcinoid tumors are considered in Chapter 36 and Chapter 38.

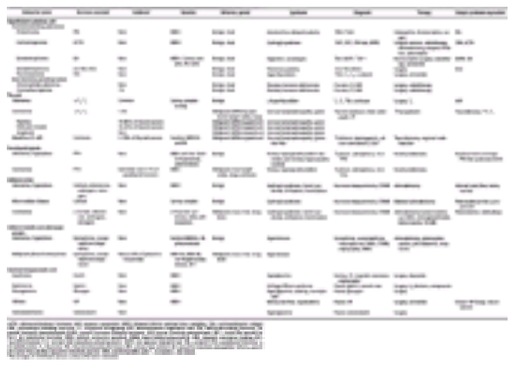

**TABLE 37-1. ENDOCRINE TUMORS IN CHILDREN AND ADOLESCENTS**

## TUMORS OF THE HYPOTHALAMIC-PITUITARY UNIT

Most tumors occupying the pituitary fossa are benign. The two main types include craniopharyngiomas and pituitary adenomas. In childhood, tumors that metastasize to the pituitary gland are exceedingly rare. Pituitary functions may be affected by neoplastic or infiltrative processes of the pituitary area, including gliomas arising from the optic chiasm or surrounding region; germ cell tumors arising from the pituitary stalk; meningiomas; and granulomatous diseases that include histiocytosis X, tuberculosis, and sarcoidosis.

The most common tumor of the pituitary fossa is the craniopharyngioma, which is a nonsecretory tumor that represents approximately 5% of all intracranial tumors in childhood and accounts for approximately 90% of neoplasms arising in the pituitary region. In contrast, pituitary adenomas comprise approximately 3% of supratentorial tumors in childhood or 6% of all surgically treated pediatric pituitary tumors. The remaining tumors are rare ( Table 37-1).[2,3,30,31,32,33,34,35 and 36] Hypothalamic hormone-secreting tumors are infrequent and usually affect adults. [37,38 and 39] However, hypothalamic hamartomas and hamartoblastomas occur in children. These tumors are nonsecretory but cause endocrine symptoms (e.g., precocious puberty) by disrupting normal hypothalamic function. [40,41 and 42]

Pituitary tumors that secrete hormones take the name of the hormone they secrete and the ending -*oma*. Prolactinomas, corticotropinomas, somatotropinomas, gonadotropinomas, and thyrotropinomas secrete, respectively, prolactin, adrenocorticotropic hormone (ACTH), somatotropin [i.e., growth hormone (GH)], gonadotropins [i.e., luteinizing hormone (LH), follicle-stimulating hormone (FSH)], and thyroid-stimulating hormone [thyrotropin (TSH)]. Each of these tumors usually produces a characteristic syndrome because of excess hormone secretion.

In the past, pituitary adenomas that did not secrete hormones and that did not stain by acid or basic stains were called *chromophobe adenomas*. Currently, immunohistochemistry is used to classify pituitary adenomas: For instance, in a patient with clinical and biochemical features of ACTH-dependent Cushing's syndrome, pituitary tissue that stains positively for ACTH indicates an ACTH-secreting pituitary adenoma. Chromophobe adenomas now are called *nonsecreting, hormonally inactive pituitary adenomas*, which account for 6% of pituitary adenomas that occur in children, as opposed to adults, in whom these adenomas account for approximately one-third of all pituitary adenomas. Fewer than 25% of pediatric patients with pituitary adenomas present before age 12. [43,44 and 45]

At present, the imaging modality of choice for detecting pituitary adenomas is the T1-weighted spin-echo magnetic resonance imaging (MRI) of the pituitary before and after administration of gadolinium. Before and after contrast, coronal and sagittal images should be obtained at 3-mm intervals focusing on the pituitary region. Pituitary adenomas usually appear as hypoenhancing lesions, as they are slowly taking up gadolinium compared to the surrounding normal pituitary tissue. In interpreting pituitary MRI scans in children, one should take into account that the normal pituitary gland may be enlarged normally during adolescence. Microadenomas, defined as pituitary adenomas smaller than 1 cm, are detected by the presently available MRI technology in only approximately 50% of cases. The detection rate of pituitary adenomas has increased over the last three decades as a result of improved imaging modalities. In a retrospective survey over 33 years, the median survival of patients with pituitary adenoma was 18 years for men and 25 years for women. Most common causes of death in patients with pituitary adenomas were cardiovascular or cerebrovascular.[46]

### Clinical Presentation

All pituitary tumors may cause symptoms arising from pressure on the adjacent structures. Headaches, visual disturbances, and manifestations from one or more hypothalamic-pituitary hormone deficiencies can be the presenting symptoms. Hyperprolactinemia may develop as a result of deficiency of the hypothalamic tuberoinfundibular dopaminergic system, which is responsible for suppression of prolactin secretion. In adolescent girls with hyperprolactinemia, menstrual dysfunction and galactorrhea may occur. Intracranial hypertension and hydrocephalus may develop in patients with (large) pituitary tumors. The usual finding on ophthalmologic examination is bitemporal constriction of the visual fields ( Fig. 37-1), because most suprasellar pituitary tumors impinge on the crossing fibers of the optic chiasm. The optic nerve fibers are arranged according to size, with the larger occupying a more inferior location, whereas smaller macular fibers occupy a more superior location. An ipsilateral central scotoma with a normal contralateral visual field is the most consistent finding on visual field testing. Other changes in the visual fields depend on the location of the tumor. Compression of the optic chiasm can produce a characteristic ophthalmoscopic optic nerve appearance of band or “bow-tie” atrophy.

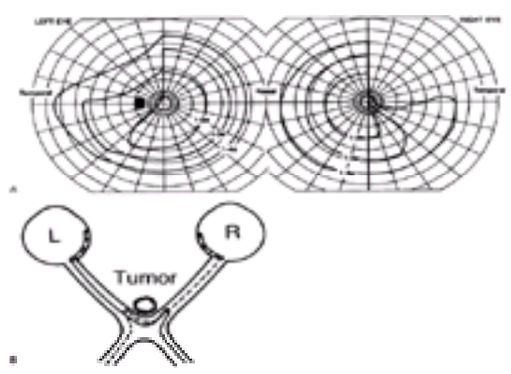

**FIGURE 37-1.** Visual field defects commonly observed with pituitary tumors. Impinging of the tumor on the anterior optic chiasm **(A)** results in bilateral superior temporal quadrantopia **(B)** owing to involvement of the lower anterior crossing nasal fibers. Further involvement of the anterior optic chiasm results in bilateral temporal hemianopia. Lateral or posterior location of the tumor results in contralateral nasal or bilateral inferior temporal defects of the visual fields, respectively.

Deficiency of one or more pituitary or hypothalamic hormones may result from pressure or encroachment by the pituitary tumor. Depending on the hormone affected, different symptoms may arise. The tests required for the diagnosis of pituitary deficiencies are summarized in Table 37-2.[7,9,14,33,47] The hormone affected most frequently is GH. Deficiency of this hormone leads to poor growth, hypoglycemia, or both in younger children. The deficiency is diagnosed by measuring the plasma GH concentration after stimulation with arginine-insulin, L-dopa, or glucagon. The attainment of symptomatic hypoglycemia (obtained by administration of 0.1 units per kg of regular insulin as an intravenous bolus) is a prerequisite for evaluating lack of response. Two abnormal test results (i.e., plasma GH elevations less than 6 ng per mL) are required for the diagnosis. Priming with gonadal steroids is recommended before GH testing in prepubertal children.

| Hormone | Tests | Response |
|---|---|---|
| GH | Arginine or insulin stimulation | GH ≥6 ng/mL |
| | L-Dopa stimulation | GH ≥6 ng/mL |
| | Glucagon stimulation | GH ≥6 ng/mL |
| ACTH | Cortrosyn stimulation | Cortisol ≥18 µg/dL |
| LH, FSH | LH-releasing hormone stimulation | LH and FSH normal for age |
| TSH | Plasma $T_4$, $FT_4$, $T_3$, TSH, TBG | |
| | TRH stimulation | TSH normal for age |
| AVP | Water deprivation | Urinary osmolality ↓<br>Serum osmolality ↑ |

ACTH, adrenocorticotropic hormone; AVP, aqueous vasopressin; FSH, follicle-stimulating hormone; $FT_4$, free thyroxine; GH, growth hormone (somatotropin); LH, luteinizing hormone; $T_3$, tri-iodothyronine; $T_4$, thyroxine; TBG, thyroxine-binding globulin; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone; ↓, decreased; ↑, increased.

**TABLE 37-2. ENDOCRINE TESTS FOR EVALUATION OF PITUITARY DEFICIENCIES**

Deficiency of ACTH leads to secondary adrenal insufficiency characterized by weakness, orthostatic hypotension, hyponatremia (if chronic lack of ACTH with subsequent atrophy of the adrenal cortex), and hypoglycemia in younger children. It is a life-threatening condition that must be diagnosed early. Diagnosis is made by measuring plasma cortisol 1 hour after adrenal stimulation with an intravenous bolus of 10 µg per kg of ACTHs 1–24 [cosyntropin (Cortrosyn)]. A normal response (i.e., plasma cortisol greater than 18 µg per dL) indicates normal function of the adrenal glands. Long-term pituitary ACTH deficiency produces adrenal atrophy and a diminished cortisol response.

Gonadotropin and TSH deficiencies may occur in patients with pituitary tumors. Gonadotropin deficiency manifests as pubertal arrest or regression in children already in puberty or manifests as delayed puberty in children affected prepubertally. Plasma LH and FSH are low for the age in these children, and bone age is delayed. TSH deficiency manifests as poor growth, diminished performance at school, constipation, cold intolerance, dry skin, and other symptoms of hypothyroidism. Measurements of serum total thyroxine ($T_4$), free $T_4$, and TSH are required for the diagnosis.

Extension of a pituitary tumor into the hypothalamic paraventricular nucleus may result in aqueous vasopressin (AVP) deficiency and diabetes insipidus (e.g., polyuria, polydipsia, dehydration, hypernatremia). The diagnosis of diabetes insipidus may be confirmed by a water deprivation test.

Certain hypothalamic tumors (e.g., hamartomas) can present with precocious puberty or hyperprolactinemia caused by compression of the pituitary stalk with subsequent increased prolactin secretion and by disruption of the normal inhibition of puberty. Hamartomas are common in genetic syndromes associated with craniofacial anomalies and abnormalities of the extremities. Patients with these genetic defects or a positive family history should be screened for these tumors by MRI.[40,41]

### Endocrine Manifestations of Hormone-Secreting Tumors

#### *Prolactinomas*

The type of pituitary adenoma that occurs most frequently in children is the prolactinoma, accounting for 53% of all tumors. Prolactinomas commonly stain for acidophilic cells and often, in addition, for GH by immunohistochemistry. The majority of such tumors in children is detected during the adolescent period. Most prolactinomas are microadenomas. Age and gender of the child determine the type of tumor presentation. Prepubertal children typically suffer from headaches, visual disturbances, or growth failure. Pubertal girls commonly show symptoms of pubertal arrest or delay, hypogonadism, or galactorrhea caused by suppression of gonadotropin secretion. Galactorrhea may not occur spontaneously and must be excluded by expressing the breast. Pubertal boys also may present with pubertal arrest or delay or growth failure (or both). Gynecomastia is not frequent. Prolactinoma should be separated from secondary hyperprolactinemia, which may be caused by any disorder that leads mechanically (e.g., hypothalamic tumors), neurogenically (e.g., nipple stimulation), or pharmacologically (e.g., antidopaminergic drugs) to loss of dopaminergic suppression of the pituitary lactotropes. Because prolactinomas have a diverse clinical picture, prolactin levels should be measured according to a low threshold. The upper limit of normal for most laboratories is 30 ng per mL. Random prolactin levels that are elevated to less than 50 ng per mL should be repeated (fasting levels, an hour after placement of an indwelling cannula). If the prolactin elevation persists, reversible factors that may cause hyperprolactinemia should be investigated further and excluded before the start of treatment (Table 37-3).[6,32,34,48,49] Prolactinomas may be seen in children with the McCune-Albright syndrome (i.e., precocious puberty, cutaneous café-au-lait spots, and polyostotic fibrous dysplasia) and in young adults with MEN I.

**TABLE 37-3. ENDOCRINE TESTS FOR EVALUATION OF HORMONE EXCESS IN CHILDREN AND ADOLESCENTS**

Medical therapy with dopamine agonists is the first line of treatment before surgical therapy, in the absence of such surgical emergency as an acute threat to vision, hydrocephalus, or cerebrospinal fluid leak. Bromocriptine is especially effective in treating smaller tumors. Its main side effects are gastrointestinal (GI) disturbances and postural hypotension. At least as efficacious as bromocriptine at reducing tumor size and prolactin levels is pergolide; it, however, has a side effect profile similar to that of bromocriptine. A newer ergot-dopamine agonist—cabergoline—causes fewer side effects than do bromocriptine and pergolide and is to be administered once or twice weekly. Rarely, prolactinomas are medically refractory. In these situations, dopamine receptor imaging can be used to gain insight into the mechanisms of drug failure.[34,50,51,52 and 53]

#### *Corticotropinomas*

Corticotropinomas are the second most common pituitary adenomas in children and the most common tumor seen prepubertally.[44,45] Most corticotropinomas are microadenomas, although diffuse corticotropic cell hyperplasia also has been described. Excess pituitary ACTH secretion (i.e., Cushing's disease) produces hypercortisolism and the characteristic features of Cushing's syndrome, including growth arrest, pubertal arrest, weight gain, hypertension, the characteristic phenotype (i.e., moon facies, buffalo hump, accumulation of supraclavicular fat), acne, purple skin striae, and weakness. Skin thinning and easy bruising are uncommon, in contrast to effects seen in adult patients with hypercortisolism. Many adolescent and young adult patients complain of mood disturbances.[54,55] However, instead of experiencing depression, memory problems, and sleep disturbances, children with Cushing's syndrome often tend to be obsessive and are high performers in school.

Corticotropinomas account for 85% of children who are older than 5 years and develop Cushing's syndrome. Other causes for hypercortisolism are primary adrenal tumors, ectopic ACTH production (bronchial or thymic carcinoids), and ectopic or eutopic corticotropin-releasing hormone–producing tumors. In children and adolescents, pseudo-Cushing's syndrome is extraordinarily rare.

The diagnosis of hypercortisolism is made by measuring 24-hour urinary free cortisol (UFC) and 17-hydroxysteroid excretion in conjunction with urinary and plasma creatinine concentrations. UFC values should be corrected for children's body surface area (usually per 1.73 $m^2$). Cushing's syndrome is confirmed further by a midnight low-dose dexamethasone (15 µg per kg) suppression test with failure of serum cortisol to suppress to less than 3 µg per dL at 8 a.m. The diagnosis of pituitary Cushing's disease is made by the following series of endocrine tests ( Table 37-3).

**Corticotropin-Releasing Hormone Test**

Measurements of plasma ACTH and cortisol are obtained before and after intravenous administration of ovine corticotropin-releasing hormone (oCRH; 1 µg per kg).[55,56 and 57] Most patients with pituitary Cushing's syndrome respond with elevations of ACTH and cortisol, but most patients with the other categories of Cushing's syndrome do not respond.

**Liddle Dexamethasone Suppression Test**

In the Liddle dexamethasone suppression test,[54,55] patients undergo six sequential 24-hour urine collections for measurement of 17-hydroxysteroids or UFC. The first two collections provide the baseline. During the next 2 days, affected patients are given 2 mg dexamethasone per day orally (30 µg per kg per day) in divided doses every 6 hours. During the last 2 days, such patients are given 8 mg dexamethasone per day orally (120 µg per kg per day) in divided doses every 6 hours.

Patients with Cushing's disease show characteristic suppression of their 17-hydroxysteroid or UFC excretion to less than 50% and 90% of baseline levels, respectively, only on the high dose of dexamethasone. At this dose, neither patients with ectopic ACTH secretion nor patients with cortisol-secreting adrenal adenomas or carcinomas respond with suppression. A suppression of serum cortisol by more than 50% after the administration of 120 µg per kg of dexamethasone (high dose) given at midnight has a sensitivity of 80% for the diagnosis of Cushing's disease. This sensitivity is comparable with that (85%) of the formal 6-day Liddle test. The advantages of the “short” high-dose dexamethasone suppression test are low costs and patient convenience, as the test does not require patient hospitalization or timed urine collections.

**Bilateral Inferior Petrosal Sinus Sampling**

If the pituitary MRI result is negative and other tests indicate ACTH dependence, oCRH-stimulated bilateral inferior petrosal sinus sampling can be used to confirm that the source of ACTH secretion is the pituitary gland.[56,57 and 58] In addition, this procedure can assist in lateralizing the adenoma with 75% accuracy. The two inferior petrosal sinuses, which drain the pituitary gland, are catheterized, and blood for measurements of ACTH is obtained simultaneously from both and from a peripheral vein. The presence of a concentration difference between either of the petrosal sinuses and the peripheral vein (ratio greater than 1.6) confirms the pituitary source of ACTH. A difference in concentration between the two petrosal sinuses (ratio greater than 1.6) suggests the location of the adenoma. The sensitivity of this test at confirming pituitary ACTH dependence is 97%.

To improve or simplify, respectively, the oCRH-stimulated inferior petrosal sinus sampling, sampling of both cavernous sinuses or the internal jugular veins has been investigated, with inconclusive results thus far.[59,60,61,62 and 63] The treatment of choice for corticotropinomas is surgical excision. For patients with noninvasive microadenomas, the cure rate is 90%, and the recurrence rate is less than 10%. For patients with large or invading tumors (e.g., cavernous sinuses), the chance of cure is still very high, but recurrence rates are greater than 10%. After removal of the adenoma, affected children become hypocortisolemic and require replacement therapy with hydrocortisone (which entails 8 to 10 mg per $m^2$ per day given in the morning, education about stress dosing of hydrocortisone, and an emergency kit of intramuscular hydrocortisone) for 6 to 12 months until the remaining and transiently suppressed nontumorous pituicytes resume appropriate ACTH secretion. Normal pituicyte function for ACTH can be confirmed by a cortisol response of more than 18 µg per dL, 30 minutes after stimulation with 250 µg cosyntropin. In patients with unresectable adenomas or more than two recurrences, radiotherapy can produce normalization of cortisol, often in association with delayed plurihormonal pituitary hormone deficiency. Approximately 80% of affected children treated with fractionated radiation doses of 35 to 50 cGy obtain cure over a 2-year interval.[34,64,65]

The molecular genetics of corticotropinomas and pituitary adenomas in general is the subject of intense investigation. Apparently, pituitary adenomas (including corticotropinomas) are monoclonal in origin. Studies of the involvement of proto-oncogenes in tumorigenesis of corticotropinomas have been disappointing, although some genes, such as *ras*, c-*erb* B-2, c-*myc*, and protein kinase C have been associated with more aggressive tumors. Abnormalities of the p53 tumor suppressor gene were found in as many as 60% of corticotropinomas but, to date, the role of this tumor suppressor gene in tumorigenesis of corticotropinomas remains unclear, as does the role of other tumor suppressor genes, including *p16, CDKN2*, *MTS1*, *INK4*, *RB1*, *p27*, *KIP1*, *CDKN4*, *hZAC*, and *NM23*. In patients with MEN I, corticotropinomas occasionally occur, although the typical pituitary adenoma in this familial tumor syndrome is a prolactinoma. For corticotropinomas and for other pituitary adenomas, the exact pathway of tumor formation remains unknown, as does the role of tumor-promoting or acquired factors.[66,67,68,69,70 and 71]

***Somatotropinomas***

GH-secreting adenomas account for some 15% of pediatric pituitary tumors. Most somatotropinomas in children and adults are diagnosed as macroadenomas. In addition, GH excess can be caused by somatotrope hyperplasia. Such hyperplasia can occur in combination with hypothalamic or ectopic tumors that secrete GH-releasing hormone. Gigantism or acromegaly has been observed in children with the McCune-Albright syndrome and in young adults with MEN I and Carney complex. Activating mutations of the Gsa subunit of the guanine nucleotide-binding proteins (G proteins) were reported for approximately one-half of sporadic somatotropinomas.[73,74]

GH excess before epiphyseal fusion leads to accelerated growth and gigantism and, after closure of the epiphyses, to acromegaly. In addition to the development of the characteristic acromegalic phenotypes, hypersecretion of GH can be associated with carbohydrate intolerance or frank diabetes, arthropathy, and the carpal tunnel syndrome.[72] In children with GH excess, an increase in colonic polyposis, malignancy, or thyroid nodules has not yet been reported, as it has in adults. In addition to the foregoing symptoms, some somatotropinomas may cause severe headaches and visual disturbances. The diagnosis is made by measuring insulin-like growth factor-1 (IGF-1) levels, which will be elevated in patients with GH excess. However, some overlap is seen with IGF-1 levels during normal puberty and pregnancy. Measuring a random GH level may be helpful, as is the determination of plasma levels of GH before and after oral ingestion of glucose (1.75 g per kg) in a glucose tolerance test. In patients with GH excess, the plasma GH concentration does not decrease after glucose administration and, paradoxically, may even rise, in contrast to the result in normal individuals, who will develop low to nonmeasurable GH concentrations after glucose administration ( Table 37-3). Somatotropinomas usually are large pituitary adenomas that are easily detected on MRI. Virtually all GH-producing pituitary adenomas possess somatostatin receptors, thus allowing for somatostatin receptor imaging with the analog octreotide. However, other pituitary tumors and pituitary metastases from somatostatin receptor–positive neoplasms, parasellar meningiomas, lymphomas, or granulomatous diseases of the pituitary also may be positive on somatostatin receptor imaging with octreotide. Furthermore, an octreoscan does not seem to have a role in deciding whether to treat pediatric patients with octreotide.[75,76] The role for an octreoscan lies more in detecting ectopic tumors that secrete pituitary hormones or hypothalamic-releasing hormones, such as GH-releasing hormone. Traditionally, surgery has been the treatment of choice for patients with GH excess from a somatotropinoma, with irradiation reserved for patients who were not surgically curable. In adults with acromegaly, long-term trials of octreotide resulted in suppression of GH to less than 5 µg per L in 65% and to less than 2 µg per L in 40%, with normalization of IGF-1 levels in 56% of cases. A drawback of octreotide therapy is the need for several daily injections. The dose required to suppress GH levels varies, depending on tumor size and receptor expression on tumor cells.

Alternatively, a long-acting, slow-release depot somatostatin analog—lanreotide—has come into use and can be administered once every 2 weeks. This drug is as effective as octreotide and successfully suppresses GH and IGF-1 levels. Medical therapy with dopamine agonists, such as bromocriptine, has been disappointing, with normalization of IGF-1 levels in only approximately 10% of patients affected by GH excess. Recently, treatment with the GH receptor antagonist pegvisomant has been shown to be potentially useful for patients with acromegaly.[77,78,79,80 and 81]

***Gonadotropinomas***

Hypersecretion of LH in prepubertal boys could lead to precocious puberty because of the excess stimulation of the Leydig cells and excessive production of testosterone. Tumors of this type, however, have yet to be described in children. Intracranial tumors that produce human chorionic gonadotropin, which has LH activity, include such germ cell tumors as choriocarcinomas, mixed germ cell tumors, germinomas, and embryonal carcinomas. These tumors lead to precocious puberty only in boys and generally are small and detectable mostly by MRI. Human chorionic gonadotropin produced by these tumors can be detected in the

cerebrospinal fluid. Gonadotropinomas secreting FSH are associated with visual disturbances and hypogonadism. [82,83 and 84]

### *Thyrotropinomas*

TSH-secreting pituitary adenomas are rare in adults and even rarer in children. Because of delayed diagnosis, these tumors often have been detected as macroadenomas leading to headaches and visual disturbances in affected patients. Newer imaging modalities (MRI) and improved biochemical hormone assays allow earlier diagnosis of these tumors. Hypersecretion of TSH can lead to hyperthyroidism. Plasma TSH, total $T_4$, free tri-iodothyronine ($T_3$), and free $T_4$ levels are elevated (Table 37-3).[85,86] This acquired syndrome should be differentiated from the genetic syndrome of pituitary resistance to thyroid hormone, with which it is biochemically identical.[85,86] Unlike patients with $T_4$ resistance, patients with thyrotropinomas usually do not respond to TSH-releasing hormone stimulation. This test has a sensitivity of 71% and a specificity of 96%. In distinction to patients with pituitary thyroid hormone resistance, patients with TSHomas have an elevated a-glycoprotein subunit (specificity, 90%; sensitivity, 75%) and an elevated ratio of alpha subunit to TSH (83% sensitivity, 63% specificity). [86,87] Treatment of choice for TSHomas is transsphenoidal surgery, often in conjunction with radiotherapy when such tumors prove large and invasive. Octreotide administration can normalize thyroid hormone levels in 80% of patients and can lead to tumor shrinkage in approximately 50% of cases, especially for residual or recurrent tumor. [86,87,88 and 89]

## Non–Hormone-Secreting Tumors

### *Chromophobe Adenomas*

Hormonally inactive pituitary adenomas are rare tumors that account for only 6% of pediatric pituitary adenomas, as opposed to 30% in some adult series. These tumors usually are discovered incidentally when affected patients undergo brain imaging for other reasons or present for evaluation of hyperprolactinemia, headaches, growth or pubertal failure, or visual disturbances. At diagnosis, these tumors usually are large and may cause elevations of plasma prolactin concentrations as a result of pituitary stalk compression and insufficient dopaminergic suppression of the lactotrophs. [90] These tumors occasionally secrete the alpha subunits of glycoprotein hormones (e.g., TSH, LH, FSH), which are hormonally inactive. They also may secrete the b-glycoprotein hormone subunits and chromogranin A.[34,91] The mainstay of therapy is surgery, if symptoms are present or arise. Because distinguishing these tumors from craniopharyngiomas is difficult, the threshold for surgical intervention in children likely is low.

### *Craniopharyngiomas*

Craniopharyngiomas account for 90% of neoplasms in the pituitary region and arise from remnants of Rathke's pouch, the anlagen of the adenohypophysis. These tumors may develop at any time in life but have a bimodal peak in incidence: one at 5 to 14 years of age and another after age 50. [34,35] Two-thirds of the tumors are calcified and can be seen on plain radiographs. Cystic components are common. Craniopharyngiomas expand locally, and symptoms reflect their location and pressure on or destruction of local structures. Headaches, visual disturbances, and panhypopituitarism with diabetes insipidus are frequent manifestations. Most headaches likely develop from stretching of the diaphragma sellae by the enlarging mass. Up to 75% of patients have GH deficiency, followed by gonadotropin deficiency in 40% and ACTH and TSH deficiency in 25%.

Despite the often large size of the tumor, the pituitary stalk is disrupted uncommonly, with approximately 20% of patients suffering from mild hyperprolactinemia due to the inability of hypothalamic (tuberoinfundibular) dopamine to reach the lactotrophs and act as a prolactin-inhibiting factor. [92] Also uncommon is the loss of the posterior pituitary function, with perhaps 15% of patients presenting with diabetes insipidus. [93,94]

The treatment of choice is surgery. Surgical management depends on many factors, including a patient's age, type of presentation (e.g., acute, hydrocephalus, existing hypothalamic problems), and tumor size. Some patients may require external fractionated radiotherapy with doses up to 56 Gy. Postoperatively, endocrine dysfunction frequently occurs regardless of the surgical approach. In predominantly cystic tumors, adjunctive localized intracavity yttrium, $^{32}P$, and other radioactive implants have proven useful for recurrent tumors. [95,96,97,98,99 and 100]

### *Hypothalamic Hamartomas*

Hypothalamic hamartomas are congenital malformations consisting of ectopic neurons of variable maturity and glial cells irregularly arranged in fibrillary matrix. They arise from cells forming the hypothalamic sulcus that divides the alar plate facing the lumen of the diencephalon into a dorsal (thalamus) and ventral (hypothalamus) region. Hypothalamic hamartomas constitute the most common identifiable central nervous system lesion causing central precocious puberty. Sometimes these tumors are associated with fits of laughter and often manifest as pedunculated masses at the base of the hypothalamus on MRI.

In one case of hamartoma, a significant amount of gonadotropin-releasing hormone was found in the tumor. [101] Most hamartomas, however, lead to precocious puberty by abolishing the normal hypothalamic control of the onset of puberty.

Hypothalamic hamartomas frequently are seen in the context of genetic syndromes associated with craniofacial and skeletal anomalies. The Pallister-Hall syndrome is autosomal dominant and is characterized by orofacial, cardiac, lung, renal, genital, anal, and limb malformations, such as postaxial polydactyly. Reduced penetrance has been found in some families with this syndrome. Screening for hypothalamic hamartoma by MRI is recommended. Other genetic conditions associated with hypothalamic hamartomas include the oral-facial-digital syndrome type VI (Varadi's syndrome) and several cases of holoprosencephaly. [40,41,102]

## Treatment and Prognosis

Surgery always is recommended for pituitary tumors that enlarge rapidly and threaten vision, regardless of the type of the tumor. Smaller tumors can be removed by transsphenoidal surgery. Larger tumors with suprasellar extensions can be removed by craniotomy or by combined craniotomy and transsphenoidal surgery. Frequently, complete tumor excision is not feasible, and mere debulking is attempted.

Transsphenoidal surgery is a low-risk procedure (Fig. 37-2).[101,102,103,104,105,106,107 and 108] Rare complications include total hypophysectomy and panhypopituitarism; cavernous sinus hemorrhage; transient or permanent diabetes insipidus or inappropriate antidiuretic hormone secretion syndrome; cerebrospinal fluid leaks; and meningitis.

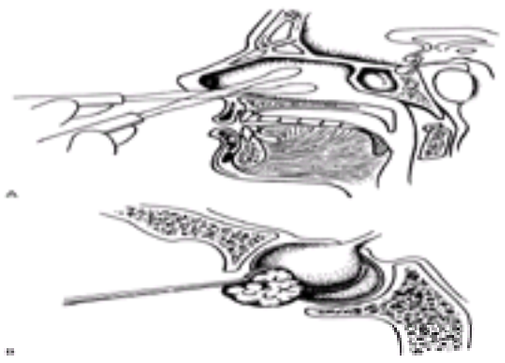

**FIGURE 37-2.** Transsphenoidal surgery. The pituitary gland is approached through the sphenoid sinus **(A)**. Transsphenoidal exposure of the pituitary gland and adenomectomy **(B)**. (Adapted from Hardy J. Transsphenoidal surgery of hypersecreting pituitary tumors. In: Kohler PO, Ross GT, eds. Diagnosis and treatment of pituitary tumors. New York: American Elsevier, 1973:179.)

Transsphenoidal adenomectomy is the treatment of choice for corticotropinomas.[109,110 and 111] Lateralization of the plasma ACTH concentration difference during bilateral sampling of the inferior petrosal sinuses and MRI of the sella turcica usually help with localizing the adenoma to one side of the pituitary. [57,58] In addition, selective venous sampling from the cavernous sinuses and intraoperative ultrasonography may help. [60,61,108] Some corticotropinomas cannot be differentiated from normal pituitary tissue during surgery, for which hemipituitectomy-hemihypophysectomy of the side of the higher ACTH concentration is recommended.

In the largest reported series of pediatric patients with corticotropinomas, remission of hypercortisolism was achieved in 48 of 49 who underwent transsphenoidal surgery.[109] Nineteen percent of these patients had one or more endocrine deficiencies postoperatively. Central hypothyroidism and diabetes insipidus were transient, both resolving within the first 2 years postoperatively in most patients. Suppression of spontaneous GH secretion occurred in all children and adolescents with Cushing's disease during their illness and up to 1 year after surgical cure, contributing to the reduced final adult height of these individuals. [110,112] These results were confirmed in another report.[113]

Bromocriptine and pergolide, drugs with potent dopamine agonist activity, are the treatments of choice for prolactinomas. [30,114] Bromocriptine doses ranging from 5 to 20 mg per day, with a gradual increase in dosage to avoid such initial side effects as nausea and orthostatic hypotension, frequently are sufficient to correct the hyperprolactinemia and to cause regression of the tumor. Pergolide is tenfold more potent than bromocriptine, with the advantage of once-daily dosing and reduced cost. Newer ergot-dopamine agonists, such as cabergoline, can be given twice weekly, are as efficacious as the other dopamine agonists, but are much more expensive. Years of treatment with dopamine agonists may be required for permanent cure. Bromocriptine, usually at higher doses (up to 25 mg per day), occasionally is helpful in the treatment of somatotropinomas and chromophobe adenomas.[53,77,114,115]

Pituitary adenomas and craniopharyngiomas usually are radioresistant. However, radiotherapy in doses as high as 5,000 cGy divided into 200-cGy fractions has been applied for the treatment of corticotropinomas and somatotropinomas if surgery has been unsuccessful. [112,113,116,117] Radiotherapy of craniopharyngiomas after subtotal excision may decrease the incidence of recurrences.[92,118]

Corticotropinomas respond relatively well to irradiation, with approximately 70% to 80% of these lesions in children being cured by 1 to 2 years after therapy. [116] Nonendocrine complications of radiotherapy have included an increase in second tumors within the radiation field, visual impairment, and problems with memory. The use of multiportal fractionated irradiation of approximately 50 Gy over a 5-week period has reduced these complications.

An alternative to radiotherapy is bilateral adrenalectomy. Patients then are committed to lifelong glucocorticoid and mineralocorticoid replacement. Hydrocortisone (12 to 15 mg per $m^2$ per day) and 9a-fluorocortisone (50 to 150 mg per day) are recommended. In approximately 15% of patients so treated, Nelson's syndrome (i.e., pituitary ACTH-secreting macroadenoma and hyperpigmentation) develops within 10 years after adrenalectomy. [119] Likely, the so-called Nelson's syndrome, first described in 1958 at a time when radiologic imaging modalities and neurosurgical pituitary skills were not as well developed as they are today, merely represents the term for a less well resected and subsequently recurrent or progressed pituitary adenoma. If the visual system is threatened, transsphenoidal surgery or radiotherapy is indicated.

Adrenolytic agents, such as o,p'-DDD (mitotane), or steroidogenesis enzyme inhibitors, such as aminoglutethimide, metyrapone, trilostane, and ketoconazole, may be employed to control hypercortisolism.[120,121,122,123 and 124] Patients tolerate most of these drugs poorly. However, ketoconazole (10 to 15 mg per kg per day) is relatively well tolerated and frequently is used. This drug has some hepatotoxicity, and liver function should be monitored in patients eceiving it. Skin rash is a common complication of aminoglutethimide treatment.[125]

When pituitary tumors are associated with pituitary hormone deficiencies, replacement treatments should be instituted. The deficiencies may develop after surgery or years after radiotherapy. The replacement treatments include GH (0.3 mg per kg per week subcutaneously divided in daily doses) for GH deficiency; hydrocortisone (12 to 15 mg per $m^2$ per day orally or 30 to 100 mg per $m^2$ per day orally or parenterally during significant stress) for adrenal insufficiency; and $T_4$ (1.6 µg per kg per day orally) for hypothyroidism. Testosterone enanthate (200 mg intramuscularly every 2 weeks) and one of the estradiol and progestin combinations may be employed for the treatment of male and female hypogonadism, respectively. Desmopressin (DDAVP; 0.1 mL intranasally, as needed) is the treatment of choice for diabetes insipidus. AVP (Pitressin) is available for subcutaneous administration. (Several sources providing more information on hormonal replacement therapies in children are provided in the reference list.[1,11,12])

The prognosis for patients with pituitary tumors generally is good. These tumors are benign, although some have a tendency to invade adjacent structures. In a series of pediatric patients with non–ACTH-secreting pituitary adenomas, those with microadenomas had a 70% operative cure rate and a 65% long-term cure rate. The recurrence rate for microadenomas was 25%. Macroadenoma patients had a 33% operative cure rate, a 55% long-term cure rate, and a recurrence rate of 33%. In the same series, macroadenoma patients required more aggressive adjuvant therapy and had higher rates of postsurgical hypopituitarism. [126] Frequently, complete removal of macroadenomas or craniopharyngiomas with suprasellar extensions is difficult and requires adjuvant radiotherapy. Treatment of these tumors by surgery, irradiation, or both methods may add to the endocrine morbidity. Monitoring of visual function is crucial.

Surgery or irradiation rarely is needed for hypothalamic hamartomas. The early identification of these tumors is necessary for timely treatment of the associated central precocious puberty with a gonadotropin-releasing hormone analog. [40,127]

## THYROID TUMORS

Thyroid tumors are divided into adenomas and carcinomas (Table 37-1).[128,129,130 and 131] Both types can secrete hormones. Medullary carcinoma, a form of thyroid carcinoma that arises from the parafollicular (C) cells of the thyroid, produces and frequently secretes calcitonin, which is a tumor marker for this type of cancer. Differentiated thyroid carcinomas usually secrete thyroglobulin. Thyroglobulin secretion, however, also occurs in hyperplastic benign thyroid conditions and depends on the amount of thyroid tissue, as it can be elevated in large goiters.

Thyroid carcinomas are malignant tumors. Despite their histologic appearance, however, the clinical course frequently is relatively benign, with an excellent survival rate when treated appropriately and in a timely manner.

Thyroid nodules can occur spontaneously or in association with hyperstimulation of the thyroid by TSH or thyroid-stimulating immunoglobulins. Nodules associated with overstimulation of the thyroid tissue are seen in iodopenic goiter, Hashimoto's thyroiditis, Graves' disease, or mixed states of Graves' disease and Hashimoto's thyroiditis. In clinically evident nodules, only 1 nodule in 20 may harbor thyroid cancer in adults, but the ratio in children is much higher. In children, thyroid carcinoma is found in approximately 40% of thyroid nodules that come to surgical exploration. Benign lesions that cause nodule formation, such as multinodular or colloid goiters, occur more often in adults than in children.[132,133,134,135,136,137,138,139,140,141 and 142]

### Epidemiology and Genetics

Thyroid carcinomas in childhood represent approximately 1.5% of all tumors before the age of 15 years and 7.0% of the tumors of the head and neck. Two-thirds of pediatric thyroid carcinomas occur in girls, with a peak incidence between ages 7 and 12. [143,144,145,146,147,148,149,150,151,152,153,154 and 155] The causative role of neck irradiation in the development of thyroid cancer has been well established.[156,157,159,160,161,162,163 and 164]

The tumorigenic effect of radiation is more severe in a child's thyroid than in an adult's. This has been demonstrated in epidemiologic studies from the Marshall Islanders, survivors of the atomic blasts in Hiroshima and Nagasaki, and the Belarus-Chernobyl area. [129] Doses exceeding 150 cGy exert a carcinogenic effect, with an average latency of 7 years between irradiation and the appearance of thyroid carcinoma. The incidence of thyroid cancer has decreased since the mid-1960s, when widespread application of radiotherapy to the neck was discontinued. The radiation was given in the neonatal period for enlarged thymus and later for tonsillitis, adenoid hypertrophy, pharyngitis, and skin diseases of the face and neck. Therapeutic irradiation and chemotherapy resulted in a 53-fold increased risk of thyroid carcinoma in patients who had survived 2 or more years after the diagnosis of a cancer in childhood. Children who received 6 cGy to the thyroid during irradiation for tinea capitis had four times the rate of thyroid cancer as did controls. [165]

The incidence of thyroid cancer after atomic fallout increases, as experience with the Chernobyl nuclear accident in the former Soviet Union has shown. [129,166] The

latter event caused a large increase in the number of new cases of this cancer in central Europe only 4 years after the accident occurred in 1990. The cancers developed by these children were unusually aggressive and carried frequent *RET*/PTC rearrangements. The same rearrangements have been described in inhabitants of New Caledonia, a French territory in the Pacific located between Australia and Fiji, and in children and young adults evaluated in Washington, DC. [167,168 and 169] Children who were younger than age 8 and lived in the resettlement zone around the Chernobyl area received an average thyroid radiation dose of 4.7 Gy, as opposed to adults, who received 1.6 Gy. Effects of radioactive iodine in these iodopenic individuals took place on grounds of endemic iodopenic goiter, which is characteristic for the Belarus region and surroundings. The significant increase of thyroid nodule pathology in children of the Republic of Belarus constituted adenoma, nodular goiter, and especially carcinoma. The gender ratio of the patients with papillary thyroid carcinomas was 1.0:1.2. In addition to the study of cancer, a study among atomic bomb survivors documented increased incidence of adenomas, cysts, and autoimmune hypothyroidism.[170]

In addition to diet (e.g., iodine load), genetic factors appear to play a significant role in the pathogenesis of sporadic thyroid cancer. Some reports have cited increased incidence of thyroid cancer in children with the Pendred, Gardner, Cowden, and familial polyposis syndromes and in those with Carney complex. [171,172] Familial incidence of papillary thyroid cancer also has been reported.

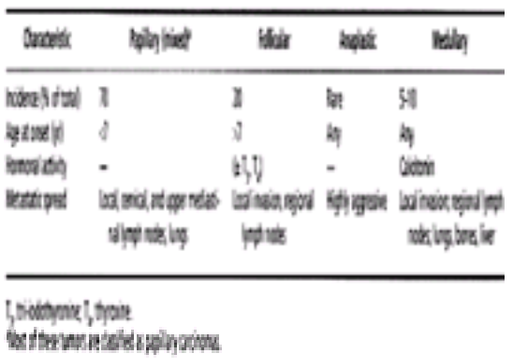
An association appears to exist between disorders of the immune system involving the thyroid gland and thyroid cancers, as reports of papillary and follicular cancer in children with Hashimoto's thyroiditis and lymphoma of the thyroid have suggested. Patients with Hashimoto's thyroiditis have been postulated to have an inherited isolated defect in immunoregulation containing an organ-specific defect in suppressor T-cell function. Such a defect adversely affects immune surveillance, and these subjects may be rendered susceptible to the development of Hashimoto's thyroiditis, thyroid neoplasia, or both conditions. Other factors, such as serum TSH, TSH receptor–activating mutations, oncogene activation, and local growth factors (e.g., IGF-1, transforming growth factor-a, epidermal growth factor) also may play a role in thyroid oncogenesis.[131,132,133,134,135 and 136]

Medullary carcinomas of the thyroid frequently are familial. They can be isolated (i.e., familial medullary thyroid carcinoma) or associated with pheochromocytoma in MEN IIA and MEN IIB. These familial cancer syndromes are transmitted in an autosomal dominant manner.[6,27,173,174 and 175] At least 30% of medullary carcinomas are of the familial type; the remainder occur sporadically. Mutations of the RET proto-oncogene, the gene responsible for the MEN IIA and MEN IIB syndromes, have been found in sporadic and familial medullary thyroid cancers. [176,177,178,179,180 and 181]

Hyperthyroidism, goiter, and benign nonfunctioning nodules frequently have been associated with the McCune-Albright syndrome. Activating mutations of the Gsa subunit of the G proteins that mediate thyrotropic action have been found in such patients. An increased incidence of thyroid nodules, and possibly cancer, also have been reported in patients with Carney complex.[182,183]

**Pathology**

Most thyroid carcinomas in childhood are differentiated tumors. [129,157,158 and 159,184,185 and 186] Rarely, undifferentiated (anaplastic) carcinomas, Hürthle cell carcinomas, or lymphomas are found. Metastases to the thyroid, which in adults derive most commonly from a primary renal, breast, or lung cancer, have not been reported in children. In principle, two types of differentiated thyroid carcinomas derive from the follicular epithelium: papillary and follicular carcinomas. Each cancer may be subdivided further into variants that give rise to such combinations as the follicular variant of papillary thyroid carcinoma, which has been observed in 21% of tumors that occurred in patients from the Belarus-Chernobyl region. [129] The relevant features of the various pathologic subtypes are listed in Table 37-4.



[, thioldihydrotyrosine; ], thyroxine.
*Most of these tumors are classified as papillary carcinoma.

**TABLE 37-4. TYPES OF THYROID CARCINOMA IN CHILDREN AND ADOLESCENTS**

Papillary carcinoma may occur in disseminated neoplastic foci (multifocal papillary thyroid carcinoma) in the gland. [128] The epithelial cells are arranged in the form of papillae containing fibrous tissue and vessels. Approximately 50% of papillary thyroid tumors contain psammoma bodies, a structure that forms when calcium salts are deposited on the dying cells of infarcted papillae. The bodies are found in the cores of papillae or in tumor stroma. Tumor cell nuclei are larger and more elongated than those of normal follicular epithelial cells and contain characteristic intranuclear inclusions. “Multifocality” and lymph node metastases are caused by intraglandular lymphatic spread. This form of thyroid cancer makes up 90% of thyroid cancers in children. [129,184] Follicular carcinoma is characterized by adenomatous, follicular formations of cells.[128] Capsular invasion or vascular invasion (or both) distinguishes this tumor from ordinary benign follicular adenoma. Metastatic spread in this cancer often occurs through the blood stream. It occurs predominantly in older children.

Anaplastic (i.e., giant- and spindle-cell) carcinomas are extremely rare in children. They are characteristically undifferentiated, rapidly growing tumors. [128,129 and 130] Medullary carcinomas account for approximately 5% of all thyroid carcinomas. They are solid tumors composed of islets of regularly sized cells with abundant granular cytoplasm. C-cell hyperplasia usually precedes medullary thyroid carcinoma when it occurs within a familial syndrome. [187] The stroma contains abundant fibrotic tissue and various quantities of amyloid-like substance. [128,173]

**Patterns of Spread**

Local cervical and upper mediastinal lymph node involvement by papillary cancer occurs in more than 50% of patients without necessarily implying a poorer prognosis, especially in children. [129,130,143,144] The most common site for distant metastases is the lung and upper mediastinum, and at least 20% of children with papillary thyroid cancer have pulmonary metastases at the time of diagnosis. Bone metastases from papillary cancers are uncommon, as are metastases to any site below the diaphragm. These tumors typically grow slowly.

Follicular carcinomas may be locally invasive but metastasize to regional lymph nodes far less commonly than do papillary cancers. However, they are more likely to spread to bone and the lungs. Follicular carcinomas are more likely to be hypersecretory and functional than are papillary cancers and may produce $T_4$, $T_3$, or both.[159]

Anaplastic carcinomas of the thyroid are extremely malignant. They usually evolve from a previously diagnosed papillary cancer or long-standing, preexisting goiter. The explosive growth of this type of carcinoma may be accompanied by hypercalcemia.

Medullary carcinomas of the thyroid can invade locally or metastasize into the regional lymph nodes. Pulmonary, bone, brain, and liver metastases also can be seen.[26,175]

**Clinical Presentation**

The most common presenting complaint in children is anterior cervical adenopathy. The cervical mass may be discrete and may have been neglected for years before the physician decides to obtain a biopsy specimen. Frequently, the mass has been diagnosed as lymphadenitis or as a congenital branchial cyst. The second most common symptom is a firm, palpable thyroid nodule, isolated or associated with a cervical lymph node. The combination of adenopathy and a thyroid nodule is found

in approximately 50% of cases. Patients are predominantly euthyroid; hyperthyroidism occurs rarely. [129,159]

Patients with thyroid carcinoma can present with a solitary nodule or multiple discrete nodules. The risk of malignancy was thought to be lower in the latter case, although recent reports are debating this observation. Every child with abnormal thyroid gland examination findings deserves a thorough workup, because thyroid nodules are uncommon at a young age. A study of 4,819 healthy children found only 22 patients with a solitary thyroid nodule. Fourteen patients underwent surgical exploration, and two were found to have papillary carcinoma. [184,188]

Obtaining affected patients' histories should include questions on a history of external irradiation to the head and neck, goitrogen ingestion, and the presence of local or systemic symptoms, such as hoarseness or dysphagia. Rapid painless growth of a nodule suggests carcinoma, whereas tenderness indicates hemorrhage in a cyst or an inflammatory process. Physical examination should be directed also to the recognition of signs of a possible genetic syndrome, such as familial medullary thyroid carcinoma, MEN IIA, or MEN IIB. A medullary carcinoma within the context of MEN IIB should be suspected in patients with a thyroid nodule, marfanoid body habitus, and multiple mucosal neuromas, appearing as whitish nodules on the tongue, the lips, and the conjunctivae. At times, rapidly developing dysphagia may result from an ectopic thyroid gland. [189]

**Diagnosis**

In children with thyroid tumors, tests of thyroid function usually confirm euthyroidism. Rarely, hyperthyroidism is seen. Serum concentrations of thyroglobulin can be elevated in patients with thyroid carcinoma but may be elevated also in patients with benign thyroid disorders. This test is useful, however, for postoperatively monitoring patients with carcinoma.

Thyroid scintigrams performed with $^{123}I$ or $^{99m}Tc$ usually show parenchyma with normal uptake and one or more “cold” or hypofunctioning nodules ( Fig. 37-3). Rarely, “hot” or hyperfunctioning nodules are seen. Discrepancies between scintigrams taken with $^{123}I$ and $^{99m}Tc$ can occur. Because a carcinoma can appear hot with $^{99m}Tc$ and cold with $^{123}I$, patients with the former finding require repeat scanning with radioactive iodine. Octreotide scintigraphy appears useful for the detection of medullary thyroid carcinoma.

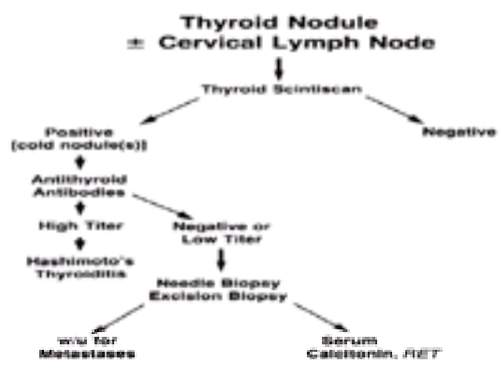


**FIGURE 37-3.** A proposed flow diagram for the diagnostic evaluation of thyroid nodules in children and adolescents. w/u, workup.

Very small nodules may not be imaged by one or both of the foregoing techniques. Ultrasonographic examination of the thyroid gland in pediatric patients provides an accurate means of assessing thyroid size and the presence and size of thyroid nodules. This study is recommended routinely as one of the first studies that should be obtained in the evaluation of a solitary thyroid nodule in a child. Chest radiographs or chest computed tomography (CT) or MRI should be obtained to exclude metastatic spread.[190]

Very high titers of antithyroglobulin or antimicrosomal antibodies render the diagnosis of Hashimoto's thyroiditis likely, but low titers are not helpful diagnostically ( Fig. 37-3). A basal serum calcitonin assay can be helpful in pointing toward or away from medullary carcinoma. If the result is equivocal or if suspicion of medullary carcinoma is high, a stimulation test using pentagastrin or calcium infusion should be performed. Recently, calcitonin stimulation also was obtained by administration of omeprazole.[191] A stimulated calcitonin concentration three times higher than the upper limit of normal suggests medullary cancer or C-cell hyperplasia, a precancerous condition.[187]

The best single diagnostic test for the diagnosis of thyroid nodules is fine-needle aspiration biopsy. [192] If the specimen obtained by this procedure is unsatisfactory, an excisional biopsy of the enlarged cervical lymph node or of the isolated thyroid nodule may be required. For younger children, an open excisional or core biopsy, rather than a fine-needle aspiration biopsy, is recommended.

**Treatment**

***Surgery***

Surgery is the treatment of choice for thyroid carcinoma. [157,159,184,185] and [186,193,194,195] and [196] Total thyroidectomy is recommended but should be carried out by an experienced endocrine surgeon to avoid complications, such as recurrent laryngeal nerve injury and postoperative hypoparathyroidism. Performance of a total thyroidectomy facilitates subsequent radioactive ablation of the thyroid remnant. This positively affects disease-free survival, as shown by univariate and multivariate analyses.[129,186,195,196] Similarly, lymph node dissection should be performed if lymph node involvement is documented preoperatively or intraoperatively. During surgery, frozen sections of sampled tissue can be obtained to assist in deciding on the extent of surgical removal, but clinical surgical judgment is of paramount importance. Postoperatively, all patients are given replacement doses of levothyroxine ($LT_4$) (2.2 mg per kg per day) to suppress TSH, thereby eliminating the growth-promoting effects of this hormone on the tumor. Side effects of this suppressive treatment, which causes mild iatrogenic hyperthyroidism, include vascular headaches in children from ages 8 to 20, insomnia, attention deficits that may persist over the long term, and effects on skeletal maturation and calcification with subsequent osteopenia.[129,130,197]

***Radioiodine***

After surgical treatment of differentiated thyroid cancer, the decision of whether to administer $^{131}I$ must be made. Most differentiated thyroid tumors accumulate $^{131}I$, which provides high levels of radiation to the cancer cells. Cancer outside the confines of the thyroid is a definite indication for such therapy. Because at the time of diagnosis more than 20% of affected children have lung metastases that may or may not be apparent on chest radiographs, $^{131}I$ therapy generally is recommended for children. Before and 5 days after $^{131}I$ therapy, a diagnostic whole-body radioactive scan should be performed. Therapeutic doses of $^{131}I$ for metastases are administered only after $^{131}I$ dosimetry and thyroid ablation therapy have been performed. [130,198,199,200,201,202,203] and [204] If no metastatic disease is seen outside the thyroid bed, $^{131}I$-induced ablation of any significant thyroid remnant is required to eliminate thyroid function. This also facilitates the use of thyroglobulin as a tumor marker for recurrent disease during periodic follow-up under hypothyroid conditions achieved by $LT_4$ withdrawal.

$^{131}I$ doses for ablation vary from center to center. Usually, approximately 29 mCi are sufficient for thyroid bed destruction in adults, but most authorities recommend ablation with 30 to 100 mCi for low-risk cases. In the past, much higher doses have been used. As children are more sensitive to radiation than adults and are at risk for developing secondary cancers for a longer projected life expectancy after radioiodine treatment, 29 mCi should be sufficient for ablation. On the other hand, in the presence of lymph node or pulmonary metastases, much higher doses of $^{131}I$ are needed. TSH stimulates tumor uptake of $^{131}I$ and enhances the probability of its detection by diagnostic scanning and its therapeutic effectiveness. Recombinant TSH has proven useful in detecting and treating residual tumor and tumor metastases.[205,206]

After preparation (e.g., avoidance of iodized substances, intravenous radiographic contrast preparations) and usually 4 weeks after surgery or 6 weeks after

discontinuation of $T_4$ replacement therapy, affected patients are given a standard thyroid-ablation dose of 29 mCi of $^{131}I$ and are placed on $T_4$ replacement. During the hypothyroid preparatory period, patients are allowed to take $T_3$ (Cytomel) to ameliorate symptoms from hypothyroidism. Cytomel must be stopped in a patient 2 weeks before scanning of that patient is undertaken. Six months after thyroid ablation, standard scanning with 1 to 5 mCi of $^{131}I$ is repeated under hypothyroid conditions. If less than 0.3% of the dose is found in the thyroid bed at 48 hours, thyroid ablation has been successful. This outcome occurs in approximately 80% of cases. Between follow-up evaluations, patients are maintained on thyroid hormone suppressive therapy (2.2 µg per kg per day).

$^{131}I$ therapy for metastatic disease is administered after successful thyroid ablation. Standard fixed therapeutic doses (150 to 200 mCi) may be given every 6 months. Alternatively, the dose may be calculated by previous dosimetry, with excellent results. More than one-half of patients with metastatic disease are rendered free of disease by $^{131}I$ therapy. Most cures are obtained after one or two therapeutic doses, although some patients may require more.

The side effects of $^{131}I$ include transient bone marrow suppression (e.g., decrease of circulating leukocytes and platelets with a nadir at approximately 6 weeks), nausea and vomiting, sialadenitis, pain in metastatic deposits, pulmonary fibrosis, and leukemia. [201] The sialadenitis may be permanent and leads to deterioration of the teeth. Azoospermia and decreased fertility may occur. [207] With use of pretreatment dosimetry for metastatic disease, serious complications, such as radiation-induced pulmonary fibrosis and leukemia, are thought to occur less frequently.

***Other Treatment***

Chemotherapy or external-beam irradiation for metastatic differentiated and anaplastic thyroid cancer have been disappointing. [159,208] Doxorubicin (Adriamycin) is the only proven active single agent, and its results often are temporary. Local control of anaplastic cancer of the thyroid has been rare until the use of a combination of low-dose (10 mg per $m^2$ per week) doxorubicin and external-beam irradiation (200-cGy fractions; total dose, 5,000 cGy). [209] This combination has been successful also in local control of bulky recurrences of differentiated cancer. [210]

**Prognosis**

The prognosis for patients with differentiated thyroid carcinoma generally is good. The survival of children and adolescents up to 1970 was approximately 82% at 20 years but, in series published since 1981, survival rates in excess of 90% have been reported. The presence of distant metastases does not necessarily predict a poor prognosis. Patients should not be overtreated with extensive surgery, $^{131}I$, or external-beam irradiation. Furthermore, $^{131}I$ successive therapies in persistent metastatic disease should be used judiciously to avoid high cumulative $^{131}I$ dose exposures, which in children and adolescents may have a high risk for the emergence of secondary neoplasias, such as leukemias.

Frequent monitoring of patients with differentiated thyroid cancer or medullary carcinoma of the thyroid is important. Physical examination, chest radiographs, and at least annual measurement of plasma concentrations of thyroglobulin and calcitonin or carcinoembryonic antigen are important. [211,212 and 213] If the serum thyroglobulin level becomes detectable or rises after completion of surgery and radioiodine ablative therapy while a patient is on TSH suppressive therapy with $LT_4$, repeat total-body scanning with different imaging modalities is indicated under hypothyroid conditions or $LT_4$ withdrawal.

Patients with thyroid cancer may survive for many years with good quality of life. [159,214] However, repeat surgery, $^{131}I$, or both may be necessary between long asymptomatic intervals.

## PARATHYROID TUMORS

Parathyroid tumors include adenomas, usually found in one or, rarely, two glands; hyperplasia, usually affecting all four glands; and carcinomas. [4,5,215,216,217,218,219,220,221,222,223,224,225 and 226] Adenomas account for approximately 80% of parathyroid tumors, hyperplasia accounts for 20%, and carcinoma accounts for only a few cases. Parathyroid tumors secrete parathyroid hormone (PTH), which is responsible for the syndrome of primary hyperparathyroidism.

Parathyroid hyperplasia or adenomatous changes also can occur in conditions characterized by chronic hypocalcemia, including hypovitaminosis D, intestinal malabsorption of calcium, PTH resistance, and renal insufficiency. [1,2 and 3,227,228 and 229] Parathyroid hyperplasia can be found also in X-linked hypophosphatemic rickets [230,231] and familial hypocalciuric hypercalcemia, a benign condition caused by mutations in the calcium sensor gene and requiring no parathyroid surgery. [232,233 and 234]

**Epidemiology and Genetics**

Primary parathyroid tumors in childhood are rare. They can occur in young persons at any age, from neonates to young adults. Most cases are not hereditary. However, familial parathyroid adenoma and hyperplastic states exist. [1,2 and 3,222] In MEN I, parathyroid disease is the most frequently occurring component of the syndrome. Even in the absence of a tumor, all of an affected individual's parathyroid glands are hypercellular in this condition. The gene responsible for MEN I has been identified on chromosome 11q13. [235] This gene acts as a tumor suppressor gene, with loss of the wild-type copy in MEN I–associated tumors. Interestingly, clonal allelic losses of chromosome 11q13 also have been observed in 25% of sporadic parathyroid adenomas, as well as a number of non–MEN I–associated, GH-producing pituitary and other tumors. [236,241]

A subset of sporadic parathyroid adenomas contains a clonal genomic DNA rearrangement involving chromosome 11 and leading to the fusion of an oncogene named *PRAD1* (located at 11q13) with a part of the PTH gene (located at 11p15). This pericentric inversion leads to overexpression of the *PRAD1* transcript and parathyroid tumorigenesis in a way similar to that described for the *bcl-2* oncogene in B-cell lymphomas. [242] Hyperparathyroidism occurs in only a minority (approximately 25%) of patients with MEN IIA and is characterized by multiglandular involvement. Mutations of the RET proto-oncogene, the gene responsible for MEN IIA and MEN IIB, have not been described in sporadic parathyroid tumors. The germline *RET* mutations in patients with MEN IIA have been suggested to cause mild parathyroid hyperplasia but require the presence of additional oncogenic hits in a given cell to provoke the development of clinically significant, monoclonal tumors. In patients with MEN IIB and mutations of the RET proto-oncogene but at a different site of the gene (exon 16), hyperparathyroidism is absent. [243]

Other genetic conditions also are associated with parathyroid hyperplasia and adenoma formation. Familial isolated hyperparathyroidism has been described in several kindreds containing an inordinate number of affected members without other endocrine manifestations. Several of these patients developed parathyroid cancer. Investigators are working to identify the gene responsible for this disorder, known as *HRPT1*. [244]

The gene for the hereditary hyperparathyroidism–jaw tumor syndrome, called *HRPT2* and considered to be an important endocrine tumor gene, has been mapped to the long arm of chromosome 1 (1q21-q31). [245,246,247,248 and 249] Familial hypocalciuric hypercalcemia is also called *familial benign hypercalcemia* and is an autosomal dominant condition in which patients excrete strikingly less calcium in their urine than do other individuals with an equivalently elevated serum calcium. In most families with familial hypocalciuric hypercalcemia, linkage was demonstrated to the G protein–coupled calcium sensor gene, *PCAR1*. Heterozygotes for mutations of this gene appear to have reduced calcium-sensing activity, with resultant activation of PTH secretion and increased renal tubular calcium reabsorption characteristic of the disease. Homozygotes or compound heterozygotes for mutations of the *PCAR1* gene present at birth with severe neonatal hyperparathyroidism due to parathyroid hyperplasia. [234]

**Pathology**

Several pathologic variants have been described in the parathyroid glands of patients with primary hyperparathyroidism. [5,221,222 and 223,227,228,229,230,231,232,233 and 234,242,243,244 and 245,250] The predominant cell in parathyroid adenomas and hyperplasia is the chief cell. Rarely, adenomas composed of oxyphil cells or a mixed population of chief and oxyphil cells are found. The normal parathyroid gland contains as much as 50% fat, but adenomatous or hyperplastic glands contain little or no fat. Classically, a capsule and a compressed rim of normal tissue are seen. In a small percentage of cases, hyperplasia of the clear cell, a variant of the chief cell, is observed.

In parathyroid carcinomas, the tumor is larger than adenomatous or hyperplastic parathyroid glands. [217,219] Histologic examination reveals infiltration of the capsule and blood vessels and mitoses. The slow-growing carcinomas of the parathyroid glands spread locally to the lymphatics. Distant hematogenous metastases are

located in the lung, liver, and bone.

### Clinical Presentation

Primary hyperparathyroidism can be associated with asymptomatic hypercalcemia, fortuitously diagnosed during an electrolyte check, or with the hypercalcemic syndrome, which may manifest as polydipsia, polyuria, mental confusion, pruritus, headache, keratitis petrificans, band keratitis, and disseminated calcifications. [1,2] and [3,250] Bone pain may occur with demineralization and resorption cysts of the phalanges, subperiosteal zones, and lamina dura in the dental alveoli, skeletal deformations, or fractures.

Osteitis fibrosa cystica describes the combination of these lesions, with characteristic brown tumors of the jaws, skull, clavicles, and other areas of the skeleton. Renal involvement with nephrolithiasis and nephrocalcinosis most commonly develops, as may gastric ulcers and pancreatitis.

### Diagnosis

The diagnosis is confirmed by demonstrating hypercalcemia, hypophosphatemia, elevation of serum alkaline phosphatase, and inappropriately high serum concentrations of PTH that cannot be suppressed by infusion of calcium. [1,2] and [3,251] Impaired renal function may manifest as alkalosis, AVP resistance, and sodium wasting. Proximal muscle weakness results from muscle atrophy that is more prominent in type II fibers. Electrocardiography shows shortening of the QT interval. Because the length of the QT interval varies considerably with cardiac rate in children, a correction for rate should be applied. Hypertension is observed in 20% to 60% of patients with severe hyperparathyroidism.

Bone radiographs may reveal characteristic lesions of osteitis fibrosa cystica and findings compatible with rickets. Nephrocalcinosis and nephrolithiasis may be evident on abdominal x-ray films or ultrasonographic or CT scans of the kidneys. Demineralization around the teeth is evidenced as loss of the lamina dura. Ectopic calcifications also may be seen.

Sometimes, adenomas of the parathyroid glands can be localized preoperatively by palpation, radiographs of the esophagus (showing a deviation as a result of impingement by a parathyroid adenoma), ultrasonographic and CT imaging, arteriography, and selective venous catheterization for determination of differences in plasma PTH concentrations. Radioactive thallium-technetium subtractive scintigraphy is the standard localization technique in cases requiring a second surgical exploration. However, in general, locating an excellent endocrine surgeon is of paramount importance. [252,253] and [254]

### Treatment and Prognosis

Treatment of parathyroid adenomas and hyperplasia (primary and tertiary hyperparathyroidism) consists of surgical removal of the afflicted parathyroid gland(s) after careful exploration of the cervical region. [5,255,256,257] and [258] The medical management of hypercalcemia is based on maintaining good hydration, increasing urine calcium excretion, and diminishing bone resorption. Hydration with saline (up to 4 L per day for a full-grown adolescent, proportionally less for younger children) and the administration of furosemide (1 mg per kg three times daily) increase renal calcium excretion. Oral phosphate, glucocorticoids, and diphosphonates have been used in the management of hyperparathyroidism until surgery is undertaken.

If an abnormal parathyroid gland is removed, a second gland should be located and excised. If the size and histology of the second gland are normal, a single adenoma is likely, and further exploration is unnecessary. If hyperplasia is suspected or if the second gland is abnormal, all parathyroid glands should be located, and all but one should be excised totally. The remaining gland should be excised partially. If no glandular abnormalities are found in the cervical region, exploration of the mediastinum should be considered. Intraoperative measurements of PTH after removal of one or more parathyroid glands may assist in determining whether enough tissue that caused hyperparathyroidism before surgery has been removed. [233] Some surgeons advocate transplantation of a portion of some of the parathyroid tissue into the muscle of the forearm to avoid hypoparathyroidism from delayed vascular failure in the portion of the gland left behind. Such a transplanted gland may resume function several weeks or months after surgery or, in rare cases, never. For the postoperative hypoparathyroid period, administration of calcium and vitamin D is necessary to keep the plasma ionized calcium concentration in the low-normal range. [259,260] and [261]

Parathyroid carcinomas are radioresistant, and so surgery is the treatment of choice. Surgical morbidity includes recurrent laryngeal nerve injury and permanent hypoparathyroidism. Failure of initial surgery to cure hyperparathyroidism is an indication for reevaluating the diagnosis and repeating localizing procedures before further surgical exploration. A missed adenoma most likely is located in the mediastinum or in the retroesophageal area of the neck. In the hands of an experienced surgeon, repeat surgery is successful in 90% of cases.

Parathyroid carcinomas occur rarely in children, but they constitute a significant cause of persistent or recurrent primary hyperparathyroidism. [220,224] They tend to be slow-growing and are curable in the early stages by adequate local excision.

The postoperative course of patients treated with parathyroidectomy usually includes transient hypocalcemia for several weeks. If the bone disease has been severe, hypocalcemia may be profound, requiring treatment with calcium and vitamin D. Hypocalcemia in association with hypomagnesemia is termed *hungry bone syndrome* and requires additional magnesium supplementation. Several months may be needed to decide whether permanent hypoparathyroidism has resulted from a compromised blood supply to the remaining parathyroid tissue.

## ADRENOCORTICAL TUMORS

Adrenocortical tumors are divided into adenomas and carcinomas. [54,55,262,263,264,265,266,267,268,269,270,271,272,273,274,275,276,277,278,279,280,281,282] and [283] Adenomas and carcinomas can secrete hormones or can be hormonally inactive. [265,266,267,268,269,270,271,272,273,274,275,276,277,278,279,280,281,282,283,284,285,286,287,288,289,290,291,292,293,294,295] and [296] The hormones secreted include cortisol, aldosterone, androgens, estrogens, and steroid biosynthesis intermediates ( Fig. 37-4). Generally, adenomas are far more efficient than are carcinomas in producing steroid hormones.

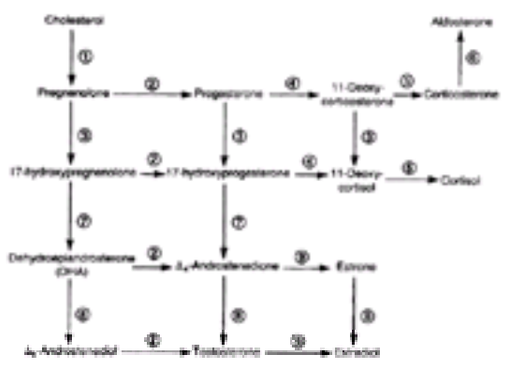

**FIGURE 37-4.** The adrenal steroidosynthesis pathway. Aldosterone, cortisol, androgens, and estrogens are manufactured from cholesterol after a series of enzymatic reactions. Numbers in circles represent enzymes: 1, cholesterol desmolase system; 2, 3-b-hydroxysteroid dehydrogenase-D5, D4-isomerase; 3, 17a-hydroxylase; 4, 21a-hydroxylase; 5, 11b-hydroxylase; 6, corticosterone methyloxidase types I and II; 7, 17,20-desmolase; 8, 17-ketosteroid reductase; 9, aromatase. Enzymatic blocks are common in tumors, resulting in accumulation of one or more steroid precursors in plasma.

Regardless of hormone secretion, adenomas generally are benign, whereas carcinomas are malignant. Adrenal tumors can be found incidentally during adrenal CT or MRI scanning or can be discovered in the course of evaluation for hypercortisolism, hyperaldosteronism, hyperandrogenism, or hyperestrogenism. [297,298] and [299] One or more adrenal adenomas frequently are found during the course of ACTH-dependent Cushing's syndrome (Cushing's disease) and, less frequently, in the ectopic

ACTH secretion syndrome. In this case, they are described as macronodular adrenal hyperplasia and should be differentiated from the micronodular form, primary pigmented nodular adrenocortical disease (PPNAD). PPNAD causes ACTH-independent Cushing's syndrome and most frequently is associated with spotty skin pigmentation (lentigines), other endocrine tumors, and myxomas of the heart, skin, and other sites. The disease is known as *Carney complex*, and in approximately 50% of cases, it is inherited in an autosomal dominant manner.[172] Unilateral or bilateral macronodular adrenal hyperplasia occasionally is ACTH-independent and may cause hyperaldosteronism or, rarely, Cushing's syndrome.

In children older than 5 years, adrenal carcinomas frequently (50% to 60%) secrete cortisol and adrenal androgens and rarely secrete aldosterone, testosterone, or estrogens.[275,276,277,278,279,280,281 and 282] Approximately 40% of adrenocortical carcinomas secrete no active hormones, but inactive steroid precursors (e.g., pregnenolone, 17-hydroxypregnenolone, and 11-deoxycortisol) or their metabolites can be found in the circulation and the urine, respectively. Occasionally, adrenocortical carcinomas secreting deoxycorticosterone or corticosterone cause hypokalemic alkalosis in the absence of hypercortisolism.[279] Generally, hormone-secreting adrenocortical carcinomas are very inefficient in producing active hormones such as cortisol, and nearly 50% of them have attained palpable size by the time they produce an endocrine syndrome. Among children younger than 5 years of age, 95% of the cases present with virilization. A higher incidence of cancers may be noted among relatives of patients with adrenocortical carcinoma.

**Epidemiology and Genetics**

Adrenal adenomas and adrenocortical carcinomas that cause Cushing's syndrome are rare tumors.[54,55] In older children and adolescents, adrenal tumors are responsible for 10% to 20% of cases of Cushing's syndrome but, in children younger than 5 years, they and the less common ectopic ACTH-secreting tumors are together responsible for approximately 80% to 90% of cases of Cushing's syndrome. In a series of 59 children with Cushing's syndrome who were between the ages of 4 and 20 years, four had PPNAD, and two had carcinomas.[109]

The genetics of sporadic adrenal adenomas and carcinomas remain largely unknown, with many genetic alterations representing merely genetic epiphenomena. One-third of adrenocortical carcinomas were found to have mutations of the p53 tumor suppressor gene.[300] Cushing's syndrome in McCune-Albright syndrome is caused by activating mutations of the Gsa subunit. The gene responsible for Carney complex, the single inherited form of adrenal hyperplasia (PPNAD) leading to Cushing's syndrome, was mapped to the short arm of chromosome 2 (2p16) and the long arm of chromosome 17, but its nature remains unknown.[172,301]

Many sporadic adrenal carcinomas demonstrate loss of heterozygosity involving the insulin-like growth factor-2 (IGF-2) locus at the short arm of chromosome 11 (11p13).[302,303] IGF-2,a gene that is paternally imprinted, is overexpressed in these tumors, and adrenal carcinomas are common in a genetic disorder, the Beckwith-Wiedemann syndrome, that has been associated with IGF-2 gene up-regulation and loss of imprinting status. Although it appears certain that growth factors are important in adrenal oncogenesis, that they are the primary genes involved remains doubtful. One study failed to identify oncogenic mutations of the Gsa subunit in adrenal tumors. An autosomal dominant disorder that predisposes to multiple neoplasias, including adrenocortical carcinoma and osteosarcoma, is Li-Fraumeni syndrome, which is caused by germline mutations of the p53 tumor suppressor gene.[304]

**Pathology**

Adrenal adenomas are generally small, encapsulated, steroid-secreting tumors with characteristically increased smooth endoplasmic reticulum and lipid droplets inside the cells.[262,263 and 264] Frequently, few signs of malignancy can be found; however, numerous mitoses and pleomorphism can be seen without capsular invasion. Micronodular adrenal hyperplasia is characterized by the presence of small nodules dispersed in both adrenal glands.[305,306,307 and 308,310] The nodules contain a brown or black pigment. Macroscopically, they give the adrenal cortex a rugged appearance. The internodular parenchyma is hypotrophic or atrophic.

In contrast, adrenocortical carcinomas are large by the time they are discovered.[262,263] They infiltrate neighboring tissues such as the kidney capsule, and they spread locally. Cells frequently are characterized by numerous mitoses, scant cytoplasm, and pleomorphism. Areas of necrosis and hemorrhage within the tumor are common, and such hemorrhage can cause death. At present, malignancy is defined by the “Weiss criteria.”

**Patterns of Spread**

Local spread characterizes adrenocortical carcinomas. By the time they are discovered, 20% of the tumors have spread locally. Tumors spread into the kidneys, the retroperitoneal and peritoneal space, the diaphragm, and the vena cava. Occasionally, the tumor grows up into the right atrium. Intrahepatic spread frequently is observed. Lung and bone metastases also are common.

**Endocrine Manifestations**

The most common endocrine manifestations are virilization and Cushing's syndrome.[54,55,112] Distinguishing this from the other forms of Cushing's syndrome is relatively easy, because the tumor is identified radiologically by CT or MRI scans and no plasma ACTH is detectable because of pituitary ACTH suppression by the elevated plasma cortisol concentration. Adrenal adenomas or carcinomas fail to respond to low or high dexamethasone doses ( Table 37-3).

Other endocrine manifestations include hyperaldosteronism characterized by hypertension, hypokalemic alkalosis, and elevated plasma concentrations and 24-hour urinary excretion of aldosterone or other sodium-retaining corticoids. Hyperandrogenism, characterized by precocious puberty in the male patient or masculinization in the female patient, and hyperestrogenism, associated with feminization and hypogonadism in boys and precocious puberty in girls, may also be seen.

**Diagnosis**

Imaging procedures are the key to the diagnosis of adrenal tumors.[264,299,311,312,313,314,315,316 and 317] Ultrasonography should be the initial imaging modality for children with adrenal masses, followed by CT scanning or MRI. The latter, especially T2-weighted relaxation imaging, is characteristically enhanced as a consequence of the high water content of adrenocortical carcinomas. In the case of micronodular adrenal disease, small rugged adrenal glands may be seen bilaterally, but often the nodules are not visible by any of the aforementioned techniques. A radioactive iodocholesterol scan allows imaging of cortisol-secreting adenomas but not of carcinomas or 50% of adrenal glands with micronodular disease.

Depending on the associated endocrine syndrome—hypercortisolism, hyperaldosteronism, hyperandrogenism, or hyperestrogenism—the diagnosis can be confirmed, respectively, by elevated 24-hour UFC, urinary aldosterone, plasma androgens or urinary 17-ketosteroids, or plasma estrogens. In the rare case of hyperaldosteronism attributable to secretion of a steroid other than aldosterone that has sodium-retaining properties, the plasma concentrations of such steroid intermediates as deoxycorticosterone and corticosterone should be measured ( Fig. 37-4). The measurement of serum 18-hydroxycorticosterone after overnight bedrest is a useful test for differentiating aldosterone-producing adenomas from primary adrenal hyperplasia (i.e., idiopathic hyperaldosteronism).[318]

**Treatment**

The treatment of all primary adrenal tumors is surgical, with laparoscopic removal of the affected adrenal gland.[5,54,55,112,113,280,319,320 and 321] Adrenal adenomas should be removed with the whole ipsilateral adrenal gland. Micronodular adrenal disease (PPNAD) or primary macronodular adrenal disease should also be cured by bilateral adrenalectomy performed laparoscopically. Unilateral adrenalectomy has been performed in a number of patients with primary adrenal hyperplasia (i.e., idiopathic hyperaldosteronism). In these patients, hypertension resolved, and medical treatment or repeat surgery was not needed.

Complete resection of the tumor by laparotomy is the treatment of choice for adrenal carcinoma. If complete resection cannot be achieved, as much of the tumor as possible should be removed. Solitary recurrences or metastases of adrenocortical carcinoma should also be removed surgically. Long-term disease-free status has been produced by complete resection of adrenocortical carcinoma, and long-term remissions have followed surgical resection of hepatic, pulmonary, or cerebral metastases.

If the patient does not have surgically curable disease, therapy with o,p'-DDD (mitotane) usually is initiated. The o,p'-DDD, an adrenocytolytic agent given at maximally tolerated oral doses (up 10 g per $m^2$ per day), ameliorates the endocrine syndrome in approximately two-thirds of patients.[54,55,322,323,324 and 325] Tumor regression or arrest of growth has been observed in as many as one-third of patients. However, mean survival does not appear to be altered, although some patients

with unresectable carcinomas have achieved long-term survival. The side effects include nausea, vomiting, diarrhea, skin reactions, and neurologic manifestations, primarily lethargy, somnolence, dizziness, and muscle weakness. Such other chemotherapeutic agents as cisplatin, 5-fluorouracil, and etoposide may be useful.

Occasionally, for the correction of hypercortisolism, steroid synthesis inhibitors (i.e., aminoglutethimide, metyrapone, trilostane, ketoconazole) or glucocorticoid antagonists [mifepristone (RU-486)] are required. [326,327,328,329 and 330] Patient staking o,p'-DDD may develop hypoaldosteronism or hypocortisolism, and fludrocortisone or hydrocortisone should be added as needed. Radiotherapy occasionally is helpful for palliation of metastases. Recently, a new interventional technique, radiofrequency ablation, has been used in a few patients. [331,332]

After removal of an autonomous adrenal adenoma or carcinoma, a period of adrenal insufficiency ensues, during which glucocorticoids must be replaced. [54,55] This abnormality of the hypothalamic-pituitary-adrenal axis can last as long as 1 year or occasionally longer. Through the first 2 postoperative days, a total of 100 mg of hydrocortisone per day or its equivalent is given intravenously. New guidelines for glucocorticoid coverage during stress periods subdivide stressors into different stress stages—for instance, considering cholecystectomy only a moderate stressor as compared to coronary artery bypass surgery. Each stress stage is assigned a different glucocorticoid coverage dose—for instance, up to 50 mg of hydrocortisone for a single day for minor stress, up to 100 mg per day for 1 to 2 days for moderate stress, and up to 150 mg per day for 2 to 3 days for severe stress [e.g., cardiac surgery such as coronary artery bypass graft (CABG)]. [333] Postoperatively, oral replacement doses of hydrocortisone (12 to 15 mg per $m^2$ per day) then are initiated. Patients often complain of weakness at these doses. This regimen is maintained until the patient is tested 3 months later with a short ACTH stimulation test [cosyntropin (Cortrosyn), 10 mg per kg intravenously, with serum cortisol measured at 1 hour]. If the response to this test is normal (plasma cortisol in excess of 18 µg per dL), an attempt is made to discontinue hydrocortisone therapy. If the result is subnormal, the therapy is continued for another 2 months, and the test is repeated. During the period of adrenal insufficiency, patients should be given extra glucocorticoids in the form of replacement when stressed. During minor stress (e.g., febrile illness), they should double the daily dose for 2 or 3 days. During major stress (e.g., trauma, surgery), they can be given up to ten times the replacement dose for 2 or 3 days. All patients should wear medical alert badges indicating that they are receiving glucocorticoid replacement.

### Prognosis

The prognosis for patients with primary adrenal adenomas and micronodular adrenal disease is excellent. Patients with idiopathic hyperaldosteronism should be followed closely after unilateral adrenalectomy for recurrence of hypertension. The prognosis of adrenal carcinoma is generally poor, with a mean survival of approximately 18 months. Highly aggressive tumors can progress rapidly in a few months. With aggressive surgical therapy, the mean survival increases to 48 months, and survival as long as 10 years has been described for some patients receiving vigilant monitoring and aggressive surgery for local recurrences or metastases. Cures have been achieved for patients undergoing operation early, while the tumor was still encapsulated.

## CHROMAFFIN CELL TUMORS

Tumors of the adrenal medulla arise from chromaffin cells and are called *pheochromocytomas*. Tumors that do not primarily develop from the chromaffin cells of the adrenal medulla but rather from extra-adrenal sympathetic nervous system structures are known as *paragangliomas*. Pheochromocytomas and paragangliomas commonly synthesize and secrete catecholamines, including epinephrine, norepinephrine, dopamine, metanephrine, and normetanephrine. [4,5,29,334,335,336 and 337] The neuroendocrine origin of pheochromocytomas is underscored by positive immunostaining for chromogranin A and synaptophysin and granules visible by electron microscopy.

### Epidemiology and Genetics

Pheochromocytomas are rare tumors. In childhood, these tumors are predominantly diagnosed between the ages of 6 and 15 years with a slight predominance in boys.[338,339,340,341 and 342,367] Malignancy in these tumors is established by the presence of distant metastases. Approximately 10% of pheochromocytomas that occur intra-adrenally are reported to be malignant, as opposed to 40% of those with extra-adrenal location of the primary tumor. Pheochromocytomas most often occur as sporadic tumors but develop also as part of a hereditary syndrome. Most familial pheochromocytomas can be subdivided into the following groups: MEN IIA, MEN IIB, VHL disease, and NF-1.[26,29,343,344] Paragangliomas (tumors that develop in extra-adrenal structures of the sympathetic nervous system such as the organ of Zuckerkandl) also can occur in a familial syndrome that has been linked to chromosome 11q23. [345] Because the genetic defects responsible for most of these disorders (*RET*, *VHL*, *NF-1*) have been identified, genetic testing is available for patients with a positive family history and for patients with apparently sporadic disease.[26,174,347,348 and 349]

Thus far, mutations in exons 10, 11, and 14 of the RET proto-oncogene (located on chromosome 10q11.2) lead to pheochromocytomas in patients with MEN IIA, and mutations in exon 16 of *RET* are found in more than 95% of patients with MEN IIB.[26,350,351] Somatic *RET* mutations are detected in fewer than 20% of sporadic pheochromocytomas.[352,353] In patients with VHL disease, mutations of the VHL tumor suppressor gene on chromosome 3p25.5 predispose to the development of pheochromocytomas (VHL type 2).[343,348] Similar genotype-phenotype correlations are not available for NF-1, because (a) pheochromocytomas in NF-1 occur in fewer than 2% of patients, (b) NF-1 has pathognomonic clinical features, and (c) the NF-1 gene is large and mutation analysis is cumbersome. Neurofibromatosis type 2 is not associated with pheochromocytoma.

### Pathology and Patterns of Spread

Pheochromocytomas and paragangliomas can occur in all locations where chromaffin tissue is found. [334,337] Approximately 85% of these tumors are located in the adrenal glands. Common extraadrenal sites are sympathetic ganglia near the kidney and the organ of Zuckerkandl. Pheochromocytomas may occur multifocally and bilaterally, especially in hereditary tumor syndromes. Approximately one-third of affected children have multiple tumors. [338,341]

Most pheochromocytomas measure less than 5 cm. They are vascular tumors and commonly contain cystic, necrotic, or hemorrhagic areas. Tumor cells contain typical catecholamine storage granules. MEN II–associated pheochromocytomas are surrounded by extratumoral adrenomedullary hyperplasia, in contrast to VHL-associated pheochromocytomas. Intracytoplasmic hyaline globules are found commonly in MEN II pheochromocytomas, whereas tumor cells in VHL pheochromocytomas demonstrate a clear-cell pattern. On histologic grounds, the diagnosis of malignant pheochromocytoma cannot be made. Malignancy is defined only by the presence of clinical, distant metastases. Bone, liver, lung, and lymph nodes are the most common sites for metastases from a pheochromocytoma. [354]

### Endocrine Manifestations

Sustained or paroxysmal arterial hypertension is the most common sign and is found in 80% of pediatric patients. [338,341,367] In contrast to adult patients with pheochromocytoma, children with this tumor experience sustained hypertension much more commonly than paroxysmal attacks. Sustained hypertension in children due to pheochromocytoma usually is refractory to conventional antihypertensive treatment. Other symptoms and signs of catecholamine excess include headache, sweating, palpitations, flushing, anxiety, tremor, nausea and vomiting, abdominal or chest pain, and visual disturbances. Fatigue and exhaustion may follow a paroxysmal attack. Weight loss, constipation, and low-grade fever are less commonly present. Polyuria and polydipsia may occur as a result of hyperglycemia, which is found in approximately one-third of pediatric pheochromocytoma patients. Orthostatic hypotension, which is seen mainly in patients with MEN II pheochromocytoma, may occur as a result of inadequately functioning neurovascular reflexes or predominant release of epinephrine from the tumor. Pheochromocytomas rarely cosecrete other hormones such as vasoactive intestinal peptide (VIP) and ACTH. In these cases, additional symptoms attributable to the respective hormone secretion (i.e., watery diarrhea, hypokalemia in the case of VIP; Cushing's syndrome in the case of ACTH) can be present in the pediatric pheochromocytoma patient. Physical examination is usually normal but can reveal hypertension and its consequences of increased heart size and retinopathy. If the patient does not have NF-1 or MEN IIB, both of which have typical pathognomonic clinical features (i.e., café au lait spots, neurofibromas, and the like in NF-1; mucosal neuromas with blubbery lips, marfanoid habitus, and the like in MEN IIB), the physical examination may be unremarkable, as no specific signs or physical findings are associated with pheochromocytoma.

### Diagnosis

Currently available assays for catecholamines and their metabolites have simplified the diagnosis of pheochromocytoma ( Fig. 37-5). Plasma and urinary catecholamines, including free metanephrine and normetanephrine, are usually sufficient to confirm the diagnosis. Some malignant tumors may secrete large amounts of dopamine, leading to increased plasma concentrations and urinary excretion of the dopamine metabolite homovanillic acid. Dopamine is also the principal active

catecholamine produced by ganglioneuromas and neuroblastomas, leading to selectively elevated urinary homovanillic acid levels. During blood sampling and urine collections, drugs (e.g., acetaminophen) and foods that stimulate catecholamine secretion or interfere with the catecholamine assays must be eliminated for a certain amount of time (e.g., acetaminophen for at least 5 days).[336,355]

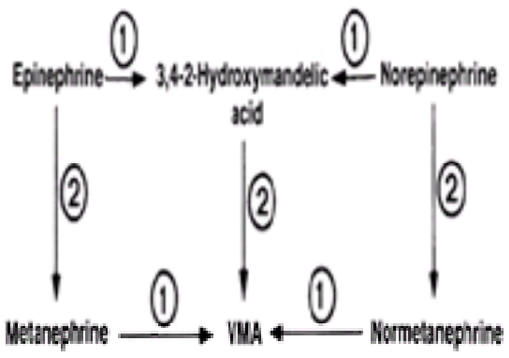

**FIGURE 37-5.** Catecholamine metabolism pathway. Numbers in circles represent metabolizing enzymes: 1, monoamine oxidase; 2, catechol-O-methyltransferase. VMA, vanillylmandelic acid.

In patients with brief and infrequent paroxysms separated by symptom-free intervals, confirmation of the diagnosis may be difficult, if such a diagnosis is based on the measurement of plasma catecholamines. Preferentially, the measurement of plasma metanephrine concentrations should be undertaken, as production of metanephrines by tumor cells occurs continuously and independently of catecholamine release. If plasma metanephrine concentrations are less than threefold elevated, performance of the glucagon test should be considered to confirm further the biochemical diagnosis of pheochromocytoma. In such cases, it may be useful to induce a paroxysm (Table 37-3).[357,358] This test should be done under the supervision of an endocrinologist, having phentolamine and a b-adrenergic blocker (in case of an epinephrine-secreting tumor) at the bedside. Injection of 1 mg glucagon intravenously can induce an attack in most patients with pheochromocytoma. The crucial time point for plasma catecholamine collection and subsequent measurements is 2 minutes after the injection of glucagon.

Another confirmatory test is the clonidine suppression test.[359] Clonidine (0.3 mg per 70 kg), an $a_2$-adrenergic agonist that suppresses the central sympathetic system, usually fails to decrease catecholamine secretion in patients with pheochromocytoma. However, the specificity of this test is not higher than 80%.

If the chemical tests are inconclusive, periodical following of a patient or initiation of a therapeutic trial with phenoxybenzamine hydrochloride may be useful. After the diagnosis of pheochromocytoma has been established, the tumor must be localized to facilitate its surgical removal. CT or MRI scans frequently are sufficient. A scintigraphic procedure in which $^{123}$I- or $^{131}$I-labeled meta-iodobenzylguanidine (MIBG) is injected leads to detectable images of pheochromocytomas 24 to 72 hours later.[360,361] The procedure is highly specific and can detect pheochromocytomas not detected by CT. However, not all pheochromocytomas produce detectable images, and so other imaging modalities—including octreoscan or positron emission tomography scanning—should be considered. Catecholamine measurements in blood samples obtained by percutaneous venous catheterization at various points along the inferior vena cava or renal, adrenal, and jugular veins can be of great value in locating small tumors.

### Treatment

As soon as the diagnosis has been confirmed, therapy with adrenergic antagonists should be initiated.[5,346,362,363 and 364] This treatment allows reduction of symptoms, lowering of blood pressure, amelioration of paroxysms, and expansion of the vascular bed and blood volume. A few days are required for preoperative preparation of patients. The agents used are primarily phenoxybenzamine (Dibenzyline), a noncompetitive a $_1$-adrenergic antagonist with a long effect (half-life of 36 hours); a calcium channel blocker; and metyrosine (Demser). Postural hypotension may be seen at the beginning of therapy with these agents. Occasionally, small doses of the b-blocking agent propranolol is required to control tachycardia or arrhythmias. Medical preparation of the patient decreases the risks of anesthesia and surgery.[5,29,365,366,367,368 and 369]

Abdominal tumors are approached transabdominally to allow exploration of the adrenal glands and the abdominal sympathetic ganglia. If bilateral adrenal tumors are found, both adrenal glands are removed, and glucocorticoid and mineralocorticoid replacement is required. The prognosis after successful surgery is excellent, as fewer than 10% of intraadrenal pheochromocytomas are malignant.

Patients with unresectable malignant tumors or metastases can be managed medically for some time. Phenoxybenzamine or a-methyltyrosine can be employed. Long-term survival of these patients has been reported but is rare. Usually, life expectancy with a malignant pheochromocytoma is less than 5 years. At present, treatment modalities include $^{131}$I-MIBG, chemotherapy, octreotide, and tumor chemoembolization.[370,371,372,373 and 374] On occasion, bone metastases respond well to irradiation given for symptomatic relief. Chemotherapy or radiotherapy alone or in combination have been disappointing in patients with unresectable malignant pheochromocytomas.

## TUMORS OF THE GASTROENTEROPANCREATIC UNIT

The rare tumors that arise from endocrine cells of gastroenteropancreatic origin and secrete peptide hormones have collectively been called *APUDomas*. The term has prevailed because these tumors apparently arise from neuroectodermal cells that have the ability to take up, decarboxylate, and store aromatic amine precursors, referred to as *amine precursor uptake and decarboxylation*, or *APUD*.[4,5 and 6,375,376,377 and 378] However, this concept is outdated, as a large body of evidence now exists to prove that essentially every epithelial stem cell can differentiate to a neuroendocrine tumor cell.[15,16,378] Most so-called APUDomas are found in the pancreas, but a few occur in the wall of the GI tract or in the retroperitoneum. Most of these tumors probably arise from pluripotential stem cells (i.e., nesidioblasts) in pancreatic ducts. Although many APUDomas contain more than one type of endocrine cell and secrete more than one hormone, they usually are named after the hormone most responsible for the clinical manifestations.

Diagnosis is made by measuring an elevated level of a gastroenteropancreatic hormone in the blood. Measurements are made on basal samples or after provocation (Table 37-3). Finding APUDomas usually is difficult during laparotomy. Preoperative localization by CT, MRI, pancreatic arteriography, octreotide scintigraphy, or percutaneous transhepatic venous sampling of portal vein tributaries for measurement of the suspected hormones frequently is attempted.[4,5 and 6,376,377,379,380 and 381]

Approximately 50% of APUDomas are malignant at the time of diagnosis. APUDomas are rare in childhood. The most frequent type is the insulinoma. Gastrinoma, VIPoma, glucagonoma, and somatostatinoma occur less frequently. The overall incidence of concurrent endocrine tumors with APUDomas is high; approximately 10% to 20% of patients with gastrinomas and 5% of patients with insulinoma have evidence of MEN I. Neuroendocrine tumors of the pancreas also are seen in VHL disease. No specific genetic defects have been associated with APUDomas. Amplification of the HER-2/neu proto-oncogene, a member of the ERBB-like oncogene family, was demonstrated in endocrine tumors of the GI tract.[382]

Treatment of these tumors should be individualized. The indolent nature of many APUDomas means that a period of watchful waiting is appropriate for certain patients. Conversely, aggressive surgical resection is recommended for metastatic tumors. Patients with the MEN syndromes may be required to have more extensive surgery because the pancreatic islet cell tumors associated with this condition are small and multifocal and their diagnosis is difficult preoperatively. Patients with Zollinger-Ellison syndrome in the scope of MEN I have a poor prognosis, and surgery for this condition is not curative, as opposed to surgery in patients with sporadic gastrinomas, which can be curative.[381] Systemic therapy for APUDomas may be separated into that directed against the cancerous cells and that which provides supportive care. Octreotide, a long-acting analog of the endogenous somatostatin, is useful in the treatment of insulinomas, nesidioblastosis, VIPomas, and the diarrhea associated with the latter (i.e., Verner-Morrison syndrome). Chemotherapeutic agents used for these tumors include fluorouracil, doxorubicin, streptozotocin, dacarbazine, etoposide, and cisplatin. The combination of streptozotocin plus doxorubicin is superior to that of streptozotocin plus fluorouracil, resulting in a significant improvement in overall survival for patients with pancreatic islet cell tumors. The latter combination appears to be more beneficial for patients with other

carcinoid tumors. Interferon therapy has been used for treating neuroendocrine tumors of the GI tract in adults. [378,383] In addition to surgical resection, several liver-directed therapies, such as arterial chemotherapy, hepatic arterial occlusion, and hepatic arterial embolization and chemoembolization, can be directed against liver metastases of these tumors.

### Insulinoma

Insulin-secreting tumors of the islets of Langerhans are called *insulinomas*.[384,385] Most of these tumors are single and benign, although a small percentage are multiple, and a small percentage are malignant. Most insulinomas are located in the pancreas. Diffuse pancreatic b-cell hyperplasia or nesidioblastosis can also be associated with excess insulin secretion and hypoglycemia in children. [383,386,387,388,389,390,391 and 392]

The signs and symptoms are predominantly those of subacute glycopenia, primarily recurrent central nervous system dysfunction at times of physical exertion or fasting. Acute hypoglycemic episodes with adrenergic discharge symptoms (e.g., sweating, hunger, tremor, seizures) can occur. Frequently, the patients are obese because of the lipogenic and antilipolytic effects of insulin. [384,386,387,393]

Pancreatic b-cell tumors do not reduce their secretion of insulin in the presence of hypoglycemia. A serum insulin level of 10 mU per mL or more with concurrent plasma glucose concentrations of less than 40 mg per dL suggests hyperinsulinism. Fasting of the patient with frequent sampling for plasma insulin and glucose concentrations is the best available test and provides a diagnosis for most patients. Alternatively, hypoglycemia caused by exogenous insulin (0.1 unit per kg per hour given intravenously) fails to cause suppression of plasma C peptide (a marker of endogenous insulin secretion) to less than 50% of the baseline value in patients with insulinomas.

The treatment of choice for insulin-secreting tumors is surgical resection. Preoperatively or occasionally postoperatively, patients are treated with oral diazoxide (5 to 15 mg per kg per day in divided doses).[384,386,393] Side effects include sodium retention (which can be treated with concomitant thiazide administration), gastric irritation, and generalized hypertrichosis. If the surgeon cannot locate the tumor, a blind pancreatectomy of the distal two-thirds of that organ can be performed, although the success rate is low.[389] Streptozotocin alone or in combination with doxorubicin has proved beneficial in adult patients with carcinomas of the islet cells. [394,395 and 396] Benign tumors either respond poorly or do not respond.

### Gastrinoma

Gastrinomas are gastrin-secreting tumors that cause gastric acid hypersecretion and the Zollinger-Ellison syndrome. [4,5,380,381,397,398,399 and 400] Most gastrinomas occur in the pancreas, but others are found in the duodenum or, rarely, in the antrum. Gastrinomas usually are small and, frequently, locating them is difficult, even during laparotomy. These tumors are identified as malignant if metastases or blood vessel invasion are found. The histologic pattern is similar for malignant and benign tumors.

The symptoms of gastrinomas are manifestations of peptic ulcer disease and its complications. Some patients present with diarrhea due to passage of large amounts of acid into the duodenum.

Hypergastrinemia in the presence of acid hypersecretion is pathognomonic of gastrinoma. [4,5,379,381,398,401,402 and 403] Plasma gastrin levels usually exceed 500 pg per mL (normal being less than 200 pg per mL). Patients with borderline hypergastrinemia (200 to 500 pg per mL) should undergo the secretin stimulation test (2 units per kg by intravenous bolus); a rise in plasma gastrin to more than 1,500 pg per mL within 15 minutes is diagnostic. An upper GI series usually shows ulceration of the duodenal bulb, prominent gastric rugal folds, and edema of the small bowel mucosa. Selective angiography, CT scanning, or octreotide scintigraphy can localize the pancreatic tumor.

Patients with gastrinomas should be started on $H_2$-blocking agents such as cimetidine or ranitidine. [4,5,381,404,405 and 406] This therapy is beneficial initially but becomes less effective with time. Tumor resection is ideal but is feasible in only a small percentage of patients. Laparotomy and removal of solitary tumors simultaneously with vagotomy may provide cure or enhance the effectiveness of $H_2$-blocking agents.

Total gastrectomy remains the treatment of choice for patients with complications of ulcer disease and for those whose disease is not controlled satisfactorily by the $H_2$-blockers. These patients require lifelong therapy with iron and vitamin $B_{12}$ replacement.

The prognosis for patients with sporadic gastrinomas is generally good, and most patients lead a relatively normal life after gastrectomy. Most patients with malignant gastrinomas live for many years. A few patients who have aggressive, rapidly growing, and metastasizing tumors may respond to streptozotocin with or without fluorouracil.[407]

### Vasoactive Intestinal Peptide–Secreting Tumor

VIPomas are pancreatic tumors that secrete VIP and are associated with a syndrome of watery diarrhea, hypokalemia, and achlorhydria (i.e., pancreatic cholera).[4,5,408,409,410,411,412,413,414,415 and 416] In addition to VIP, serotonin, substance P, calcitonin, pancreatic polypeptide, and some of the prostaglandins may be present in high concentrations in the blood.

Complete removal of the tumor is curative. On occasion, the tumor cannot be found, and subtotal pancreatectomy is required. Malignant VIPomas may respond to the combinations of chemotherapeutic agents mentioned in the previous section. [417]

### Glucagonoma

Glucagonomas are pancreatic tumors that secrete glucagon. [4,5 and 6,418,419,420 and 421] The syndrome produced is characterized by migratory necrolytic dermatitis, weight loss, stomatitis, anemia, and hyperglycemia or frank diabetes mellitus. Glucagonomas can be benign and confined to the pancreas or malignant with metastases to the liver, regional lymph nodes, adrenal glands, or bones. Surgical removal, if feasible, is indicated.

### Somatostatinoma

Somatostatinomas are pancreatic tumors that secrete somatostatin.[4,5 and 6,422,423 and 424] The syndrome produced is characterized by hyperglycemia or frank diabetes mellitus, diarrhea, and malabsorption. Most somatostatinomas are malignant and give rise to hepatic metastases. Surgery is indicated if the disease is localized. Chemotherapy with streptozotocin may be helpful.

## ECTOPIC HORMONE–SECRETING TUMORS

Ectopically secreted hormones are peptides that cause endocrine syndromes similar to those caused by the entopically produced or exogenously administered “parent” hormones (Table 37-1).[4,5,6 and 7,425,426 and 427] Frequently, however, ectopic hormones are biochemically different from the parent hormones. For example, tumors may manufacture large precursors that possess a fraction of the biologic activity of the parent hormone. [20] The ectopic hormone cannot always be confirmed as a moiety similar to the true hormone. If the chemical identity of the hormone cannot be confirmed, the hormones are given the name of the normal circulating hormone and the suffix *-like*.

Many of the ectopic hormone–secreting tumors have been described only in adults, but it is theoretically possible that they can develop also in children. Ectopic CRH-secreting tumors (e.g., metastatic prostatic carcinoma, ganglioneuroma, lung carcinoma) are rare and have been described only in adults. [38,428,429 and 430] These tumors are associated with Cushing's syndrome. Ectopic ACTH-secreting tumors have been described in adults and children. [6,431,432,433 and 434] They are associated with severe Cushing's syndrome and are produced by carcinomas of the lung, thymus, pancreas, thyroid, adrenal medulla, and other tissues. Ectopic tumors secreting GH-releasing hormone (GHRH) have been described in adults and adolescents and are associated with gigantism and acromegaly. [37,435,436,437,438,439,440,441,442 and 443] A

primary jejunal tumor with lymph node and liver metastases and a metastatic foregut carcinoid tumor, both of which secrete GHRH, have been reported. No ectopic tumors secreting GH have been described in children. In adults, ectopic GH synthesis has been attributed to pancreatic, gastric, bronchial, and mammary carcinomas.[6,444,445,446 and 447] Ectopic chorionic gonadotropin secretion has been described in children, causing precocious puberty in boys by stimulating Leydig cells. [6] Chorionic gonadotropin is secreted by placental trophoblastic neoplasms, testicular and pineal tumors, hepatoblastomas, and carcinomas of the lung, stomach, pancreatic islet cells, and colon.[448,449,450,451,452,453 and 454] Tumors secreting the inactive alpha subunit, which then serves as a marker, include malignant insulinomas, gastrinomas, VIPomas, and intestinal or pulmonary carcinoids.[449,455]

Ectopic AVP-secreting tumors producing the inappropriate antidiuretic hormone syndrome have been reported in adults. [6,456] Several neoplasms, commonly small-cell or oat-cell carcinomas of the lung and carcinoma of the colon or, less commonly, prostatic or adrenocortical carcinomas, have been associated with ectopic AVP secretion.

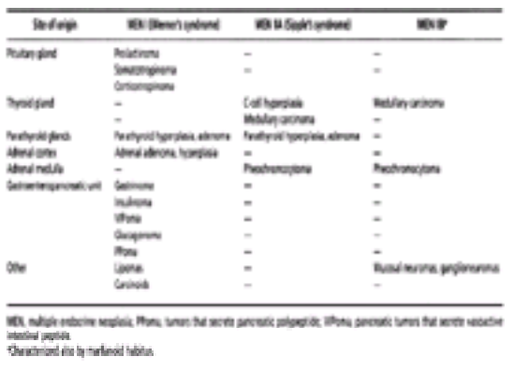
Ectopic calcitonin secretion has been observed with bronchial carcinoids and with lung, breast, and other tumors. [456] This hormone does not produce an endocrine syndrome. Ectopic PTH or PTH-like substances have been described with many cancers.[457,458,459 and 460] Ectopic PTH is presumably a form of a PTH precursor that remains unrecognized by many antibodies raised against mature PTH. Osteoclast-activating factor or some prostanoic substance stimulating bone resorption may be the PTH-like hormone.

No ectopic steroid or thyroid hormone syndrome exists, because it would entail the random synchronous activation of multiple enzymes required for biosynthesis of these hormones. However, adrenal rest tumors can be found in many ectopic areas, primarily the liver, pelvis, or testes, which can “ectopically” secrete such steroid hormones as cortisol.

Many hormones of the gastroenteropancreatic unit are secreted ectopically by several tumors. Some nonpancreatic tumors have been associated with hypoglycemia.[20] These tumors are fairly large by the time hypoglycemia is noticed and include retroperitoneal fibromas and fibrosarcomas, some hepatomas, some tumors of the adrenal cortex, and others. This phenomenon, known as *tumor hypoglycemia*, is caused by “big IGF-2,” which has cross-reactivity with the insulin receptor. Most affected patients are in the final stages of a neoplastic disease. Treatment includes surgical extirpation or irradiation of the tumor and frequent feedings, intravenous glucose infusions, or administration of glucocorticoids. Ectopic secretion of gastrin, glucagon, somatostatin, and VIP has been described.[4,6,461,462,463 and 464]

## MULTIPLE ENDOCRINE NEOPLASIA SYNDROMES

MEN syndromes are familial disorders in which neoplastic changes arise simultaneously in more than one endocrine gland. [3,4,5,6 and 7,26,174,175,235,465,466] The neoplastic changes include hyperplasia, benign adenomas, and carcinomas. Three distinct patterns of glandular involvement and overlapping or atypical combinations of gland involvement have been described. The three combinations are referred to as *MEN I*, *MEN IIA*, and *MEN IIB* (the latter sometimes still being labeled as *MEN III*; Table 37-5).[222,239,465,467,468,469,470,471 and 472,474] Carney complex is a distinct type of MEN that is characterized by the additional features of recurrent cardiac and skin myxomas and lentigines. Other genetic disorders with multiple endocrine tumors are VHL disease (i.e., pheochromocytoma, neuroendocrine tumors of the pancreas), NF-1 (pheochromocytoma), and the Li-Fraumeni syndrome (adrenocortical carcinoma).



| Site of origin | MEN I (Wermer's syndrome) | MEN IIA (Sipple's syndrome) | MEN IIB |
|---|---|---|---|
| Pituitary gland | Prolactinoma | – | – |
| | Somatotropinoma | – | – |
| | Corticotropinoma | | |
| Thyroid gland | – | C cell hyperplasia | Medullary carcinoma |
| | – | Medullary carcinoma | – |
| Parathyroid glands | Parathyroid hyperplasia, adenoma | Parathyroid hyperplasia, adenoma | – |
| Adrenal cortex | Adrenal adenoma, hyperplasia | – | – |
| Adrenal medulla | – | Pheochromocytoma | Pheochromocytoma |
| Gastroenteropancreatic unit | Gastrinoma | – | – |
| | Insulinoma | – | – |
| | VIPoma | – | – |
| | Glucagonoma | – | – |
| | PPoma | – | – |
| Other | Lipoma | – | Mucosal neuroma, ganglioneuroma |
| | Carcinoid | – | – |

MEN, multiple endocrine neoplasia; PPoma, tumors that secrete pancreatic polypeptide; VIPoma, pancreatic tumors that secrete vasoactive intestinal peptide.
*Characterized also by marfanoid habitus.

**TABLE 37-5. COMPARISON OF CLUSTERS OF INVOLVED TUMORS IN MULTIPLE ENDOCRINE NEOPLASIA SYNDROMES**

### Epidemiology and Genetics

Approximately one-half of the MEN and Carney complex cases occur sporadically and represent de novo (somatic) mutations of the responsible genes. The remaining patients belong to kindreds, in which these conditions are inherited in an autosomal dominant manner with variable penetrance and expression. Affected relatives with the same type of MEN syndrome may have different neoplasms that appear at different ages.[26,476] Combinations of multiple endocrine tumors that do not fit any of the distinct MEN syndromes may occur in a single patient.[477]

The gene for MEN I has been localized to chromosome 11q13 and subsequently identified. It acts as a tumor suppressor gene and encodes the protein menin. Menin's function still remains unknown.[235,478] Germline mutations of the RET proto-oncogene on chromosome 10q11.2 have been described in almost all patients with MEN IIA and MEN IIB. *RET* comprises 21 exons, with 6 so-called hotspot exons (numbers 10, 11, and 13–16). Patients with MEN IIA have mostly germline mutations in exons 10 and 11, whereas 95% of patients with MEN IIB have germline mutations in exon 16 at codon 918. Transfection assays with *RET* have shown that its mutations lead to a “gain of function”—that is, are activating mutations. The encoded protein of *RET* is a receptor tyrosine kinase that becomes constitutively activated when mutations in *RET* are present. The mechanisms by which *RET* mutations lead to tumor formation *in vivc* remain largely unknown but have recently been elucidated. It may well be that the mutated *RET* allele exerts a dominant effect if imbalanced with the wild-type allele. [350] Interestingly, *RET* mutations can also be found in patients with Hirschsprung's disease, a disorder in which part of the colon is aganglionic, leading to a megacolon formation. This may be explained by the expression pattern of *RET*: The three tissues principally involved in MEN II are thyroid C cells, adrenal medulla, and intestinal autonomic ganglia, all derived from neural crest cells.[26,176,347,466] The genetic locus for Carney complex, an autosomal dominant heterogeneous disorder with variable expression and evidence of genetic anticipation, was mapped initially to chromosome 2 (2p16) and recently was reassigned to chromosome 17q24. [172,301,309]

The VHL gene acts as a tumor suppressor gene, which, according to Knudson's hypothesis, requires two hits to cause tumorigenesis: The first hit is an inactivated copy of one *VHL* allele by a germline mutation, deletion, or hypermethylation, and the second hit is an inactivation of the second VHL gene copy by point mutation, gene deletion, or hypermethylation.

#### Multiple Endocrine Neoplasia Type I

The parathyroids are the glands most frequently affected in MEN I (i.e., Werner's syndrome). [236] Hyperparathyroidism, usually due to hyperplasia of all four glands, occurs in approximately 90% of patients. Islet cell tumors occur in approximately 20% of patients. Nearly 50% of GI endocrine tumors in MEN I secrete gastrin. VIPomas, glucagonomas, somatostatinomas, and tumors secreting pancreatic polypeptide (PPomas) have also been reported. More than one-half of the gastrinomas, VIPomas, glucagonomas, and PPomas associated with MEN I are malignant, whereas most of the insulinomas are benign.[236,476]

Pituitary involvement in MEN I usually occurs as a solitary adenoma. Signs and symptoms of a pituitary adenoma are apparent in approximately 20% of MEN I patients. The most common adenomas are prolactinomas, and the second most common are somatotropinomas. Corticotropinomas are third most common but are rare (approximately 5%). Chromophobe adenomas can also occur (5%). Adrenocortical involvement includes silent adenomas, adrenocortical hyperplasia, cortisol-secreting adenomas and, rarely, carcinomas. Benign and malignant thymic and bronchial carcinoid tumors can be associated with MEN I. Single or multiple lipomas and angiofibromas are observed in approximately 30% of MEN I patients.[27,479] The clinical picture of the endocrine tumors that compose the MEN I syndrome

is generally the same as that for sporadic tumors. Hyperparathyroidism, the Zollinger-Ellison syndrome, hypoglycemia, pancreatic cholera, migratory necrolytic erythema, specific and nonspecific symptoms from pituitary adenomas, Cushing's syndrome from cortisol-secreting adrenal adenomas or ectopic ACTH syndrome from gastrinomas or carcinoids, carcinoid syndrome, and gigantism or acromegaly can occur.

Laboratory findings are related to the specific hormonal syndrome. Therapy is directed toward the specific tumor and endocrine syndromes and is referred to in other parts of this chapter.

### Multiple Endocrine Neoplasia Type IIA

The thyroid C cells are most frequently involved in patients with MEN IIA (i.e., Sipple's syndrome), with medullary carcinoma of the thyroid occurring in approximately 95% of the patients.[26,175,465,469] Pheochromocytoma occurs in approximately one-half of patients, although probably all patients with a germline *RET* mutation have adrenomedullary hyperplasia from birth.[480] These tumors usually are intra-adrenal and frequently bilateral and multifocal. Approximately one-fifth of patients develop frank hyperparathyroidism, mostly associated with parathyroid adenoma hyperplasia.

The clinical and laboratory findings of MEN IIA are those expected on the basis of the hormones secreted by the tumors (catecholamines, PTH). Approximately 50% of patients with MEN IIA and pheochromocytoma are asymptomatic despite having continuous metanephrine secretion into the bloodstream from the adrenomedullary tumor. Treatment is directed to the type of tumor (total thyroidectomy for medullary thyroid cancer, adrenalectomy for pheochromocytoma, parathyroidectomy for hyperparathyroidism).

### Multiple Endocrine Neoplasia Type IIB

All patients with MEN IIB have some aspect of a distinct marfanoid phenotype.[1,26,174,175,470,473,476] This is characterized by a slender body build, long and thin extremities, abnormal laxity of joints and, in many cases, a high arched palate, pectus excavatum, or pes cavus. The facies is characterized by enlarged, thick (blubbery) lips, a result of embedded mucosal neuromas. Mucosal neuromas also are observed on the surface of the lips and tongue and may be found on the eyelids and the cornea. Ganglioneuromas may be present diffusely at any level in the GI tract, causing constipation or diarrhea due to abnormal control of intestinal motility.

Medullary thyroid carcinoma is particularly aggressive in MEN IIB and occurs frequently in childhood cases (mean patient age, 20 years), 10 to 15 years earlier than the mean age of presentation of MEN IIA. Pheochromocytomas behave similarly to those observed in MEN IIA.

Treatment of MEN IIB includes standard therapy for medullary thyroid carcinoma and pheochromocytoma. However, because medullary thyroid carcinoma in this MEN type is very aggressive, total thyroidectomy may become necessary as early as the first year of life.[175,475] Superficial mucosal neuromas may be removed if they cause a cosmetic problem. Constipation or diarrhea should be treated symptomatically. As many as 30% of patients require laparotomy and colon segment excision for megacolon.

### Carney Complex

Carney complex is a familial multiple neoplasia and lentiginosis syndrome.[481] Historically, the complex was characterized by the association of PPNAD, a pituitary-independent, primary adrenal form of hypercortisolism; lentigines, ephelides, and blue nevi of the skin and mucosae; and a variety of nonendocrine and endocrine tumors. The latter include myxomas of the skin, heart, breast, and other sites; psammomatous melanotic schwannoma; GH-producing pituitary adenoma; testicular Sertoli cell tumor; and possibly other benign and malignant neoplasms, including tumors of the thyroid gland and ductal adenoma of the breast. The existence of the complex as an unrecognized, inherited syndrome was first suggested in 1982 by Schweizer-Cagianut et al.,[309] but patients with lentigines (lentigo simplex) or ephelides and blue nevi had been described earlier under different pseudonyms, such as *NAME* (for *n*evi, *a*trial myxoma, *m*yxoid neurofibromas, and *e*phelides) and *LAMB* (for *l*entigines, *a*trial myxoma, *m*ucocutaneous myxoma, and *b*lue nevi) syndromes. Carney complex shares with the other MENs the presence of endocrine tumors and the characteristic spotty skin pigmentation, in addition to the familial lentiginoses, among which are the Peutz-Jeghers syndrome, the syndrome of lentigines and hypertrophic cardiomyopathy (known by the acronym *LEOPARD*), and the syndrome of arterial dissections with lentiginosis.[28,172,301,481] The tumors of the complex can appear as early as in the first decade of life. Cardiac myxomas can cause sudden death, and so echocardiographic screening for the presence of these tumors in all affected family members is essential. Open heart surgery is always recommended for the excision of these tumors, which can cause embolization or myocardial infarction if left unresected. PPNAD can be an indolent cause of mild, periodic Cushing's syndrome that may not be clinically detectable.[482]

### Prognosis

The prognosis for patients with MEN I generally is good in the presence of a discrete parathyroid, pancreatic islet, or pituitary adenoma. Parathyroid hyperplasia occurs in approximately one-third of patients. Pancreatic islet cell carcinoma and carcinoids are slowly progressive.

The prognosis for patients with MEN IIA generally is good also. The risk of postoperative recurrence of medullary thyroid carcinoma and pheochromocytoma is diminished if the tumor is excised early, before the disease becomes extensive. Thus, total thyroidectomy is recommended for children older than 5 years who have a family history of MEN II and a *RET* germline mutation, as they will develop medullary thyroid cancer on the basis of thyroid C cell hyperplasia.[26,175,475,483] Hyperparathyroidism in this syndrome has a good prognosis.

The prognosis for patients with MEN IIB is worse than that for MEN IIA patients. Medullary carcinomas in MEN IIB patients generally are more aggressive, and the patients have a 50% 10-year survival rate.

Patients with Carney complex generally have a good prognosis. However, frequent recurrences of the cardiac and skin myxomas and the other tumors are a significant cause of morbidity and mortality in these patients. In a series of 51 patients, sudden death or a near-death event occurred in 16%, all during childhood, adolescence, and young adulthood.[172]

Screening is of paramount importance in all forms of MEN and Carney complex, because earlier or even preventive therapy improves the prognosis remarkably. Patients at risk include those with known MEN, a positive family history of MEN, ganglioneuromas and cutaneous neuromas, a marfanoid somatic phenotype, Zollinger-Ellison syndrome, parathyroid hyperplasia, multicentric medullary carcinoma of the thyroid, or multicentric or bilateral pheochromocytomas. Screening tests include measurements of serum calcium, gastrin, glucose, and prolactin levels in MEN I; basal and stimulated (calcium gluconate or pentagastrin, omeprazole) plasma calcitonin, 24-hour urinary free catecholamines, metanephrines, and vanillylmandelic acid, and serum calcium levels in MEN IIB; and basal and stimulated plasma calcitonin and 24-hour urinary free catecholamines, metanephrines, and vanillylmandelic acid levels in MEN IIA ( Table 37-3). Patients with Carney complex should be screened frequently by echocardiography for cardiac myxomas and clinically and biochemically for PPNAD, somatotropinoma, and other tumors.[107,191,481,484,485,486] and [487]

## ACKNOWLEDGMENTS

We thank Nicholas J. Sarlis, M.D., Ph.D., at the National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, Molecular and Cellular Endocrinology Branch, for helpful and very valuable comments on the diagnosis and treatment of pediatric and adult thyroid tumors.

# MANAGEMENT OF INFREQUENT CANCERS OF CHILDHOOD

CHARLES B. PRATT
ALBERTO S. PAPPO

## INTRODUCTION

The preceding chapters have dealt with the principles of pediatric oncology and the management of more common tumors of childhood. This chapter describes some of the less frequently encountered malignant tumors. Much of the information presented may be related to tumors of adults rather than children, but the basic principles of treatment remain the same. Pediatric hematologists-oncologists require some knowledge of the diagnosis, management, and treatment derived from the more extensive experience of medical, surgical, and radiation oncologists in dealing with these rare tumors of childhood.

Some information regarding the staging of these tumors is required by the pediatric oncologist, who should confer with surgeons and pathologists to give information to patients, parents, and radiation oncologists. References to the fifth or subsequent edition of the American Joint Committee on Cancer (AJCC) Staging Handbook [1] is required for such tumors as gastric, colon, renal cell, pancreatic, and nasopharyngeal carcinomas, as well as melanoma.

The tumors are discussed in descending anatomic order, from the nasopharynx through the trunk, to the skin. Some references that are pertinent to adult tumors as well as childhood tumors are included.

## OROPHARYNGEAL CANCER

Oropharyngeal tumors are rare yet challenging to pediatric oncologists, surgeons, and radiotherapists. The most common of these cancers is nasopharyngeal

carcinoma, which is discussed separately.

There is increasing evidence of the use of smokeless tobacco products by adolescent and preadolescent boys. [2,3,4 and 5] Known carcinogenic agents in smokeless tobacco may be associated with oral carcinoma, principally squamous cell carcinoma. [6,7,8,9,10 and 11] Although rare at the present time, this may become a significant problem for the future generations if there is continued use of these products. Risk is increased with increasing length of exposure, with greatest risk for anatomic sites where the smokeless tobacco is held in contact for the longest time. Figures related to incidence of head and neck carcinomas in patients younger than 20 years are not available except for nasopharyngeal, parotid, and minor salivary gland carcinomas. [12]

It has been noted that 8% to 36% of male high school and college age students regularly use smokeless tobacco products. The mean age for initiating the use of these products is 12 years. The average use of chewing tobacco or snuff has been estimated at six times daily. The average duration per dip or chew is 1 hour. [6,12]

There is concern that smokeless tobacco products may lead to cardiovascular disease as well as increased risk of oral cancer, primarily because of the pharmacological properties of nicotine and other constituents in tobacco smoke. There is, however, no evidence to date of relationships between smokeless tobacco use and bladder cancer; yet there have been suggestions of links between smokeless tobacco and prostate cancer.

The National Youth Tobacco Survey of more than 15,000 students showed the current cigarette smoking habits among middle and high school students by race and ethnicity.[13] This study indicated that although middle school smoking rates were similar for blacks, Hispanics, and whites, black high school students had a significantly lower rate of cigarette smoking than did the other two groups (15.8% for black vs. 32.8% for white and 25.8% for Hispanic). [10]

The physical changes associated with chewing tobacco or using snuff include alterations in the texture, color, and contour of the mucosal lining and periodontal degeneration.[4] This has been seen in more than half of the teenagers surveyed for changes related to smokeless tobacco. Leukoplakia, a precancerous condition, occurs in more than one-third of the users. Other lesions may take on the characteristics of ulcers, blisters, and gum and lip lesions, and include lesions induced by cancer chemotherapy agents.[14]

Pediatricians and health departments should continue to assist in educating middle school and high school students regarding the use of these products. Without specific changes in the use of these products, there most probably will be an inordinate number of oral cancers of young adults within the next decades.

Benign tumors and other cancers also may involve the oropharynx or neck. [15,16,17,18,19,20,21,22,23 and 24] These include dermoid cysts, leiomyosarcomas, myofibromas, fibromatoses, cystic hygromas, hemangiomas, and teratomas. Life-threatening obstructive complications requiring surgical intervention may be required but would rarely require the use of chemotherapy or radiation therapy.

## NASOPHARYNGEAL CARCINOMA

Nasopharyngeal carcinoma has been known in the past as lymphoepithelioma or epidermoid carcinoma. [25,26] It is a primary malignancy of the nasopharyngeal epithelium that accounts for one-third of the nasopharyngeal neoplasms in children. About one-third of these neoplasms of the undifferentiated type are diagnosed in adolescents or young adults. [27,28,29,30,31 and 32]

### Epidemiology

There are marked differences in the geographic distribution of nasopharyngeal carcinoma. The incidence is approximately one case in 100,000 among the white population of North America, yet the incidence may be as high as 20 in 100,000 in Southeast Asia, 25 in 100,000 in Hong Kong, and 8 to 10 per 100,000 in North Africa. There may be an increased incidence of nasopharyngeal carcinoma in black teenagers in the United States. [30]

### Biology

Nasopharyngeal carcinoma is associated with Epstein-Barr virus (EBV) infection. [33,34,35,36,37 and 38] The EBV DNA may be demonstrated in malignant cells of biopsy specimens. These cells also express the EBV nuclear antigen. Markedly elevated antibody titers to various EBV antigens may be present, yet the greatest specificity and clinical importance are the titers of immunoglobulin A (IgA) and IgG antibodies to the viral capsid antigen. These titers usually correlate with the total tumor burden and decrease with successful therapy. They may also increase before the appearance of recurrent disease, and thus are a useful indicator of disease activity.

### Pathology

The World Health Organization Classification of nasopharyngeal carcinoma recognizes three subtypes: type I is squamous cell carcinoma; Type II is nonkeratinizing carcinoma, and type III is undifferentiated carcinoma. Most cases of children and adolescents are type III. Type I is more typically found in older adult patients. Types II and III are associated with elevated EBV titers, yet type 1 is not. Type II and III may be accompanied by inflammatory infiltrate of lymphocytes, plasma cells, and eosinophils, which are often abundant. Two histologic patterns have been described called the Regaud [25] and the Schmincke[26] type, with collections of epithelial cells surrounded by lymphocytes in connective tissue, or in which the tumor cells are intermingled with inflammatory cells. Both patterns may be present in the same tumor.

### Clinical Presentations and Patterns of Spread

Nasopharyngeal carcinoma generally originates in the fossa of Rosenmüller and metastasizes initially to cervical lymph nodes, which causes the usual presenting sign and complaint of patients. Other areas of spread include direct extension throughout the oropharynx with epistaxis, trismus, blockage of the Eustachian tubes, hearing loss, and extension into the base of the skull with nerve palsies ( Fig. 38-1). Distant metastases may be present in the lung, mediastinum, bones, and visceral organs.

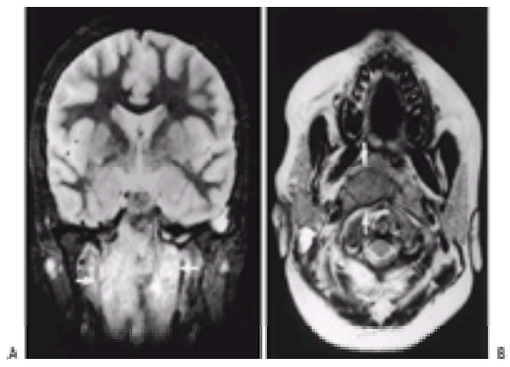

**FIGURE 38-1.** Coronal stir image **(A)** and transverse T2 image **(B)** of a nasopharyngeal carcinoma in a 12-year-old Hispanic boy. Images demonstrate large nasopharyngeal tumor (*arrows*) but do not demonstrate extension of tumor to the dura, which was found on additional views.

Cervical lymphadenopathy may be the only presenting symptom. The diagnosis is often made by lymph node biopsy. [39,40,41 and 42] Metastatic spread may result in bone pain or symptoms related to organ dysfunction at the sites of visceral metastasis. A paraneoplastic syndrome of marked osteoarthropathy with joint swelling, clubbing, and bone and joint pain may occur with widespread disease or with relapse. [43,44 and 45]

### Differential Diagnosis

Differential diagnosis includes other malignancies that may present with primary or secondary tumors in the nasopharynx. [44] Rhabdomyosarcoma and non-Hodgkin's lymphoma are the most frequent malignant tumors, whereas the most frequent benign tumor of this site is angiofibroma, [46] which usually presents with bleeding and is not associated with lymphadenopathy. Thyroid cancer may also present with significant cervical lymphadenopathy.

### Evaluation

The child with nasopharyngeal carcinoma should have studies to define the extent of disease and rule out distant metastatic spread. The size and location of cervical lymph nodes should be documented and indirect nasopharyngoscopy should be performed if the primary tumor is not obvious. Neurologic examination should focus on the cranial nerves. Computed tomography (CT) and magnetic resonance imaging (MRI) should include appropriate views of the skull and brain. CT evaluations of the chest and abdomen and a radionuclide bone scan should be performed to detect metastatic disease. If there is invasion of tumor through the base of the skull, cerebrospinal fluid examination should be considered to identify tumor cells. Bone marrow examination is unnecessary unless there is a strong suspicion of a process involving the bone marrow.

EBV titers should be assayed by a laboratory familiar with a full battery of the EBV serology, including monospot, EA, D titers, IgA and IgG anti–viral capsid antigen. [33,34,35,36,37,38 and 39] Direct consultation with the clinical laboratories is usually necessary to ensure the performance of the most important tests.

### Staging and Prognosis

The extent of the tumor at diagnosis is as described by the tumor, node, metastases (TNM) classification of the AJCC ( Table 38-1). [1,47,48] Because there is a high incidence of lymph node metastasis at diagnosis, most children and adolescents with this tumor are staged as having stages III and IV, yet these stages have little effect on planning of therapy and assessment of prognosis.

**TABLE 38-1. STAGING OF NASOPHARYNGEAL CARCINOMA[a]**

Various investigators have noted survival rates varying from 8% to 75%, with an overall 75% survival rate for T1 and T2 lesions, and 37% for T3 and T4 lesions. At St. Jude Children's Research Hospital, 78% of patients were disease-free with T1 or 2 lesions, with a 24% disease-free survival for patients presenting with T3 and T4 lesions. [49]

### Treatment

#### *Surgery and Radiation Therapy*

The nasopharynx is difficult to approach surgically. Because nasopharyngeal carcinoma generally has spread at the time of diagnosis, the principal role of surgery for therapy is to obtain adequate tissue for diagnostic purposes from an involved lymph node or the primary site. Other requirements may be myringotomy, or tympanostomy, if otitis media is present or expected. [50]

Involved areas are rarely accessible for resection after radiation therapy, which remains the primary therapeutic modality for nasopharyngeal carcinoma. The volume for radiation should include the nares; pharynx; posterior nasal cavity; posterior maxillary sinus; base of the skull, including the sphenoid and cavernous sinuses; and the cervical lymphatics, including the supraclavicular nodes. Recommended doses are 6,000 to 7,000 cGy. [41,51,52,53,54,55 and 56] Radiation therapy may be also given with curative intent for recurrent disease, locally or distally.

#### *Chemotherapy*

Most therapeutic trials for adults and children combine chemotherapy with irradiation. [51,52,53,54 and 55] These tumors and other head and neck cancers are unquestionably responsive to agents such as cisplatin, carboplatin, 5-fluorouracil (5-FU), methotrexate, and bleomycin. [51,52,53,54,55,56,57,58,59 and 60] At the present time the basic treatment regimens prefer to omit bleomycin. A multi-institutional study of this tumor in children and adolescents has demonstrated an excellent survival rate with the use of neoadjuvant cisplatin plus 5-FU and methotrexate/leucovorin given as four courses before irradiation. Twenty of twenty-one patients with advanced disease achieved long-term disease-free survival. [49]

#### *Complications of Treatment*

Xerostomia is a primary side effect of treatment. It may begin during radiation treatment along with mucositis. Sialadenitis may develop within a few months after completion of therapy. Other late effects include fibrosis of the neck and trismus. Muscle atrophy may be expected if children receive large doses of irradiation, and this may be associated with other problems, such as hypothyroidism, which require long-term routine follow up. Patients should continue to be evaluated for complications related to the chemotherapy and irradiation, including secondary tumors.

## AMELOBLASTOMA/ADAMANTINOMA

Ameloblastoma is also known by the term *adamantinoma*. [60,61,62 and 63] The ameloblastoma usually arises on the maxilla or mandible, and adamantinoma generally refers to tumors of long bones. The tumor may be benign or malignant, related to the development of the enamel of the teeth. Surgical excision is the treatment of choice, and no recognized chemotherapeutic regimen is used in an adjuvant situation. Local recurrence is more frequent for mandibular lesions than for maxillary lesions. [62] Sensitivity of recurrent tumors to irradiation is recognized; however, sensitivity to chemotherapy is unknown. Pulmonary metastases have been discovered many years after treatment of the primary tumors of the long bones. [63]

## SALIVARY GLAND TUMORS

The diagnosis and management of salivary gland tumors are complicated by their diverse nature and relative infrequency. [64,65] Most of these neoplasms originate in the parotid gland, with 10% to 15% arising from submandibular, sublingual, or minor salivary glands. These lesions may be primary or secondary after treatment with previously delivered radiation therapy. [66,67] Among the cancerous lesions in children, mucoepidermoid cancer is followed in frequency by acinic cell carcinoma, undifferentiated carcinoma, and adenocarcinoma. [68,69] These lesions must be differentiated from such tumors as hemangioma, mixed tumor, and other benign lesions.

Staging is that of the AJCC, with surgical removal being the treatment of choice when feasible. Additional consideration for irradiation therapy should be given for lesions that may not be completely resected.[70] Cisplatin-based therapy is most extensively used for these malignant lesions. Karyotypic abnormalities of these tumors has been reported,[71] as well as association with EBV.[72] Prognosis for patients with these tumors is generally good.

## CANCERS OF THE LARYNX

Both benign and malignant tumors of the larynx are rare.[73] Benign tumors may include polyps and papillomas in association with cough, hoarseness, dysphagia, and cervical lymphadenopathy. Rhabdomyosarcoma is the most common malignant tumor to involve this area (see Chapter 32). Guidelines established for the treatment of laryngeal carcinoma in adults should be used for children or adolescents with this tumor, and should include surgery, radiation, or both. Rehabilitative efforts should begin with pre-operative counseling. An electronic speech device may be used immediately after surgery; approximately 10% of patients develop satisfactory esophageal speech. The electrolarynx transmits sounds from the neck or mouth, with speech from the neck being more easily understood than oral speech. The efforts of the American Cancer Society are involved with rehabilitation, including information, support, and social outlets for pediatric patients, patterned after those for adults. Long-term attention should be directed toward thyroid size and function for survivors who have received radiation therapy.

There has been an increasing emphasis of the role of juvenile papillomatosis involving the larynx and the development of cancer.[73,74,75,76,77,78 and 79] Juvenile papillomatosis, even though it is a benign overgrowth of epithelial tissues, is induced to proliferate by infection with the human papilloma virus. This may affect primarily the larynx or other parts of the respiratory tract. Surgical removal of polyps is the primary therapy, yet refractory and recurrent cases may respond to cytotoxic agents, interferon,[74] or external beam irradiation. Malignant degeneration to squamous cell or epidermoid carcinoma often follows long-standing cases of juvenile papillomatosis. Prognosis for such patients is poor, but therapy should be attempted, depending on the extent of this disease, using wide surgical resection, radiation therapy, or chemotherapy with regimens commonly used for the treatment of adult head and neck cancer.

## BRONCHOGENIC CARCINOMA

Primary lung cancers are extremely rare in childhood. Among these rare tumors, most pediatric cases of bronchogenic carcinoma are undifferentiated or adenocarcinoma; squamous cell carcinomas also have been reported.[80,81 and 82] These tumors may occur in children of any age, but they are more usually found during adolescence. These tumors may be associated with papillomatosis.[83] Management of children with bronchogenic carcinoma should be according to reasonable adult guidelines with resection of operable tumors. Radiation therapy and chemotherapy may be of some benefit in unresectable cases.

## PLEUROPULMONARY BLASTOMA

A rare dysontogenetic tumor of childhood, pleuropulmonary blastoma can present as a pleural or pulmonary mass.[84] Histologically, pleuropulmonary blastoma of childhood differs from adult pulmonary blastoma because of its primitive and embryonic stroma, absence of a carcinomatous component, and potential for sarcomatous differentiation.[84,85] Dehner and colleagues have subclassified pleuropulmonary blastoma of childhood into three subtypes: type I is exclusively cystic, type II exhibits both cystic and solid components, and type III is a solid tumor without epithelial-lined cystic spaces.[84] Type I tumors appear to have a better survival; however, transition from type I to type III is possible.[86] The histologic origin of this malignancy is uncertain, but it is thought to be an expression of the somatopleural mesoderm or the thoracic splanchnopleure. Cytogenetic analysis of pleuropulmonary blastoma has revealed many abnormalities, including del(2)(q31;q33), del(9)(q22), and del(17)(p11.2).[87] Recurrent chromosomal abnormalities including trisomies of chromosomes 8 and 2 also have been reported in a few cases of pediatric pleuropulmonary blastoma.[88,89] Abnormalities of the p53 tumor suppressor gene, Wilms' tumor suppressor gene, and the putative second genetic locus for Wilms' tumor were not found in preliminary investigations.[87] Pulmonary cystic lung disease has been reported to be present at the time of pathologic diagnosis in 38% of cases.[84]

This tumor is strikingly associated with a familial history of cancer. Priest and colleagues[87] documented an association with other tumors or dysplasias either in the index case or in family members in 12 of 45 patients (approximately 25%). Diseases associated with pleuropulmonary blastoma included pulmonary cysts, cystic nephromas, thyroid adenomas, thyroid carcinoma, rhabdomyosarcoma, germ cell tumors, Langerhans' cell histiocytosis, medulloblastoma, synovial sarcoma, brain sarcomas, other pleuropulmonary blastomas, Hodgkin's disease, and acute lymphoblastic leukemia. These observations suggest that pleuropulmonary blastoma is a strong marker for familial disease.[87] The median age at presentation is 34 months.[84] Presenting symptoms are not specific and commonly include respiratory distress, fever, chest or abdominal pain, pulmonary infections, pneumothorax, cough, anorexia, and malaise. Therapy includes surgical resection with lobectomy or pneumonectomy and chemotherapy and radiotherapy.[84,90] Chemotherapy with commonly used agents for sarcomas, such as vincristine, dactinomycin, and cyclophosphamide, and other agents, such as doxorubicin and cisplatin, have been used in the preoperative and adjuvant settings with mixed results.[84,90] The use of radiotherapy is also controversial. The overall prognosis is poor: half of all patients treated die within the first 2 years after diagnosis.[84] Patients with mediastinal or pleural involvement have a significantly poorer clinical outcome. Recurrences are usually local or involve the brain (44% of cases) and the skeletal system.[87]

## THYMOMA

In pediatrics, 43% of mediastinal tumors occur in the anterior portion of the mediastinum, whereas in adults, 54% of mediastinal tumors occupy this anatomic location.[91] Primary malignant lesions involving the anterior mediastinum include lymphomas, germ cell tumors, carcinoids, carcinomas, thymolipomas, cysts, metastatic tumors, and thymoma, most of which can be confused because of the similarity of the gross and microscopic appearance.[91] Thymoma, an epithelial malignancy arising from the thymus gland, accounts for nearly half of all primary anterior mediastinal tumors in adults.[92] The epithelial cell is the cell of origin of thymomas and thymic carcinomas, whereas the lymphocytic component is considered benign.[93]

### Epidemiology and Symptomatology

Thymomas are rare in adults and in children. Fewer than 10% of thymomas occur in patients younger than 20 years, and they account for less than 15% of anterior mediastinal masses in this age group, with only about 30 cases described in the medical literature.[91,94,95] Thymomas usually present in the fourth and fifth decades of life without a clear sex predisposition. Nearly half of all adult patients are asymptomatic at the time of initial diagnosis, and the malignancy is discovered incidentally during imaging studies of the chest.[93] One-third of adult patients present with a variety of symptoms, including cough, chest pain, hoarseness, superior vena cava syndrome, and dysphagia. Approximately 30% of patients with thymoma have myasthenia gravis.[93,96] Conversely, 10% to 15% of adult patients with myasthenia gravis have an underlying thymoma.[96] In addition to myasthenia gravis, a variety of other paraneoplastic syndromes have been associated with thymoma. These syndromes occur in 5% to 10% of adults with thymoma and include pure red cell aplasia, hypogammaglobulinemia, and autoimmune or immune disorders such as scleroderma, dermatomyositis, systemic lupus erythematosus, rheumatoid arthritis, and thyroiditis.[93,96] Endocrine disorders associated with thymomas include hyperthyroidism, Addison's disease, and panhypopituitarism.[91,97,98]

### Pathology and Staging

Thymomas are generally located anterior to the great vessels of the mediastinum, which may be displaced posteriorly by the tumor. The masses are usually round with smooth or lobulated margins and may protrude to one or both sides of the mediastinum. Calcifications may be seen. The nomenclature for pathologic classification of thymic neoplasms is still evolving. Thymomas can be subdivided into three main categories: predominantly lymphocytic, mixed lymphoepithelial, and predominantly epithelial. It is well established that the epithelial cell is the malignant component of thymomas and that a predominance of this pattern is associated with a greater risk of invasion and a poor clinical outcome.[93,96] A prominent organoid pattern has been reported in pediatric cases.[99] The invasiveness of the tumor rather than the histologic architecture predicts clinical outcome.

Thymomas generally are slow-growing tumors. Although almost all are potentially invasive, metastasis to distant organs or regional lymph nodes is rare. Involved organs have included bone, liver, kidney, brain, spleen, and colon.

Appropriate evaluation of patients suspected of having thymoma or other mediastinal tumors includes chest radiographs and CT of the chest. MRI can distinguish vascular structures from tumor but does not offer a clear advantage over CT. The differential diagnosis of other anterior mediastinal masses includes Hodgkin's disease and non-Hodgkin's lymphoma, thymolipoma, carcinoids, germ cell tumors (e.g., primary germinoma, nonseminomatous and mixed germ cell tumors), and

thymic carcinomas. In the Mississippi Valley, histoplasmosis should be included in the differential diagnosis of mediastinal tumors.

The staging system devised by Masoka and colleagues as been widely adopted.[92,93] This postsurgical staging system classifies thymomas into two general categories: noninvasive (stage I) and invasive (stages II to IV). Invasive thymomas can be further subclassified into minimally invasive (II), extensively invasive (III), or metastatic (IV). Prognosis is highly dependent on clinical stage. Survival rates for stage I tumors range from 89% to 95%, whereas only 30% to 70% of patients with invasive thymomas are expected to be long-term survivors.[91,93,96]

**Treatment**

Surgery is the preferred modality for staging and treating patients with thymoma. The surgical incision of choice is a median sternotomy. [93] This approach allows adequate visualization of mediastinal structures and is relatively painless. An attempt should be made to resect all disease. Thymomas are usually staged at the time of initial surgical explorations because 30% of patients will have invasive disease at time of initial surgical exploration. [96,100]

For patients with completely resected encapsulated tumors, the intrathoracic failure rate after complete surgical excision is less than 5%; thus, adjuvant radiotherapy does not appear to offer a therapeutic advantage for these patients. [96]

Because thymomas are relatively radiosensitive,[101] radiation therapy is recommended for patients with invasive disease regardless of the degree of surgical resection. Patients with completely resected invasive disease who are treated with surgery alone have a 38% local failure rate compared to a 0% to 5% local failure rate when radiation therapy is added.[93,96] Dosage recommendations are based on the age of the child and the extent of invasiveness of the tumor. Dosages of 3,500 to 4,500 cGy delivered over 3 to 6 weeks are recommended for control of incompletely resected thymomas.[101]

Chemotherapy is generally reserved for patients with advanced-stage disease who have not responded to irradiation or corticosteroid therapy. Doxorubicin and cisplatin are recognized as effective agents for the treatment of this tumor, although responses also have been reported with alkylating agents. [93] The combination of cisplatin and etoposide has also proved active in patients with metastatic or recurrent disease. [102] The addition of ifosfamide to this regimen has produced similar results (50% response rate).[96] Taxol and carboplatin have been successful in selected cases with recurrent disease. [103] Preliminary results of a combined modality therapy trial using cisplatin, doxorubicin, cyclophosphamide, vincristine, and radiotherapy have shown a 77% response rate in patients with advanced-stage disease.[96]

Because thymomas have a high uptake of indium-labeled octreotide, trials using this somatostatin analogue have been recently conducted in patients with refractory disease. A durable complete remission has been noted in a patient with pure red cell aplasia and heavily pretreated thymoma using high-dose octreotide and prednisone.[104] In another trial, 7 of 13 patients with chemotherapy-refractory disease responded to prednisone and octreotide. [96]

In studies of adults and children at large institutions, 5-year survival rates ranged from 65% to 83% for encapsulated tumors and 30% to 54% for invasive tumors. The overall survival rate for patients with invasive thymoma and myasthenia gravis appears to have improved due to earlier detection of thymomas in this population.[91,105,106] and [107]

Complications of therapy may be related to the use of radiation. These complications may include pneumonitis, mediastinitis, pericarditis, and myocarditis.

## BRONCHIAL ADENOMAS

Most cases of bronchial adenoma are in fact carcinoid tumors or slow-growing malignancies such as mucoepidermoid carcinomas. [108,109] and [110] The primary treatment of these tumors is surgical resection. Other lung tumors that may enter into a differential diagnosis include leiomyosarcoma, primary or secondary rhabdomyosarcoma, myofibroblastic tumors, and hemangioendotheliomas. Bronchial adenomas,[108,109] and [110] also referred to as *mucoepidermoid tumors*, should be considered in the differential diagnosis of any patient with a persistent radiographic abnormality and clinical features simulating bronchial asthma. These low-grade epidermoid tumors generally do not metastasize but may be associated with cardiac disease [111] as well as secondary tumors.[112] Chemotherapy is generally unnecessary except in the presence of distant metastases.[113]

## MESOTHELIOMA

The pleural, pericardial, and peritoneal surfaces are the primary sites of mesotheliomas: the tunica vaginalis may also be a primary site. [114,115] and [116] These tumors may occur as primary or secondary malignant neoplasms and may be composed of epithelial, sarcomatous, and mixed histologies. [117,118] and [119] There is no widely accepted staging system for mesothelioma. It is, however, known that if these tumors are not treated, death usually results within 12 to 15 months from diagnosis. The determinations of which patients should be selected for surgery and chemotherapy are not understood. [120] Radiation therapy may be used for palliation of pain. Hyperthermia may enhance the effects of both radiation and chemotherapy. [121] One of our patients with a primary mesothelioma had a partial response with ifosfamide and another had long-term disease control with 5-FU plus leucovorin. High-dose methotrexate with leucovorin may be of some value. [122]

Many adults with mesothelioma have had a prior history of exposure to asbestos at industrial sites. Information about the risk for children exposed to asbestos is not available.

Secondary mesotheliomas have developed after malignant ovarian teratoma, Hodgkin's lymphoma of the neck, and non-Hodgkin's lymphoma (Burkitt's type) of the abdomen in three of our patients who had previous radiation and chemotherapy. [119] Prolonged survival was possible for one of these patients. Benign and malignant mesothelioma cannot be differentiated on histologic grounds. Poor prognosis is associated with diffuse or invasive lesions and those that recur.

## TUMORS OF THE HEART

Benign tumors are the most frequent of the cardiac tumors and may include myxomas and neurofibromas, tumors of muscle, or tumors of nerves.[123] Other tumors can include metastatic tumors such as melanoma, rhabdomyosarcoma, leukemia, and carcinoma of other sites.[124,125] The primary cardiac tumors may also include benign and malignant teratoma, hemangioma, chondrosarcoma, and rhabdomyosarcoma. Most symptoms include abnormalities of heart rhythm, enlargement of the heart, pericardial fluid, and congestive failure. Successful treatment requires surgery, which may include heart transplantation, and appropriate chemotherapy for the type of cancer being treated.[126]

## CANCER OF THE ESOPHAGUS

Cancer of the esophagus is rare in children and occurs more frequently in boys than in girls. Most tumors are epithelial in origin, represented by squamous cell carcinoma or its variants. Sarcomas of the esophagus are rare. The most common benign tumor of the esophagus is leiomyoma. Adult and pediatric patients with this cancer present with dysphasia, difficulty swallowing, and weight loss. There may be associated vomiting, cough, hemoptysis, hematemesis, regurgitation, and bone pain if there are metastases. Literature reviews of pediatric patients for this tumor appear in case reports from India. [127,128] The diagnosis must be made by histologic examination. Generally, barium-contrast radiography is followed by endoscopy and biopsy. A tissue biopsy should be obtained through endoscopy, with which there have been major strides in the diagnosis, staging, and treatment of esophageal cancer. [129] Early stage carcinomas of the esophagus are generally asymptomatic and may be detected incidentally.

The therapy for patients with esophageal cancer is based on the anatomical extent of the disease, as noted by the TNM classification. [1]

## CANCER OF THE STOMACH

Cancer of the stomach accounted for approximately 24,000 new cases in 1999 in adults.[1] Thus it remains an exceptionally rare cancer of children and adolescents but

remains one of the most common causes of cancer deaths in the United States.[140]

### Epidemiology

In 1936 gastric cancer was the leading cause of cancer-related deaths of men in the United States. The death rate and frequency of this disease have, however, declined worldwide since that time.[130] There are no recognized genetic syndromes associated with gastric cancer. Familial occurrence of this cancer is rare.

### Pathology

Approximately 95% of the tumors of the stomach are adenocarcinomas. Gastric adenocarcinomas are classified according to the degree of histologic differentiation. Approximately half of all stomach neoplasms are located in the distal stomach.[131,132,133 and 134] Nodal and omental involvement may be encountered. Other less frequent tumors include lymphomas, squamous cell carcinoma, carcinoids, leiomyosarcoma, gastrointestinal stromal tumors (GISTs), and gastrointestinal autonomic nerve tumors (GANTs).[135] Differential diagnosis includes Peutz-Jeghers–type polyps in the stomach, hemangioma, leiomyosarcoma, and liposarcoma. Gastric carcinomas spread by the lymphatics and blood vessels, by direct extension, and through seeding of the peritoneal surfaces. These lesions may infiltrate the submucosa, extend directly, and involve the duodenum or esophagus, liver, pancreas, or colon. Blood-borne metastases may involve the lungs, liver and skin. [136]

### Clinical Presentations

Cancers of the stomach produce vague epigastric discomfort, which may or may not be associated with weight loss and anorexia.[133,134,135 and 136] Iron deficiency anemia may be present with occult blood in the stool. These cancers may not produce symptoms until metastases are noted. For these reasons, individuals with weight loss and abdominal pain, nausea and vomiting, change in bowel habits, anorexia, dysphagia, weakness, hematemesis, or other vague abdominal symptoms should be investigated.

### Diagnosis

A biopsy through a gastroscope is the most accurate method of identifying gastric carcinoma. Fiberoptic endoscopy may be complemented with upper gastrointestinal series. Chest radiographs and CT scans should also be performed along with appropriate laboratory studies, including blood chemistry determination and complete blood cell count.

### Staging

The TNM classification is used for staging. This information is obtained from surgical exploration and from clinical data when resection is not carried out. Staging follows the latest AJCC Staging Handbook.[1]

### Prognostic Considerations

Prognosis for carcinoma of the stomach depends on the extent of disease and the treatment. There is little information about the outcome for patients younger than 21 years at the time of diagnosis and treatment.

### Treatment and Complications

Complete surgical excision with appropriate margins is the procedure of choice for this cancer. Surgery should include subtotal gastrectomy with resection of associated lymph nodes. The recommendation has been made that total gastrectomy not be performed unless there is potential for cure, because extended resection may be associated with increased mortality rate without adding to the likelihood of cure. The preferred methods for combining surgery and radiation for gastric carcinoma differ. Preoperative, intraoperative, and postoperative radiation have been given. [136] Although this tumor has been regarded as a somewhat unresponsive tumor, radiation therapy with curative intent is associated with tumor doses greater than the tolerance of surrounding tissues. The greatest benefits have been with combined radiation and chemotherapy after surgery. As expected, there are no data available on irradiation therapy for children.

Effective chemotherapy regimens do not exist for gastric carcinoma.[136] Adjuvant chemotherapy continues to be investigated. Among the agents being used are 5-FU without leucovorin, nitrosourea with or without doxorubicin, mitomycin, and irinotecan. Patients who respond to combinations of agents generally survive longer. There are no contemporary treatment data available related to results in children, and, as expected, complications may be related to the modalities used.

The effects of *Helicobacter pylori* infections during childhood and later gastric carcinoma are not defined. [137,138 and 139]

## PANCREATIC CANCERS

For adults, pancreatic cancer is the fourth most frequent cause of death, exceeded only by colon, lung, and breast cancers. [140,141] These carcinomas are among the most aggressive of the visceral malignancies and account for about 27,000 deaths in the United States annually. Pancreatic carcinoma is the seventh most common cancer in the United States.[140] Annual age-adjustedincidence rates for all carcinomas in patients younger than 20 years is 1.4 per million; thus, specific figures are unavailable for pancreatic cancers in this age group. Several cases of the usual adult type of pancreatic carcinoma have been reported for children, whereas most of the carcinomas in children are termed pancreatoblastoma.

There are no recognized genetic syndromes associated with pancreatic carcinoma in children or adolescents. [142,143,144,145,146,147 and 148] There is evidence to suggest that melanoma-prone families with mutations that impair p16 function may be at high risk of developing pancreatic cancer. [149] Although endocrine tumors of the pancreas may be associated with other hormone-producing tumors such as gastrinoma and insulinoma, congential pancreatoblastoma has been found in association with the Beckmann-Wiedemann syndrome.

### Pathogenesis, Natural History, and Patterns of Spread

The causes of pancreatic cancers in children are unknown. These tumors may arise in the head, body, or tail of the pancreas. [141] In most instances, the tumors are nonfunctioning, and symptoms differ according to the site of origin. Functioning tumors may produce a variety of symptoms. Islet cell carcinomas produce an overabundance of insulin, leading to hypoglycemia that may be associated with fatigue, restlessness, and malaise, followed by clouding of the sensorium, staggering gait, hyperthermia, and coma; these may appear as intermittent attacks, most frequently in the early morning hours. [142,143,144 and 145] Nonfunctioning islet cell tumors are usually associated with peptic ulcer and the elaboration of gastrin by the tumor; some patients develop watery diarrhea, hypokalemia, and achlorhydria.

The natural history of each of these tumors and of pancreatoblastoma is marked by wasting and pain. [143,146,147] Patients usually present with a large abdominal mass. There may be mechanical obstruction of duodenum and gastric outlet by tumors at the head of the pancreas, which may be associated with jaundice and intestinal hemorrhage. Venous obstruction may lead to varices, hemorrhage, and ascites. Tumors of the body or tail of the pancreas may erode into the stomach and cause hemorrhage. Ascites associated with involvement of the liver and peritoneum may result in hepatic failure, and patients may die because of progressive weight loss and anorexia.

### Diagnosis

With the objective of establishing diagnosis and extent of disease, the usual diagnostic imaging studies should be used along with evaluation of the chest by CT. Differential diagnosis should include benign neoplasms such as papillary cystic tumor and hemangiomas. Radiographic studies should include contrast studies of the gastrointestinal tract, abdominal ultrasonography, and CT or MRI scans of the abdomen. Primary tumors of the head of the pancreas may cause deformity of the duodenal-C loop, or gastric antrum, and may be associated with mucosal abnormalities detected at gastroscopy. Retrograde endoscopic cholangiopancreatography

may be helpful, as may be arteriography for patients being considered for resection.

Serum markers including carcinoembryonic antigen, alpha-fetoprotein, CA19-9, and pancreatic oncofetal antigen may be of value in the diagnosis and in follow-up.[150,151] Other markers such as amylase, lipase, alkaline phosphatase, lactic dehydrogenase, transaminase, leucine aminopeptidase, and pancreatic ribonuclease may aid in diagnosis and determination of the success of treatment.

### Pathology

Pediatric malignant tumors of the pancreas, in descending order of origin, include malignant papillary cystic carcinoma [152] and pancreatoblastoma[152,153,154,155,156 and 157] as well as tumors of islet cell origin such as insulinoma and gastrinoma. [158,159 and 160] Other cancers of duct cell origin are adenocarcinoma and squamous cell carcinoma; acinic cell carcinoma, liposarcoma, and lymphoma may involve the pancreas.

Surgical staging for this tumor uses the grading system of the AJCC, and the reader is referred to the most recent edition of that handbook. [1]

### Prognostic Considerations

Fewer than 10% of adult patients with carcinoma of the pancreas survive, yet better results have been observed in children. Most patients in the pediatric age group who develop this rare type of carcinoma die, usually because the diagnosis may not be made until after the development of locoregional disease. Most tumors of the pancreas are not radiosensitive or chemosensitive, thus the only potentially curable patients are those diagnosed at an early stage when the tumor is confined to the body of the pancreas. For these individuals surgical resection provides the only chance for long-term disease-free survival. Pancreatoblastoma may defy these statements.

### Treatment

The principles of treatment for pediatric patients with pancreatic tumors have been derived from the adult experience. [141,158] Various operations that have been developed since 1935 include pancreatoduodenectomy, total pancreatectomy, regional pancreatectomy, and distal pancreatectomy. The standard operation for resection is a pancreaticoduodenectomy, referred to as the *Whipple procedure*. Too few pediatric patients have been treated with radiation therapy for pancreatic carcinoma or pancreatoblastoma to make meaningful data available. For adults the treatment dosage has been 4,500 cGy over 4 to 6 weeks. Complications may include bowel obstruction, biliary obstruction, and biliary fistula. Studies for adults are presently ongoing to evaluate the use of adjunctive conventional or intraoperative radiation therapy.

### Localized Tumors

Chemotherapy for pancreatic carcinoma varies from that given for pancreatoblastoma. The agents for metastatic pancreatic carcinoma include 5-FU, streptozotocin, mitomycin C, gemcitabine, and doxorubicin, associated with response rates of 7% to 36%. [141,161,162 and 163] For pediatric patients with pancreatoblastoma, the usual agents include vincristine, cyclophosphamide, doxorubicin, cisplatin or carboplatin, dactinomycin, or bleomycin. [153,155,157] Surgical excision and radiation therapy are necessary after obtaining chemotherapy response in unresectable lesions to prevent regrowth of tumors. [162,163]

## GASTROINTESTINAL STROMAL TUMORS

Although these tumors occur in middle-aged and older individuals and are rare before the age of 40 years, recent evidence is that more tumors are being classified into this category than in the past. Such tumors as leiomyosarcoma and synovial sarcoma have in some instances been reclassified as GISTs. [164]

These tumors may arise at any place in the gastrointestinal tract and are histologically different from true leiomyosarcomas, leiomyomas, leiomyoblastomas, and malignant tumors of peripheral nerve sheath. Greater than one-half of these tumors arise in the stomach and have spindle cell as well as epithelioid characteristics. Other sites include the esophagus and the small intestine. [166]

A group of malignant small intestinal tumors, sometimes referred to as plexosarcomas, have been termed *GANTs*.[165,166] These tumors were histologically heterogenous spindle cell or epithelioid tumors of stomach, small intestine, mesentery, and retroperitoneum. These tumors have been reported in patients with neurofibromatosis type I.

Nearly all GISTS have expressed the C-kit gene that is located on the long arm of chromosome 4. [167] This genetic mutation is not found with true smooth muscle tumors including leiomyomas and leiomyosarcomas. Chromosome deletions have been reported on the 9p and 22q preferentially in malignant GISTs. [167]

The GANTs[164] are characterized by ultrastructural features resembling autonomic nerve cells, without epithelioid, Schwannian, or smooth muscle differentiation. In children there may be a prevalence in females in the second decade with predominance of smaller gastric tumors and the possibility for more significant prognostic value related to age. In the past these tumors have been treated with the usual agents for soft tissue sarcomas; as soon as possible after surgery some tumors require the use of chemotherapy or radiation therapy, with agents used for sarcomas.

## RENAL CELL CARCINOMA

Renal cell carcinoma (e.g., clear cell carcinoma, renal cell adenocarcinoma, hypernephroma) was first studied by Grawitz, [168] who believed that the tumor arose from ectopic adrenal tissue because of its microscopic similarity to adrenal cells. Because of this similarity, he named this tumor *hypernephroma*, a misnomer that is occasionally still used.

Renal cell carcinoma is the most common primary malignancy of the kidney in adults, accounting for 2% of adult cancer cases. [169] In children, the overwhelming majority of renal malignancies are nephroblastomas, and only 7% of all primary renal tumors in patients younger than 21 years are renal cell carcinomas. [170] Referral patterns to the Armed Forces Institute of Pathology seem to indicate that the incidence of renal cell carcinoma may approach that of Wilms' tumor in the second decade of life.[171,172] Although renal cell carcinoma in adults occurs with a male to female ratio of 2:1, childhood series show a slight female predominance. [170,173,174]

### Risk Factors

Almost all of the information regarding risk factors in renal cell carcinoma have been derived from case-controlled studies. In adults, cigarette smoking, obesity in women, and renal dialysis have been linked to an increased incidence of renal cell carcinoma. [169]

Renal cell carcinoma occurs in both sporadic and familial forms. Von Hippel-Lindau disease (VHL) is a dominantly inherited disorder characterized by germline mutations of the tumor suppressor gene VHL, which is located on chromosome 3p25.[175] This syndrome is characterized by retinal angiomas, central nervous system hemangioblastoma, multiple renal cysts that grow slowly over years, and the development of renal cell carcinoma. The latter can be multicentric or bilateral, usually of the clear cell histologic subtype. Renal cell carcinoma can develop in the preexisting cysts or de novo and has been reported to occur in up to 60% of patients with VHL.[175] In addition,VHL is also associated with the development of pheochromocytomas, pancreatic cysts, islet cell tumors of the pancreas, endolymphatic sac tumors, and papillary cystadenomas of the epididymis and adnexal tissues in women.

Tuberous sclerosis, a disorder characterized by multiple hamartomas, renal angiomyolipomas, seizures, and learning disabilities has also been associated with the development of renal cell carcinoma of the clear cell type. [175] Familial renal cell carcinoma has been associated with a constitutional chromosomal translocation, t(3:8)(p14;q24). The *TRC8* gene, which maps to the 8q24 breakpoint, appears to play a major role in the genesis of renal cell carcinoma of the clear cell type in these patients.[175,176] Chromosome studies of nonfamilial tumors have shown a high incidence of abnormalities of chromosome 3. Hereditary papillary renal cell carcinoma has been reported in several families. Germline *MET* proto-oncogene mutations have been reported in as many as 80% of cases.[175] In children,VHL gene

abnormalities are very rare. There is a growing body of evidence that translocations or deletions involving the Xp11.2 loci define a subgroup of younger children with papillary renal cell carcinoma. A specific chromosomal translocation, t(X;1)(p11;q21), which fuses the *TFE3* and *PRCC* genes, has been recently identified.[177]

### Pathology and Patterns of Spread

Microscopically, the tumor tissue resembles renal tubules. Four major patterns of growth have been described: papillary, solid, cystic, and sarcomatoid. The papillary subtype predominates in some series of children with renal cell carcinoma.[178] There is apparently little prognostic significance to these patterns, and in some cases, several patterns can be found within the same tumor. In addition, three different types of cellular morphology may be identified: clear cells, granular cells, and sarcomatoid cells.

Renal cell carcinoma typically metastasizes by hematogenous and lymphogenous spread. Lungs, bones, liver, lymph nodes, and the mediastinum are common metastatic sites.

### Clinical Presentation

Unlike in children with Wilms' tumor, which often presents as an abdominal mass, children with renal cell carcinoma typically present with abdominal or flank pain, gross hematuria, or both. A palpable mass is apparent in only 60% of cases[179] and often must be demonstrated by ultrasound or CT. Calcifications are seen in 24% to 50% of the cases.[179,180 and 181] A variety of paraneoplastic syndromes have been reported in adults, including hepatic dysfunction that resolved after resection of the primary tumor.[182] Other syndromes are caused by ectopic production of various hormones including parathormone (hypercalcemia), erythropoietin (polycythemia), gonadotropin (gynecomastia), and various other substances.[183,184] These syndromes have not been a notable feature of renal cell carcinoma in childhood.[173]

Children with renal cell carcinoma are typically older than children with Wilms' tumor, with a median age at diagnosis of 11 years.[185] However, the diagnosis has been made in children as young as 14 months.

### Differential Diagnosis

The obvious lesion to be considered in the differential diagnosis is Wilms' tumor, the most common renal neoplasm in childhood (see Chapter 28). Beckwith pointed out the occasional difficulty in differentiating Wilms' tumor from renal cell carcinoma, because some tumors have histologic characteristics that may be transitional between the two diagnoses.[172] Also to be considered are other space-occupying lesions of the pediatric kidney, including multilocular cysts, nephroblastomatosis, angiomyolipoma, congenital mesoblastic nephroma, benign stromal tumors, intrarenal neuroblastoma, renal teratoma, malignant rhabdoid tumor, clear cell sarcoma, lymphoma (especially Burkitt's), and renal sarcomas (e.g., rhabdomyosarcoma, liposarcoma).

### Evaluation

Renal cell carcinoma should be considered as part of the differential diagnosis, particularly in older children who present with pain or hematuria and a renal lesion. Studies to be obtained include a complete blood count (to evaluate anemia, erythrocytosis), biochemical profile (to evaluate hypercalcemia), renal ultrasound with attention to the patency of the inferior vena cava, CT of the chest, abdominal CT or MRI with and without intravenous contrast infusion, and a bone survey and radionuclide bone scan.

### Staging

Renal cell carcinoma in childhood has occasionally been staged according to the National Wilms' Tumor Study criteria. Although pediatric oncologists are most familiar with this staging system, it seems more appropriate to use one of the staging systems developed specifically for this tumor in adults. The TNM classification provides the most accurate description of disease extent and stratifies patients into four stages based on the size of the tumor (less than or equal to 7 cm vs. greater than 7 cm). It also takes into account whether the tumor is confined to the kidney or invades vessels, Gerota's fascia, perinephric tissues, and lymph nodes, and whether distant metastases are present.[1,186]

### Prognostic Considerations

The stage at diagnosis is the most important prognostic factor. Table 38-2 summarizes the experience in 93 children reported in seven series.[170,173] The long-term survival rates approached 100% for patients with tumors less than or equal to 7 cm and confined to the kidney (stage I). Patients with tumors larger than 7 cm or those with tumors that extended beyond the kidney or had lymphatic metastases to a single regional node (stage 2 and 3) had an intermediate prognosis, whereas patients with metastatic disease fared very poorly (only 1 of 32 survived).[174,185] Although other variables, such as tumor grade and renal vein invasion, correlate with stage at diagnosis, they do not appear to be independent prognostic variables. Review of 84 children with renal cell carcinoma reported actual survival rates of 56% and 50% at 5 and 10 years, respectively.[181] Most recurrences and deaths occur within the first 2 years after diagnosis, but late recurrences are not infrequent.

| Stage | Number of patients | Total number of patients/survivors (%) |
|---|---|---|
| I | 27 | 27/26 (96) |
| II | 15 | 15/9 (60) |
| III | 19 | 19/13 (68) |
| IV | 32 | 32/1 (3) |
| Total | 93 | 93/49 (53) |

**TABLE 38-2. CLINICAL CHARACTERISTICS AND OUTCOME OF 93 CHILDREN WITH RENAL CELL CARCINOMA**

### Surgery

The primary therapy of localized renal cell carcinoma is radical nephrectomy, with resection of the kidney and tumor, the adrenal gland, surrounding perinephric fat, Gerota's fascia, and the regional lymph nodes. Complete retroperitoneal node dissection should be reserved for large tumors (greater than 7 cm) when metastatic lymph nodes are documented. Low-stage tumors can be treated with partial nephrectomy using laparoscopic techniques. The local recurrence rate in this setting is 1% to 3%.

### Radiotherapy

The role of preoperative or postoperative radiotherapy in the management of renal cell carcinoma is much less clear than that of surgery. Although some series of adult patients have found enhanced survival with the addition of radiotherapy, other randomized studies have found no difference in outcome between treated and untreated groups. This situation is even more ambiguous for children, in whom renal cell carcinoma is a much rarer disease. Empiric administration of postoperative radiotherapy (4,000 to 4,500 cGy in 150-cGy fractions) has been recommended for children with stage III disease.[174] Radiotherapy can provide significant palliation by decreasing pain, mass effects, or hematuria from unresectable primaries or metastatic disease.

### Chemotherapy

No single chemotherapy agent or combination of agents has yet proved to be of significant benefit to the majority of patients with advanced disease. The combination of gemcitabine and 5-FU has produced responses in 17% of patients with metastatic disease. [187,188] Renal cell carcinoma may prove amenable to therapy with biologic response modifiers. Numerous trials have demonstrated complete or partial responses in 15% to 20% of patients treated with interferon-alfa and interleukin-2 (IL-2).[189] High-dose IL-2 has produced objective responses in 15% of patients. Of interest, the patients who achieve a complete response to IL-2 (approximately 7%) appear to have durable responses. [189,190] Combination therapy using a variety of biologics and chemotherapeutic agents, including interferon, IL-2, 13- *cis*-retinoic acid, floxuridine, and vinblastine, have also been performed.

Fortunately, at least half of pediatric patients with renal cell carcinoma are curable by surgery alone. Adjuvant radiotherapy remains controversial but should be considered when the disease has extended beyond the renal fossa. There is no satisfactory chemotherapy for renal cell carcinoma, but further refinement and development of immune and biologic therapies may provide a significant alternative for the treatment of this disease. For example, a recent report has documented regression of human renal cell carcinoma in seven patients who were treated with hybrid cell vaccination using monocyte-derived dendritic cells as fusion partners to tumor cells.[191]

## COLORECTAL CARCINOMA

Although colorectal carcinoma is one of the most frequent tumors of adults, it rarely occurs in individuals younger than 20 years. [192,193]

### Epidemiology

Colorectal carcinoma is rare in populations with limited meat intake. Thus it is more common in the West than in Africa. [194,195] It is thought to be related to the long transit time of fecal material in the bowels of persons consuming relatively low-fiber diets.

There are approximately 150,000 new cases of colorectal carcinoma in adults annually. [192,193] The Surveillance, Epidemiology, and End Results program data suggests that only about 80 cases occur in patients younger than 20 years. [193] Thus, the incidence is approximately one case per million persons in this age group.

For children and adolescents these tumors may occur in any site in the large bowel and are not usually associated with a family history of large bowel cancer.[196,197,198,199,200,201,202,203,204,205,206] and [207] There had been suggestions of an increased incidence of ovarian cancer in the families of younger patients with colorectal carcinoma.[207] There is no gender predilection for cancer, with most cases that occur in patients younger than 20 years centering around the age of 15 years.[203,204] and [205] Most of the case reports have come from the central Mississippi Valley, in which some patients had been exposed to pesticides and herbicides. [203] Long-standing ulcerative colitis patients are at increased risk, which increases with the duration and severity of colitis, with this risk increasing to approximately 20% after the age of 40 years.[208] There is a shifting incidence of the sites of primary lesions from the left to the right colon. [209] Black Americans have an increasing occurrence of colorectal cancer.[140,209]

### Genetics

There are several recognized conditions that may be associated with the development of colorectal carcinoma in young patients. These include familial adenomatous polyposis, inherited as a dominant trait with 90% penetrance, which may be associated with the appearance of multiple cancers by the age of 37 years. [210,211] Early diagnosis and colectomy can eliminate the risk of development for these patients. Other syndromes associated with colorectal carcinoma in young people include Turcot's syndrome, for which the frequent mutation of the adenomatous polyposis coli gene has been found; Oldfield's syndrome; and Gardner's syndrome ( Table 38-3).[213,216] There may be an association of neurofibromatosis and polyposis coli, and one individual with multiple adenomatous polyps and multiple colonic carcinomas had a deletion of the p53 gene, also in association with neurofibromatosis. [214,217,218] and [219]

| Name | Description | Reference |
|---|---|---|
| Gardner's | Osteoma, polyposis, multiple sebaceous cysts | 200 |
| Peutz-Jeghers | Mucocutaneous pigmentation of lips, perioral region, buccal mucosa, polyposis, ovarian granulosa cell tumors | 201 |
| Turcot's | Congenital brain tumors | 202–204 |
| Oldfield's | Multiple sebaceous cysts, polyposis | 205 |
| Rendu-Osler-Weber | Hepatic telangiectasia, juvenile polyps | The authors' unpublished observations |

**TABLE 38-3. POLYPOSIS SYNDROMES ASSOCIATED WITH COLORECTAL CARCINOMA**

The genetic events associated with the development of colorectal carcinoma have been elucidated by Vogelstein and colleagues [220] and others.[221,222] The familial adenomatous polyposis syndrome is caused by a constitutional mutation of a gene on chromosome 5. These investigators hypothesized that the inherited gene defect in familial adenomatous polyposis gives rise to widespread epithelial proliferation, which precedes the development of adenomas in these patients. Mutations of a kRAS gene on chromosome 12p and deletions of the tumor suppression gene 253 are also associated with the development of colorectal carcinoma. The loss of another tumor suppressor gene located on chromosome 18, dcc (deleted in colon cancer), is associated with progression of intermediate to late adenoma. For children and adolescents there is no evidence that a family history of bowel cancer confers a greater risk for the development of bowel cancer before the age of 20 years. The same is true for persons younger than 20 years belonging to families with hereditary colorectal carcinoma, cancer family syndromes, or familial juvenile polyposis (Fig. 38-2). Individuals with the Peutz-Jeghers syndrome may develop bowel cancer because of the risk associated with polyposis involving the upper and lower gastrointestinal tracts.[213]

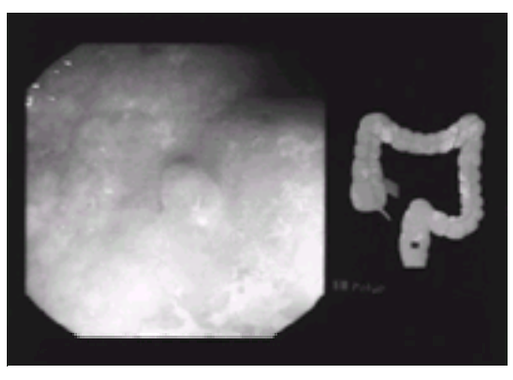

**FIGURE 38-2.** Endoscopic photograph of an adenomatous polyp in the rectum of a 20-year-old man. He had bloody stools and pain before diagnosis of a stage III mucinoses carcinoma of the cecum in 1987 at the age of 10 years. Additional polypectomies were performed in 1988 (before colon resection to the peritoneal reflection in 1989). The figure demonstrates a polyp seen in 1997.

## Biology

Signs and symptoms may be absent or innocuous. A change in bowel habits, such as constipation or diarrhea, and change in the caliber of stools may be observed before the development of tarry stools, rectal bleeding, or other changes in bowel habits. There may be a decrease in appetite and weight loss.

The signs and symptoms of colorectal carcinoma are related to its primary site within the large bowel. [193] Tumors involving the cecum and descending colon, which may be associated with familial colon carcinoma, may develop large masses before symptoms appear. Tumors of the rectum and sigmoid may be associated with changes in the caliber of the stool, dyschezia, and hematochezia.

The diagnosis of colorectal carcinoma in young individuals is often delayed because it is seldom suspected. Acute bowel symptoms necessitate immediate abdominal exploration, at which time perforation of the large bowel may be observed with multiple metastatic deposits. Intestinal obstructions due to tumor occur more frequently in adolescents than in adults with this cancer. [202,205,206]

The natural history of colorectal carcinoma in young individuals differs from that of adults, with tumors of the young being more advanced at diagnosis. [194,196] These tumors, therefore, may not be resected in early stage and may spread throughout the peritoneal cavity to involve the omentum, peritoneum, mesenteric lymph nodes, liver, and ovaries, and spread through the bloodstream to the lungs and eventually the brain, bones, or both. Peritoneal seeding in females frequently involves the ovaries, which may reach tremendous size due to tumor involvement. Greater than one-half of the neoplasms of the colon in younger patients are mucinous adenocarcinomas, which occurs in approximately15% of adults with colon carcinoma. [223]

## Ancillary Clinical Studies

Examination of the stool for occult blood may produce positive results when no gross blood can be seen on the stool or discoloring the stool. Hepatic and renal function are seldom contributory, as are studies of the urine. Hepatic function abnormalities may be related to metastatic involvement of the liver. Anemia may be related to blood loss or malnutrition. Carcinoembryonic antigen levels should be determined, yet fewer than 75% of the colon carcinomas in children may produce this protein. The frequency and positivity of this assay increase with increasing stage of disease.

## Imaging Studies

Direct or fiberoptic colonoscopy should be useful in locating the site of any lesion of the large bowel. The entire length of the colon should be evaluated, especially to note any association with polyps. Conventional radiographic studies include barium enema with air contrast to define the tumor and the remainder of the colon. These radiographs, performed in association with CT scans of the abdomen and chest, may define areas of spread to the liver, lungs, or enlarged lymph nodes, and metastases that may involve the pelvis and cul de sac, especially the ovaries. Radioisotope studies should also include a bone scan. If the bone scan is positive, a bone marrow aspiration or biopsy may be appropriate to determine if there has been spread to the marrow.

## Pathology

Colorectal carcinoma arises from the mucosal surface of the bowel, generally at the site of an adenomatous overgrowth of polyp. Tumor may extend into the muscularis area to the serosa and perforate the serosa into the omental fat, lymph nodes, liver, ovaries, and other loops of bowel. Some lesions may obstruct the bowel lumen. There also may be implants along the abdominal scar, at the anastomotic site, or throughout the peritoneum. Rarely is more than one cancer present simultaneously. Multiple lesions may have the same or different histology and may have the same or different stages of development. Carcinoma *in situ* may occur in one or more polyps and may be associated with the prior delivery of radiation therapy. Synchronous primaries have the same prognosis as single colon cancers. [228]

The gross appearance of colonic lesions depends on the extent of involvement of the lumen of the bowel and the extent of the disease outside the bowel wall. Because these tumors are derived from endoderm, all the cytologic characteristics will be that of carcinoma, yet they may be well-differentiated or poorly differentiated and contain pools of mucin. These tumors may grow to huge sizes, and in females, ovarian involvement may be massive and may result in difficulty in the differential diagnosis between bowel cancer and ovarian cancer.

The differential diagnoses include malignant carcinoid, leiomyosarcoma, malignant fibrous histiocytoma, and metastatic tumor from other sites. All may have similar presentations; metastases may be identified only by histologic or metastatic site. When individuals with this tumor present with an acute abdomen with associated pain and possible perforation, the diagnosis of acute appendicitis is most often considered.

## Staging

Staging systems have been proposed over the past 50 years for this tumor. The TNM Classification of the AJCC has been most frequently used for definitions for reporting requirements of tumor registries (Table 38-4). The staging system of the National Institutes of Health Consensus Development Conference reflects these definitions as well as the Dukes' Classification. [225]

**TABLE 38-4. STAGING OF COLORECTAL CARCINOMA**

## Treatment

General surgical principles: Biopsy is required for the diagnosis of colorectal carcinoma. [192] A biopsy may be obtained by colonoscopy or at laparotomy, at which time definitive surgery may or may not be feasible. Surgical staging procedures include biopsy of any known enlarged lymph nodes, biopsy of the ovaries in female patients, resection of the omentum, and biopsy of the liver. Complete excision is the goal for the surgeon, with secondary aims being related to palliation by resection of bulky tumors or metastases. Debulking provides little for the patient with extensive metastatic disease. Removal of single or multiple hepatic metastases may become a life-saving procedure for patients who had excision of the large bowel, nodal dissections, and metastases to the liver. Decisions regarding colostomy remain the prerogative of the surgical oncologist.

### *Chemotherapy and Radiation Therapy*

Tumor involvement of the rectosigmoid area or anus that are considered unresectable at the time of diagnosis should be treated initially with radiation therapy before

any surgical procedure other than biopsy.[192] Chemotherapy options are expanding from the use of 5-FU with leucovorin.[226,227] The use of interferon alfa-2A with 5-FU has been associated with significant intolerance of pediatric patients to interferon, and this treatment for adults was not associated with an increase in the survival rates for individuals with stage III or IV disease.[204,227,228] Irinotecanhas also been used in combination with 5-FU and leucovorin.[229,230] This topoisomerase inhibitor has significant activity in human xenografts as well as patients in phase I and II studies. Studies from France and Japan have indicated the activity of oxaliplatin for colorectal carcinoma.[231]

Intraoperative radiation therapy has been advocated for disease known to have metastasized to the mesentery or mesenteric lymph nodes. This procedure is performed while the bowel is displaced from the peritoneal cavity.

### *Complications of Therapy*

Complications of therapy are sometimes difficult to separate from the complications of the disease, which may be nutritional or obstructive or may be related to the effects of metastatic disease on other organ systems. Patients who have survived colon carcinoma may be at increased risk for development of secondary leukemias.[232]

### *Therapeutic Trends*

Current therapies are unsatisfactory for patients with stage III and IV tumors because these tumors are detected after the development of extension of disease. Clinical suspicion is not raised for the teenager with diffuse abdominal discomfort or mass. Surgery is the only modality known to be effective in providing cures, although adjuvant chemotherapy extends life. Few patients with extensive metastatic disease are cured. Irradiation of pulmonary or brain metastases may provide therapeutic benefit and symptomatic relief of the sequelae of these metastases.

Refinement of tumor cloning assays for prediction of response to treatment may be of significance for individuals with this tumor. Specific histologies may respond to varying chemotherapeutic agents.

For individuals at high risk of developing primary or recurrent colorectal carcinoma, annual colonoscopy has been recommended. For children, this probably should not be performed except at biennial intervals. Screening for fecal occult blood has not proved to be of significant value for the treatment and management of pediatric patients.

Recent studies have noted high frequency of microsatellite instability in 17% of 607 patients with colorectal carcinoma.[233,234] and [235] This was associated with significant survival advantage independent of all standard prognostic factors including tumor stage, and individuals with this occurrence had decreased likelihood of their tumors metastasizing to regional lymph nodes.[234,235] Microsatellite instability is a characteristic pattern of genetic instability, which occurs in microsatellite DNA that occurs in most hereditary nonpolyposis colorectal cancers. Studies at Memorial Sloan-Kettering Cancer Center on 29 patients younger than 21 years noted that tumors appear to develop by means of two pathways, either involving a tumor suppressor gene or loss of heterozygosity and other features involving a mutation.[233,234,235,236,237,238,239,240,241,242] and [243] Other genetic and developmental factors may account for the aggressive course of this disease.

The chemopreventive effects of nonsteroidal antiinflammatory agents on colorectal carcinoma involve the interaction of the adenomatous polyposis coli tumor suppressor pathway and the nuclear hormone receptor peroxisome proliferator–activated receptor gamma.[241,242,243,244,245] and [246] Both the number and size of colonic polyps was reduced in patients who were receiving aspirin and other nonsteroidal antiinflammatory drugs.

## PAPILLARY SEROUS CARCINOMA OF THE PERITONEUM

Papillary serous carcinoma of the peritoneum is an unusual tumor that may arise on the surface of the ovaries and spread to the omentum, abdominal, and pelvic peritoneum.[247,248,249,250] and [251] This tumor rarely affects adolescents and significantly resembles papillary carcinoma of the ovaries seen in adults. This tumor may be derived from Müllerian cells. The presenting signs are abdominal distension and pain. Treatment usually consists of debulking and cisplatin-based therapy, with or without paclitaxel. The prognosis for survival is poor, yet individuals may have an indolent course with recurrences over many years. Differential diagnosis must include mesothelioma of the peritoneum and surface carcinoma of the ovary.

## CARCINOMA OF THE BLADDER

Primary tumors of the bladder are rare in childhood. The most frequent of bladder cancers in pediatric patients is rhabdomyosarcoma (see Chapter 32). The most common carcinoma is transitional cell carcinoma, which may be encountered as a second malignant neoplasm after extensive treatment with cyclophosphamide.[252,253] and [254] Diagnosis and treatment are the same for children and adolescents as they are for adults.

## CERVICAL, VAGINAL, AND VULVAR TUMORS

Tumors of the cervix, vagina, and vulva are extremely rare in children and adolescents.[254,255,256,257,258] and [259] Rhabdomyosarcoma is the most common tumor of these sites, yet squamous cell tumors may also occur. Cervical squamous cell carcinoma has been observed more frequently with increasing age through adolescence.

Clear cell carcinoma of the vagina and cervix has been observed in the daughters of mothers who received diethylstilbestrol for the prevention of spontaneous abortion. Other abnormalities have included vaginal adenosis.[260,261,262,263,264] and [265] Treatment for the clear cell adenocarcinoma of these sites requires vaginectomy, hysterectomy, and lymphadenectomy. The role of radiation is not clearly defined. Other tumors of these sites include carcinomas, papillomas, nodular fasciitis, and sweat gland tumors. Principles for their treatment depend on the site, stage, and pathologic features.

## CANCERS OF THE BREAST

Although breast tumors of children and adolescents are usually benign, carcinomas have been reported. Primary malignant tumors of the breast include carcinomas, yet other tumors such as rhabdomyosarcoma and lymphoma may originate in the breast (Fig. 38-3).[266,267,268,269,270,271,272,273] and [274] Breast carcinomas may affect males and females. Recommendations regarding radiation therapy and chemotherapy for childhood and adolescent breast carcinoma are unavailable because no large contemporary series has been reported.

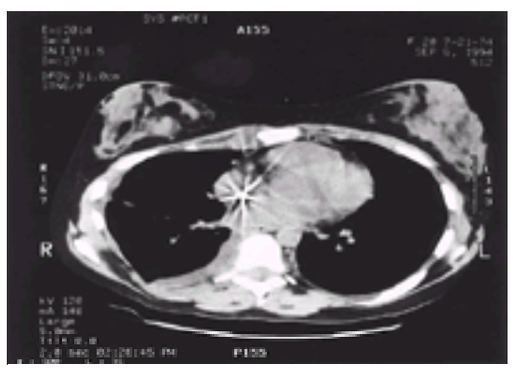

**FIGURE 38-3.** Axial noncontrast computed tomographic scans of thorax demonstrating multiple bilateral breast metastases from alveolar rhabdomyosarcoma in a 20-year-old woman. Film also demonstrates right pleural effusion and erosion of a right posterior rib. Primary site was paraspinal.

Another category that concerns pediatric oncologists are metastatic tumors that may involve the breasts. [272,273] This has been seen more commonly in individuals with alveolar rhabdomyosarcoma of other sites. Another category of tumors of the breast includes secondary neoplasms, which include carcinomas. These tumors generally follow radiation therapy delivered to the chest for such diseases as Hodgkin's disease or cystosarcoma phylloides. [274] Giant fibroadenomas are also tumors that may occur after puberty. These tumors may be slow in growth and not suggest malignancy; most are benign, present as a mass, and should be excised.

Epidemiology studies of breast cancer and aggregation in families have been commented on in Chapter 2 in relationship to the Li-Fraumeni syndrome. [275,276]

## CARCINOID TUMORS

Carcinoid tumors are rare; they are of epithelial origin and may be benign or malignant. [277,278,279,280,281,282,283,284,285 and 286] Female predominance has been noted with this tumor. They may be located in the esophagus or bronchi, or in the large or small bowel, appendix, pancreas, or ovary. On occasions a primary site cannot be discerned. The most common site is the appendix, in which most tumors are benign. [281,282,284] Approximately 1 in 200 appendices removed for acute appendicitis is found to have a carcinoid. Generally they require no treatment unless there has been evidence of metastatic spread to lymph nodes or omentum, or if a tumor is greater than 2 cm in size. These tumors contain argentaffin cells derived from Kulchitsky's cells of the small intestine. These secretory cells are thought to have endocrine functions, as the tumors may produce symptoms referred to as the carcinoid syndrome, characterized by elevated levels of serotonin in the blood and urine. [286,287 and 288] With the carcinoid syndrome, affected patients have periodic flushing, diarrhea, bronchoconstriction, peripheral vasomotor symptoms, and cyanosis. [286,287 and 288] These symptoms are attributed to circulating 5-hydroxytryptamine (serotonin) and histamine. Urinary levels of 5-hydroxyindoleacetic acid are elevated. Treatment is surgical if possible. The appropriate diagnostic evaluation depends on the tumor sites. Octreotide scans and measurement of 24-hour urinary excretion of 5-hydroxyindoleacetic acid may confirm the diagnosis.

If the tumor is malignant and has spread in a manner similar to colorectal carcinoma, chemotherapy may be beneficial. [289,291] Patients with intra-abdominal and pulmonary metastases may be treated with combinations of chemotherapy that include doxorubicin.

Regional ileocolectomy has been advocated for extension of carcinoids to the meso-appendix and serosal fat with indeterminate or inadequate surgical resection margins. [287]

Although malignant carcinoid is rare, it may present with massive hepatic enlargement and metastases in association with the carcinoid syndrome. [290,291] Rarely is the carcinoid tumor considered at the time of initial presentation, which may result in diagnostic delay.

Patients with metastatic disease at diagnosis fair poorly in that curative treatment for these individuals is undefined. Octreotide and its analogs may palliate the symptoms, yet both the long-acting and the short-acting somatostatin derivatives may not completely control the symptoms.

Bronchial carcinoids may present with evidence of obstructive bronchial disease or pneumonia. Most bronchial carcinoids are not malignant, but they may require lobectomy for resection of tumor. [289]

## CHORDOMA

This rare neoplasm arises from notochordal remnants in the midline of the neuraxis and involves adjacent bone. The coccyx, sacrum, and base of the skull are most often involved. [292,293,294,295 and 296] Differential diagnosis includes myxoid chondrosarcoma and metastatic carcinoma. This tumor is generally fatal because of a high rate of local recurrence. The most common complaints for the sacrococcygeal tumors include pain, constipation, and sensory loss. These individuals present with a large presacral mass.

Surgery is the most important of the modalities to be used initially, but radiation therapy with doses of 5,500 to 7,000 cGy may prolong local control. Little information is available regarding appropriate chemotherapy. With dissemination there may be widespread disease in lung, liver, and bone.

## CANCER OF UNKNOWN PRIMARY SITES

From 1973 to 1987, more than 1 million cases of cancer diagnosed in residents of Surveillance, Epidemiology, and End Results program areas, and approximately 2% were designated as cancers of unknown primary sites. [297] The most frequent diagnosis was adenocarcinoma. [298,299 and 300] There has, however, been a decline in the numbers of cancers assigned to unknown primary sites. Other more common types of tumors in this category would include melanomas or embryonal tumors such as rhabdomyosarcoma and neuroblastoma. [301,302,303,304 and 305] The patients generally present with lymph node metastases or generalized disease. Comparative studies have been made for melanoma patients who presented with an unknown primary site in comparison to patients with known primary sites. [305] Molecular and cytogenetic studies may be useful in the diagnosis and prognosis of these tumors. [306] After completion of the diagnostic pathological studies and imaging studies, treatment should be based on the pathology regardless of knowledge of the primary site. [302,303,304,305,306,307 and 308] For these patients, prompt initiation of treatment may lead to clinical response and possible cures.

## CANCERS OF THE SKIN

More than 700,000 cases of basal cell and squamous cell carcinoma occur annually in the United States, accounting for nearly 40% of all adult cancers. [309] Basal cell carcinoma is the most common form of skin cancer in adults and accounts for 75% of the cases. The mortality rate for these two cancers is 2,100 per year. The incidence of melanoma, a less frequent but more invasive and fatal skin neoplasm, has drastically increased over the past 60 years. In 1997, over 40,000 cases of melanoma were diagnosed in the United States, and 7,200 of those patients died from their disease. [309] In children younger than 20 years, melanoma is the second most common epithelial cancer, accounting for 30.9% of all cases. [310]

Basal cell and squamous cell carcinomas may be curable with surgery and radiation therapy and will not be discussed at length in this chapter. Small lesions may respond to a single dose of 2,200 cGy, but larger lesions may require fractionated doses up to a total of 6,000 cGy.

### Epidemiology

Increased total sun exposure has been implicated as an important factor underlying the pathogenesis and increased incidence of skin cancer. The incidence of melanoma and nonmelanoma skin cancers increases exponentially with age, and its incidence is also highly dependent on regional differences. [311] Ultraviolet B wavelengths (290 to 320 nm) are responsible for formation of cyclobutane pyrimidine dimers and pyrimidine photoproducts whose altered repair leads to mutations and the formation of squamous cell carcinomas in mice. Ultraviolet A wavelengths (320 to 400 nm) are more abundant in sunlight and also cause oxidative DNA damage and immunosuppression which, in certain animals, can cause melanoma. Melanocytes, unlike keratinocytes, have a limited proliferative capacity. Cumulative sun exposure has been linked to the development of basal and squamous cell carcinomas, whereas intermittent high-dose exposures (sunburns), particularly during childhood, have been correlated with an increased risk of melanoma. [309,312] The risk for basal and squamous cell carcinomas increases in light-skinned individuals and in those who freckle easily, and is related to the amount of solar exposure received.

Experimental skin cancer was produced in mice by exposure to ultraviolet light in 1928. Epidemiologic data from various global latitudes have shown an increase in squamous cell and basal cell carcinomas in white populations closer to the equator. [314] Certain phenotypes are associated with greater susceptibility to skin cancer within any geographic area; these persons tend to have poor tanning ability with easy sunburning and often have blue eyes, light hair, and fair skin. There is no gender difference in the incidence of any types of skin cancer in the pediatric age groups.

There are two major effects of ultraviolet radiation on the skin that may be responsible for its carcinogenic effects. These are photochemical alteration of DNA and alterations in immunity. As predicted, xeroderma pigmentosum cells in culture fail to repair ultraviolet damage to DNA because the thymine dimers are not excised. [316] Chemical carcinogens may also be associated with the development of basal cell and squamous cell carcinomas. This was first described by Pott, who noticed the

high incidence of carcinoma of the scrotal and penile skin in chimney sweeps in England. [310]

Ionizing radiation is also associated with carcinogenesis of the skin. [312] Early reports involved workers using early x-ray machines. In children, radiation-associated basal cell carcinomas generally have occurred in patients treated for acute lymphocytic leukemia with central nervous system prophylaxis or for Hodgkin's disease with mantle irradiation techniques.

**Melanoma**

Childhood melanoma is rare, accounting for 1% to 2% of all pediatric malignancies. Of the estimated 46,000 new cases of melanoma diagnosed in the United States each year, only 1% to 4% occur in patients younger than 20 years and 0.4% among those younger than 14 years. Melanoma is second only to thyroid cancer as the most common carcinoma of children.[309,313,314] At our center, melanoma accounted for 1% of all solid tumors and 0.5% of all cancers among children who were seen or treated over a 33-year period. Contributing factors to the development of melanoma which appear to be restricted to the pediatric population include the following:

1. Congenital melanomas may develop *in utero* in the absence of melanoma in the mother. They can arise in a giant melanocytic nevus or may develop de novo. Cutaneous melanoma is the most common transplacentally transmitted neoplasm and carries a poor prognosis.[314,315]
2. Giant congenital melanocytic nevi affect fewer than 1 in 20,000 newborns and are precursor lesions of melanoma ( Fig. 38-4).[316,317] The life time risk of developing melanoma has been estimated to be 4.6% to 8.5%.[320] Over one-half of all giant congenital melanocytic nevi–associated melanomas develop during the first decade of life.[314,316,317]

**FIGURE 38-4.** Giant pigmented nevus in a 4-year-old child. Notice the “bathing trunk” appearance of the nevus and numerous satellites on all portions of the body. Lesions have faded with the aging of this patient.

3. Xeroderma pigmentosum is a rare (1:500,000) inherited excisional DNA repair disorder characterized by photosensitivity, a greater than1,000-fold increased risk of skin cancer in patients younger than 20 years, and in some cases, neurologic manifestations. [312,318] Malignant skin neoplasms develop in 70% of patients. The median age at diagnosis is 8 years. Fifty-seven percent develop squamous and basal cell carcinomas, and up to 22% develop melanoma. [318]
4. Immunosuppression: Children with immunodeficiencies have a three- to sixfold increased risk of developing melanoma, and those with Hodgkin's disease have an eightfold increased risk.[315] Melanoma after renal transplantation and immunosuppressive therapy has also been described. [319] A significant increase in nevus counts (mean, 66 per patient) has also been observed in children after completion of maintenance chemotherapy for acute lymphoblastic leukemia or Hodgkin's disease.[320]
5. Neurocutaneous melanosis is a rare syndrome characterized by large or multiple congenital nevi associated with meningeal melanosis or melanoma. The majority of patients have giant pigmented lesions along the posterior midline or in the head and neck region. In symptomatic patients, neurologic manifestations are evident by age 2 years and include hydrocephalus, seizures, papilledema, headaches, and mental retardation. Prognosis is poor, with only 18% of patients expected to survive. Leptomeningeal melanoma has been reported in 64% of cases and only 18% of affected children survived. [321] An asymptomatic form of neurocutaneous melanosis characterized by abnormal brain MRI T1 shortening in the amygdala, cerebellum, or pons has been recently described. All patients had giant congenital melanocytic nevi involving the skin underlying the dorsal spine or scalp, and 23% had MRI abnormalities. Yet, only 1 of 46 patients evaluated developed neurological symptoms.[322]
6. Mole phenotype: It is estimated that 44% of melanomas in people younger than 30 years arise in a small nevus that was present at birth or during early childhood.[323,324] The risk of developing melanoma in patients with atypical moles and a negative family history is approximately 5%; however, the risk is significantly higher for patients who are members of melanoma-prone families (two members diagnosed with melanoma).[324] Interestingly, 10% of melanomas occurred in patients younger than 20 years, and the median age at diagnosis of melanoma decreased by 11 to 16 years per generation. [324,325] More recently, germline mutations of the *p16* gene, which localizes to region 9p21, have been implicated in the development of melanoma in families prone to this malignancy.[326]

The majority of published reports of pediatric melanoma are single-institution studies, in which diagnostic criteria, staging systems, and therapy regimens have varied widely. Furthermore, too few patients with advanced-stage disease have been reported, so definitive conclusions regarding therapy recommendations cannot be made. The available literature suggests, however, that the natural history and response to therapy of pediatric melanoma is stage dependent, similar to that in adults. Among 588 pediatric patients reported in ten separate series, the sex distribution was similar among males and females. Most patients were white, and at least 80% of cases presented during the second decade of life. Primary tumors occurred most frequently in the extremities, followed by those in the trunk and the head and neck region. Metastatic disease at presentation was rare, with only 11 cases reported. Associated conditions, such as preexisting mole, pigmented lesion, or giant congenital melanocytic nevus were reported in 115 of the 588 patients. Xeroderma pigmentosum, familial and congenital melanoma, and dysplastic nevus syndrome were seen infrequently.[327]

The more common types of melanomas are characterized by indolent, peripheral enlargement of relatively flat, complex colored, primary lesions. The indolent growth phase (i.e., radial growth phase) may take place over several years, during which the tumor has little competence to metastasize. The ability to metastasize is associated with penetration of the tumor into deeper cutaneous tissues (i.e., vertical growth phase). Common clinical manifestations include increased size of a preexisting mole, bleeding, itching, color change, palpable subcutaneous mass, and palpable lymphadenopathy. [328]

The patterns of spread of melanoma in pediatric patients are in all ways similar to those of adults with the disease, with satellitosis and regional lymph nodes becoming involved before involvement of abdominal viscera, lungs, bone, or brain ( Fig. 38-5). Survival of patients with pediatric melanoma is similar to that of adults and is stage dependent. Thick melanomas, nodal involvement, or metastatic disease at diagnosis predict a poor clinical outcome. In one series, 74% of recurrences were seen in children whose lesions were greater than or equal to 1.5 mm. Other pediatric series showed uncharacteristically high incidences of late recurrences and nodal metastases. In a study from our institution that spanned 21 years, all children with lesions smaller than 1.5 mm survived, but only 10 of 22 patients with 1.5-mm or larger lesions survived. None of the patients whose melanomas were characterized by a Breslow's thickness of less than 1.5 mm developed nodal disease; in contrast, 63% of those whose tumors were at least 1.5 mm in thickness developed nodal metastases.[329]

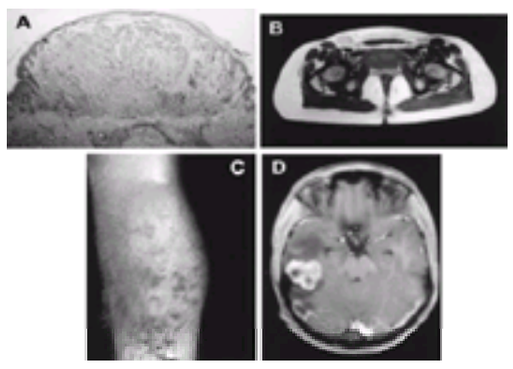

**FIGURE 38-5.** Various clinical and pathologic aspects of pediatric melanoma. **A:** Nodular melanoma in an adolescent. Breslow's thickness at diagnosis was 2.7 mm. **B:** Axial T1 pelvic magnetic resonance imaging (MRI) showing T1 hyperintense right inguinal nodal metastases from malignant melanoma in a 13-year-old girl. **C:** Sixteen-year-old boy who, at the time of recurrence of melanoma, developed multiple in-transit metastases, a phenomenon believed to represent lymphatic dissemination of the disease. **D:** Axial T1 MRI of brain with contrast showing a large enhancing right temporal lobe metastases from melanoma with surrounding edema in a 13-year-old girl.

### *Staging*

Table 38-5 depicts the current AJCC staging system for melanoma of the skin, published in January 2000. This new classification stratifies patients according to the thickness of the primary tumor, presence or absence of nodal metastases, ulceration, or metastatic disease. [330] Incorporation of this system in future pediatric melanoma trials will allow uniform reporting of cases and should facilitate interpretation of results when analyzing and comparing single-institution reports. Because comprehensive guidelines for staging children with newly diagnosed melanoma have not been established, we use the National Comprehensive Cancer Network guidelines at our center to stage the majority of pediatric patients with melanoma. In our experience, however, routine diagnostic imaging of asymptomatic patients can identify metastases in one-fourth of pediatric patients. [331] We therefore recommend that children with malignant melanoma who present with localized thick lesions (greater than 4 mm) and those with regional nodal disease undergo chest CT and MRI of the locoregional nodal draining basin to define the primary tumor burden. Because bone scintigraphy and head MRI do not efficiently detect clinically silent metastases, we do not recommend their routine use in asymptomatic patients with thick lesions.

**TABLE 38-5. CURRENT AMERICAN JOINT COMMITTEE ON CANCER STAGING SYSTEM FOR CUTANEOUS MELANOMA**

### *Treatment*

#### Primary disease

As in adults, early detection and early surgical removal of primary melanoma remain the most effective treatment for children. Suspicious skin lesions (i.e., those with irregular borders, pigmentation, or texture) should be surgically removed and submitted for histopathologic examination. If melanoma is documented, the invasiveness and depth of the lesion should be determined. Lesions less than or equal to 1 mm in thickness should be resected with a 1-cm margin; those 1 to 4 mm are excised with a 2-cm margin. To minimize the risk of local recurrence, we use margins of at least 2 cm for lesions greater than 4 mm in thickness. [332]

The routine use of elective lymph node dissection has been largely discontinued given the results of the most recent adult Intergroup Surgical Melanoma trial in which only a subset of patients, (lesions 1 to 2 mm thick, age younger than 60 years, no ulceration) benefited from this procedure. [333] In addition, the advent of intraoperative lymphatic mapping with selective lymphadenectomy has proven highly effective and sensitive in identifying occult nodal disease. This procedure is routinely used at our center to stage all patients with melanoma who present with lesions greater than or equal to 1mm in thickness.

**Adjuvant Therapy**. The role of adjuvant therapy in pediatric melanoma has not been prospectively studied. An Eastern Cooperative Oncology Group trial documented the efficacy of adjuvant interferon alpha-2b in prolonging relapse-free and overall survival in adult patients with high-risk, completely resected melanoma.[334] However, a subsequent trial has failed to demonstrate a significant survival advantage for patients who received this treatment modality. [335] Thus the role of this treatment modality in children with completely resected nodal disease and with lesions greater than 4 mm remains uncertain and warrants future study.

#### Disseminated Disease

**Chemotherapy**. Dacarbazine has been used before surgery with encouraging results in four children with melanoma. [336] Hayes and Green[337] reported responses to vincristine, dactinomycin, and cyclophosphamide in seven of nine children with advanced-stage melanoma. We studied a regimen that incorporated alternating courses of cisplatin and etoposide to the vincristine/dactinomycin/cyclophosphamide with concurrent interferon alfa-29. Three of four children with advanced stage disease (IIb–IV) who were treated with surgery and chemotherapy remain disease-free, whereas only one of four children with unresected disease survived.

**Interleukin 2**. IL-2 has modest activity in adult melanoma.[338] Two pediatric trials have used IL-2 in the treatment of refractory solid tumors, but no significant responses were observed. Only one response (in a child with renal cell carcinoma) was observed. Currently, there is insufficient information documenting the clinical activity of IL-2 in pediatric melanoma.

**Other Therapies**. Davidoff and colleagues[339] treated children whose melanomas were thicker than 1 mm or had aggressive features (e.g., ulceration or head and neck location) with subcutaneous injections of $2.5 \times 10^7$ irradiated allogeneic cultured melanoma cells. The response, tolerance, or side effects to this treatment were not described in this report.

**Biochemotherapy**. We are currently using a concurrent biochemotherapy regimen devised by Legha and colleagues [340] for patients with metastatic disease. This regimen incorporates cisplatin, dacarbazine, vinblastine, IL-2, and interferon. In adults, 64% of patients achieved an objective response and nearly half of those who achieved a complete response were long-term survivors.

Finally, it is obvious that melanoma may be a preventable disease. With a decrease in the enthusiasm for sun exposure by young persons and with the judicious use of sunscreen products, a significant reduction in the frequency of melanoma and nonmelanoma skin cancer may be expected.

#### Nevoid Basal Cell Carcinoma Syndrome (Gorlin's Syndrome)

Gorlin's syndrome is an autosomal dominant disorder characterized by developmental abnormalities including rib and craniofacial anomalies, odontogenic keratocysts of jaws, epidermal skin cysts, and palmar or plantar pits (Fig. 38-6). In addition, these patients are prone to the development of a variety of tumors, including fibromas of the ovaries and heart.[341] Approximately 5% of patients with Gorlin's syndrome develop medulloblastomas. It is estimated that up to 10% of patients with medulloblastoma have Gorlin's syndrome. The gene found to be mutated in Gorlin's syndrome, *patched,* is located at 9q22 and influences development by regulating transcription of several genes including *gli,* members of the tumor growth factor b, and Wnt family of transcription factors.[342]

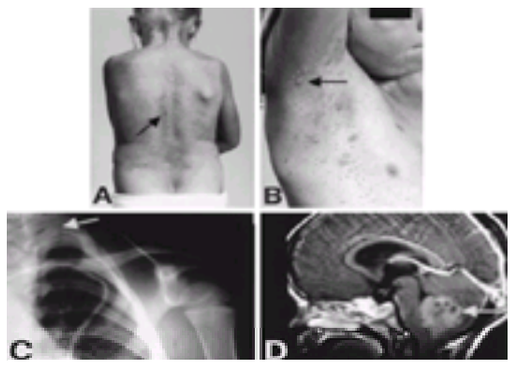

**FIGURE 38-6.** The clinical spectrum of Gorlin's syndrome. **A:** Multiple basal cell carcinomas (*arrow*) along the craniospinal radiation therapy field in a patient with Gorlin's syndrome who was treated for medulloblastoma. **B:** Multiple epidermal cysts and basal cell carcinomas (*arrow*) in the right axillary region. **C:** Posteroanterior radiograph of chest shows fusion of the first and second ribs (*arrow*). **D:** Sagittal T1 brain magnetic resonance imaging demonstrating enhancing fourth ventricle medulloblastoma (*arrow*).

# ONCOLOGIC EMERGENCIES

SUSAN R. RHEINGOLD
BEVERLY J. LANGE

## INTRODUCTION

Emergencies can appear at any time during a child's course of care for cancer. Some emergencies are the initial manifestation of cancer or develop as the diagnosis is being made; others arise as a consequence of therapy or at the time of tumor recurrence. Oncologic emergencies can arise from metabolic perturbations that result from the malignancy or therapy to treat the malignancy, from space-occupying lesions that obstruct vital organs, or from hematologic abnormalities.

This chapter addresses pediatric oncologic emergencies by system—thoracic, abdominal, genitourinary, metabolic, and central nervous system—and summarizes the management of cardiovascular collapse and shock, the end result of uncompensated emergent situations. Chapter 40 reviews management of emergencies associated with cytopenias and hemostasis and the use of blood component therapy. Infectious complications are addressed in Chapter 41 and principles of pain management in Chapter 43.

## CARDIOTHORACIC EMERGENCIES

Respiratory distress is a common presenting symptom of intrathoracic malignancies and is often the sole symptom of a cardiothoracic emergency occurring at any time. The causes of respiratory distress can be classified by their location in the thorax. In the anterior mediastinum, superior vena cava syndrome (SVCS) and superior mediastinal syndrome (SMS) are the major emergencies. Intracardiac masses, cardiac tamponade, and myocardiopathy or myocarditis are the emergent events in the middle mediastinum. Mass lesions in the posterior mediastinum do not cause respiratory symptoms but may cause cord compression (see the section on Neurologic Emergencies). Intrapulmonary processes include infiltrates, pneumothoraces, masses, and fibrosis; intrapleural processes, masses and effusions; and cardiac processes, masses, effusions, fibrosis, and failure.

### Superior Vena Cava Syndrome and Superior Mediastinal Syndrome

*SVCS* refers to the signs and symptoms resulting from compression, obstruction, or thrombosis of the superior vena cava. The term *SMS* is used when tracheal compression also occurs. In children with mediastinal masses, tracheal compression and respiratory embarrassment usually coexist with SVCS and, therefore, *SVCS* and *SMS* often are used synonymously.

#### *Etiology*

SVCS in children is rare. In 1983, Issa et al.[1] summarized the frequency and causes of SVCS in 150 children and adolescents. Although most were thrombotic complications of cardiovascular surgery for congenital heart disease, the most common primary cause of SVCS in children was cancer.[1,2] Mediastinal granulomas, infections such as histoplasmosis, or venous thrombosis from central venous lines (CVLs) may cause SVCS and SMS that are clinically indistinguishable from cancer.[3,4]

Table 39-1 lists the frequency of SVCS and SMS among 3,721 children with cancer treated at St. Jude clinically indistinguishable from cancer.'s Research Hospital.[2] Almost 70% of patients with non-Hodgkin's lymphoma (NHL) and 30% with Hodgkin's disease (HD) presented with mediastinal masses. Patients with neuroblastoma, germ cell tumors, sarcomas, and acute lymphoblastic leukemia (ALL) also were found to have mediastinal masses at diagnosis. In up to 75% of children with mediastinal masses, some respiratory compromise was evident.[5] SVCS was most commonly associated with NHL, followed closely by ALL, but also occurred with other tumors.[2]

| Diagnosis | No. of patients | Mediastinal mass (%) | SVCS with mediastinal mass (%) |
|---|---|---|---|
| Acute lymphoblastic leukemia | 1,464 | 130 (8.4) | 6 (4.6) |
| Acute nonlymphocytic leukemia | 392 | 9 (2.3) | 0 |
| Hodgkin's disease | 333 | 102 (30.6) | 2 (2.0) |
| Non-Hodgkin's lymphoma | 330 | 230 (69.7) | 8 (3.4) |
| Neuroblastoma | 332 | 69 (20.8) | 3 (4.3) |
| Germ cell tumors | 114 | 10 (8.8) | 2 (20.0) |
| Sarcomas | 696 | 26 (3.7) | 3 (11.0) |

From Ingram L, River G, Shapiro DDN. Superior vena cava syndrome associated with childhood malignancy. Analysis of 24 cases. Med Pediatr Oncol 1990;18:476, with permission.

**TABLE 39-1. INCIDENCE OF MEDIASTINAL MASS AND SUPERIOR VENA CAVA SYNDROME (SVCS) AT ST. JUDE CHILDREN'S RESEARCH HOSPITAL BETWEEN 1973 AND 1988**

### *Pathophysiology*

The SVC is a thin-walled vessel with low intraluminal pressure. It is surrounded by lymph nodes and the thymus. Tumor or infection in the mediastinal nodes or thymus can compress the SVC, causing venous stasis. The adjacent pericardium and coronary or collateral vessels fill with tumor or clot. The trachea and right main stem bronchus in young children are more compliant and compressible than in the adult. Symptoms of compression are especially pronounced in infants, as their tracheas and bronchi have small intraluminal diameters. Compression, clotting, and edema combine to minimize tracheal airflow and reduce venous return from the head, neck, and upper thorax, causing the signs and symptoms of both SVCS and SMS.

### *Evaluation*

The most common symptoms of SVCS and SMS in children are dyspnea, cough, dysphagia, orthopnea, and hoarseness (Table 39-2).[2,6] Anxiety, confusion, lethargy, headache, distorted vision, and syncope indicate carbon dioxide retention and central venous stasis. Symptoms typically are aggravated when the patient is supine [as for an abdominal examination or computed tomography (CT) scan] or is placed in a fetal position (as for lumbar puncture). Characteristic physical findings include edema, plethora, and cyanosis of the face, neck, and upper extremities; cervical and thoracic venous distention; conjunctival suffusion and edema; and wheezing or stridor.[2,6] Signs of pleural and pericardial effusions may coexist. In adults, onset of SVCS caused by a malignant tumor, usually lung cancer, is insidious. In children and adolescents, the symptoms often progress rapidly over days.

| Finding | No. (%) |
|---|---|
| Coughidyspnea | 11 (68) |
| Dysphagiaorthopnea | 10 (63) |
| Wheezing | 5 (31) |
| Hoarseness | 3 (19) |
| Facial edema | 2 (12) |
| Chest pain | 1 (6) |
| Pleural effusion | 8 (50) |
| Pericardial effusion | 3 (19) |

From Ingram L, River G, Shapiro DDN. Superior vena cava syndrome associated with childhood malignancy. Analysis of 24 cases. Med Pediatr Oncol 1990;18:476, with permission.

**TABLE 39-2. SYMPTOMS AND PHYSICAL FINDINGS IN PATIENTS WITH SUPERIOR VENA CAVA SYNDROME AT INITIAL PRESENTATION**

A child with some or all of these signs and symptoms must undergo chest radiography. Figure 39-1A shows mediastinal widening on a posteroanterior film. Figure 39-1B shows the mass to be in the anterior mediastinum as it is opacifying the retrosternal space. Most children with SVCS will have a mass in the anterosuperior mediastinum. Pleural and pericardial effusions are more common in NHL than in HD or other malignancies.[6] A chest radiograph may show tracheal deviation. Patients with tumors larger than 45% of the transthoracic diameter are more likely to be symptomatic than are those with ratios of less than 30% (i.e., smaller tumors).[6,7] CT scans can delineate the distortions of normal anatomy and more accurately assess the extent of tracheal compression. CT can be performed with the patient in the prone position if the supine position aggravates the respiratory distress. If the cause of symptoms is suspected to be a thromboembolism or pericardial effusion, an echocardiogram should be obtained. Pulmonary function tests and volume flow loop assess pulmonary reserve and resilience.

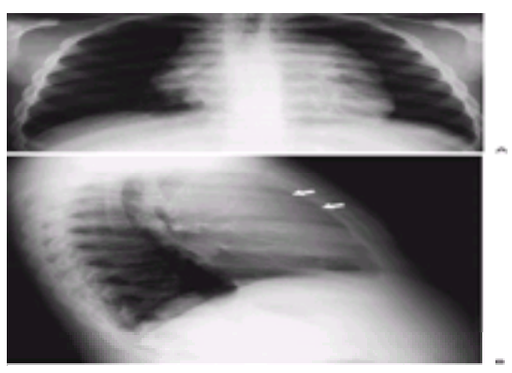

**FIGURE 39-1.** Posteroanterior **(A)** and lateral **(B)** views of the chest show anterior mediastinal widening in a 16-year-old boy with Hodgkin's disease. Note soft tissue opacifying the retrosternal space (*arrows*) on the lateral view **(B)**. (Courtesy of James S. Meyer, M.D., Children's Hospital of Philadelphia.)

When cancer is the probable cause of SMS, it is desirable to obtain a tissue specimen for diagnosis. However, a child with SVCS or SMS may not tolerate anesthesia for a mediastinal biopsy.[8] During general anesthesia, respiratory muscle tone decreases, abdominal muscle tone increases, the caudal movement of the diaphragm disappears, bronchial smooth muscle relaxes, and lung volume diminishes.[8] These changes aggravate the effects of extrinsic compression of the vena cava. Tracheal intubation may be extremely difficult, and some patients will not be able to be extubated until the tumor bulk has been reduced. Conscious sedation or anti-anxiolytics may also be contraindicated, as they decrease respiratory drive and dilate peripheral vessels, thereby reducing venous return.[8,9]

Several recent reports suggest a stepwise approach to diagnosis.[8,9] An algorithm appropriate for pediatric patients is shown in Figure 39-2. Diagnosis should be made in the most expeditious and least invasive manner possible. A differential diagnosis must be generated on the basis of history, physical examination, and simple laboratory tests. A complete blood cell count (CBC) showing cytopenias or blast cells may indicate leukemia, whereas a leukocytosis with an extreme leftward shift may favor diagnosis of a bacterial infection, which rarely causes SVCS or SMS. Marrow aspiration performed under local anesthesia with the patient upright or prone may reveal leukemia or lymphoma. In a patient with a central venous catheter, echocardiography may demonstrate a thrombus. Pleurocentesis or pericardiocentesis can offer immediate relief and provide diagnostic material. If an enlarged peripheral lymph node is present, node biopsy is faster and less invasive than is a

mediastinal biopsy. Patients who cannot tolerate these procedures will not tolerate general anesthesia or even conscious sedation.

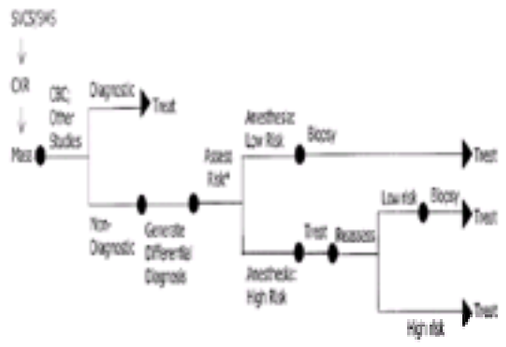

**FIGURE 39-2.** Assessment and management of a child with respiratory distress, superior mediastinal syndrome (SMS), or superior vena cava syndrome (SVCS) and an anterior mediastinal mass. Initial assessment for anesthetic risk may include computed tomography of the chest, echocardiography, pulmonary function tests, and flow volume loop. If the patient cannot tolerate these studies, or if the studies indicate severely compromised cardiopulmonary reserve, the patient is a high anesthetic risk. CBC, complete blood cell count; CXR, chest radiograph.

***Therapy***

In a child who presents with SVCS or SMS as an initial symptom of malignancy, establishing a tissue diagnosis may be impossible, and starting empiric therapy may be medically necessary. Traditionally, emergency therapy consisted of irradiation, as most lymphomas are exquisitely radiosensitive. However, an increasingly popular trend is to initiate emergent systemic chemotherapy. No established standards exist.

Between 1988 and 1994, 10% of pediatric oncology patients at the Children's Hospital of Philadelphia referred for emergent radiotherapy had respiratory difficulties associated with SMS; 83% responded to the radiotherapy.[10] In NHL, radiotherapy is effective, and improvement can occur within 12 hours.[10] However, some lymphomas are so radioresponsive that doses as low as 200 cGy to a circumscribed area of the tumor can cause rapid dissolution of the mass and regional lymph nodes, making subsequent tissue diagnosis impossible. Loeffler et al.[11] reported that of 19 patients with mediastinal masses, emergency prebiopsy irradiation rendered the histologic specimen uninterpretable in 8. Seven of the eight patients were treated empirically for HD or NHL. Four had no tumor recurrence, three had recurrence with the disease they were assumed to have had, and the one untreated patient developed recurrent seminoma. The authors point out that patient management was not altered by prebiopsy therapy or by continued empiric therapy.[11]

A second problem is respiratory deterioration, presumably from tracheal swelling after irradiation. The phenomenon of postirradiation deterioration is limited to children and adolescents, perhaps because of the greater compressibility of their respiratory structures and the inability of their relatively narrow lumina to accommodate postirradiation edema. Increasingly, radiation oncologists are using highly focused radiation portals, such as a small field centered on the trachea only, to circumvent the problem of swelling of small airways.[10,12] Another option consists of using small, bilateral, opposing fields encompassing the trachea, SVC, and proximal right auricle. The daily dose is governed by the presumed radiosensitivity of the tumor, with 100 to 200 cGy given twice daily for radioresponsive tumors such as lymphoblastic lymphoma or leukemia. A dose of intravenous methylprednisolone (1 mg per kg) followed by prednisone at 40 mg per $m^2$ daily, divided into two or three doses, may prevent worsening of the respiratory distress but may confound the ability to make a diagnosis.

Chemotherapy, including steroids or cyclophosphamide or both, is a reasonable alternative to irradiation. Unfortunately, chemotherapy can also confound the diagnosis, as the histologic picture may be rendered uninterpretable within 48 hours.[7,9] Failure to persist with treatment for the presumed leukemia or lymphoma, even if a histologic diagnosis is not made, may allow the disease to progress to a more advanced stage.[9,11] Chemotherapy rather than irradiation is indicated in ALL accompanied by a high leukocyte count and a mediastinal mass causing SMS or SVCS. Chemotherapy treats both life-threatening problems: SVCS and hyperleukocytosis. However, if renal failure is present or impending, irradiation is the treatment of choice for the SVCS or SMS, to avoid tumor lysis syndrome (TLS).

Progressive symptoms may be caused by a less responsive neoplasm such as a teratoma, large-cell lymphoma, neuroblastoma, germ cell tumor, or benign tumor, making surgical resection inevitable. Surgery should be performed with the patient in the semi-Fowler's position, with advance preparations made for a change of position to lateral or prone, and with cardiopulmonary bypass facilities and a rigid bronchoscope on standby.[8]

If signs or symptoms of SVCS develop in a child with a CVL, one must be concerned about an extensive thromboembolism. This situation is usually a subacute emergency. If there are no contraindications, the catheter should be kept in place initially for infusion of thrombolytic therapy. Recent recommendations from the Children's Thrombophilia Network for systemic thrombolytic therapy are to use tissue plasminogen activator (TPA) at a dose of 0.1 to 0.6 mg per kg per hour for 6 hours.[13] Fibrinogen, fibrin split products, prothrombin time, and activated partial thromboplastin time should be monitored closely. Systemic heparin therapy should be begun either during or immediately after thrombolytic therapy with a loading dose of 75 units per kilogram, followed by a maintenance dose of 20 units per kilogram for children older than 1 year. The infusion rate should be modified to achieve a partial thromboplastin time of 60 to 85 seconds.[13] For less symptomatic CVL-associated thromboembolisms, heparin alone at the aforementioned doses may suffice and has fewer systemic side effects. Continued anticoagulation for 3 to 6 months with oral Coumadin or subcutaneous low-molecular-weight heparin is recommended.[14]

## Pleural and Pericardial Effusions

***Etiology and Pathogenesis***

An effusion represents the escape of fluid into a potential space. Effusions are exudates or transudates. Exudates have protein concentrations in excess of 2.5 g per dL, a specific gravity greater than 1.015, a pH of less than 7.3, and a high white blood cell (WBC) count. Exudates are caused by either the primary malignancy or infection. In contrast, transudates result from a sympathetic response to tumor in the chest or abdomen, fluid overload, heart failure, or hypoproteinemia. Protein concentration, specific gravity, pH, and cell counts are low in transudates. Chylous effusions can occur from obstructed lymphatic channels.[15]

***Evaluation***

Symptoms of both pericardial and pleural effusions include dyspnea, orthopnea, chest pain, and cough.[16] Small, clinically silent pleural and pericardial effusions often are detected incidentally on radiographs and echocardiograms. Asymptomatic effusions can be monitored without intervention. However, a large accumulation of pericardial fluid can cause cardiac tamponade and rapid decompensation. Therefore, emergent thoracentesis or pericardiocentesis is indicated to relieve respiratory or cardiac distress, obtain diagnostic fluid, or eliminate a potential reservoir for such drugs as methotrexate. Fluid should be sent for measurement of cell count, protein content, cytology, Gram stain, culture, and assays of appropriate immunologic and biologic markers.

***Therapy***

In a child with untreated cancer and respiratory distress, a single removal of fluid often is sufficient, as the fluid usually does not reaccumulate once therapy is under way. In contrast, children with advanced malignant disease may develop recurrent effusions that compromise their duration and quality of life. Palliative measures include repeated centeses, placement of a percutaneous catheter, or instillation of a sclerosing agent into pleural or pericardial cavities to cause irritation and adhesion of the potential space. Owing to the resultant scarring, fibrosis, and adhesions, the instillation of a sclerosing agent can make difficult the interpretation of images obtained subsequently. In pediatrics, the use of sclerosing agents usually is reserved for palliation of refractory pleural disease.

Tetracycline is the most widely used sclerosing agent and has the fewest side effects. The effusion is drained, and 500 to 1,000 mg of tetracycline in 20 mL of 0.9% saline is instilled into the cavity.[17,18] The procedure may need to be repeated daily for several days. In one study, tetracycline prevented reaccumulation of pericardial

fluid in 30 of 33 patients.[18] A review of 1,168 patients showed a 93% success rate with talc.[16] Talc itself is inexpensive, but its instillation requires thoracoscopy and, usually, general anesthesia. In 8 of 11 children with malignant solid tumors, intracavitary cisplatin, 100 to 200 mg per $m^2$, with 16 to 52 g of thiosulfate per $m^2$ (or 300 mL per $m^2$ in an infant) in 2 L of warmed normal saline or 50 to 210 mg per $m^2$ without thiosulfate rescue eliminated the intracavitary disease.[19] Intracavitary therapy achieved drug concentrations 40-fold higher than systemic therapy.[19] If sclerosing agents fail, surgical pleurectomy or pericardiectomy may be necessary. However, surgery entails substantial morbidity and potential mortality for patients with resistant metastatic disease.

## Cardiac Tamponade

### *Etiology and Pathogenesis*

Cardiac tamponade occurs when the left ventricle fails to maintain output because of compression by pericardial fluid or leukemic infiltration, inflammation or infection of the pericardium, constrictive fibrosis from previous irradiation, or occlusion from tumors of the cardiac muscle or endocardium.[20,21] Infectious pericarditis or myocarditis probably is the most common cause of tamponade in immunocompromised children with cancer. Intracardiac masses such as marantic vegetations or clots also can cause cardiac tamponade. A Wilms' tumor thrombus can extend from the renal vein through the tricuspid valve to fill the right cardiac chambers. Although leukemia may cause pericardial effusions at diagnosis, cardiac tamponade is rarely the presenting symptom of an undiagnosed malignancy.

### *Evaluation*

Gradual accumulation of fluid allows the pericardium to accommodate a large volume, but rapid accumulation of several hundred milliliters can cause sudden decompensation. Symptoms of impending tamponade resemble those of congestive heart failure: cough, chest pain, dyspnea, hiccups, and abdominal pain. Signs include tachycardia, cyanosis, hypotension, and a pulsus paradoxus of greater than 10 mm.[22] Tamponade must be differentiated from congestive heart failure, infectious pericarditis or myocarditis, and therapy-induced cardiomyopathy. Constrictive pericarditis may cause friction rubs, diastolic murmurs, and atrial arrhythmias.

Radiographs of large pericardial effusions often show a typical “waterbag” cardiac shadow on an anteroposterior view and an abnormal space between the pericardial fat and pericardium on the lateral view. Pleural effusions may also be noted. The echocardiogram may show low-voltage QRS complexes, flattened or inverted T waves, and electrical atrial and ventricular alternans.[22] Echocardiography of the posterior wall displays two echoes, one from the cardiac muscle and one from the pericardium. An echocardiogram may also reveal a thickening of the pericardium consistent with pericarditis or pericardial tumor.

### *Therapy*

Supportive care for malignant pericardial effusion and constrictive pericarditis consists of hydration, oxygen, and patient positioning to maximize cardiac output. Diuretics are contraindicated as hypovolemia decreases stroke volume.[22] Definitive treatment of tamponade caused by an effusion is immediate removal of fluid under echocardiographic guidance. Of nine pediatric patients treated by percutaneous catheter drainage at the Memorial Sloan-Kettering Cancer Center, all experienced symptomatic relief, and eight showed complete echocardiographic resolution.[20] Alternative but more invasive procedures, such as subxyphoid pericardiotomy or pericardial window, are associated with a high diagnostic accuracy, low morbidity and mortality, and a high rate of success.[21] These procedures are the treatment of choice for persistent symptomatic effusion that is unresponsive to medical management and for tamponade from constrictive pericarditis. Pericardial fluid should be sent for protein assessment, cell counts, Gram's stain, culture, and cytology. Instillation of sclerosing agents should be reserved for palliation in patients with recurrent or refractory tumor. In patients with a Wilms' tumor thrombus extending into the right side of the heart, if the mass does not occlude the chambers, therapy with dactinomycin and vincristine may reduce the size of the thrombus within a week (see Chapter 30).

## Massive Hemoptysis

### *Etiology and Evaluation*

Massive blood loss into the respiratory tree can cause thrombus formation within the bronchial tree, leading to asphyxiation, or less likely, exsanguination. In general, pediatric tumors do not cause massive hemoptysis. The most common etiology of mild hemoptysis in an oncology patient is aspiration of blood from epistaxis, whereas the most common cause of massive hemoptysis is invasive pulmonary aspergillosis. The incidence of hemoptysis in pulmonary aspergillosis ranges from 2% to 26%.[23] The chest radiograph may show a nodular or cavitary lesion, a peripheral wedge-shaped infiltrate, or disseminated infiltrates. A CT scan should be obtained to determine the extent of fungal disease (Fig. 39-3). The differential diagnosis includes all invasive fungi and, less frequently, bacterial pneumonias and consolidations with such invasive organisms as *Staphylococcus aureus* and *Klebsiella* and *Pseudomonas* species. A CBC, along with prothrombin time, partial thromboplastin time, and assessment of fibrinogen and fibrin split products should be obtained immediately to look for coagulation abnormalities.

**FIGURE 39-3.** Computed tomographic image of the chest viewed at lung windows shows a fungus ball (*curved arrow*) within an air cyst in a 20-year-old woman with Langerhans' cell histiocytosis. Note extensive cystic disease and parenchymal destruction in both lungs. (Courtesy of James S. Meyer, M.D., Children's Hospital of Philadelphia.)

### *Therapy*

Therapeutic objectives are to prevent asphyxiation, localize the site of the bleeding, and arrest hemorrhage. If the site of bleeding is known, the patient should lie on the side of the hemorrhage to prevent collection of blood into the normal lung. Preventing asphyxiation may require intubation. Oropharyngeal tubes should be large enough to allow passage of a bronchoscope.[22] Nasotracheal intubation may cause epistaxis, making localization of the bleed difficult.[22] Thrombocytopenia or a coagulopathy should be corrected and erythrocytes transfused as needed. When the patient has been stabilized, a chest radiograph should be obtained and bronchoscopy undertaken if the hemoptysis persists. If the source of bleeding is identified transcatheter embolization (selective intrabronchial coagulation with a hemostatic complex consisting of the fibrin precursors, calcium chloride, and thrombin) or occlusion of the hemorrhaging vessel with a balloon catheter have proven successful in patients with massive pulmonary hemorrhage from causes other than *Aspergillus* infection.[23,24,25 and 26] Unfortunately, these measures are unlikely to be successful in massive hemoptysis from *Aspergillus*, with its extensive angioinvasion and necrosis. Shapiro et al.,[27] using a subcutaneous No. 12 French Ring-McLean sump catheter, first to aspirate the cavity and then to instill *N*-acetylcysteine (10% solution, 2 mL in 20 mL of sterile saline) and 40 mg amphotericin B, report successful treatment of massive hemoptysis in six patients with localized aspergillomas.[27] Instillations were separated by 8 hours.

In most cases of hemoptysis, the bleeding eventually stops. In a patient with known fungal disease experiencing recurrent episodes of hemoptysis, the lesion should be widely excised, which may involve resection of a bronchopulmonary segment or a lobectomy. Medical management of mild hemoptysis from pulmonary aspergillosis is possible as cavities seal off and form linear scars (see Chapter 41). If medical management is undertaken, it is prudent to manage the patient in the hospital until the hemoptysis has resolved and the lesion is regressing. If an undiagnosed malignancy is found to be the cause of the hemoptysis, surgical resection is indicated when possible. Initiating chemotherapy or emergent radiotherapy can also improve symptoms rapidly.

### Pneumothorax or Pneumomediastinum

#### *Etiology and Evaluation*

A *pneumothorax* is air in the pleural space; *pneumomediastinum* is air in the mediastinum, often with subcutaneous emphysema. A tension pneumothorax arises when inspired air accumulates in the pleural space and is not expelled with expiration due to a one-way valve effect. A tension pneumothorax eventually will cause mediastinal shift and circulatory collapse.[28]

A pneumothorax or pneumomediastinum is a rare presenting symptom of an undiagnosed malignancy. Either is more likely due to infection, chemotherapy-induced emesis, esophageal perforation, recurrent or metastatic disease, pulmonary fibrosis from radiation or bleomycin, pulmonary histiocytosis, or idiopathic causes.[29,30] and [31]

Patients present with cough, dyspnea, or pleuritic chest pain, but often a pneumothorax is found incidentally on chest radiography. Examination may show decreased breath sounds on the affected side, tachycardia, tachypnea, shifting of the trachea, hyperresonance to percussion, or subcutaneous emphysema.[28] A chest radiography may show a collapsed lung. In pneumomediastinum, air can be seen tracking through the soft tissue and under the skin.[30] Shifting of the cardiac shadow and trachea indicates a tension pneumothorax that must be relieved immediately.[28] Pulse oximetry or an arterial blood gas evaluation can be used to assess oxygenation. CT with contrast esophagography can rule out esophageal perforation as a cause of pneumomediastinum.[30]

#### *Treatment*

The patient should immediately be placed on 100% oxygen. If the lesion is small, oxygen may suffice. If the lesion is large or a tension pneumothorax or pneumomediastinum is present, the excess pleural or mediastinal air must be evacuated.[28] Needle thoracentesis can be performed immediately, but a chest tube should be placed for long-term evacuation.[29] Tension pneumomediastinum can be relieved using a subxiphoid incision and placement of a chest tube retrosternally.[30] In the case of recurrent pneumothoraces, pleurodesis with mechanical abrasion or a chemical agent (see the section Pleural and Pericardial Effusions) can prevent recurrence. Treatment of the underlying problem, such as antibiotics for infections or steroids for pulmonary fibrosis, should be initiated as soon as the patient is stabilized.[30]

### Retinoic Acid Syndrome

#### *Etiology and Pathophysiology*

All-*trans*-retinoic acid (ATRA) is used to treat acute promyelocytic leukemia (APML), but up to 26% of patients develop the retinoic acid syndrome 2 days to several weeks after starting ATRA.[32] Overall mortality ranges from 5% to 13%.[32] Manifestations include unexplained fever, respiratory distress, weight gain, fluid retention, pleural and pericardial effusions, hypotension, and renal failure. The syndrome only occurs during induction therapy and appears to be unique to patients with APML.[32]

The onset of symptoms often coincides with the development of hyperleukocytosis that occurs as a result of the ATRA-induced proliferation and differentiation of leukemic promyelocytes. Autopsy shows pulmonary interstitial infiltration with maturing myeloid cells and endothelial cell damage. The pathogenesis is unknown. As the retinoic acid syndrome has been described in patients with low peripheral WBC counts, it is unlikely to be only a result of the mechanical effects of high numbers of leukocytes. Release of cytokines that enhance capillary permeability, promote leukocyte aggregation, and up-regulate leukemic cell binding to the endothelium may contribute to the retinoic acid syndrome.

#### *Evaluation and Differential Diagnosis*

The retinoic acid syndrome should be considered in any patient who develops respiratory distress while receiving ATRA. Chest radiography may reveal pulmonary edema or infiltrates and a pleural or pericardial effusion. The differential diagnosis includes pneumonia or sepsis with bacteria or fungi, congestive heart failure, acute respiratory distress syndrome, or any other cause of interstitial pneumonitis.

#### *Therapy*

If the retinoic acid syndrome develops, dexamethasone, 10 mg intravenously every 12 hours in adults and 0.5 to 1.0 mg per kg per dose every 12 hours in children, often reverses the process.[32] ATRA and other chemotherapeutic agents may be withheld if the symptoms are life threatening. When the symptoms resolve, ATRA therapy may resume at a reduced dose and under close observation. The dose can be slowly escalated back to full dose over several days.[32]

## ABDOMINAL EMERGENCIES

In the 1970s and early 1980s, abdominal emergencies in cancer patients were managed with intensive medical therapy and avoidance of surgical intervention; the outcome, however, was poor.[33,34] More recently, judicious use of surgery has led to better overall results.[34] Today advances in diagnostic imaging, interventional radiology, endoscopy, and laparoscopy allow earlier diagnosis with less invasive management overall. Even when an acute abdomen in a child with cancer appears to be treatable with medical management alone, an early surgical consultation is advisable.

### Etiology and Pathophysiology

Although a child with cancer can develop an acute abdomen for the same reasons as can any other child, an acute abdomen unrelated to the underlying malignancy or its treatment is unusual.[34] Many uncommon abdominal emergencies occur commonly in the immunocompromised host, including esophagitis, gastric hemorrhage, typhlitis, perirectal abscess, hemorrhagic pancreatitis, and massive acute hepatic enlargement from tumor.[35,36]

Abdominal emergencies in the child with cancer arise because of hemorrhage, mechanical obstruction, perforation, and inflammation.[34,37,38] Hemorrhage may result from thrombocytopenia, coagulopathy, mucosal ulceration, or abnormal tumor vessels. Obstruction results from compression of a gastrointestinal lumen by a tumor or abscess or from therapy-induced ileus. Perforation can result from unresolved obstruction, localized ulceration, and segmental necrosis. Abdominal processes that are localized in healthy children may be generalized in the neutropenic or immunosuppressed child. Moreover, the inflammatory response may be blunted by a lack of WBCs. Wound healing may be slow because of the effects of malnutrition and chemotherapeutic agents, notably corticosteroids, on fibroblast proliferation and collagen production.[39]

### Evaluation and Differential Diagnosis

Pain is the principal symptom of an acute abdominal process, regardless of the patient's state of compromise ( Table 39-3).[36] Determination of the location, quality, and timing of pain in relation to status of the cancer, recent medications, and surgical history is important. Gastrointestinal hemorrhage is a sign of a serious intra-abdominal process. Changes in vital signs (including fever, hypertension or hypotension, and tachycardia), the presence of blood in vomitus or stool, abdominal distention, or absence of flatus or stool are less specific indications of an acute abdomen. At the same time, the practitioner must remember that in an immunosuppressed patient, fever does not always accompany infection.

**TABLE 39-3. DIFFERENTIAL DIAGNOSIS OF ABDOMINAL PAIN IN PEDIATRIC CANCER PATIENTS**

The practitioner should perform the examination in a manner that causes the least discomfort possible. Encouraging the child to participate may make the examination easier. On observation, one should note whether the child lies still, is willing to move, or winces with cough, movement, or motion of the bed. Observation may also reveal distention, asymmetry, and surgical scars. Auscultation can help to differentiate ileus from obstruction. Complete absence of bowel sounds or waves, rushes, and paroxysms are more likely indications of obstruction. An occasional tinkle or drip-drop plunking sound is often heard when an ileus is present. Compressing the head of the stethoscope gently into the abdomen during auscultation can reveal guarding or tenderness.

Inspection of the perineum and anus is important in the febrile neutropenic patient. Although rectal examination is mandatory to evaluate obstruction and peritonitis even in a neutropenic patient, such an examination should be performed once by an experienced examiner. Thrombocytopenia, neutropenia, and pain are not contraindications to a gentle rectal examination (e.g., using the fifth finger in infants). Pain detected on rectal examination may be the result of generalized serositis, mucositis, or abscess.

## Laboratory and Diagnostic Studies

Selective use of laboratory and radiographic studies may distinguish the child who requires immediate surgical intervention from one who will respond to medical management. Serial CBCs can help monitor hemorrhage and reveal neutropenia that interferes with pus and abscess formation. Blood cultures that are persistently positive despite a patient's treatment with appropriate antibiotics may indicate the presence of an abscess or necrotic bowel. Electrolyte changes may reveal metabolic deficits from fluid shifts before such deficits are clinically apparent. Traditionally, abdominal paracentesis and diagnostic lavage were performed to give information about extraluminal bleeding, intestinal perforation, or infection. These techniques are being replaced by laparoscopy, which permits therapeutic intervention in addition to offering diagnostic potential. [40]

Diagnostic radiologic studies begin with supine, erect, and left lateral decubitus abdominal films. [41,42] Obstruction, especially high small-bowel obstruction, pneumatosis intestinalis, and intra-abdominal free air, can be diagnosed by these studies. A chest radiograph may reveal pneumonia as the etiology of upper quadrant abdominal pain. Barium studies may help to diagnose esophagitis or colitis, but direct examination with endoscopy or colonoscopy has replaced contrast studies in the evaluation of the gastrointestinal tract in both immunocompromised and healthy children. [42] Abdominal ultrasonography (US), CT, magnetic resonance imaging (MRI), and angiography all may be used to locate and characterize mass lesions. In a large retrospective study, the presence of peritoneal signs on examination and pneumatosis intestinalis on radiography were highly associated with the presence of an acute surgical process in children receiving chemotherapy. [34]

## Hemorrhage

### *Esophageal Varices*

Esophageal varices can develop as a consequence of fibrosis, cholangitis, and cirrhosis. They occur in patients with Langerhans cell histiocytosis, refractory abdominal tumors compressing the portal vein, or chronic viral hepatitis. Variceal bleeding is brisk, and patients may have associated hematemesis and melena. A CBC, prothrombin time, partial thromboplastin time, and blood type and cross-match should be obtained immediately. Initial management includes elevation of the head of the bed to 30 to 45 degrees, judicious volume expansion with normal saline or Ringer's lactate solution, and correction of anemia. Overexpansion may contribute to continued bleeding, rebleeding, thrombocytopenia, and coagulation abnormalities. [43] Febrile patients should receive broad-spectrum antibiotics, as bleeding varices may be a sign of sepsis in a patient with cirrhosis. Passage of a nasogastric tube and gastric lavage may be initiated as follows: 50-mL volume of normal saline at room temperature through a 12 French tube in infants, and 100 to 200 mL through a 14 French tube in older children. [43] Lavage should continue for 5 to 10 minutes, and a record should be kept of volumes in and out. [43]

Emergent management is indicated if bright red blood persists in the lavage fluid. Systemic infusion of vasopressin through a large-bore intravenous line or CVL decreases blood flow through the portal circulation. Vasopressin infusion rates are as follows: in children younger than 5 years, 0.1 unit per minute, increasing hourly by 0.05 units per minute to a maximum of 0.20 units per minute; in children aged 5 to 12 years, 0.30 units per minute; and in those children older than 12 years, 0.40 units per minute.[43] Infusion should continue for 12 to 24 hours, with cardiac monitoring for evidence of myocardial ischemia or arrhythmias and frequent observation for signs and symptoms of limb ischemia. If bleeding persists, endoscopy with endoscopic variceal ligation or sclerotherapy may be useful, preferably performed within hours of the onset of bleeding. [43] Balloon tamponade under direct observation with a Sengstaken-Blakemore tube or Linton tube may control refractory bleeding but is associated with considerable morbidity and mortality. [43] Splenorenal shunts are a last resort.

### *Upper Gastrointestinal Hemorrhage*

Hematemesis and melena may consist of blood swallowed from epistaxis or oropharyngeal mucositis or may signify upper gastrointestinal hemorrhage. Children with cancer are prone to multiple punctate, shallow gastric and duodenal ulcers (i.e., stress ulcers, Cushing's ulcers). Children taking high-dose corticosteroids, those with increased intracranial pressure, and those who underwent high-dose irradiation are at especially high risk of gastritis and ulcers. [44,45] Chemotherapy-induced emesis can cause Mallory-Weiss tears, which are mucosal lacerations at the gastroesophageal junction resulting from large gradients between the intragastric and intrathoracic pressure incurred during emesis.

Children with increased intracranial pressure receiving steroids for posterior fossa tumors and any patient on long-term steroid therapy should be treated empirically with antacids or an $H_2$-blocker (ranitidine, 1.0 to 1.5 mg per kg intravenously every 6 hours or 2 mg per kg orally twice daily). [43] Medical management of bleeding consists of $H_2$-blockers, antacids, lavage, and correction of thrombocytopenia and coagulation abnormalities, as described for esophageal varices. Endoscopy is indicated for uncontrolled or recurrent bleeding, and hemostasis may be achieved with a heater probe or multipolar electrocoagulation. [43] Sclerotherapy is not indicated. Surgery for persistent bleeding must be individualized but most often entails vagotomy, pyloroplasty, and oversewing of the ulcer.

### *Lower Gastrointestinal Hemorrhage*

Typhlitis resulting from infection with *Clostridium difficile,* cryptosporidium, and fungi are associated with bloody stools. Intussusception due to tumor, surgery, or an abscess can cause intermittent bleeding or “currant-jelly” stools. Most major lower gastrointestinal hemorrhage in the pediatric cancer patient is multifactorial (e.g., *C. difficile* enterocolitis in a child with thrombocytopenia and coagulopathy). [45] Hemorrhoids and anal fissures occasionally cause bleeding in children with cancer. Rarely is the bleeding significant, often being reported as blood in the toilet bowl or on the toilet paper. Management is directed at each of the underlying causes.

## Gastrointestinal Obstruction

The differential diagnosis of bowel obstruction in the child who has had adjuvant therapy or previous abdominal surgery includes obstipation or paralytic ileus induced by vinca alkaloids, narcotics, or tricyclic antidepressants, adhesions or strictures, and intussusception. Small-bowel intussusception usually occurs days to weeks

postoperatively (Fig. 39-4).[46] Although rare in children, bowel obstruction from primary cancer may be the presenting symptom of a Burkitt's lymphoma of the ileum. It may also complicate palliative care in patients with refractory sarcomas, particularly desmoplastic small-cell sarcoma, or with typical adult colon or ovarian stromal cell cancer. Presacral teratomas and pelvic sarcomas may occlude the rectum.

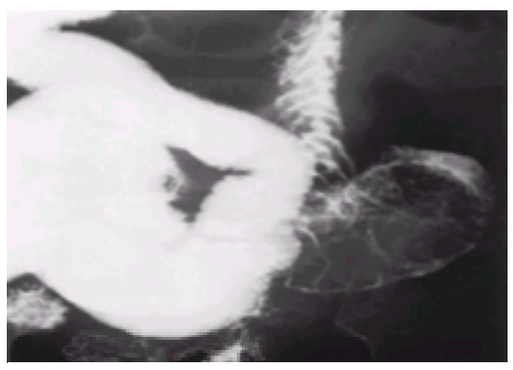

**FIGURE 39-4.** Contrast study of a 3-year-old girl 6 days after removal of a Wilms' tumor shows evidence of complete small-bowel obstruction. The study illustrates a filling defect from small-bowel intussusception.

A patient history, physical examination, and plain-film radiographs that document obstipation can help to differentiate between narcotic or vincristine-related ileus and a surgical abdomen. Small-bowel obstruction is managed initially by taking a patient off anything administered by mouth and placing a nasogastric tube for decompression. A Miller-Abbott or other long intestinal tube alone may be indicated immediately postoperatively, but its use is unwarranted in the child who has had an abdominal procedure in the distant past. Evaluation for the underlying etiology should proceed as described in the section Laboratory and Diagnostic Studies. Use of a stool softener and passage of a small, well-lubricated rectal tube may relieve rectal obstruction until cytotoxic therapy reduces the tumor mass.

### Gastrointestinal Perforation

Perforation may be the outcome of unresolved obstruction, ulcers, or gastritis unresponsive to medical therapy, infections such as typhlitis, or erosion by the primary tumor.[36] In the case of abdominal Burkitt's lymphoma, perforation may occur at presentation, during steroid therapy, or after clinical resolution in association with lysis of a penetrating metastasis. Abdominal radiographs may reveal air under the diaphragm, tracking into the liver and along the flank. Perforations are a surgical emergency and are managed either by resection of the affected area and secondary closure or by primary reanastomosis.[36] In massively disseminated abdominal Burkitt's tumor, cytotoxic therapy may be necessary to reduce the tumor burden before surgical access is possible.

### Gastrointestinal Infection and Inflammation

Fungal or viral esophagitis, the most common esophageal problem in children with cancer, is discussed in Chapter 41. Neutropenic enterocolitis, typhlitis, and appendicitis have very similar presentations in children with cancer. Occasionally, the more commonplace abdominal emergencies in healthy children, such as appendicitis, are overlooked in the oncology patient. At St. Jude Children's Research Hospital, 16 cases of appendicitis were seen among 6,099 children with cancer (0.5%).[47] Fourteen of the cases occurred among the 2,794 children with acute leukemia.[47] The clinical diagnosis was delayed in 37.5%, with typhlitis being the most common confounding consideration. In diagnosing appendicitis, both US and CT scans are superior to clinical evaluation alone.[42,48]

Whereas appendicitis may be the cause of right lower quadrant pain in the child with cancer, in the child with prolonged neutropenia, typhlitis is the major concern. Typhlitis is a necrotizing colitis localized to the cecum. Fever usually is present, although this is an undependable sign. Typhlitis usually occurs subsequent to cytotoxic chemotherapy, but one 3-year-old child had typhlitis on presentation of ALL.[49] Shamberger et al.[50] found that one-third of patients with acute myelogenous leukemia (AML) had documented typhlitis during induction therapy.

Bacterial or fungal invasion of cecal mucosa may progress from inflammation to full-thickness infarction and perforation. *Pseudomonas* species, *Escherichia coli*, and other gram-negative bacteria, *S.aureus*, alpha-hemolytic streptococci, and *Clostridium* species are the common bacterial pathogens. *Candida* and *Aspergillus* species are the major fungal pathogens.[49,50,51,52] and [53] Fungus was found at postmortem examination in 24% of patients with leukemia and typhlitis.[53]

Radiographic studies may demonstrate pneumatosis intestinalis or nonspecific thickening of the bowel wall. In a retrospective review of 24 children with typhlitis, Sloas et al.[52] found that CT and US were more sensitive than plain-film radiography: False-negative rates were 15% for CT, 23% for US, and 48% for plain-film radiography. Figure 39-5 exhibits the appearance of typhlitis on a CT scan.

**FIGURE 39-5.** Computed tomographic scan showing a poorly defined soft tissue mass and indicating a phlegmon (*arrowheads*) and thickened cecal wall (*curved arrow*) in a patient with typhlitis. (Courtesy of Dr. James Meyer, Children's Hospital of Philadelphia.)

In the past, the mortality rate from typhlitis ranged from 20% to almost 100% with either surgical or medical treatment.[49,50,52,54] Shamberger et al.[50] have proposed four criteria for surgical intervention in typhlitis: (a) persistent gastrointestinal bleeding despite resolution of thrombocytopenia and correction of clotting abnormalities; (b) evidence of free air; (c ) need for vasopressor support or large volumes of fluid, suggesting uncontrolled sepsis from intestinal infarction; and (d) development of symptoms of an intraabdominal process that would normally require an operation. Pneumatosis and localized peritoneal signs are not sufficient to warrant surgical exploration in the absence of one or more of the preceding indications. Using these criteria, 70% to 80% of patients can be managed medically with broad-spectrum antibiotics to cover gram-negative pathogens and clindamycin or metronidazole for gastrointestinal anaerobes and fungi.[52]

Patients who do not have typhlitis but who demonstrate signs and symptoms of enterocolitis may have transverse colitis, intussusception, or antibiotic-related pseudomembranous or clostridial enterocolitis.[55] *C. difficile* colitis is now the major cause of nosocomial diarrhea in the United States and Western Europe.[56] Although use of second- and third-generation cephalosporins, clindamycin, ampicillin, and amoxicillin are associated with the highest risk of *C. difficile* colitis, even a single dose of almost any antibiotic may predispose the patient to this condition.[56] The specific therapy for *C. difficile* colitis is oral metronidazole (5 mg per kg every 6 hours, up to a maximum of 4 g per day) or oral vancomycin (125 mg four times daily or 50 mg four times daily in patients weighing less than 30 kg).[56]

### Perirectal Abscess

Anorectal pain, tenderness, and discomfort with bowel movements may indicate a perirectal abscess or fistula. Perirectal abscesses occur in patients with neutropenia, especially those with AML.[57] Superficial lesions are obvious; deeper lesions require cautious rectal examination. In a neutropenic patient, the only physical finding may be tender, brawny, woody edema with a dense cellulitic reaction. Most abscesses are caused by a mixture of aerobes, including staphylococci, *E. coli*, pseudomonads, and streptococci, enterococci, and other fecal anaerobes.[58] Initial therapy includes antibiotics to cover aerobic and anaerobic gram-negative and gram-positive bacteria. Sitz baths may relieve pain. If the abscess or induration is well-circumscribed or progresses, incision and drainage of the lesion may be necessary.[57,59] Early, aggressive medical management often eliminates the need for incision and drainage, particularly while the patient is neutropenic. Follow-up evaluation of the patient is important, but repeated rectal examinations should be avoided.

### Cholecystitis and Biliary Obstruction

Inflammation of the liver and biliary tract can present as localized right upper quadrant pain or jaundice. Acute cholecystitis and particularly acute acalculous cholecystitis occur in children who are septic, stressed, and volume-depleted. Biliary obstruction as a result of primary tumor is rare: Lymphoma and neuroblastoma occasionally block biliary flow, and rhabdomyosarcoma of the common duct occurs.[60]

US or CT can distinguish calculous from acalculous cholecystitis.[61] Hydration, broad-spectrum antibiotics, and nasogastric decompression usually treat the acute cholecystitis. Antibiotics should cover gram-negative bacilli and, in the neutropenic patient, fungi. Endoscopic or combined endoscopic-cutaneous decompression is successful in most patients, and stent placement may provide effective palliation for up to 6 months.[62,63]

### Veno-Occlusive Disease

Veno-occlusive disease consists of rapid, usually painful hepatic enlargement, more than a 5% weight gain, ascites, and hyperbilirubinemia that occurs most frequently within the first 2 weeks of cytoreductive therapy for bone marrow transplantation. Weight gain in excess of 15% and serum bilirubin in excess of 10 mg per dL by day 10 are harbingers of multisystem organ failure.[64] Recently, cases of veno-occlusive disease have occurred during 6-thioguanine therapy for ALL and after vincristine and dactinomycin with or without cyclophosphamide therapy for rhabdomyosarcoma and nephroblastoma.[65,66] and [67] Treatment of veno-occlusive disease is primarily supportive. In the nontransplant setting, 6-thioguanine, vincristine, or actinomycin should be withheld until symptoms improve.

### Acute Massive Hepatomegaly in Neuroblastoma

Massive hepatomegaly may complicate stage IV-S neuroblastoma in the neonate and may be fatal.[68] Unless life-threatening respiratory embarrassment is present, supportive care and observation are sufficient until the disease resolves spontaneously. If hepatomegaly compromises respiratory function, the therapeutic options include chemotherapy, irradiation and, rarely, surgical enlargement of the abdominal wall with a Silastic pouch.[69] Radiotherapy involves lateral portals (with the child positioned supine) and fields encompassing most of the liver but sparing the ovaries and kidneys and extending from the dome to the posterior portion of the right hepatic lobe. A midplane dose of 150 cGy given on three successive days is the standard at the Children's Hospital of Philadelphia.

### Hemorrhagic Pancreatitis

When vomiting and abdominal pain occurs in a child receiving L-asparaginase or corticosteroids or in a child with increased intracranial pressure, pancreatitis should be included in the differential diagnosis.[70,71] and [72] Standard-risk ALL therapy is associated with a 2% incidence of pancreatitis.[73] Serum chemistries, including pancreatic amylase and lipase and, in some situations, the urinary amylase-creatinine ratio, help to establish the diagnosis. A US or CT scan of the pancreas should be obtained. Randomized trials of nasogastric tubes for suction or to allow resting of the pancreas have not proven such instrumentation to be beneficial unless the patient has intractable emesis or an ileus.[74] Fluid loss should be replaced, and antibiotics appropriate for the immunologic status of the patient should be started. Imipenem may be of specific benefit in necrotizing pancreatitis.[74] Parenteral nutrition may be necessary.[75] Recent reports suggest that octreotide (5 µg per kg per day divided into twice-daily doses) may ameliorate the clinical course of hemorrhagic pancreatitis.[76,77]

The indications for and timing of surgical drainage of a pancreatic abscess depend on the child's condition and the evolution of the process on sequential US or CT examinations.[42,78] Although an area of phlegmon can be treated conservatively, localized abscess and pancreatic dissolution require emergent open drainage. A CT scan with contrast medium may show a phlegmon as a diffuse homogeneous area, and an abscess may appear as a loculation or loculations of various densities within the pancreas.[42] If pancreatitis evolves into a pseudocyst, supportive care permitting maturation of the cyst beyond 6 weeks often facilitates effective internal drainage.[71,79] Percutaneous CT-guided drainage may also be effective.

## GENITOURINARY EMERGENCIES

Renal complications in children with malignancies can be divided into primary complications caused by the tumor itself, such as obstruction of the urinary tract and renal vein thrombosis, and complications that are secondary to the therapy, such as hemorrhagic cystitis.[80] Acute renal failure, hypertension, and TLS can be both primary and secondary. A discussion of TLS is included in the section Metabolic Emergencies.

### Oliguria and Anuria

In a child whose urine output is reduced or absent, it is necessary to determine whether the cause is prerenal, renal, or postrenal. Septic shock is the most common prerenal cause of reduced urine output in children receiving cancer treatment. Chemotherapy-induced emesis, profuse infectious diarrhea, negligible oral intake, and metabolic abnormalities all can cause intravascular depletion and oliguria.[80] Bulky abdominal or pelvic tumors, including retroperitoneal sarcomas and lymphomas, germ cell tumors, stromal ovarian tumors, and adrenal or celiac axis neuroblastomas may compress or obstruct the ureters or bladder, causing postrenal failure (Fig. 39-6).[80] Chemotherapy, antibiotics, and antifungals can cause renal insufficiency.[80] Narcotics, vincristine, phenothiazines, and herpes zoster can affect the sacral nerves and cause temporary urinary retention.

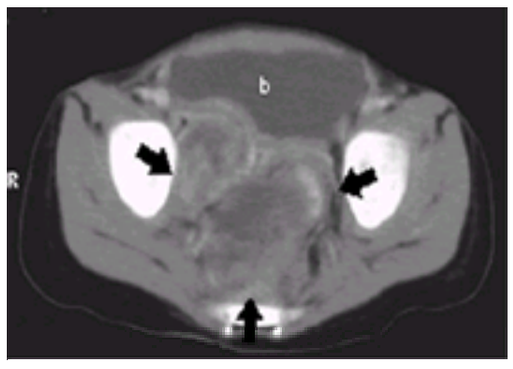

**FIGURE 39-6.** Computed tomographic image of the pelvis viewed at soft tissue windows shows lobulated presacral mass (*arrows*), displacing the bladder (b) anteriorly in a 2-year-old girl with a sacrococcygeal teratoma. Masses in these locations often compress the ureters and cause upper urinary tract obstruction. (Courtesy of James S. Meyer, M.D., Children's Hospital of Philadelphia.)

In a child presenting with a new abdominal or pelvic mass, the practitioner should inquire about urinary or bowel dysfunction and should obtain blood urea nitrogen (BUN) and creatinine (Cr) levels. CT or US of the abdomen and pelvis can reveal both a large mass and renomegaly.[81] If there is no evidence of impending renal failure, contrast may be used. Delayed filling of the bladder may be noted. Postrenal oliguria from mass effects must be differentiated from TLS, as both can present

with elevated uric acid, potassium, and phosphorus, although very elevated BUN and Cr levels are more consistent with postrenal failure.

Vigorous hydration quickly corrects oliguria in patients with prerenal failure but should be avoided in postrenal failure. In most cases of obstructive uropathy, the placement of a urinary catheter past the obstruction or surgical placement of ureteral stents will lead to rapid improvement. Treatment of the underlying tumor with surgery, irradiation, or chemotherapy will ultimately relieve the obstruction. Nephrotoxic drugs may have to be stopped and replaced with less toxic agents.

### Hypertension

#### *Etiology and Differential Diagnosis*

Hypertension is defined as systolic or diastolic blood pressures exceeding the ninety-fifth percentile for age and gender. [82] Symptoms include headache, irritability, lethargy, confusion and, ultimately, seizures and coma. Hypertension can be due to renal artery compression or renal parenchymal compression leading to increased renin production.[83] These most commonly occur in Wilms' tumor, neuroblastoma, ganglioneuroblastoma, abdominal lymphomas, and pheochromocytomas. Of note, Wilms' tumors and neuroblastomas can produce renin ectopically. [83] Renal vein thrombosis can cause arterial systolic hypertension and hematuria. [84] Cushing's triad, consisting of hypertension, bradycardia, and respiratory depression, indicates increased intracranial pressure in a child with a brain tumor, central nervous system (CNS) leukemia, or a CNS infection. Hypertension can also be a secondary effect of medications including steroids, cyclosporin A, and amphotericin B. Finally, pain alone can cause significant hypertension in children, often associated with tachycardia.

#### *Evaluation*

Vital signs including frequent blood pressure monitoring should be obtained. Crying, fever, or pain may temporarily elevate the blood pressure. Signs of increased intracranial pressure warrant a CT scan of the brain. Urine and plasma catecholamine levels and plasma renin levels may be elevated in paraneoplastic hypertension.[83] Radiologic evaluation should include CT of the abdomen to rule out an underlying malignancy and Doppler US to evaluate renal blood flow.

#### *Therapy*

Treatment of hypertension typically results in rapid improvement of neurologic sequelae. A modest reduction in blood pressure can prevent stroke, encephalopathy, and congestive heart failure. Excessively rapid reduction in blood pressure reduces perfusion of end organs. Recommended intravenous therapy for patients with normal renal function includes nitroprusside (0.5 to 8.0 µg per kg per minute by infusion), diazoxide (2 to 5 mg per kg per dose intravenously), and hydralazine (0.2 to 0.4 mg per kg per dose intravenously).[82] If a patient is fluid overloaded, furosemide (0.5 to 1.0 mg per kg) is indicated. Sublingual nifedipine (5 to 10 mg per dose for children weighing more than 10 kg) acts rapidly and is especially useful to treat asymptomatic hypertension. A long-acting angiotensin-converting enzyme inhibitor or calcium channel blocker dosed once or twice daily provides long-term control. [82] For hypertension caused by increased intracranial pressure, dexamethasone or mannitol can decrease cerebral edema, in turn decreasing the blood pressure (see the section Neurologic Emergencies). Definitive treatment of hypertension caused by the tumor consists of treatment of the tumor with cytotoxic therapy.

### Hemorrhagic Cystitis

#### *Etiology and Evaluation*

Signs and symptoms of hemorrhagic cystitis are dysuria, urgency, and frequency, with leukocytes, erythrocytes, or clots found in the urine because of bleeding and inflammation of the bladder. Hemorrhagic cystitis can cause substantial blood loss and urinary obstruction. In the immunosuppressed patient, adenovirus, cytomegalovirus, and polyomavirus BK can incite hemorrhagic cystitis.[85] Therapy with cyclophosphamide or ifosfamide is the most common cause of this disease. [85] Acrolein, the principal metabolite of these two drugs, is toxic when it precipitates in the bladder. [85] The early phases of cystitis are mucosal edema, ulceration, epithelial necrosis, and submucosal fibrosis.[85,86] Cystitis may occur hours to months after cyclophosphamide or ifosfamide administration. Long-term complications include bladder fibrosis and contraction, urinary reflux, renal failure, and transitional cell bladder tumors. [85,86]

The diagnosis is made by history and urinalysis. Patients usually present with gross hematuria and the passing of painful clots. US may demonstrate a boggy, edematous, hemorrhagic bladder or, possibly, a fibrotic bladder with hemorrhage. Direct examination may be necessary to locate large areas of bleeding.

#### *Therapy*

Chemotherapy-induced cystitis is best prevented by vigorous hydration and brisk diuresis to reduce accumulation of acrolein in the bladder during cyclophosphamide or ifosfamide infusion.[86] Concurrent use of the uroprotective agent sodium 2-mercaptoethane sulfonate (mesna), which binds acrolein, has decreased the need for prophylactic bladder irrigation and hyperhydration. [86]

If prevention fails, immediate treatment consists of hydration, correction of thrombocytopenia and coagulation abnormalities, transfusion of packed red blood cells, and placement of a double-lumen Foley catheter for continuous bladder irrigation. Bladder spasms may be controlled with oral oxybutynin chloride (5 mg twice daily in children older than 5 years), baclofen (3 to 5 mg every 8 hours orally, titrated up every 3 days), belladonna, or opioids. Concurrent bladder irradiation and chemotherapy with radiomimetic agents should be stopped. Patients who continue to bleed may need endoscopy and electrocoagulation. If electrocoagulation fails, instillation of formalin, alum, or prostaglandin $E_2$ ($PGE_2$) may be helpful. Traditionally, the treatment was a 0.25% solution of formalin instilled into the bladder through a Foley catheter while the patient was anesthetized.[85,87] The risks of formal in include obstruction, extravasation, and bladder constriction. In patients with reflux, formalin is contraindicated and alum instillation is preferred. A newer, less toxic therapy is $PGE_2$. The instillation of $PGE_2$ resulted in resolution of hematuria in all patients within 5 days of infusion without any systemic side effects.[88]

## NEUROLOGIC EMERGENCIES

Neurologic emergencies in children with cancer can be a direct effect of the malignancy, as with spinal cord compression in neuroblastoma or increased intracranial pressure from a CNS tumor, or they can result indirectly from abnormalities of metabolism, hemostasis, or organ system dysfunction. Altered mental status, seizures, cerebellar dysfunction, and cerebrovascular accidents (CVAs) may be the sequelae of cancer therapy or supportive care agents.

A common mistake in evaluating a child with cancer and acute neurologic deterioration is the omission of a careful, detailed neurologic examination. The child often is considered too weak, too uncooperative, or in too much pain to be put through a formal neurologic evaluation. The reason for the child's misery frequently lies in the CNS impairment itself. Without neurologic localization of the deficit, unnecessary, potentially harmful investigations may be carried out, further delaying diagnosis and possibly increasing morbidity and mortality.

### Acute Alterations in Consciousness

#### *Etiology and Pathogenesis*

Table 39-4 lists the causes of acute alterations in consciousness (AAC) in the child with cancer. Given the myriad etiologies of AAC in the ill, unstable child with cancer, a comprehensive evaluation is necessary to determine a specific cause.

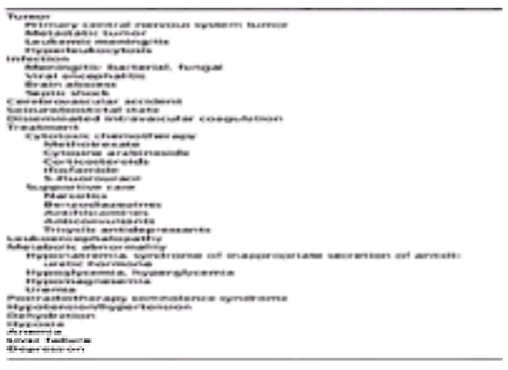

**TABLE 39-4. ETIOLOGY OF ACUTE ALTERATIONS IN CONSCIOUSNESS IN CHILDREN WITH CANCER**

A state of full awareness depends on the integrity of the cerebral hemispheres and the ascending reticular activating system (ARAS), a polysynaptic neuronal network lying in the central core of the brainstem, thalamus, and hypothalamus.[89] The ARAS receives input from and projects to all portions of the CNS. AAC range from lethargy, in which the patient has difficulty maintaining an aroused state, to coma, in which the patient is unresponsive to all pain and stimuli. Coma or other forms of altered consciousness result from diffuse derangement of cerebral function or damage to the ARAS. Drugs usually cause alterations in consciousness by derangements of diffuse bilateral cerebral function. Increased intracranial pressure from a localized mass may cause herniation or compression of the brainstem and disruption of the ARAS.[89]

***Evaluation and Differential Diagnosis***

The evaluation of a child with AAC begins with a rapid assessment of the airway, breathing, and circulation, with emergent stabilization as indicated. It then proceeds with a history and formal neurologic examination. A focused history includes the patient's affect and behavior leading up to the acute change, history of similar episodes, seizure activity, recent illness, fever or other infectious symptoms, recent medications, chemotherapy and radiotherapy, and status of the malignancy.

Clinical findings can localize the level of brain involvement. Altered breathing pattern, abnormal pupillary size and reactivity, abnormal extraocular movements, lack of spontaneous motor function, and reduced response to verbal or physical stimuli may indicate cerebral herniation. A diffuse increase in intracranial pressure may cause rostrocaudal or central herniation characterized by a symmetric downward displacement of the brain through the tentorium and gradual progressive failure of diencephalic and brainstem functions. In contrast, lateral mass lesions cause uncal herniation, shifting the brain and compressing the third nerve and lateral midbrain. Uncal herniation tends to be rapid and unpredictable and may culminate in a nonstereotypic brainstem herniation, with sparing of some brainstem functions (e.g., pupillary responses) despite compromise of lower brainstem functions (e.g., breathing). In the later stages of herniation, symptoms of the two forms often overlap. [89]

The causes of AAC can be focal or diffuse. Focal intracranial mass lesions that cause AAC with or without localized signs include primary CNS tumors, infarctions, hemorrhages, metastases, and abscesses. Acute thrombotic or, rarely, embolic CVAs can cause neurologic deterioration. [90] Subdural hematomas and intracranial hemorrhages may complicate coagulopathy, profound thrombocytopenia (usually fewer than 10,000 platelets per microliter), or L-asparaginase therapy.[90] Spontaneous hemorrhage into intracranial tumors, especially medulloblastomas and high-grade gliomas, or into metastatic tumors may occur with normal platelet counts and normal coagulation. Metastatic spread of tumor to the CNS occurs late in the disease in children with sarcomas, lymphomas, and primary renal tumors. Children with cancer who are immunosuppressed are prone to fungal or bacterial brain abscesses, meningitis, and sinusitis (see Chapter 41).

Diffuse disorders causing up to one-fourth of encephalopathy cases and mental status changes in children with cancer include metabolic derangements, drug toxicity, and infectious encephalitis.[91] Metabolic derangements that alter consciousness include anoxia, ischemia, uremia, hepatic failure, and electrolyte abnormalities. Metabolic disturbances infrequently lead to increased pressure and central herniation. Viral encephalitis, most commonly from varicella or herpes simplex, may result in acute coma. Seizures cause more than 50% of acute mental status changes in young patients; therefore, the postictal state must be differentiated from other changes in consciousness. Leukemic meningitis and hyperleukocytosis are relatively infrequent causes of AAC.

Table 39-4 lists the commonly used chemotherapeutic and supportive care agents that acutely alter a person's level of consciousness. Corticosteroids may cause personality changes and, occasionally, hallucinations and psychosis. [92] Repetitive high doses of cytosine arabinoside may cause symptoms of cerebellar dysfunction, seizures, coma, or death during an infusion or days later. [93,94] Both high-doseparenteral methotrexate and intrathecal methotrexate can cause transient encephalopathy or seizures, believed to be secondary to a direct toxic effect on the brain. [95,96] High-dose methotrexate can also cause focal neurologic deficit, presumably due to acute intracellular metabolic derangements. [95,97] Ifosfamideis associated with acute somnolence, neurologic deterioration, and coma, especially after prior cisplatin exposure or in patients with renal insufficiency. [98,99] The introduction of new drugs, use of higher doses of standard drugs, and the wider use of means to overcome the blood–brain barrier (e.g., intra-arterial infusion) are introducing more acute neurotoxicity. Intra-arterial infusions of bischloroethylnitrosourea (BCNU, carmustine) and cisplatin have been related to acute neurologic deterioration, seizures, strokes, and encephalopathy. [100,101] AAC may occur in patients with a familial deficiency of dihydropyrimidine dehydrogenase who are receiving 5-fluorouracil. [102] Thiotepaand BCNU, given in high doses in bone marrow transplant regimens, can result in severe, life-threatening encephalopathy. [100,101] Retinoids such as ATRA and fenretinide may lead to pseudotumor cerebri, a complication especially common in children.[32]

Neurotoxic agents prime the CNS for neurologic compromise. In this setting, relatively mild metabolic derangements or sedative drugs may suppress consciousness seemingly disproportionate to the insult. High-dose narcotics can sedate profoundly, and their rapid termination can lead to withdrawal symptoms. Benzodiazepines, widely used for conscious sedation, may acutely cause dysphoria. Poor excretion of narcotics due to hepatic dysfunction or overdoses due to malfunction of patient-controlled analgesia devices can lead to toxic drug levels. Transdermal fentanyl or scopolamine patches can cause sedation and, when placed behind the ear, ipsilateral pupillary constriction.

Up to one-half of patients receiving high-dose interleukin-2 experience disorientation and confusion; less common are paranoia and combativeness, and somnolence and coma are rare.[103] The interferons can cause subacute somnolence, altered cognition, psychiatric symptoms, conceptual disorganization, focal neurologic deficits, cortical blindness, coma, and death.[103]

***Therapy and Recommendations***

First, life-threatening respiratory and circulatory disturbances must be corrected. Next, a CBC, serum glucose, electrolytes, and ammonia level, hepatic and renal function tests, blood cultures, and a coagulation profile should be obtained. Symptoms or signs of increased intracranial pressure should be managed with intravenous dexamethasone (first dose, 1 to 2 mg per kg) and, possibly, infusion of mannitol in a 20% solution at 0.25 to 2.00 g per kg and, finally, if necessary, rapid-sequence intubation and hyperventilation. [89] Hyperventilation sufficient to decrease the partial pressure of blood carbon dioxide to 20 to 25 mm Hg reduces cerebral blood flow, but excessive hyperventilation may result in ischemia of the brain. [89] When stabilized,patients with presumed mass lesions or with unexplained coma should undergo emergent CT scanning or MRI with osmotic contrast agents only if there is no hyperviscosity or hyperosmolality. In patients with signs or symptoms of increased intracranial pressure in whom sepsis or meningitis is suspected, broad-spectrum antibiotics should be given prior to imaging. Neurosurgical intervention may be indicated for mass lesions or hydrocephalus unresponsive to medical management. Lumbar puncture should not be performed until a mass lesion has been ruled out. Thrombocytopenia and coagulopathy should be corrected before a lumbar puncture or surgery is attempted.

For chemotherapy-related neurologic alterations that threaten life or function, the medication should be discontinued or the dose reduced. The specific antidote for ifosfamide encephalopathy is methylene blue.[104] In the situation of high-dose cytosine arabinoside–induced neurologic dysfunction, the drug should be discontinued. Steroids may ameliorate the neurologic effects of interleukin-2 but may also interfere with the agent's efficacy. Acute CNS deterioration due to elevated methotrexate levels, stemming from either altered clearance or overdose, can be treated with leucovorin or carboxypeptidase (see the section Intrathecal Chemotherapy Overdoses or Errors). Acute methotrexate encephalopathy usually is reversible, and many patients tolerate subsequent use of methotrexate. Management of radiation-induced CNS necrosis is primarily supportive. When large areas of focal necrosis are present, surgical debulking may be helpful. [105] Although hyperbaric oxygenation and

anticoagulation have been recommended for the treatment of radiation-induced vasculitis, their efficacy is unproven. [106] In children with AAC who are receiving narcotics, 1 to 2 mg naloxone can be given intravenously, intramuscularly, or sublingually to reverse the sedation rapidly. The antidote for midazolam is flumazepine, 0.01 mg per kg initially, then 0.005 mg per kg every minute to a maximum dose of 1 mg.

## Cerebrovascular Accidents

### *Etiology*

In children with cancer, CVAs are due to cerebral arterial or venous thrombosis, intracerebral hemorrhage, local or metastatic spread of tumor, antineoplastic agents, hematologic abnormalities, or primary CNS infections; embolic causes are exceptional. [90] When a CVA occurs at the onset of illness, it usually is associated with disease-related coagulation abnormalities. During treatment, most strokes are related to a specific chemotherapeutic agent or infection. At the end stages of disease, sepsis, disseminated intravascular coagulation (DIC), CNS infection, and progressive tumor are common causes of CVA. Strokes occurring months to years after children have completed therapy generally are the result of radiation-induced vascular damage. [107]

### *Pathogenesis*

Patients with AML—especially APML, acute monoblastic leukemia, or any form of leukemia with hyperleukocytosis (see the section Hyperleukocytosis)—are at especially high risk for strokes at diagnosis or early in treatment. [108,109 and 110] Myelodysplasia or leukemia with peripheral hypereosinophilia and acute megakaryoblastic leukemia are associated with an increased risk of stroke. Leukemic promyelocytes enhance thrombin activation, and their high levels of expression of annexin II increase production of plasmin, a fibrinolytic protein, causing DIC and CVA. [108] The CVA usually occurs early in treatment of APML and may even be the presenting symptom.

L-Asparaginase as a single agent or in combination with vincristine and prednisone is associated with increased risk of venous thrombosis, especially near the end of induction therapy in ALL.[111] The majority of thromboses occur in the CNS.[112] The frequency of thrombotic complications in children with ALL varies from 2% to 12%. Children receiving L-asparaginase acquire a deficiency of antithrombin III but have enhanced thrombin formation, creating a prothrombotic state. [111] Intrathecal methotrexate occasionally causes CVA.[113]

During induction treatment for ALL or NHL, visual hallucinations progressing to confusion and stroke-like episodes may occur. They are associated with bilateral cortical or subcortical white-matter lesions. The etiology of these spells is believed to be vascular, possibly associated with hypertension or vincristine. [114] Transient ischemic events, similar to complicated migraine, may occur after cranial irradiation and chemotherapy. [115]

Radiotherapy may cause delayed large- and small-vessel occlusions. [107,116] Total doses of radiotherapy in excess of 5,000 cGy have been related to large-vessel occlusions. The peak incidence of large-vessel occlusions is 6 months to 3 years after treatment, but occlusions may take place up to two decades later. [116] Rarely, patients develop a CVA after lower doses or conventional fractions of radiation (180 to 200 cGy). More commonly, radiotherapy causes small, focal vascular occlusions. Mineralizing microangiopathy with dystrophic calcification is seen histopathologically in many children who have died of cancer but rarely is reported in children who have received less than 2,000 cGy. Intrathecal or parenteral methotrexate and cytosine arabinoside potentiate the risk of radiation-induced damage. [117]

Hemorrhagic CVA can occur preterminally, especially in children with neuroblastoma metastatic to the dura or torcula and in those with platelet-resistant thrombocytopenia.[91] Neuroblastoma may also cause lateral and transverse sinus thrombosis by compression from metastases to the calvarium that are adjacent to the venous channels.[91]

### *Evaluation and Differential Diagnosis*

In evaluating a child with cancer and a presumed CVA, it is important to consider the type, extent, and status of the cancer, the antineoplastic treatment, and any associated medical conditions. In a critically ill child with uncontrollable cancer, no specific evaluation may be indicated. CVAs usually present as acute impairments in motor function or speech, often with associated seizures. If symptoms do not clear within 24 hours after the ictus, a structural CNS lesion must be ruled out. A major CVA, such as a sagittal sinus thrombosis or a brainstem stroke, can cause obtundation, which must be differentiated from lethargy or coma.

When the child is medically stable, emergent CT or MRI should be performed with and without contrast medium. MRI often is more specific, as patients with small subcortical or small-vessel infarcts may have normal CT scans. Magnetic resonance angiography can help to confirm a specific diagnosis, such as postradiation vessel-occlusive vasculopathy,[107] but is rarely needed at the onset of symptoms. Follow-up imaging studies 7 to 10 days later may document infarction and demonstrate the full extent of damage.[118] Care should be taken to evaluate the torcular region of the calvarium and dura in children with neuroblastoma, to rule out the possibility of a sinus thrombosis. [91] If the CT or MRI scan does not show a focal mass lesion, lumbar puncture can be performed for analysis of opening pressure, protein and glucose levels, cell count, cytology, and bacterial, viral, and fungal cultures.

### *Therapy and Recommendations*

The management of a child with a CVA is primarily supportive. If there is evidence of DIC, supportive care includes platelet and fresh frozen plasma transfusions. The use of heparin is controversial. Heparin may be useful in patients whose CVA is thromboembolic but is contraindicated in hemorrhagic CVA. [13] The platelet count in children with hemorrhagic strokes should be kept above 75,000 per microliter to prevent further bleeding. In patients with DIC secondary to sepsis and low antithrombin III levels, replacement of antithrombin III in high doses tends to improve overall survival. [119] If CVA is a presenting or early symptom of malignancy, treating the underlying disease with cytotoxic therapy may prevent additional CVAs. Antibiotics or antifungal agents should be started if there is concern of infection.

The use of ATRA to treat APML often resolves the associated coagulopathy in 5 to 7 days [108]; however, many CVAs occur earlier. ATRA is believed to reverse the annexin II–mediated fibrinolysis by blocking transcription of the annexin II gene in t(15,17)-positive cells. [108] In patients with L-asparaginase–related CVA or coagulation abnormalities, prophylactic treatment with fresh frozen plasma (10 mL per kg) has been investigated, but it does not affect the antithrombin III deficiency.[111] Use of the newer antithrombin III concentrates is controversial.

In children with neuroblastoma metastatic to the torcular region, emergency irradiation of the sinus area can resolve symptoms rapidly. [91] Treatment of nonmetastatic sagittal sinus thrombosis with no evidence of hypernatremia includes corticosteroids and hyperosmolar agents to decrease the intracranial pressure. Anticoagulants may cause extension of a venous infarct.

In the child with an intracerebral hemorrhage, surgery may be lifesaving, but operative intervention may be unwarranted in patients with uncontrolled coagulopathy or in those at the end stage of their disease.

## Seizures

### *Etiology and Pathogenesis*

Seizures are transient, involuntary alterations of consciousness, behavior, motor function, sensation, or autonomic function due to excessive rate and hypersynchrony of neuronal discharges. Table 39-5 lists common causes of seizures in children with cancer. Seizures account for up to 60% of neurologic consultations on pediatric oncology services.[91,120] They are primarily due to the underlying malignancy, especially primary CNS tumors, tumors metastatic to the CNS, and meningeal leukemia, and to antineoplastic therapy. Intrathecal cytarabine and intrathecal and high-dose intravenous methotrexate can cause seizures, especially in children who have received cranial irradiation. [91,96] Whether vincristine directly causes seizures or whether vincristine-related seizures are due to the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and hyponatremia remains unclear. Radiation-induced small-vessel disease, cerebral necrosis, and leukoencephalopathy provoke seizures.[105] CVAs, CNS infections, coagulopathy, and metabolic derangements also cause seizures. [91]

**TABLE 39-5. ETIOLOGY OF SEIZURES IN CHILDREN WITH CANCER**

### *Evaluation and Differential Diagnosis*

A seizure is a symptom of an underlying pathologic process. The investigation of the seizure is similar to that previously discussed for AAC and CVA and should take place as soon as the seizure is controlled. A history of any previous seizures, family history of seizures, and a list of medications and cancer chemotherapy or radiotherapy should be obtained. A CBC, serum electrolyte levels (including magnesium, calcium, and phosphorus), renal and hepatic functions, and coagulation studies should be checked. Emergent CT or MRI with and without contrast is indicated to look for hemorrhage or a mass lesion. On T2-weighted images, methotrexate-induced encephalopathy and seizures may appear as diffuse hyperintensities in the white matter and cerebral subcortical calcifications. [96] If, on CT or MRI, an obstructing mass lesion is ruled out, cerebrospinal fluid (CSF) should be obtained for cell counts, glucose, and protein, as well as cytology, bacterial and viral culture, and viral titers as clinically indicated. Electroencephalography can localize abnormal electrical activity in the brain.

### *Therapy and Recommendations*

Most seizures are self-limited; a prolonged seizure requires emergent management. [121] Adequate ventilation and circulation must be secured and metabolic abnormalities corrected, followed by the initiation of anticonvulsants. Table 39-6 lists recommended anticonvulsants and their doses. Either of the benzodiazepines, lorazepam or diazepam, is the initial therapeutic agent because of the rapid onset of action. [121] For treatment of prolonged or multiple seizures, phenytoin is added as it is not as sedating as are the barbiturates. Valproic acid and carbamazepine should be avoided owing to their potential marrow suppression. Most children with cancer and seizures receive antiepileptic medication while evaluation is under way. Those without markedly abnormal electroencephalograms and normal neuroimaging usually can discontinue therapy without a recurrence. Children whose first seizure is prolonged or who have repetitive seizures experience an increased incidence of seizure recurrence and generally require prolonged therapy with anticonvulsants. [91]

| Drug | Dose (mg/kg) | Duration of action | Advantages | Disadvantages |
|---|---|---|---|---|
| Diazepam | i.v.: 0.2–0.5 (max. 10 mg)<br>p.r.: 0.2–0.5 (max. 20 mg) | i.v.: 20–30 min<br>p.r.: up to 4 h | Rapid onset, rectal formulation | Short duration, respiratory depression, hypotension |
| Lorazepam | i.v.: 0.05–0.2 mg/kg/dose | 12–24 h | Rapid onset, longer duration of action | Respiratory depression, hypotension, drowsiness |
| Phenytoin | i.v.: 18 to 20 mg/kg bolus at 1–3 mg/kg/min | Up to 12 h | Rapid onset, minimal sedation | Arrhythmia, wide QT interval |
| Phenobarbital | i.v.: 18 to 20 mg/kg bolus at 1 mg/kg/min (max. 30 mg/kg) | Up to 24 h | Long half-life | Sedation, respiratory depression, bradycardia |
| Fosphenytoin sodium | i.m.: 10–20 mg PE/kg, 3 mg/kg/min (max. 150 mg/min) | Up to 12 h | Intramuscular formulation | Emesis, ataxia, rash, pruritus |

**TABLE 39-6. ANTICONVULSANTS FOR STATUS EPILEPTICUS IN CHILDREN WITH CANCER**

Antibiotics are indicated in febrile, neutropenic patients, those with meningeal signs or symptoms, and those in whom infection is a concern. In the case of CNS infection, metabolic abnormalities, and most therapy-related seizures, antiepileptics can be withdrawn after correction of the underlying abnormality if the follow-up electroencephalogram shows no epileptiform activity and no residual focal CNS defect is apparent.

### Intrathecal Chemotherapy Overdoses or Errors

Intrathecal (i.t.) chemotherapy is used frequently in the treatment of ALL, AML, and NHL and, unfortunately, overdoses and errors in administration occur. The symptoms noted with i.t. methotrexate overdoses range from none to headache for doses of less than 100 mg to seizure and coma within hours for doses in excess of 500 mg.[122] The only reported overdose of i.t. cytarabine (200 mg) was associated with dilated pupils for an hour. [123] Two inadvertent instillations of i.t. anthracyclines were notable for their delayed onset of neurologic symptomatology (16 and 17 days); one ended in death. [124] Infusion of i.t. vincristine, a CNS neurotoxin, causes a rapidly ascending paralysis and coma.[125] Of note, infusions of more than 500 mg of i.t. methotrexate and mistaken i.t. administration of vincristine at any dose usually are fatal.[124]

Immediate action is necessary for any chance of complete recovery after an i.t. overdose or error. If the interval between the overdose and recognition of the problem is less than 2 hours, as much CSF as possible should be drained. [122] Simple CSF drainage within 1 to 2 hours of infusion can allow the recovery of 30% to 50% of the initial drug dose.[124,126,127] If more time has elapsed, CSF can be exchanged with saline or Ringer's lactate solution. Ventricular catheter placement for ventriculolumbar perfusion should be considered if the patient's clinical condition continues to deteriorate or if the overdose is severe.

Overdoses of less than 100 mg methotrexate require minimal intervention; doses of greater than 500 mg usually are fatal, and doses between these extremes need aggressive therapy as outlined previously. [122] With the advent of i.t. carboxypeptidase $G_2$ ($CPDG_2$), survival without sequelae has occurred after i.t. methotrexate doses of more than 500 mg, even when discovered 2 hours after the initial instillation. [127,128] $CPDG_2$ is a member of a class of enzymes that hydrolyzes the C-terminal glutamate residue from folic acid and classic antifolates such as methotrexate, thereby converting methotrexate rapidly to a nontoxic metabolite. A pediatric study of the efficacy of $CPDG_2$ for the management of i.t. methotrexate overdoses in excess of 100 mg recommends immediate drainage of CSF by gravity for 5 minutes, followed by intrathecal administration of 2,000 units (two vials) of $CPDG_2$. High-dose systemic leucovorin (100 mg every 6 hours for four doses) and intravenous dexamethasone (0.5 mg per kg) every 6 hours for 24 to 72 hours should be administered concomitantly to decrease the severity of the chemical meningitis. [129] CNS drainage and systemic leucovorin usually suffice for i.t. methotrexate doses of less than 100 mg. [127] i.t. Leucovorin has been associated with worsening neurotoxicity [127] and should not be administered.

Only one of eight reported children survived accidental administration of i.t. vincristine. [124,125] CSF was drained from the surviving child within 5 minutes of the drug's administration, followed by three CSF exchanges with Ringer's lactate solution and fresh frozen plasma and 18 hours of ventriculolumbar perfusion with these same substances. The child also received glutamic acid (10 g intravenously over 24 hours, then 250 mg orally every 8 hours), leucovorin (25 mg intravenously every 6 hours for 1 week), and pyroxidine (50 mg intravenously every 8 hours for 1 week).[125,126] Of note, the only adult reported in the literature to have survived i.t. vincristine also underwent CSF exchange with Ringer's lactate solution and ventriculolumbar perfusion with Ringer's lactate solution and fresh frozen plasma. [130]

Intravenous corticosteroids have been used in several i.t. chemotherapy errors, as they theoretically decrease meningeal inflammation. However, insufficient data are

available to permit evaluation of their efficacy. i.t. Administration of corticosteroids is contraindicated because one must drain and exchange CSF immediately.

## Spinal Cord Compression

### *Etiology and Pathogenesis*

A mass that compromises the integrity of the spinal cord, conus medullaris, or cauda equina requires urgent attention to minimize long-term neurologic dysfunction. Epidural compression may occur with a known malignancy or may be the presenting symptom of an undiagnosed malignancy. Acute compression of the spinal cord occurs in 3% to 5% of children with cancer, often at diagnosis. [131,132] Another 5% to 10% of patients develop back pain that must be differentiated from spinal cord compression. Table 39-7 shows the frequency of epidural metastases among 2,259 children with malignant solid tumors at St. Jude Children's Research Hospital from 1962 to 1987.[132] Sarcomas account for most spinal cord metastases, whereas neuroblastoma, germ cell tumors, lymphoma, and dropped metastases from primary CNS tumors account for most of the remainder.[132] Spinal cord compression can occur with almost any tumor type, including Wilms' tumor [133] and leukemia.[134]

| Pathology | No. of cases of SCC (%) | Total cases |
|---|---|---|
| Ewing's sarcoma | 30 (17.9) | 168 |
| Neuroblastoma | 32 (7.9) | 402 |
| Osteogenic sarcoma | 16 (6.5) | 243 |
| Rhabdomyosarcoma | 14 (4.9) | 287 |
| Hodgkin's disease | 8 (2.0) | 404 |
| Soft tissue sarcoma | 4 (3.9) | 102 |
| Germ cell tumor | 5 (3.8) | 130 |
| Wilms' tumor | 2 (0.7) | 290 |
| Hepatoma | 1 (1.4) | 69 |
| Other* | — | 164 |

**TABLE 39-7. INCIDENCE OF SPINAL CORD COMPRESSION IN CHILDREN WITH SOLID MALIGNANT TUMORS**

The spinal cord and cauda equina may be compressed by tumor in the epidural or subarachnoid space or, less commonly, by metastatic spread to the cord parenchyma. Epidural compression occurs by extension of a paravertebral tumor through the intervertebral foramina. Compression of the vertebral venous plexus by the tumor causes vasogenic cord edema, venous hemorrhage, and ischemia.[135] Metastatic involvement of the vertebral bodies and secondary compression of the spinal cord, which is common in adults with cancer, are rare in childhood. [136] Treatment-related myelitis may mimic cord compression.[136]

### *Evaluation and Differential Diagnosis*

Children with cancer and back pain should be considered to have spinal cord compression until proven otherwise. Local or radicular back pain occurs in 80% of children with cord compression.[131] Pain can start weeks to months before diagnosis. Long-standing cord compression can present as progressive weakness, sensory abnormalities, and paresis.[137] Once neurologic abnormalities are apparent, paraplegia and quadriplegia can occur rapidly and may be irreversible. [137] Compression at the level of the cauda equina may present with urinary and fecal incontinence.

Detailed neurologic examination, with attention given to extremity strength, reflexes, and determination of a sensory level, is essential. A rectal examination assesses sphincter tone. Localized tenderness to vertebral percussion occurs in many patients, and the level of maximal spinal tenderness is a reliable localizing sign. Most patients have objective loss of motor strength in the extremities at the time of diagnosis. Based on clinical findings, the level of spinal cord involvement can usually be determined (Table 39-8), but the absence of weakness or sensory abnormalities does not exclude spinal cord compression. History and physical examination can usually rule out vincristine neuropathy as the cause of back pain.

| | Location | | |
|---|---|---|---|
| Sign | Spinal cord | Conus medullaris | Cauda equina |
| Weakness | Symmetric, profound | Symmetric, variable | Asymmetric, may be mild |
| Tendon reflexes | Increased or absent | Increased knee, decreased ankle | Decreased, asymmetric |
| Babinski | Extensor | Extensor | Plantar |
| Sensory | Symmetric, sensory level | Symmetric, saddle | Asymmetric, radicular |
| Sphincter abnormality | Spared until late | Early involvement | May be spared |
| Progression | Rapid | Variable, may be rapid | Variable, may be rapid |

**TABLE 39-8. CLINICAL LOCALIZATION OF EPIDURAL CORD COMPRESSION**

Traditionally, spine radiographs have been the first radiologic study performed, owing to ease of performance and availability; however, abnormalities are revealed by this method in fewer than half the affected children. Historically bone scans, lumbar myelography, and metrizamide CT were the standard diagnostic tests. They have been supplanted by T1- and T2-weighted MRI scans, performed with and without gadolinium enhancement. [118,138] MRI demonstrates epidural disease, intraparenchymal spread of tumor, and small lesions compressing nerve roots in the cauda equina. [118,137,138] Any child who is not ambulatory at the time of clinical presentation, independent of the duration of dysfunction before evaluation, should undergo imaging immediately. In those children with localizing back pain and no focal findings on neurologic examination, MRI can be arranged within 24 hours. If MRI is not available, CT myelography should be performed. [135] CSF laboratory studies are essential in the evaluation of subarachnoid disease and meningeal leukemia or carcinomatosis. CSF protein concentration is elevated in patients with complete spinal cord block, but protein may be normal in patients with partial obstruction.

### *Therapy and Recommendations*

If the history suggests rapidly progressive spinal cord dysfunction or physical examination documents an anatomic level of dysfunction, the recommended approach is dexamethasone in a bolus dose of 1.0 to 2.0 mg per kg, followed by MRI investigation.[136,137] For the child with cancer and back pain in whom cord compression is possible but in whom loss of function and rapid neurologic progression of symptoms are not apparent, the situation is a subacute emergency and a lower dose of dexamethasone (0.25 to 0.50 mg per kg orally every 6 hours) suffices. Loblaw and Laperriere [139] have found evidence to support the use of high-dose dexamethasone (96 mg per day) in adults but little evidence supporting the use of moderate-dose dexamethasone (16 mg per day) in conjunction with radiotherapy.

If an epidural mass is compressing the spinal cord, the cord must be decompressed immediately. Although it reduces vasogenic cord edema and often results in neurologic improvement, dexamethasone is not an alternative to definitive spinal decompression. Local radiotherapy, surgical decompression, and chemotherapy all have their advocates. However, no randomized, controlled studies or prospective studies compare short- and long-term outcomes. A clear indication for surgery is the unknown primary tumor. For the child with epidural disease without known dissemination, surgery offers the dual benefit of decompression plus identification of the tumor type. Because pediatric tumors frequently enter the spinal canal by way of the intervertebral foramina, surgery involves laminectomy and posterior decompression.[137] Resection of multiple vertebral lamina in an infant or young child causes problems of growth and spinal stability. For the rare child or adolescent with spinal cord compression from vertebral body metastases or a radioresistant tumor, vertebral body resection may be needed. Surgery is indicated also if the

symptoms progress despite radiotherapy.[139]

If the diagnosis is known and the tumor is radioresponsive, radiotherapy is often the treatment of choice. The portal should include the full volume implicated on radiographic study plus a margin, depending on disease and patient-related factors. Supervoltage techniques are used, and daily doses between 180 and 400 cGy are given concomitantly with dexamethasone. Total dose depends on tumor histology and response to initial therapy. In adults, ambulatory radiotherapy and surgery offer similar outcomes, but radiotherapy is associated with decreased morbidity and mortality. [139] In an infant or young child, high-dose, wide-field radiotherapy will impair growth of the spine, spinal cord, and surrounding tissues.

A third alternative, chemotherapy, may be appropriate for patients with spinal cord compression due to lymphoma, leukemia, and neuroblastoma. [134,140] High-dose dexamethasone and systemic chemotherapy often result in prompt symptomatic improvement and reduction in mass size.[134] Ultimately, the optimal treatment often involves a combination of radiotherapy, surgery, and chemotherapy, planned by a multidisciplinary team.

The prognosis for patients with spinal cord compression depends on the neurologic findings at presentation. Patients who are ambulatory when treatment is started remain ambulatory.[137] In adults, patients who are paraplegic at the time of treatment rarely regain function. [139] However, in a recent series, one-half of the children who were not ambulatory at the beginning of treatment regained the ability to walk after emergency treatment. [131]

### Hyperleukocytosis

#### *Etiology*

Hyperleukocytosis is defined as a peripheral leukocyte count exceeding 100,000 per microliter, but clinically significant hyperleukocytosis occurs with WBC counts of more than 200,000 per microliter in AML and in excess of 300,000 per microliter in ALL and chronic myelogenous leukemia (CML). Hyperleukocytosis occurs in 9% to 13% of children with ALL, 5% to 22% of children with AML, and almost all children with CML in the chronic phase. [141,142 and 143] Hyperleukocytosisis more common in infant ALL, AML, T-cell ALL with a mediastinal mass, and hypodiploid ALL. [141]

Hyperleukocytosis can cause death by CNS hemorrhage or thrombosis, pulmonary leukostasis, and the metabolic derangements that accompany tumor lysis. Table 39-9 classifies complications experienced by 234 children with acute leukemia and hyperleukocytosis. Of the 73 patients with AML, 23% died during early induction from pulmonary leukostasis or intracerebral hemorrhage. In contrast, 5% of 161 patients with ALL died of complications of TLS (see the section Metabolic Emergencies).[142]

| Complications | ALL (N = 161) | ANLL (N = 73) | p Value* |
|---|---|---|---|
| Metabolic† | 22 | 4 | .09 |

**TABLE 39-9. EARLY COMPLICATIONS IN PATIENTS WITH HYPERLEUKOCYTOSIS**

#### *Pathogenesis*

Hyperleukocytosis directly increases blood viscosity by increasing the packed leukocyte volume. It indirectly increases blood viscosity by the formation of leukemic cell aggregates and thrombi.[144] Leukemic blasts are not easily deformed and tend to trap plasma between them. As myeloblasts are larger (350 to 450 $mm^3$) than lymphoblasts (250 to 350 $mm^3$), the former cause greater increases in viscosity, and myeloblasts are also more likely to aggregate owing to their "stickier" nature. [142,144] At very high WBC counts, leukemic aggregates proliferate within the cerebral vasculature and in the brain itself, resulting in damage to vessels and hemorrhage. [145] Tryka et al.[146] characterized the pathology of pulmonary leukostasis as "leukemic cell lysis pneumonopathy," in which degenerating aggregates of blasts in the vessels and interstitium release their intracellular contents, damaging alveoli diffusely. Leukemia-associated respiratory failure is exacerbated by pulmonary hemorrhage and possible toxins released from the blast cells that damage pulmonary endothelium. [147]

#### *Evaluation and Differential Diagnosis*

Frequently, a CBC revealing the significantly elevated WBC is obtained prior to arrival at a tertiary care center. The child with a WBC exceeding 100,000 per cubic milliliter should be evaluated for signs and symptoms of hyperleukocytosis. Many will be asymptomatic, but others will present with mental status changes, headaches, blurred vision, seizures, coma, and symptoms of stroke, papilledema, and retinal artery or retinal vein distention, all attributable to the hyperviscosity in the cerebral vessels.[142,144] Pulmonary leukostasis causes dyspnea, hypoxia, acidosis, and cyanosis. Priapism, clitoral engorgement, and dactylitis have been described with hyperleukocytosis.[148,149] Additional laboratory studies include serum electrolytes, uric acid, renal function tests, and a coagulation profile. A chest radiograph may reveal a mediastinal mass or diffuse interstitial infiltrates.

#### *Therapy and Recommendations*

No controlled studies are available on the management of hyperleukocytosis. As outlined in the section Tumor Lysis Syndrome, intravenous hydration at two to four times the maintenance volume, alkalinization with sodium bicarbonate, and allopurinol should be started. [150] Patients with platelet counts of fewer than 20,000 per microliter should receive platelet transfusions to prevent cerebral hemorrhage, as platelets do not add substantially to blood viscosity. In contrast, packed red cells increase viscosity.[151] The hemoglobin level should not be raised above 10 g per dL; most children are asymptomatic with hemoglobins of 7g per dL. Exchange transfusion or leukapheresis can rapidly lower the WBC count and may improve coagulopathy. [148] Pediatric studies found a 52% to 66% mean reduction in WBCs with exchange transfusion and a 48% to 62% reduction with leukapheresis. [141,152] Maurer et al.[153] noted a significantly lower incidence of severe TLS in patients with ALL (WBCs in excess of 200,000 per $mL^3$) who underwent leukapheresis as compared to those who did not. Neurologic abnormalities, respiratory distress, and priapism have improved after leukapheresis in patients with AML, ALL, and CML. [148] Whether leukapheresis reduces the risk of CNS hemorrhage in AML is unknown. [148] Problems associated with leukapheresis are the need for anticoagulation, difficulty with access in small children, and limited availability in many hospitals. Exchange transfusion and leukapheresis are only temporizing. Systemic antileukemic therapy must be initiated as soon as problems such as SVCS, SMS, and compromised renal function have been addressed.

Cranial irradiation to a dose of 400 cGy has been administered to prevent CNS hemorrhage. However, the risk of CNS hemorrhage in ALL is small: No cases occurred in 136 patients with counts between 100,000 and 400,000 per microliter. [142] Most pediatric oncologists do not use prophylactic CNS irradiation. [148,152]

## METABOLIC EMERGENCIES

### Tumor Lysis Syndrome

TLS consists of the metabolic abnormalities that result from the death of tumor cells and release of their contents into the circulation. The classic triad of TLS includes

hyperuricemia, hyperphosphatemia, and hyperkalemia. Symptomatic hypocalcemia can develop secondary to formation of calcium phosphate from the hyperphosphatemia. Although TLS can occur before any cytotoxic therapy, its manifestations usually appear 12 to 72 hours from the initiation of therapy.

### *Etiology and Pathophysiology*

TLS occurs in patients with tumors that have a high growth fraction, large volume, or wide dissemination and that are sensitive to cytotoxic therapy. It occurs most commonly in Burkitt's lymphoma, lymphoblastic lymphoma, and ALL, particularly T-cell–lineage ALL with hyperleukocytosis and extensive extramedullary disease. TLS has also been noted in neuroblastoma, medulloblastoma, breast carcinoma, and small cell lung carcinoma.[154] TLS is rare in AML and CML, despite high WBC counts. The literature contains descriptions of children who present with hyperuricemia and acute renal failure as the initial manifestation of occult lymphoproliferative malignancy.[154,155 and 156] Among 37 patients with Burkitt's lymphoma, Cohen et al.[157] determined that bulky abdominal tumors, elevated pretreatment serum uric acid and lactate dehydrogenase concentrations, poor urine output, or low glomerular filtration rate predisposed a patient to severe metabolic derangements. Andreoli et al.[158] found that advanced age (10.4 ± 5.4 years) correlated with development of renal failure in children with ALL. This may, in part, be due to the progressive decline in the fractional excretion and clearance of uric acid that accompanies advancing age. These researchers did not find a high WBC to be a predictor of renal failure.[158]

TLS is a direct result of the release into the circulation of the nuclear and cytoplasmic degradation product of malignant cells. Potassium, the principal intracellular cation, increases in the serum, and its excretion is reduced in renal insufficiency. A rapid rise in potassium can cause cardiac arrest in minutes or hours. Elevated uric acid comes from the breakdown of the released nucleic acids. In the presence of hyperuricemia, renal excretion of uric acid initially increases but then decreases as uric acid crystals precipitate in the collecting ducts of the renal tubules owing to the acid environment of the kidney.[155] Lymphoblasts are especially rich in phosphate, having four times the content of normal lymphocytes.[159] Elevated levels of serum phosphate are exacerbated by a metabolic acidosis, which induces a shift of intracellular phosphate into the extracellular space.[155] When the solubility product factor (Ca × P) reaches 60, calcium phosphate precipitates in the microvasculature, causing a secondary hypocalcemia.[159] Precipitation of uric acid crystals and calcium phosphate within the renal tubules and microvasculature leads to acute renal failure.

### *Evaluation and Differential Diagnosis*

In a patient at risk for TLS, pertinent historic information includes the time of onset of symptoms referable to the malignancy. Symptoms can include abdominal pain or fullness, back pain, vomiting, diarrhea, dehydration, anorexia, cramps, spasms, tetany, seizure, and alterations in consciousness suggestive of hypocalcemia. On examination, special attention should be given to blood pressure, cardiac rate and rhythm, abdominal masses, presence of pleural effusions or ascites, signs of SVCS or SMS, and signs of cerebral anoxia.

Initial studies include a CBC, determination of serum sodium, potassium, chloride, bicarbonate, calcium, phosphorus, uric acid, BUN, and Cr levels, and urinalysis. If the serum calcium is low, an ionized calcium and serum albumin assessment should be obtained as well. An electrocardiogram is essential if the serum potassium level is greater than 6.0 mEq per L. It may show QRS widening and peaked T waves. When the leukocyte count is high, the serum potassium can be artifactually elevated by spontaneous lysis of leukocytes, platelets, and erythrocytes (i.e., pseudohyperkalemia).[160] In pseudohyperkalemia, no cardiac or electrocardiographic changes occur, and the actual potassium concentration can be determined from plasma rather than serum.[160] Hypocalcemia can cause a prolonged $QT_C$ interval on electrocardiography. Patients with electrocardiographic abnormalities should be placed on a cardiac monitor. Because acute renal insufficiency due to obstruction can have manifestations similar to those of TLS, US or CT should be performed on any child with an abdominal or pelvic mass, to rule out obstructive renal failure. Obstructive renal failure can be improved rapidly with urinary catheterization and is exacerbated by hydration.[81] A chest radiograph may reveal a mediastinal mass.

### *Therapy*

Early and aggressive intervention effectively reduces the morbidity associated with TLS. Patients with newly diagnosed leukemia or NHL should receive hydration, alkalinization, and allopurinol (Table 39-10). For most patients, this regimen suffices to prevent clinically significant tumor lysis and renal failure. When severe metabolic abnormalities have improved, cytotoxic therapy can commence.

$D_5{}^1/_2NS$, 5% dextrose with 0.25% normal saline

**TABLE 39-10. MANAGEMENT OF PATIENTS AT RISK FOR TUMOR LYSIS SYNDROME**

Hydration is probably the most critical factor in treatment. Increased hydration translates to increased urinary outflow and an improved glomerular filtration rate. Patients should receive two to four times the maintenance fluid volume as 5% dextrose in 0.25% normal saline, with 40 to 80 mEq of sodium bicarbonate per liter, to produce a urine pH of 7.0 to 7.5. Urine output should be maintained at more than 100 mL per $m^2$ per hour, with a specific gravity of no more than 1.010. Potassium and calcium should not be added to hydration fluids unless a patient has symptomatic deficiencies. Although contraindicated in the patient with volume depletion, diuretics and mannitol may be indicated in patients with poor urine output because of accumulation of the infused fluid in the third space.[155] If urine output falls below 60 mL per $m^2$ per hour, mannitol can be given at 0.5 mg per kg over 15 minutes, followed by furosemide (0.5 to 1.0 mg per kg).

Allopurinol (250 to 500 mg per $m^2$ per day to a maximum of 800 mg) directly inhibits the formation of uric acid by blocking the enzyme xanthine oxidase, which converts hypoxanthine and xanthine to uric acid. An alternative widely used in Europe but still under investigation in the United States is urate oxidase (Uricase), which converts uric acid to allantoin and does not require alkalinization.[155]

Alkalinization of the urine aids in solubilizing uric acid. Sodium bicarbonate should be discontinued when plasma levels of uric acid normalize and cytotoxic therapy begins.[161] Overzealous alkalinization (urine pH in excess of 7.5) can lead to worsening nephropathy. At a pH above 7.5, xanthine and hypoxanthine stones may form and, at a pH of 8 or higher, calcium phosphate may crystallize in the kidneys.[161]

Patient weight should be measured once or twice daily. Serum electrolytes must be monitored; the frequency of obtaining them depends on the risk level of the patient. In a patient with disseminated Burkitt's lymphoma who presents with TLS, metabolic studies should be repeated 4 hours after initiation of therapy and monitored at least four times daily. Additional interventions should be started when metabolic abnormalities are worsening, in an attempt to avoid dialysis. Aluminum hydroxide, a phosphate binder (15 mL every 8 hours, escalated to a continuous nasogastric infusion as needed), will increase excretion of phosphate. Sodium polystyrene sulfonate (Kayexalate, 1 g per kg orally with 50% sorbitol), a potassium-binding resin, may help to lower a rising potassium level. Calcium gluconate (100 to 200 mg per kg per dose) can shift potassium intracellularly and stabilize myocardial conduction. Insulin (0.1 units per kilogram of rapid-acting insulin) with 2 mL per kg of 25% glucose in water as an intravenous bolus also promotes intracellular influx of potassium.[135] When hyperphosphatemia is present, treatment of hypocalcemia with intravenous infusions of calcium gluconate (100 to 2,000 mg per kg per dose) should be reserved for those individuals with signs and symptoms of hypocalcemia such as tetany, arrhythmias, or seizures. Increasing the serum calcium level will increase the calcium-phosphorus solubility factor product, favoring calcium phosphate deposition and renal failure.

When medical interventions fail to correct electrolyte disturbances or oliguria persists, dialysis may be necessary. Table 39-10 outlines the indications for starting

dialysis. Hemodialysis is preferable to peritoneal dialysis as it corrects electrolyte abnormalities more rapidly. Uric acid and phosphate levels fall as urine output increases.[155] Peritoneal dialysis is contraindicated with an abdominal or pelvic tumor. Continuous venovenous hemofiltration has been used prophylactically in patients with Burkitt's lymphoma to prevent renal failure,[162] but the benefits are unclear. Because tumor lysis often occurs in the setting of a high leukocyte count, some practitioners have advocated leukapheresis or exchange transfusion to reduce the tumor load and subsequent massive tumor lysis. These methods have not been subjected to any controlled analysis.

## Hypercalcemia

Hypercalcemia is defined as a serum calcium level in excess of 12 mg per dL. Levels higher than 12 mg per dL affect multiple organ systems, and levels exceeding 20 mg per dL can be fatal.

### *Etiology and Pathophysiology*

Over a span of 29 years at St. Jude Children's Research Hospital, hypercalcemia occurred in 25 children with cancer. [163] The 25 represented an incidence of 0.4%, much lower than the 5.0% to 20.0% noted in adults with cancer.[164] Of the 25 affected children, 10 had ALL and 4 had rhabdomyosarcoma.[163] Lymphomas, rhabdoid tumors, Ewing's sarcoma, neuroblastoma, brain tumors, hepatoblastoma, and ovarian carcinoma in teenagers may cause hypercalcemia. [163,165,166 and 167] As contrasted to patients with solid tumors and lymphomas who developed hypercalcemia later in their disease course and whose hypercalcemia proved to be more resistant to therapy, children with acute leukemia were more likely to present with hypercalcemia, and their hypercalcemia was more likely to respond to therapy. [163]

Malignant hypercalcemia can be caused by a defect in renal excretion, an increase in bone resorption, or a combination of both. Seymour and Gagel [168] classified malignant hypercalcemia into three categories: humoral, osteolytic, and calcitriol-mediated. Most common in adults is humoral hypercalcemia. The tumor produces an ectopic hormone that causes parathyroid hormone–like effects: increased osteoclastic bone resorption, increased renal resorption of calcium, and increased renal phosphate loss. Parathyroid hormone rarely is elevated in these patients, but a parathyroid hormone–related peptide has been found to be elevated in children with rhabdomyosarcoma and in women with breast cancer who have hypercalcemia.[169] $PGE_2$ in breast cancer and growth factors secreted by tumors can also cause bone resorption.[170]

In osteolytic hypercalcemia osteoclasts activated at the site of bone metastases resorb bone with the participation of various cytokines. Osteoclast-activating factor has been associated with hypercalcemia in patients with multiple myeloma and Burkitt's lymphoma. [171,172] Calcitriol-mediated hypercalcemia is most frequent in HD and NHL.[168] The calcitriol syndrome is characterized by increased intestinal absorption of calcium, increased renal excretion, and normal serum phosphate levels and metabolism.[168]

### *Evaluation and Differential Diagnosis*

Gastrointestinal, renal, neuromuscular, and cardiovascular symptoms dominate the clinical picture of malignant hypercalcemia ( Table 39-11). Early nonspecific symptoms include nausea, constipation, and polyuria, but increasing serum calcium levels lead to profound muscle weakness, renal insufficiency, bradyarrhythmias, and coma. Anorexia, vomiting, and polyuria initiate a self-sustaining spiral of dehydration, which leads to a decreased glomerular filtration rate and reduced renal calcium excretion. The early symptoms can mimic TLS in the patient with newly diagnosed leukemia, and the two disorders can overlap. Harguindey et al. [165] found that all seven of their patients with malignant hypercalcemia had elevated BUN and uric acid levels, normal or increased phosphorus concentration, and a metabolic alkalosis. Serum calcium, phosphate, BUN, Cr, uric acid, and ionized calcium levels should be determined. Serum levels of parathyroid hormone, parathyroid hormone–related peptide, and 25-(OH) vitamin D and 1,25-$(OH)_2$ may help to define the origin of the hypercalcemia. An electrocardiogram may reveal a prolonged PR interval with broad T waves. A bone scan or skeletal survey may show bony metastases.

**TABLE 39-11. SIGNS AND SYMPTOMS OF HYPERCALCEMIA OF MALIGNANCY**

Medications that exacerbate hypercalcemia of malignancy include thiazide diuretics, oral contraceptives, tamoxifen, antacids with calcium carbonate, and lithium. Hypervitaminosis A or D, renal disease, granulomatous disease, adrenal insufficiency, fractures, and immobilization may also contribute.

### *Therapy*

Calcium levels exceeding 12.0 mg per dL require immediate correction. Treatment consists of four components: hydration, increased renal calcium excretion, decreased calcium mobilization from bone, and treatment of the underlying malignancy. For serum calcium levels of less than 14 mg per dL, hydration with furosemide diuresis may suffice.[158,173] With higher serum calcium levels, the recommended therapy is vigorous forced diuresis starting with normal saline repletion at two to three times maintenance volume. When a good urine output is obtained, furosemide (2 to 3 mg per kg every 2 hours) is started. [135] Furosemide blocks calcium resorption by the kidney and can decrease serum calcium by 3 mg per dL in 48 hours. Forced diuresis requires monitoring of both intravascular volume and serum and urine electrolytes; profound fluid shifts and potassium and magnesium losses may accompany sodium, calcium, and fluid excretion.

Prednisone, 1.5 to 2.0 mg per kg per day, slowly reduces the serum calcium level if hypercalcemia is mediated by osteoclast-activating factor, $PGE_2$, or calcitriol. Salmon calcitonin (4 MRC units per kilogram) acts within hours to reduce the serum calcium level by inhibiting bone resorption and promoting calcium excretion. Resistance to exogenous calcitonin develops within days, although the combined use of steroids and calcitonin may provide control for longer periods. Mithramycin, an antineoplastic antibiotic, lowers calcium within days but is too cytotoxic for prolonged use. [135]

Bisphosphonates inhibit osteoclast-mediated resorption of bone and reduce osteoclast viability. Bisphosphonates are highly effective in the treatment of hypercalcemia and have a long duration of action. Side effects include transient lymphopenia, fever, myalgia, gastrointestinal upset and, most seriously, prolonged hypocalcemia, hypophosphatemia, and hypomagnesemia. Although most data on the use of bisphosphonates for hypercalcemia involve adults, the literature on bisphosphonate use in the pediatric population is growing. Most pediatric data concern intravenous pamidronate. [174] Clinical response occurs in 12 to 48 hours after administration, and serum calcium levels usually normalize within 3 to 7 days. [174] Body et al.[175] determined that the proper starting dose in adults was 0.25 to 1.50 mg per kg. A recommended starting dose for children is 0.5 to 1.0 mg per kg infused over 4 to 6 hours, with close monitoring of serum calcium, phosphate, and magnesium levels.[174,176] A subsequent dose of 1 mg per kg can be given if necessary. Oral bisphosphonates are available, but pediatric experience with them is limited.

## Syndrome of Inappropriate Secretion of Antidiuretic Hormone (Hyponatremia)

Excessive secretion of antidiuretic hormone (ADH) accompanying a normal or low plasma osmolality or serum sodium concentration is termed *inappropriate* because it further depresses the levels of these chemicals. Symptoms of excessive ADH secretion are not usually apparent until the plasma sodium level falls to less than 120

mmol per L. A fall in the serum sodium level to less than 120 mmol per L within 24 hours or a gradual decrease in serum sodium to less than 115 mmol per L can be life threatening.

### *Etiology and Pathophysiology*

SIADH is characterized by the release of ADH without any relation to plasma osmolality. Excessive secretion of ADH increases water resorption by the kidneys and incites dilutional hyponatremia.[170] Hyponatremia associated with SIADH is associated with the use of vincristine, vinblastine, cyclophosphamide, ifosfamide, cisplatin, and melphalan.[177,178] Cyclophosphamideand ifosfamide are believed to reduce free-water clearance independent of ADH, and the resultant hyponatremia is aggravated by aggressive hydration, which is used to prevent cystitis related to cyclophosphamide and ifosfamide. [177]

SIADH can also occur in the setting of CNS injury or CNS disease; stress, pain, surgery, or positive-pressure ventilation; pulmonary infection and inflammation; and tumors, such as small cell lung carcinoma, lymphoma, or gastrointestinal carcinoma.[177] CNS disease stimulates release of ADH from the posterior pituitary.

### *Evaluation and Differential Diagnosis*

Most hyponatremia is asymptomatic and usually is diagnosed by routine laboratory studies. Early symptoms include fatigue, nausea, and anorexia; later manifestations are lethargy, confusion, seizures, and coma.[170] Although severe hyponatremia in children with cancer often is related to SIADH, the most common cause of mild hyponatremia is iatrogenic: simple overhydration with a hypotonic solution such as 5% dextrose in 0.25% normal saline. Hyponatremia can also be caused by failure to administer stress doses of glucocorticoids in a patient who has recently discontinued systemic steroids. Hypothyroidism, heart failure, acute renal failure, pancreatitis, and use of diuretics may exacerbate hyponatremia. Diabetes insipidus occurs in children with Langerhans' cell histiocytosis or with suprasellar tumors, either from the tumors or after irradiation. Diabetes insipidus usually presents with polydipsia, polyuria, and hypernatremic volume depletion. However, if the patient has been replacing losses with water or other hypotonic solutions, hyponatremia may develop. In patients with CNS tumors and renal damage, SIADH may need to be differentiated from cerebral salt wasting.[179,180]

The following studies should be obtained: renal and liver function tests, serum osmolality, and urinalysis, including a specific gravity, urine sodium and creatinine levels, and osmolality. The diagnosis of SIADH is made if the serum osmolality (usually less than 280 mmol per L) is lower than the urine osmolality (often greater than 500 mmol per L).

### *Therapy and Recommendations*

Fluid restriction is the mainstay of therapy for mild hyponatremia due to water intoxication, chronic SIADH, or acute SIADH if the sodium level exceeds 120 mmol per L and the patient is asymptomatic.[181,182] In cases of severe neurologic involvement (seizures, coma), boluses of 3% hypertonic saline to replace sodium losses should be started, followed by 1 mg of furosemide per kg to diurese free water. The rate of sodium correction should not exceed 2 mmol per L per hour, as too rapid a correction of sodium can cause cerebral edema, further neurologic deterioration, and death. [181,182] Urine output should be monitored closely, and frequent monitoring of serum electrolytes also is essential.

## Shock

Shock occurs when cardiovascular dysfunction results in inadequate perfusion of vital organs. Shock is common in children with cancer. The American Heart Association classifies shock according to either its etiology or its effects on blood pressure or cardiac output. [183]

### *Etiology and Pathophysiology*

The etiologic classifications are hypovolemic shock, cardiogenic shock, and distributive shock ( Table 39-12). Many entities fall into two categories. Hypovolemic shock is the most common type. In pediatric cancer patients, it usually is associated with bacterial sepsis. Hypovolemic shock may also occur with an addisonian crisis in patients who have received high doses of glucocorticoids in the previous 6 months and then have discontinued them. Pancreatitis may cause hypovolemic and distributive shock.

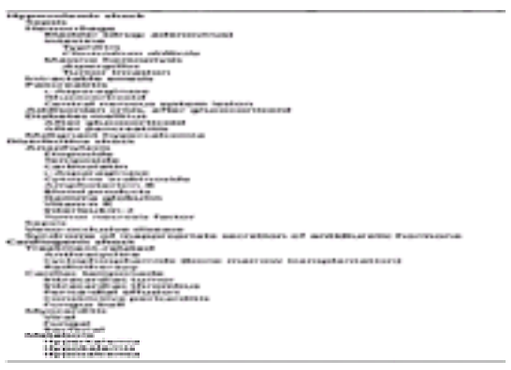

**TABLE 39-12. COMMON CAUSES OF SHOCK IN THE CHILD WITH CANCER**

Distributive shock occurs when there is inappropriate distribution of the blood volume. In cancer patients, the most common causes of distributive shock are drug-related anaphylaxis and sepsis (Table 39-12). Distributive shock occurs with high-dose boluses of interleukin-2. Delayed anaphylactic shock may take place weeks after administration of interleukin-2, when patients receive radioactive contrast. Hematopoietic growth factors and interferons have also been associated with anaphylactic reactions. Amphotericin-B causes hypotension and rigors, which, if uncontrolled, can lead to ventilation-perfusion defects, causing a patient in compensated shock to decompensate fully, with respiratory and cardiac failure.

Cardiogenic shock occurs in patients who have received moderate or high doses of anthracyclines with or without cardiac irradiation. It can occur after high-dose cyclophosphamide use during bone marrow transplant cytoreduction. A mass within the cardiac chambers or constrictive or effusive pericarditis can lead to cardiogenic shock.

Shock is a manifestation of inadequate organ perfusion secondary to inadequate cardiac output. [183] In hypovolemic shock, the cardiac output is low; in cardiogenic shock and in anaphylaxis, it may be high, with a mismatch between blood flow and organ needs. The body attempts to compensate for inadequate perfusion first by increasing heart rate and then by reducing perfusion to the kidneys, splanchnic bed, and skin. [183] Only when these mechanisms fail to compensate does hypotension ensue.

### *Evaluation and Differential Diagnosis*

The respiratory and cardiovascular systems must be assessed rapidly. Increased heart and respiratory rates; signs of respiratory distress (air hunger, nasal flaring, retractions, stridor, grunting, use of accessory muscles); weak peripheral pulses; pale, gray, or mottled skin; and cold extremities may be indications of impending cardiovascular collapse. Airway patency should be assessed, as masses can block the airway and cause shock. Capillary refill time should be used to assess peripheral perfusion. The status of the brain is best assessed by the level of consciousness, the patient's ability to respond to normal stimuli and to pain, the patient's generalized muscle tone and pupil size, and the presence of posturing or seizures.

### *Therapy*

For detailed management of shock, the reader is referred to the Textbook of Pediatric Emergency Medicine.[184] Therapies include establishing an airway and providing 100% oxygen by the least traumatic means possible. Initial fluid resuscitation should be 20 mL per kg of 0.9% normal saline or Ringer's lactate solution given as a rapid bolus over 10 to 20 minutes. In the absence of a response, this can be repeated up to 60 mL per kg or more in the first hour.[184] Concomitantly, the underlying etiology should be sought and treated. If the cause is presumed to be sepsis, cultures should be obtained and appropriate antibiotics started without delay. A chest radiograph is needed if the patient has respiratory symptoms. A CBC, electrolytes assessment, and tests of renal and hepatic function are necessary to determine proper replacement fluids. If there is evidence of hemorrhage, the patient should receive packed red cells (see Chapter 40), platelets, coagulation factors, and a surgical evaluation if there is a surgically correctable cause of hemorrhage.

In anaphylactic shock, the suspected drug should be discontinued immediately. Epinephrine 1:1,000 (0.01 mL per kg) should be given subcutaneously. If there is poor peripheral perfusion, epinephrine 1:10,000 (0.01 mL per kg) is given intravenously at a rate of 0.01 mg per kg over 1 to 2 minutes. Antihistamines—either diphenhydramine (1 to 2 mg per kg intravenously or intramuscularly) or hydroxyzine (0.5 to 1.0 mg per kg)—should be given. The use of steroids in anaphylaxis may prevent late-phase reactions. Steroids often are used for blood product reactions.

In cardiogenic shock, an electrocardiogram and an echocardiogram should be obtained immediately. An abnormal rhythm must be appropriately corrected. Use of adrenergic agents should be planned with the consultation of cardiologists and intensivists. If there is cardiac tamponade, the cause of the tamponade must be relieved surgically and emergently.

# HEMATOLOGIC SUPPORTIVE CARE AND HEMATOPOIETIC CYTOKINES

ZORA R. ROGERS
VICTOR M. AQUINO
GEORGE R. BUCHANAN

## INTRODUCTION

The success of more intensive treatment of children with cancer during the last two decades is associated directly with advances in supportive care. Hematopoietic cytokines, safer blood products, and a better understanding of the potential benefits and risks of their use are the focus of this chapter. The pathophysiology, differential diagnosis, and practical aspects of management of hematologic complications of childhood cancer are discussed, with emphasis on therapy, including transfusion and cytokine support.

## ANEMIA

### Pathophysiology

Anemia is the most commonly appreciated and readily managed of the hematologic complications of childhood cancer. The relatively long survival of erythrocytes (120 days) usually leads to a slow decline in hemoglobin concentration and indolent development of symptoms. However, this insidious onset may lead to physicians' underappreciation of the toll that fatigue, related to anemia, takes on their patients. [1]

The primary cause of anemia in children with cancer is decreased erythrocyte production. This may be due to replacement of normal hematopoiesis by malignant cells (leukemic blasts or metastatic solid tumor cells), transient marrow aplasia due to chemotherapy, or suppression of erythropoiesis due to inflammation, either related to the malignancy itself or accompanying infection (e.g., anemia of infection or chronic disease). Acute or chronic blood loss facilitated by concomitant thrombocytopenia also may occur. Rarely, hemolysis due to chemotherapeutic agents,[2] infection, or alloantibodies induced by prior transfusions may occur as well. [3]

If the bone marrow is not producing red blood cells, the rate of decline in the hemoglobin concentration should be 1/120th of the red cell mass per day, or approximately 0.7 to 1.0 g per dL per week. A more rapid decline in hemoglobin suggests bleeding or hemolysis. With marrow suppression, the reticulocyte count is inappropriately low for the degree of anemia, and leukopenia, thrombocytopenia, or both are common. Children with cancer also often have a component of the anemia of inflammation or chronic disease, characterized by defective iron recycling, relatively decreased serum erythropoietin concentrations, and inhibition of erythropoiesis by such cytokines as tumor necrosis factor (TNF) and interleukin-1b (IL-1b). [4] Thus, patients with newly diagnosed solid tumors, even without marrow infiltration, may have a mild hypoproliferative anemia.

Parvovirus B19, the cause of erythema infectiosum (also known as *fifth disease*) in healthy children and transient aplastic crises in patients with chronic hemolytic anemia, may produce prolonged erythroid aplasia in immunosuppressed individuals. The primary infection may be transmitted by respiratory droplet contact or transfusion.[5,6] Persistence of parvovirus may inhibit erythropoiesis for months.[7,8] Neutropenia and thrombocytopenia also may occur, interfering with continued chemotherapy.[5,9] Repeated infusion of intravenous immunoglobulin may provide neutralizing anti-B19 antibodies, resulting in more rapid return of erythropoiesis. [10] Persistence of infection due to other viruses, such as cytomegalovirus (CMV) or Epstein-Barr virus (EBV), also may lead to erythroblastopenia or pancytopenia. In such cases, specific antiviral therapy and immunoglobulin treatment may be beneficial in treating the infection and reestablishing hematopoiesis.

Bleeding in association with thrombocytopenia, most commonly from epistaxis or gastrointestinal hemorrhage, usually is clinically evident. However, the volume of blood loss from occult gastrointestinal bleeding or repetitive blood sampling for laboratory monitoring may be inapparent and substantial.

Hemolysis is an unusual mechanism of anemia in pediatric cancer patients ( Table 40-1). Sepsis and disseminated intravascular hemolysis (DIC) are clinically evident causes. Bone marrow transplant conditioning or prior intensive chemotherapy may produce a thrombotic microangiopathy resembling thrombotic thrombocytopenic purpura (TTP) or hemolytic uremic syndrome (HUS) that may be more cryptic in presentation. [2,11]

| Pathophysiology | Laboratory finding | Clinical example |
|---|---|---|
| Microangiopathy | Blood smear: schistocytes, helmet cells | DIC (sepsis, APML); thrombotic microangiopathy after BMT[456] or chemotherapy[2] |
| Immune mediated | Blood smear: microspherocytes, positive direct antiglobulin (Coombs') test | Hodgkin's disease; drugs (teniposide, mitomycin-C)[2,11]; transfused ischemagglutinins[1]; alloantibodies[39] |

APML, acute promyelocytic leukemia; BMT, bone marrow transplantation; DIC, disseminated intravascular coagulation.

**TABLE 40-1. HEMOLYTIC ANEMIA IN CHILDREN WITH CANCER**

Immune-mediated hemolysis may result from untreated Hodgkin's disease, thymoma, a chemotherapeutic agents such as teniposide, or prior transfusions. Delayed hemolytic transfusion reactions, due to pretransfusion antibody titers that have waned to undetectable levels, are increasingly problematic with aggressive treatment of multiple relapses. Mild immune-mediated hemolysis may result from isohemagglutinins in the plasma in which transfused platelets are suspended. [3] This last problem can be avoided by use of ABO and Rh type-specific platelets.

## Indications for Erythrocyte Transfusion Support

Red blood cells should be transfused to maintain oxygen-carrying capacity rather than empirically to maintain an arbitrary value. When a patient is otherwise healthy and not dehydrated, oxygen delivery usually is sufficient above a hemoglobin concentration of 7.0 g per dL, a number recently endorsed by a National Institutes of Health Consensus Panel on perioperative transfusion. [12,13] Others have demonstrated that healthy adults may be able to tolerate hemoglobin concentrations as low as 5.0 g per dL without inadequate tissue oxygen delivery. [14] Indeed, avoiding transfusion may even be beneficial for certain patients. A large Canadian study demonstrated that severely ill intensive care unit patients randomly assigned to receive transfusion only if their hemoglobin concentration declined to below 7.0 g per dL had mortality lower than that in those who received red cell transfusions for a hemoglobin value below 10 g per dL. [15] However, no objective criteria exist by which to determine when to transfuse red cells to individual patients or how to evaluate the effects of that therapy. [16,17]

The child's disease state, coexisting thrombocytopenia, planned invasive procedures, and status relative to starting or recovering from a cycle of chemotherapy should be considered in assessing when to transfuse erythrocytes. When the hemoglobin value is below 6 to 7 g per dL, most children with cancer display symptoms of anemia, such as malaise, lassitude, decreased activity, or irritability that resolve with transfusion. With higher hemoglobin values, similar symptoms may occur without convincing evidence that anemia is the cause. Unless affected children have significant symptoms of anemia, transfusion need not be given routinely if leukemic remission or recovery from chemotherapy-induced aplasia is imminent. Conversely, if an invasive procedure is planned, particularly if such patients are significantly thrombocytopenic, a hemoglobin of approximately 10 g per dL may minimize significant perioperative bleeding by providing a cushion and by exercising a beneficial effect on hemostasis. [17,18] Similarly, red cell transfusion support should be considered for affected children who have a modest degree of anemia (hemoglobin of 8 to 10 g per dL) and are receiving or have just received intensive myelosuppressive chemotherapy, in preparation for the inevitable decline in both platelets and red cells.

## Erythrocyte Replacement Therapy

### *Whole Blood*

Although whole blood was the principal erythrocyte-containing product used before the 1960s, individual component therapy of packed red blood cells, single-donor platelets, or fresh frozen plasma (FFP) now is preferred. Whole blood rarely is available without advance planning and offers little advantage over packed erythrocytes plus crystalloid or FFP, even for treatment of hemorrhage or for exchange transfusion. [19]

### *Packed Red Blood Cells*

Each unit of packed red blood cells is prepared by the centrifugation of one unit of single-donor whole blood. The product is collected from a donor in varying volumes of anticoagulant and additives that determine the final hemoglobin concentration. A citrate-phosphate-dextrose-adenine anticoagulant (CPDA-1) commonly is used. CPDA-1-preserved units contain approximately 250 mL, with a hematocrit of 65% to 80% and may be stored for up to 35 days. [19,20] Additive solutions containing adenine and saline (Adsol or AS) may be added to anticoagulated packed red blood cells. This allows for storage of red cells for up to 42 days and is preferred for blood bank inventory reasons. Units of AS-added cells have a final volume of approximately 350 mL with a hematocrit of 55% to 60%. [19]

The volume of a red cell transfusion in children should be ordered in mL per kg of recipient body weight. The standard transfusion volume is 10 mL per kg. This should raise a recipient's hemoglobin by 2.5 to 3.0 g per dL or hematocrit by 8% to 9% if CPDA-1-anticoagulated cells are used and should raise the hemoglobin by 2.0 g per dL or the hematocrit by 6% to 7% if AS-preserved cells are used. The maximum volume of erythrocytes that can be administered safely in a 4-hour transfusion generally is 15 mL per kg in hemodynamically stable patients. Neonatal intensive care units may employ up to 17 mL per kg as their standard volume. Each episode of transfusion must be completed within 4 hours after the unit or aliquot has been entered.

Children with a hemoglobin concentration of less than 5 g per dL, particularly if signs of congestive heart failure or hypertension are present, should receive smaller repeated transfusions, perhaps accompanied by a diuretic. [21] A safe initial transfusion volume is the number of mL per kg equal to the hemoglobin value given over 4 hours. That is, if the hemoglobin value of a 10-kg child is 4 g per dL, 40 mL of packed cells may be given over 4 hours without significant risk of volume overload. Multiple small-volume transfusions, separated by several hours to allow cardiovascular stabilization, can restore oxygen-carrying capacity within 24 hours. In small children, a single unit of red cells can be divided into sterile aliquots by the blood bank to provide several transfusions from one unit and, thus, one donor exposure. Rapid transfusion of a large volume of erythrocytes in such circumstances may result in pulmonary edema.

A partial exchange transfusion, either performed manually in aliquots of 10 to 50 mL or by automated erythrocytapheresis, may be preferable to repetitive transfusion for severe anemia. This procedure requires good vascular access but has the advantage of rapid isovolumetric correction of the anemia. The volume of blood for manual exchange can be estimated by a variety of formulas. [22,23]

### *Component Processing*

Leukocyte depletion and irradiation of red cells are reviewed later in this chapter.

### *Red Cell Substitutes*

Red cell substitutes, including human or bovine cell-free hemoglobin solutions, perfluorocarbon emulsions, or liposome-encapsulated hemoglobin, are being investigated in advanced clinical trials. Side effects are not understood completely but include both gastrointestinal complaints and vasoconstriction for hemoglobin derivatives and thrombocytopenia and dose limitations for the perfluorocarbon products. The major difficulty remains their very short (12- to 48-hour) duration of action, inadequate for most needs of pediatric oncology patients. [24]

### *Recombinant Human Erythropoietin Therapy*

The etiology of the anemia observed in children with cancer includes inappropriate erythropoietin production in response to a decreased hemoglobin level. [25] Cytotoxic chemotherapy contributes further to the impaired erythropoietin response to anemia. [26] Recombinant human erythropoietin has been shown to have efficacy in the treatment of anemia in adults and children with chronic end-stage renal disease [27,28] and [29] and has been evaluated for the treatment of the anemia of prematurity as well. [30,31] The use of erythropoietin in patients undergoing cytotoxic chemotherapy, therefore, is logical.

The specific uses of erythropoietin for pediatric patients undergoing chemotherapy remain poorly defined. Most studies of erythropoietin have focused on adult patients. In a series of double-blind placebo-controlled trials, thrice-weekly subcutaneous injections of erythropoietin, 100 to 300 units per kg per dose, generally resulted in a rise in hemoglobin concentration of 1 to 2 g per dL in patients receiving moderately intensive chemotherapy. [1,32,33,34,35,36,37,38,39,40,41,42] and [43] Small studies of pediatric patients undergoing moderate-dose chemotherapy suggested a similar effect. [36,43,44] Furthermore, studies of adults have suggested that the increase in hemoglobin concentration caused by erythropoietin may be associated with an improved quality of life. [32,42,45] Studies currently under way are assessing the effect of

erythropoietin on the quality of life of children who are undergoing chemotherapy for solid tumors or leukemia.

Randomized trials evaluating erythropoietin use in patients undergoing allogeneic bone marrow transplantation (BMT) have demonstrated that erythropoietin therapy can hasten erythroid engraftment.[46,47,48 and 49] However, the effect is modest at best, and the cost of the erythropoietin use exceeds the cost of the erythrocyte transfusions. In the setting of autologous BMT, randomized studies have not found any reduction in red blood cell transfusion requirements or time to erythrocyte engraftment with erythropoietin use.[50,51] Nonrandomized studies of pediatric patients undergoing either autologous or allogeneic BMT report that the efficacy of erythropoietin is similar to that reported in adult trials. [43,52]

Despite these data, the role of erythropoietin therapy in the supportive care of pediatric cancer patients remains undefined. The agent is expensive, requires an additional injection for patients who already may be receiving other cytokines, and may not be effective in patients whose chemotherapy treatments are intensive. The quality-of-life benefits seen in adult patients may not pertain to children. Given the increasing safety of red blood cell transfusions (see Complications of Blood Transfusion Support), the advantage of erythropoietin therapy with regard to enhanced safety might be considered marginal. However, in certain groups of patients, such as Jehovah's Witnesses, erythropoietin may play an important role.

## HEMOSTASIS

Normal hemostasis *in vivo* is maintained by a balance between hemorrhagic and thrombotic regulatory pathways. Pediatric cancer patients are at risk for impairment of hemostasis as a result of thrombocytopenia, platelet dysfunction, DIC, and liver disease and the prothrombotic tendencies of common therapies, such as L-asparaginase or indwelling central venous lines. Overall, thrombocytopenia is the most common complication leading to hemorrhage encountered by pediatric oncologists, and the primary form of hematologic support is platelet transfusion.

## THROMBOCYTOPENIA

### Pathophysiology

Thrombocytopenia, defined as a platelet count of less than 150,000 per $mm^3$, results from one or more of four basic mechanisms: decreased production, increased destruction, hypersplenism (i.e., splenic sequestration), or consumption that accompanies brisk bleeding or extensive transfusion. Decreased production of platelets usually is caused either by marrow replacement by leukemia or by solid tumor, or marrow suppression secondary to chemotherapy or infection.

Peripheral destruction of platelets with inadequate marrow compensation may occur on an immune basis or may be due to mechanical factors. Immune-mediated thrombocytopenia has been described in children with leukemia and other forms of cancer, but its occurrence may be coincidental. [53,54] Immune complexes may be deposited on the platelet membrane during infection and can result in thrombocytopenia from ingestion of the platelet by mononuclear phagocytes in the spleen. The thrombocytopenia that may occur after dactinomycin (actinomycin-D) therapy appears to be immunologic and responds to treatment with prednisone. [55]

Thrombocytopenia from mechanical platelet injury occurs in DIC, complicating acute promyelocytic leukemia (APML) or solid tumors, such as neuroblastoma. Significant thrombocytopenia from hypersplenism is uncommon except in the massive chronic splenomegaly seen in such disorders as Langerhans' Cell histiocytosis, hemophagocytic syndromes, and juvenile chronic myelogenous leukemia.

### Indications for Platelet Transfusion Support

There is no doubt about the need for platelet support in children who have cancer and have a platelet count below 50,000 per $mm^3$ and extensive cutaneous mucosal or internal bleeding.[56] Patients with cancer and platelet counts between 20,000 and 100,000 per $mm^3$ may be at risk of hemorrhage with invasive procedures, such as lumbar puncture or surgical incision. A minimum platelet count of 50,000 per $mm^3$ has been recommended widely for surgical procedures on the basis of consensus rather than scientific evidence.[57] Similarly, a platelet count of 20,000 per $mm^3$ often is advised for lumbar puncture. A minimum platelet concentration is not needed before bone marrow aspiration or biopsy, as direct pressure can control bleeding.

The more difficult questions are the degree of thrombocytopenia that should trigger prophylactic platelet transfusions and the considerations other than platelet number that should affect management decisions regarding transfusion use. Life-threatening hemorrhage, either intracranial or gastrointestinal, are fortunately too rare to serve as an end point for therapeutic trials of prophylactic platelet transfusion. Thus, designing prospective randomized clinical trials with clinically relevant end points is difficult. Consensus guidelines do exist, but they are conflicting and, in practice, may not always be followed. [56,58,59] In the United States today, approximately 75% of platelet concentrates are given for prophylaxis rather than as treatment of overt bleeding. [57,60]

In 1962, Gaydos et al.[61] established a quantitative relationship between platelet count and significant hemorrhage in patients with newly diagnosed acute leukemia. Although the frequency of days during which bleeding was observed increased slightly with a platelet count below 20,000 per $mm^3$, no threshold that predicted hemorrhage was found.[61,62] However, in the early 1960s, most patients would have been treated with aspirin routinely, rendering the data inapplicable to pediatric patients of today.[62] In 1978, Slichter and Harker[63] produced the first good evidence of a clinical platelet threshold below which bleeding increased. Using a sensitive radioisotopic technique, they demonstrated an increase in stool blood loss only with platelet counts below 5,000 to 7,000 $mm^3$.

Two descriptive studies subsequently examined the risk of thrombocytopenic bleeding and found an increase in hemorrhage only if the platelet count was below 10,000 per $mm^3$.[64,65] Four other studies more recently assessed the risk of bleeding when transfusions were given for measured platelet counts below 10,000 per $mm^3$ versus below 20,000 per $mm^3$. All studies demonstrated the absence of difference in bleeding episodes, number of patients with bleeding, or deaths caused by hemorrhage between the groups.[66,67,68,69,70 and 71] Administering platelet transfusions only for overt bleeding or for a platelet count below 10,000 per $mm^3$ resulted in a mean reduction of 30% (range, 22% to 40%) in the total number of platelet transfusions across all studies. [71]

Similar findings emerged from studies of patients undergoing BMT. Specifically, no difference was seen in bleeding events regardless of assignment to prophylactic platelet transfusion below either 10,000 per $mm^3$ or 20,000 per $mm^3$. Further, hemorrhagic cystitis, mucositis, infection, and graft-versus-host disease—all complications of transplantation that increase the bleeding tendency—were present in nearly all patients who experienced major hemorrhages. [66,72] This finding suggests that clinical status rather than platelet count can predict who will have bleeding complications, even in high-risk BMT patients. Thus, more intensive platelet transfusion support could be reserved for patients with these other risk factors for bleeding.

On the basis of these studies, a new consensus has been formulated, as summarized in Table 40-2. For stable cancer patients, a platelet threshold of 5,000 to 10,000 per $mm^3$ is considered safe, and prophylactic platelets should be given only if the platelet count falls below this level. [59,60,62,64,71,73,74] Assuming that patients have normally functioning platelets, fatal bleeding is unlikely to occur at a platelet count over 5,000 per $mm^3$.[59,65] However, if children have other risk factors for thrombocytopenic bleeding, including infection, coagulopathy, a sudden increase in cutaneous hemorrhage, oral blood blisters, retinal hemorrhages, or a rapidly falling platelet count, transfusion to maintain a platelet count of 20,000 per $mm^3$ is suggested.[59,60,62,64,71,73,74]

| Clinical status | Platelet count per $mm^3$ | Intervention |
|---|---|---|
| Well | >5,000–7,000 | Observe for bleeding |
| Febrile, stable | <10,000 | Transfusion |
| Mucosal bleeding or febrile, unstable | <20,000 | Transfusion |
| Extensive mucosal or internal bleeding | <50,000 | Transfusion |
| Invasive procedure | | |
| Surgery | <50,000 | Transfusion |
| Lumbar puncture | <20,000 | Transfusion |
| Bone marrow | <5,000 | Transfusion |

**TABLE 40-2. PLATELET TRANSFUSION TRIGGERS IN CHILDREN WITH CANCER**

## Platelet Transfusion

### *Random-Donor Platelet Concentrates*

A unit of platelets is separated from a single-donor unit of whole blood by centrifugation. The platelets then may be stored for up to 5 days at 24°C with continuous agitation to prevent clumping. Each unit contains approximately 5.5 to 10.0 × $10^{10}$ platelets in 40 to 70 mL of plasma and anticoagulant preservative.[19,20] When more than one unit of random-donor platelets is ordered, the blood bank generally pools the individual units for ease of administration. However, in very young children or when volume overload is a concern, the blood bank can further concentrate the pooled platelets by gentle centrifugation on request. This results in a 10% to 20% loss of platelets in the transfused product.[20]

The volume of platelets to be transfused depends on the weight of the child and the post-transfusion platelet count desired. In previously nontransfused patients, 1 unit per $m^2$ of body surface area should raise the 1-hour post-transfusion platelet count by 10,000 to 12,000 per $mm^3$. Thus, 1 unit per 6 to 8 kg of body weight should increase the platelet count by 40,000 to 60,000 per $mm^3$ over the pretransfusion value. For practical purposes, a minimum of 2 units of platelets should be used for infants, 4 units for young children, and 6 units for adolescents.

Achieving the normal 7- to 10-day survival for transfused platelets rarely is attainable. Prior blood product administration may have led to formation of alloantibodies to human leukocyte antigen (HLA) class 1 or platelet-specific antigens, thus promoting immune destruction of the transfused platelets.[75] Alternatively, patients may consume the transfused platelets to stop hemorrhage or in processes such as DIC. To determine why a posttransfusion platelet increment is less than expected, platelet values 1 hour and 8 to 24 hours after the transfusion can be compared. If patients are alloimmunized, both the 1-hour and 8- to 24-hour posttransfusion values will be inappropriately low and somewhat similar. If the platelets are being consumed, the 1-hour value will be notably higher than the 8- to 24-hour measurement.

Fortunately, the incidence of platelet refractoriness appears low, even in the intensively transfused BMT recipient.[76,77 and 78] Administration of single-donor apheresis platelets (see Apheresis Platelets) and leukoreduction to fewer than 5 × $10^6$ residual leukocytes per unit, particularly if performed before storage, may reduce further the incidence of alloimmunization.[79] ABO and Rh type-specific platelets will survive longer in the recipient and should be used whenever possible.[80] Platelet cross-matching by a variety of techniques may allow also for selection of platelet products likely to result in improved posttransfusion counts.[81] Intravenous immunoglobulin and protein A column immunoabsorption therapy are of limited effectiveness in raising platelet transfusion increments in patients with platelet alloantibodies.[82,83]

### *Apheresis Platelets*

Increasingly, single-donor platelets are being obtained by mechanical apheresis. The donors, who must have adequate veins, spend approximately 90 minutes having their platelets removed by differential centrifugation, and red cells are returned. Apheresis platelets may be donated every 5 to 15 days as compared to the 8-week minimum interval for whole blood donation. Although dependent on the instrument and software used for collection, apheresis platelet units contain approximately 3 to 6 × $10^{11}$ platelets. This is equivalent to 6 to 10 units of random-donor platelets in a volume of 200 to 300 mL.[84] Apheresis products now account for more than 50% of all platelet concentrates transfused in the United States.[60] For smaller patients, apheresis units may be divided using sterile technique in the blood bank, with one-fourth or one-half of an apheresis unit then being transfused instead of 2 to 4 random-donor units. In cases of platelet refractoriness, HLA-matched or platelet cross-match-compatible donors can be collected by apheresis for specific recipients.[84]

If available, platelets obtained by apheresis are preferred to random-donor units, as they reduce the number of donors to whom the patient is exposed, thereby decreasing the risk of alloimmunization and transfusion-transmitted diseases.[60] However, the Trial to Reduce Alloimmunization to Platelets (TRAP), which compared methods of leukocyte reduction (single-donor filtered vs. unfiltered vs. filtered apheresis) from platelets, could not document reduced alloimmunization with apheresis platelets as compared to pooled single-donor concentrates if both were filtered.[85]

### *Methods of Transfusion*

Platelets can be infused rapidly by gravity over 20 minutes when the volume status allows. Apheresis units may be given over 20 to 240 minutes as clinically indicated. As with all blood products, transfusion must be completed within 4 hours of entry into the unit. For patients who are refractory to platelets and have ongoing bleeding, a constant infusion of platelets may be beneficial. In this approach, either one or two random-donor units or one-half of an apheresis unit of platelets is administered slowly over 4 hours. Administering platelets in this manner may not increase the platelet count but should enhance hemostatic efficacy.

## Agents with Thrombopoietic Activity

Agents that stimulate patients' own production of platelets are a potentially promising new approach to minimize the need for allogeneic platelet transfusion in children with cancer. Colony stimulating factors (CSFs) such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) do not have thrombopoietic activity in clinical trials.[86,87,88,89,90,91,92,93 and 94] A variety of other agents have been studied, including IL-1,[95,96,97 and 98] IL-3,IL-6,[97,98,99,100,101,102,103 and 104] IL-11, and thrombopoietin. Clinical trials evaluating these agents demonstrate only a modest decrease in platelet transfusion requirements.[105] Accordingly, their role in the treatment of patients undergoing myelosuppressive chemotherapy or stem-cell transplantation is unknown. Phase III trials for some of these agents are in progress. Hematopoietic growth factors currently licensed in the United States, and the indications for which they were approved, are summarized in Table 40-3. The following sections review those agents most recently under clinical investigation.

| | | | |
|---|---|---|---|
| G-CSF | Chemotherapy-induced neutropenia; neutropenia after stem-cell transplantation; chronic or congenital neutropenia; peripheral blood stem-cell mobilization | Pediatric and adult | 5–10 μg/kg per day i.v. or s.c. |
| GM-CSF | Chemotherapy-induced neutropenia; neutropenia after stem-cell transplantation; peripheral blood stem-cell mobilization | Pediatric and adult | 250–500 μg/$m^2$ per day i.v. or s.c. |
| Erythropoietin | Chemotherapy-induced anemia; anemia due to chronic renal failure; anemia due to zidovudine therapy in HIV patients; reduction of blood transfusions in surgical patients | Pediatric and adult | 50–300 units/kg i.v. or s.c. 3 times weekly |
| Interleukin-11 | Prevention of chemotherapy-induced thrombocytopenia and reduction in the need for platelet transfusions in nonmyeloid malignancies | Pediatric and adult | 25–100 μg/kg per day s.c.<br>50 μg/kg per day s.c. |

G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HIV, human immunodeficiency virus.

**TABLE 40-3. HEMATOPOIETIC GROWTH FACTORS CURRENTLY LICENSED BY THE U.S. FOOD AND DRUG ADMINISTRATION**

## Interleukin-3

IL-3 belongs to a family of glycoprotein hormones that have been shown to modulate proliferation and functional activity of hematopoietic cells *in vitro* and *in vivo*.[106] It is produced by activated T cells, natural killer cells, and mast cells.[107,108 and 109] In preclinical models, IL-3 was shown to stimulate myelopoiesis, erythropoiesis, and thrombopoiesis.[107,110,111] When given in combination with GM-CSF, IL-3 has been shown *in vitro* to have a synergistic effect on progenitor cell cycling rates and results

in an increase in white blood cell counts as compared to GM-CSF alone. [112]

Phase I trials of IL-3 both as a single agent or combined with other hematopoietic cytokines have been performed in patients with advanced malignancy,[113,114,115,116,117,118,119,120,121,122 and 123] secondary hematopoietic failure,[124] and myelodysplastic syndromes.[124,125] IL-3 has also been studied in children with nonmalignant disorders, such as aplastic anemia,[124,125,126,127 and 128] Diamond-Blackfan Anemia,[129,130 and 131] Fanconi's Anemia,[130] and amegakaryocytic thrombocytopenia.

Clinical trials have shown only a modest decrease in platelet transfusion requirements with IL-3 use in patients receiving myelosuppressive chemotherapy. The most favorable of these studies suggested that IL-3 may shorten the time to both platelet and neutrophil recovery, but other reports describe little or no response. [105] One study showed no cost savings associated with use of IL-3 in patients undergoing autologous BMT. [132] Several studies have shown that sequential IL-3 and GM-CSF may be used safely in the collection of peripheral stem cells, although phase III trials to assess the contribution of the IL-3 are not available. [133,134] IL-3 also has been combined sequentially with GM-CSF in patients receiving chemotherapy [135,136,137 and 138] or undergoing autologous BMT.[139,140] These studies have shown variable results when the contribution of IL-3 to platelet recovery is evaluated. Adverse effects of IL-3 include fever, headache, chills, bone pain, facial swelling, and mild local erythema at the site of subcutaneous injection.[113,115]

**PIXY-321**

PIXY-321 is a fusion protein consisting of human recombinant GM-CSF and human recombinant IL-3 coupled by a flexible amino acid linker sequence that allows the binding domains to fold into their native conformation.[141] PIXY-321 binds to cells via either its GM-CSF or IL-3 domains and has comparable or greater affinity for GM-CSF or IL-3 receptors in competitive binding studies than does either protein alone. [142] It stimulates the proliferation of normal human megakaryocyte and myeloid progenitors[143] and induces bilineage platelet and neutrophil production in preclinical models. [144]

PIXY-321 has been studied in several phase I studies in humans, and minimal toxicity has been encountered. [145,146,147,148 and 149] After chemotherapy, PIXY-321 reduces the incidence of severe neutropenia but, after several cycles of therapy, more severe thrombocytopenia occurs than is seen in untreated controls. [150] Further, 92% of patients developed neutralizing antibodies after two courses of PIXY-321. [151] Interest has waned in this use of the agent, and it no longer is being produced.

**Interleukin-11**

IL-11 exerts its primary effect on maturation of megakaryocytes by increasing their ploidy. [152,153] It exerts a synergistic effect when combined with other early-acting hematopoietic growth factors, such as IL-3 and stem-cell factor.[153,154,155 and 156] Inpreclinical trials, IL-11 stimulated platelet production in mice, [153,157] and the response was characterized by an increase in platelet counts, peaking at approximately 14 to 21 days after initiation of therapy. Multilineage effects also were seen in these models.[157]

IL-11 has been studied both in patients undergoing chemotherapy and in the autologous bone marrow setting. Women undergoing chemotherapy for breast cancer were treated with doses ranging from 10 to 100 µg per kg per day for 14 days during a 28-day prechemotherapy safety trial. IL-11 was associated with mean 76%, 93%, 108%, and 185% increases in platelet count at doses of 10, 25, 50 and 75 µg per kg per day, respectively. [158] However, a randomized trial in patients with breast cancer undergoing autologous BMT did not demonstrate a decrease in platelet transfusions in women who received 25 or 50 µg per kg per day of IL-11 as compared with placebo.[159] IL-11, at doses of 25, 50, and 75 µg per kg combined with G-CSF, was administered to children who received ifosfamide, carboplatin, and etoposide. In this phase I/II study, apparently the use of IL-11 decreased the number of platelet transfusions and accelerated platelet recovery as compared with historical controls.[160]

Adverse reactions observed among patients receiving IL-11 have included edema, transient anemia, arrhythmias, fever, chills, fatigue, myalgias, and headache. Manifestations of heart failure (dyspnea, edema, conjunctival injection, increased pleural effusions) were observed and likely were due to the increased intravascular volume that results from renal sodium retention, hypotension, and allergic reactions with IL-11 administration. [161] IL-11 currentlyis approved by the U.S. Food and Drug Administration (FDA) for the prevention of severe chemotherapy-induced thrombocytopenia after myelosuppressive chemotherapy in patients with nonmyeloid malignancies. It is not indicated for patients receiving myeloablative chemotherapy prior to stem-cell transplantation. The recommended dose is 50 µg per kg per day in adults and 75 to 100 µg per kg per day in children.

**Thrombopoietin**

Thrombopoietin is a hematopoietic growth factor that regulates megakaryopoiesis through its interaction with a specific cell-surface receptor encoded by the c- *mpl* proto-oncogene.[162,163,164,165 and 166] Thrombopoietin also acts on the erythroid lineage and primitive hematopoietic progenitors as a synergistic growth factor. [167,168] In mice, injection of exogenous thrombopoietin increased platelet counts fourfold to sixfold within 1 week but had no effect on leukocyte or red cell numbers. [168,169 and 170] In nonhuman primates, thrombopoietin resulted in increased platelet counts, with a peak between 12 and 14 days after initiation of treatment. [171]

Two molecules currently are undergoing clinical trial: a recombinant human thrombopoietin identical to the native molecule (rHuTPO) developed by Genetech (San Francisco, CA) and a recombinant nonglycosylated molecule (MGDF) developed by Amgen (Thousand Oaks, CA). MGDF contains the receptor-binding portion of the native molecule coupled to polyethylene glycol to protect it from degradation. [105] Adverse events encountered with the use of MGDF and rHuTPO included nausea, arthralgia, deep venous thrombosis, and pulmonary embolism. Injection-site reactions occur but appear to be rare. [105]

Clinical experience with these agents has been limited. In a dose escalation study that randomly assigned patients to MGDF or placebo after chemotherapy, a dose-dependent, lineage-restricted increase in platelet counts was seen. Recovery to baseline platelet count was seen in 17 days for the MGDF-treated patients versus 22 days for placebo.[172] In a second study, 53 patients with lung cancer were treated with MGDF in a dose-escalating fashion. Patients who received MGDF had higher median nadir platelet counts and platelet count recovery to baseline in 14 days versus 21 days in those receiving placebo. [173] In a phase I trial of rHuTPO, a single dose of 2.4 mg per kg was administered to 12 patients with sarcoma, and platelet counts rose 3.6-fold at 12 days. Platelet function was normal, and no adverse reactions were reported.[165] Randomized trials are under way to determine the efficacy of these agents in decreasing the duration of thrombocytopenia and the need for platelet transfusions.

The impact of thrombopoietic growth factors on clinical practice has been limited, and their efficacy has been modest at best. Whether newer agents will be shown to have an impact on the degree of thrombocytopenia and the use of platelet transfusion remains to be seen.

***Other Treatments for Thrombocytopenia***

In addition to platelet transfusion support, other nonspecific measures may be of value for patients with severe thrombocytopenia. Avoidance of invasive procedures, such as insertion of urinary catheters and nasogastric tubes, intramuscular injections, rectal examinations, and deep venipunctures as well as application of firm local pressure for 5 to 15 minutes after epistaxis or puncture wounds will minimize bleeding complications. Further, antiplatelet agents, such as ibuprofen, ketoprofen, or aspirin should be avoided by patients with severe thrombocytopenia, particularly if bleeding is present.

P>Epsilon-aminocaproic acid (Amicar), a fibrinolytic inhibitor, would not be expected to enhance primary hemostasis greatly, but some clinicians attest to the utility of antifibrinolytic agents in thrombocytopenic patients with mucosal hemorrhage. [174] Prophylactic use of the antifibrinolytic agent tranexamic acid in one study has been shown in one study to decrease the use of platelet transfusions in (AML) patients receiving chemotherapy. [175] Topical agents such as Gelfoam or topical thrombin also may promote local hemostasis in thrombocytopenic patients. Desmopressin enhances the adhesion of platelets to vascular endothelium and shortens the bleeding time in mildly thrombocytopenic patients. It is thought to be of questionable value in patients with platelet counts below 50,000 per mm $^3$.[176,177] However, one study suggested that desmopressin controlled hemorrhage even in markedly thrombocytopenic children. [178]

Prednisone in low doses may reduce hemorrhage in thrombocytopenic patients as a consequence of its nonspecific effects on capillary stability. [179] Estrogen or

high-dose birth control pills may be of value for menometrorrhagia.

## COMPLICATIONS OF BLOOD TRANSFUSION SUPPORT

### Immunologic Complications

Every blood product transfusion carries a risk of an untoward event. Immunologic and infectious events are the most common. The current estimate of risk for each type of common transfusion-related event is summarized in Table 40-4.

| Infection or event type | Rate | Reference |
|---|---|---|
| Human immunodeficiency virus | 1:660,000* | Goodnough,[19] Schreiber[181] |
| Hepatitis A | 1:1,000,000 | Schreiber[215] |
| Hepatitis B | 1:63,000 | Schreiber[215] |
| Hepatitis C | 1:125,000* | Holland[213] |
| Human T-cell leukemia virus I and II | 1:641,000 | Goodnough,[19] Schreiber[181] |
| Bacterial contamination: | | |
| Red blood cells | 1:65,000–500,000 | Goodnough,[19] Blajchman[198] |
| Platelets | 1:12,000 | Goodnough[19] |
| Transfusion reactions: | | |
| Acute hemolytic transfusion reaction (fatal) | 1:250,000–1,000,000 | Linden[196] |
| Delayed hemolytic transfusion reaction | 1:1,000 | Noy[93] |
| Transfusion-related acute lung injury | 1:5,000 | Goodnough[19] |

*May be decreased further by nucleic acid testing (see text).

**TABLE 40-4. ESTIMATED RISK OF EVENT PER UNIT OF BLOOD PRODUCT TRANSFUSED**

### *Transfusion Reactions*

Fatal hemolytic transfusion reactions continue to occur at a rate of 1 in 250,000 to 1,000,000 transfusions. [180] Approximately one-half are due to acute hemolytic reactions from ABO incompatible transfusion caused by administrative errors (e.g., mislabeled specimens or administering blood to the wrong patient). [19,181] Less severe acute hemolytic transfusion reactions also are encountered. These reactions manifest as fever, chills, back or abdominal pain, dark urine, pallor, bleeding, or shock during the transfusion. Spherocytes are present on the peripheral blood smear; plasma free hemoglobin and bilirubin will rise; the urine will show hemoglobinuria (dipstick positive for blood but no red cells on microscopy); and a positive direct antiglobulin test will occur. [182] Clinical features of common immune transfusion reactions are reviewed in Table 40-5. In the presence of suspected reaction, the transfusion should be stopped, and the remaining product, plus a post-transfusion sample of the patient's blood, should be sent to the blood bank for analysis. Management consists of vigorous hydration to maintain urine flow until hemoglobinemia and hemoglobinuria resolve. [19]

| Type of Reaction | Incidence (%) | Antibody Directed Against | Symptoms |
|---|---|---|---|
| Acute hemolytic | <0.01 | ABO antigens | Fever, hemolysis |
| Non-hemolytic, febrile | 0.5–1.0 | HLA antigens on white cells | Fever, headache, chills |
| Allergic | 0.25 | Plasma proteins | Hives |
| Anaphylactic | 1 in 700 | IgA | Stridor, periorbital swelling |

IgA, immunoglobulin A.

**TABLE 40-5. TYPES OF TRANSFUSION REACTIONS**

Approximately 1 in 1,000 adult transfusion recipients have a delayed hemolytic transfusion reaction. These are characterized by low-grade fever, jaundice, and a hemoglobin increment lower than expected 2 to 14 days after transfusion. [19] Delayed hemolytic transfusionreactions occur in previously alloimmunized patients in whom transfused cells provoke the amnestic production of antibody that was not detectable by routine cross-match prior to transfusion. [19,183] Preventing these reactions is difficult, but good communication between physician and blood bank concerning a patient's history of prior transfusion outside the institution and review of transfusion records may minimize the risk.

Non-hemolytic transfusion reactions are the most frequent acute adverse event related to transfusions. Fever does not always occur during such episodes. These reactions can include components that are both inflammatory (chills, rigors, and discomfort, which may be accompanied by fever) and allergic (pruritus, urticaria, erythema, and flushing).[79] Classically, febrile nonhemolytic transfusion reactions were thought to be caused by antileukocyte antibodies in patients' plasma, resulting in release of endogenous pyrogens. Febrile nonhemolytic transfusion reactions to red cells still are believed to be caused by this mechanism, and removal of leukocytes by filtration or apheresis can decrease their frequency. [184]

Cytokines, such as IL-1, IL-6, and TNF-asecreted by the residual leukocytes in platelet concentrates, now are believed to be a major cause of platelet reactions. Commercially available filters cannot remove these inflammatory cytokines once they are formed in stored blood products. Thus, prestorage leukofiltration offers the most effective approach to preventing febrile nonhemolytic transfusion reactions due to platelet components. [184,185]

Febrile non-hemolytic transfusion reactions can begin at any time during or after completion of a transfusion. Therapy consists of stopping the transfusion temporarily and treatment with diphenhydramine and acetaminophen. If an allergic reaction is unusually severe—a so-called anaphylactoid reaction characterized by wheezing, bronchospasm, laryngeal edema, or hypotension—epinephrine and parenteral steroids should be considered, and the other therapies should be repeated. [19,186] If a reaction continues or recurs when the transfusion is restarted, the remainder of the product should be discarded. Patients who repetitively experience febrile nonhemolytic transfusion reactions will benefit from blood product leukofiltration (discussed in the section Leukocyte Depletion) and premedication with the same agents.[19] The most severe such reactions occur in the 1 in 700 individuals who are IGA–deficient and have been given immunoglobulin A–positive products. [187]

### *Transfusion-Related Acute Lung Injury*

Transfusion-related acute lung injury (TRALI) is a clinical syndrome usually occurring within 4 to 6 hours of transfusion of blood components containing plasma. It is characterized by dyspnea, hypoxia, fever, and noncardiogenic pulmonary edema. [186] It usually occurs in already sick patients and resembles adult respiratory distress syndrome. Thus, the recognized frequency of 1 in 5,000 transfusions is likely to be an underestimate. [181] It is most often associated with red cell and FFP transfusion from multiparous female donors. Transfused leukoagglutinins formed through prior exposure to paternal antigens during pregnancy are thought to interact with recipient white blood cells. These white cell complexes are sequestered in the pulmonary microvasculature, leading to increased vascular permeability and exudation of fluid and protein into the alveoli. [188] Biologically active lipids arising from donor blood cell membranes during storage also have been implicated as a contributory cause.[189]

Therapy for transfusion-related acute lung injury is supportive, with fluids to maintain blood pressure and cardiac output and supplemental oxygen or ventilatory support if needed. Pressor agents may be useful to manage hypotension. Corticosteroids are of marginal value. [186] Diuretics appear to be detrimental.[188] Mortality is

estimated to be between 5% and 10% of recognized cases.[188]

### *Special Considerations in Transfusion Therapy of Children with Cancer*

Unmodified erythrocyte and platelet products contain a large number of leukocytes that can induce alloimmunization. These HLA antibodies are responsible for most platelet refractoriness and may increase the chances of allograft rejection should a hematopoietic stem-cell transplant be needed. Furthermore, transfused immunocompetent donor lymphocytes may proliferate in immunosuppressed hosts, transmitting active CMV infection or causing graft-versus-host disease (GVHD). GVHD is discussed further in the section titled Transfusion-Associated Graft-Versus-Host Disease. The two approaches used most commonly to prevent these problems have been leukocyte depletion by filtration and irradiation of blood products before transfusion. [190]

### *Alloimmunization*

#### Leukocyte Depletion

Leukocytes can be removed from blood products by centrifugation, washing, freezing then thawing, and leukofiltration. [185] The first three techniques are labor intensive, involve obligate loss of product, and leave behind relatively large numbers (10% or more) of initial leukocytes. Commercially available red cell or platelet filters, although expensive, are simpler to use. Filtration removes 3 to 4 logs, or more than 99.5%, of white blood cells. [185,191]

Critical appraisal of numerous studies demonstrates that filtration can leukodeplete cellular blood products to below $5 \times 10^6$ leukocytes per unit, the level that is believed to minimize HLA alloimmunization.[79] This has reduced the frequency of HLA alloimmunization from between 70% to 97% in patients given nonfiltered products to 5% to 25% with filtration.[70,79,190] Variation in the frequency of alloimmunization may be related to whether filtration is employed before storage or at the bedside. Pre-storage filtration prevents the accumulation in the plasma of cytokines (TNF-a, IL-1b, IL-6, IL-8), leukocyte metabolites, and fragments that contribute to febrile nonhemolytic transfusion reactions.[192] Similarly, pre-storage—but not post-storage—leukofiltration has been shown to block the immunomodulatory solid tumor growth–promoting effect of transfusion reported in animal models.[185]

Reduction of leukocytes by filtration also decreases the transmission of CMV and, in theory, Creutzfeldt-Jakob prion disease in blood products from infected donors.[191,193] Leukofiltration, predominantly performed after storage at the bedside, has decreased the rate of acquisition of CMV in initially negative BMT and heavily treated leukemia patients to 0.5%. This is essentially the same as the 0.8% rate seen in recipients of unfiltered, serologically CMV-negative donor products and far below the 18% value for recipients of unscreened, unfiltered products. [191]

Leukodepletion conveys significant benefits to pediatric cancer patients, with data favoring pre-storage over bedside filtration. The United Kingdom has adopted universal prestorage filtration for all blood components, and similar proposals are being considered in the United States. Although filtration, which decreases alloimmunization and CMV transmission, is more cost efficient than CMV serotyping of donors (discussed in the section Cytomegalovirus), convincing cost-benefit analyses of the entire approach are not available.

#### Irradiation

Gamma irradiation of blood products with between 15 and 50 Gy will prevent leukocyte proliferation in a recipient without significant adverse effects on the transfused cells.[185] FDA regulations currently require 25 Gy to the center plane and 15 Gy to the entire container. [185] Platelet function appears undisturbed by this process. However, prolonged storage of red cells after irradiation may lead to increases in plasma potassium, adenosine triphosphate, pH, lactate dehydrogenase, and plasma free hemoglobin. Although some investigators recommend that gamma-irradiated red cells be washed before intrauterine transfusion, this does not appear to be necessary in other settings.[185,194]

The Trial to Reduce Alloimmunization to Platelets (TRAP) compared the effect of leukofiltration to ultraviolet B (UV-B) irradiation of platelet concentrates in nonalloimmunized AML patients.[85] Investigators found no difference in the rate of HLA alloimmunization between patients whose transfused platelets were filtered (18%) and those whose platelets were treated with UV-B irradiation (21%). By comparison, patients who received nonfiltered, nonirradiated platelets had a much higher rate of alloimmunization (45%). Similarly, the rate of acquired platelet refractoriness was equivalent in the filtered (8%) and the irradiated (10%) groups, and the rates in both were lower than in the control group (16%). The study concluded that filtration and UV-B irradiation of platelets are equally effective in preventing HLA alloimmunization.[58,85,190]

#### Rh Incompatibility

Whenever possible, Rh-matched red cell and platelet products should be used. [19] Although Rh antigens are not expressed on platelets, Rh-positive platelets (or red cells) should not be given to Rh-negative female recipients who are likely to survive into adulthood. If this becomes necessary owing to lack of Rh-negative product, administration of an anti–D immunoglobulin product immediately thereafter has been advocated. However, no studies documenting the utility of this strategy have been performed. Rh sensitization of immunosuppressed cancer patients is infrequent (7.8% in an early series). [195]

#### Transfusion-Associated Graft-Versus-Host Disease

Transfusion-Associated GVHD occurs when immunocompetent passenger T lymphocytes in cellular blood products engraft in a recipient. Clinical manifestations begin 4 to 30 days after transfusion and include fever and an erythematous maculopapular skin rash. Anorexia, nausea, vomiting, watery or bloody diarrhea, and elevated liver enzymes and bilirubin may be seen.[196,197] Eventually, this process results in severe bone marrow aplasia. It is associated with serious morbidity and mortality in 75% to 90% of affected patients.[197,198]

Originally described in children with immunodeficiency and in newborn recipients of *in utero* transfusion, numerous cases of GVHD in heavily immunosuppressed bone marrow transplant recipients have been reported.[197] In rare cases, it has been recognized in patients receiving chemotherapy for neuroblastoma, Hodgkin's and non-Hodgkin's lymphoma, acute lymphoblastic and myelocytic leukemia, and chronic lymphocytic leukemia. [197,199] Recognition of cases in immunocompetent individuals who share an HLA haplotype with HLA homozygous blood donors (i.e., relatives who provide directed donations or members of inbred populations) provides information regarding pathogenesis.[198]

Transfusion-associated GVHD may be prevented by gamma irradiation of blood products with 25 Gy. [198] Leukofiltration probably is not adequate prevention but has not been studied rigorously.[78] Irradiation of blood products to prevent transfusion-associated GVHD clearly is indicated for patients with immunodeficiency or recipients of *in utero* intrauterine transfusion, when the donor is a family member of the recipient, or if both are part of an inbred population. [197] Recipients of hematopoietic stem-cell grafts also should receive irradiated blood products. Available data do not support routine irradiation of all blood products given to pediatric cancer patients or to patients in whom a BMT is intended until the immunosuppression of the transplant conditioning begins. However, as a matter of convenience, leukofiltered and irradiated products often are prescribed routinely for all pediatric cancer patients, even for those who are not treated intensively or who may never need a bone marrow transplant. The cost of such products is the only disadvantage.

#### Infectious Complications

The infectious complications of blood transfusions in children with cancer are similar to those in children who do not have malignant disease and are exposed to a similar number of blood donors.

### *Bacterial Infection*

An underappreciated risk of transfusion is bacterial contamination during collection of transfusion products with a variety of microorganisms that proliferate during storage. These infections can cause fever and chills beginning during or shortly after a transfusion. Infection most commonly is due to *Yersinia enterocolitica* and other gram-negative organisms. Contamination usually is related to the length of storage, but *Yersinia* has been reported in red cells stored for only 1 week. Recent

incidence figures suggest that between 1 in 65,000 and 1 in 500,000 units transfused have bacterial contamination, with a 50% mortality in reported cases. [181,200]

Platelet units are contaminated most commonly with *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Serratia marcescens*, and *Staphylococcus epidermidis*. Approximately 1 in 12,000 platelet units are contaminated, far more often than red cell units, because bacteria proliferate readily during even 5 days' storage at 24°C. Overall mortality is 26% when reactions are reported due to bacterial contamination of platelets. Many cases may be missed because affected patients may have only mild symptoms and a blood culture positive with a common bacterial skin contaminant.[181] Management consists of prompt evaluation of any fever that begins within 6 hours after receipt of a blood product and administration of antibiotic therapy to patients who appear toxic. Preventative approaches using psoralens and ultraviolet-A light to produce nonimmunogenic and sterile blood products are being investigated. [181]

### *Parasitic Infection*

Although rare in the Western world, malaria, Chagas' disease (due to infection with *Trypanosoma cruzi*), and *Babesia* can be transmitted by transfusion. Global population movements and increasingly wide geographic distribution of pathogens have increased seroprevalence among unexpected donor populations, requiring awareness of the potential for transfusion transmitted infection with these unusual pathogens. [201,202]

### *Viral Infection*

With current pretransfusion testing, transmission of viral infections is extremely rare and thought to occur primarily during a window period: the interval soon after infection when a donor is infectious but when standard screening tests will be negative. [203] The estimated risks of infection now are lower than ever before and are expected to decrease further when PCR basednucleic acid testing for viral genomes (NAT testing) is fully implemented. [181,202,203 and 204] Each group of viruses is considered separately here.

#### Human Immunodeficiency Virus

Recognition that human immunodeficiency virus (HIV) infection could be transmitted by blood transfusion occurred in 1982. Even before implementation of HIV antibody testing in March 1985, high-risk donor voluntary deferral programs decreased the risk of infection per unit by nearly 3 logs. [181] Serologic testing for HIV-1 and HIV-2 decreased the per-unit risk to 1 in 493,000 by 1993.[205] In late 1995, p24 antigen testing further diminished the estimated risk of HIV infection per unit transfused to 1 in 676,000.[181] Nucleic acid testing should shorten the window period from 16 to 10 days and thus further decrease the risk of infection to approximately 1 in 1,000,000 units.[205] Nevertheless, transmission of HIV remains one of the most feared consequences of transfusion therapy.

#### Human T-Cell Lymphotrophic Virus I and II

Human T-lymphotrophic viruses (HTLV-1 and -2) are human retroviruses isolated from individuals with lymphoproliferative disorders, acute T-cell leukemia, and lymphoma. HTLV-1 has been associated also with myelopathy. HTLV-1 and HTLV-2 are proviruses and incorporate into host DNA, causing a lifelong carrier state. [206]

Transmission of HTLV-1 and HTLV-2 has been documented with cellular blood component transfusion. [181,206] Interestingly, donor lymphocytes that are required for transmission become noninfectious when stored, and they lose the ability to proliferate. [202] Thus, for this pathogen, blood product storage decreases the risk of infection. Specific screening antibody tests demonstrate a very low seroprevalence rate. [181,205]

Transfusion of HTLV-1 has resulted in myelopathy–tropical spastic paraparesis in 4% to 8% of recipients, although serologic evidence of infection will develop in 20% to 60% of recipients. One case of T-cell leukemia has been reported after HTLV-1–positive transfusion in a patient with acute myelogenous leukemia in remission.[181,182,183,184,185,186,187,188,189,190,191,192,193,194,195,196,197,198,199,200,201,202,203,204,205 and 206]

#### Hepatitis Virus and Posttransfusion Hepatitis

Hepatitis continues to result from blood transfusion in children with cancer. The specific viruses responsible for transfusion-related disease have progressed alphabetically from hepatitis B (HBV) to C (HCV) to G virus (HGV) and beyond. Since the 1943 report first describing posttransfusion hepatitis, a pattern of successive antigen identification and application of specific serologic testing of the blood supply has decreased the incidence of posttransfusion viral hepatitis due to all viruses from 23% of recipients in the 1960s to fewer than 1 in 10,000 recipients today. [207]

Transfusion-transmitted HBV infection declined markedly after introduction of all volunteer blood donors and a third-generation screening test for HBV in the late 1970s.[181] Today, HBV accounts for approximately 10% of posttransfusion hepatitis, a percentage that likely will decline further as vaccination becomes more widespread. The risk of transfusion-acquired infection with HBV now is estimated to be 1 in 63,000 units transfused. [205] Acute disease develops in 35% of persons infected with the virus, approximately 5% develop chronic infection, and 2% develop fulminant hepatic failure leading to death or need for a liver transplant. [202,207]

Although hepatitis A virus (HAV) can be transmitted by transfusion, more commonly it is food borne. After identification of the HAV in 1973, it became clear that a substantial proportion of new posttransfusion hepatitis cases were not caused by infection with HAV or HBV. Consequently, the term *non-A, non-B hepatitis* was coined. By the late 1970s and early 1980s, the prevalence of non-A, non-B hepatitis in multiply transfused patients was reported to be as high as 10%. [207]

Before the identification of HCV in 1988, an association between an increased alanine aminotransferase (ALT) level in donor blood and development of non-A, non-B hepatitis in recipients of that blood was observed. Surrogate testing for ALT and anti–hepatitis B core protein subsequently reduced the rate of posttransfusion hepatitis to 2% to 3% of heavily transfused recipients.[207] ontinuous refinement of HCV testing has now brought the risk of transfusion-acquired HCV to fewer than 1 in 100,000.[205] Nucleic acid testing should decrease the risk to 1 in 125,000 units. [203] The increasing sensitivity of specific HCV testing has rendered likely that surrogate ALT and hepatitis B core antibody testing, which now contribute little to identifying potentially infectious units, soon will be discontinued. [207,208]

Evidence indicates that additional viruses may account for many of the rare remaining posttransfusion hepatitis cases. HGV, which shares 25% genetic homology and coinfection with HCV, can be transmitted by transfusion.[209] Heat inactivation, as applied to plasma products to inactivate HCV, also prevents HGV transmission. [209] HGV is present in up to 5% of blood donors and in 7% to 90% of multiple transfusion recipients. [202,209]

The clinical consequences of transfusion transmission of HGV appear relatively mild, as infection does not appear to correlate with significant liver disease. [210] HGV-infected patients develop a mild hepatitis with slight ALT elevations. [211] Interestingly, coinfection with HGV does not appear to alter the course of infection with HAV, HBV, or HCV.[212] Initially, HGV was thought to be responsible for post-hepatitis aplastic anemia, but recently the virus was demonstrated to be contracted by transfusion given after affected patients became ill.[213] Currently, HGV screening of blood donors is not required. Undoubtedly, additional viruses capable of causing posttransfusion hepatitis will be identified in years to come.

#### Late Effects of Posttransfusion Hepatitis in Pediatric Cancer Patients

Because donor screening for posttransfusion hepatitis is now so effective, children currently being treated for cancer should have a low risk of acquiring hepatitis from transfusion. However, 17% to 40% of children treated a decade or more ago and cured of their cancer are chronically infected with these agents, most commonly HCV.[214,215,216 and 217] Most such patients are asymptomatic, with elevated but fluctuating ALT values. [218] Some HCV-infected cancer survivors may develop biopsy-proven cirrhosis, although this condition is more common in HBV- and HCV-coinfected individuals. [217,218] Routine follow-up of children cured of cancer, especially those who were transfused before widespread use of the third-generation HCV screening of the blood supply in 1995, should include measurement of ALT and testing for HCV infection.[218] If screening reveals a transfused cancer survivor to have persistently elevated ALT values but to be HCV-seronegative, sensitive PCR-based RNA screening for HCV is indicated.[214,215] HCV-infected patients may benefit from treatment with interferon-a, particularly in combination with ribavirin.[219,220]

Although the current risk of transfusion-associated hepatitis is low in the United States, transmission rates for HCV and other hepatotropic viruses remain markedly

higher in some areas of Western Europe and developing countries. Thus, for children with cancer treated in other locales, the risk for liver disease after treatment remains a major concern.[217,221]

### Cytomegalovirus

CMV is a cell-associated herpesvirus that causes hepatitis, an infectious mononucleosis-like illness and, in heavily immunosuppressed oncology or transplant patients, a severe, often fatal enteritis and interstitial pneumonitis. [191] CMV can be transfused by the unmanipulated leukocytes of infected donors and thus produce severe primary infection or reactivation disease in previously infected immunosuppressed patients. [191] Use of seronegative donors, removal of leukocytes by filtration, and irradiation of blood products to prevent the replication of CMV-containing leukocytes have been used to decrease the transmission risk.

The seroprevalence rate of CMV can range from 20% to 100% of blood donors, depending on geographic location. [222] Thus, finding adequate numbers of serologically negative donors to exclusively supply blood product needs is difficult. The 3-log reduction of white cells accomplished with the use of leukocyte depletion filters (discussed in the section Leukocyte Depletion) has been considered as effective as the exclusive use of seronegative blood in preventing transfusion transmission of CMV, even to ransplant recipients.[223]

However, debate continues over a possible small benefit from the use of seronegative rather than filtered blood products. [202,224] Cell-free samples from seropositive blood units have been demonstrated after PCR amplification to contain low levels of infectious CMV. [225] Not clear is whether the virus originated from leukocytes during storage or whether CMV already was present in the plasma while all leukocytes were intact. [202] Further studies will be necessary to determine the magnitude of this risk in transfusion recipients.

### Parvovirus B19

The nonenveloped parvovirus B19 may result in a persistent infection leading to prolonged erythroblastopenia or pancytopenia in immunocompromised patients with leukemia, prior renal transplantation, or acquired immunodeficiency syndrome. [5,6 and 7,202] Infection via transfusion has been documented but is rare. [5] Parvovirus B19 is implicated also in postinfection arthropathy and vasculitic phenomena in immunologically normal individuals. [5] Some estimates maintain that 0.03% to 0.60% of blood donors are viremic with B19.[226] However, donor screening must be PCR-based because seroconversion does not correlate with infectivity. [5] At present, no such screening is implemented or planned, so parvovirus B19 transmission by transfusion continues to exist. [202]

### Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease (CJD) is a neurodegenerative disease, the human form of spongiform encephalopathy. Most likely it is transmitted by an infectious prion. CJD exists in forms that are familial (10% to 15% of cases), sporadic (85% to 90% of cases), and acquired (1% of cases). Acquisition is from transplantation of dura mater or use of cadaveric human growth hormone. A theoretical risk of transmission by blood products exists, and animals inoculated intracerebrally with blood from CJD patients have developed a similar disease. [202,227] The FDA has mandated the withdrawal of blood products from persons in whom CJD develops and suggests notification of recipients. In some centers, the withdrawal and look-back notification are applied to blood products from relatives of CJD cases as well. However, nothing can be done to prevent the disease, and physicians can only offer reassurance that the risk is at this time only theoretical and not documented. [227]

#### *Other Complications of Transfusion*

### Hemochromatosis

Transfusion-related hemochromatosis or iron overload is of concern in intensively treated or transplanted survivors of childhood cancer. [228] Iron-induced injury may potentiate the hepatic damage of viral infection or chemotherapy. If erythrocyte transfusion volume was substantial during therapy, screening of childhood cancer survivors by serum ferritin or transferrin saturation is indicated. If these screening tests suggest iron overload, determination of hepatic iron concentration by biopsy followed by phlebotomy or iron chelation therapy, if indicated, must be undertaken. The management of iron overload is beyond the scope of this chapter but is reviewed elsewhere.[229]

### Immunomodulation and Enhancement of Tumor Growth

Immunomodulation from allogeneic blood transfusion is important in improving renal allograft survival and in decreasing recurrent spontaneous abortion. [230,231] Although the mechanisms and mediators of this immunosuppressive effect are beyond the scope of this chapter, this condition appears to be induced by a recipient's response to the transfusion of allogeneic leukocytes. [231,232] Adult surgical patients appear to have an increased risk of postoperative infection if allogeneic transfusion is required. Whether this is due to clinical confounders, such as volume of blood loss, or to duration of the operation is unclear. [232,233] A large number of conflicting studies further suggest that the “allogeneic transfusion effect” may promote the growth of adult surgically treated cancers, such as colon or breast carcinomas, sarcomas, and non-Hodgkin's lymphoma.[233] Prestorage leukoreduction appears effective in ameliorating these effects. [185,231] No convincing data confirm that allogeneic blood transfusion enhances neoplastic growth or negatively influences disease-free survival in pediatric malignancies. [228]

## WHITE BLOOD CELLS

Opportunistic infections associated with prolonged periods of severe neutropenia (i.e., gram-positive and gram-negative bacteria and fungal pathogens) continue to be a major source of morbidity and mortality in children undergoing myelosuppressive chemotherapy. Improvements in supportive care, with broad-spectrum antibiotics and hematopoietic CSFs such as G-CSF and GM-CSF, have allowed for the administration of higher doses of conventional chemotherapy and myeloablative regimens followed by autologous or allogeneic stem-cell support. This increased dose intensity has led to improved disease-free survival for certain pediatric malignancies. As the dose intensity of chemotherapeutic regimens continues to rise, the depth and duration of chemotherapy-induced neutropenia—defined as an absolute neutrophil count (ANC) of less than 500 cells per $mm^3$—also will increase.

### Pathophysiology

#### *Decreased Numbers*

The most important risk factor for development of serious infection in a cancer patient with newly diagnosed disease or during myelosuppressive chemotherapy is the severity and duration of neutropenia. [234] Decreased numbers of neutrophils result from the underlying malignancy or are secondary to treatment. Prolonged neutropenia is an important risk factor in the development of infection, especially with fungal pathogens, such as *Candida* and *Aspergillus* species. The rate of decrease in the number of neutrophils also may be associated with an increased risk of infection. [234]

#### *Decreased Function*

Qualitative defects of neutrophil function are common in cancer patients. A number of descriptive studies have demonstrated varying degrees of impaired function in neutrophils isolated from patients undergoing chemotherapy. Documented defects include impairment of superoxide generation, phagocytosis, and microbicidal activity *in vitro*. These defects may be due to the underlying malignancy, chemotherapeutic agents, radiation therapy, or the presence of viral infections, such as CMV.[234]

### Granulocyte Transfusions

Attempts to prevent and treat infections with granulocyte infusions have been inconclusive. Wide interest was seen in the use of granulocyte transfusions in the 1970s and 1980s, and a series of clinical studies performed at that time demonstrated moderate success in certain clinical situations. However, these studies were hampered by infusion of relatively low numbers of neutrophils and the possible development of alloimmunization owing to the development of antineutrophil antibodies.[235] Even at present, the requirement that infusion of granulocytes be undertaken shortly after collection, development of leukocyte incompatibility,

questionable clinical efficacy, and occasional adverse reactions (e.g., CMV infection, pulmonary infiltrates) have resulted in infrequent use of therapeutic granulocyte infusions for neutropenic cancer patients.

Opportunistic infections, especially due to fungal pathogens, continue to be a source of morbidity and mortality despite the use of CSFs and antifungal agents. The superior collection techniques available today and the use of CSFs or steroids to stimulate donor neutrophil counts prior to collection allow collection of larger numbers of granulocytes. Therefore, granulocyte transfusion has once again become an area of clinical research.

### *Granulocyte Collection and Infusion*

Granulocytes are collected via apheresis using a specialized centrifuge. [235] Cells are separated on the basis of density, and the erythrocytes and platelets are returned to the donor. Granulocyte collections taken by centrifugation from healthy, unstimulated donors usually yield between 0.5 and 1.0 × $10^{10}$ cells per liter of donor blood. The addition of rouleaux-inducing agents, such as hydroxyethyl starch, pentastarch, or dextran, can enhance the sedimentation of red cells from the granulocytes and increase yield.[235] Donor granulocyte counts also are increased by the administration of corticosteroids or CSFs that mobilize granulocytes from the marginating pool into the circulating pool or increase their production. [236,237,238 and 239] Granulocytes always are irradiated prior to infusion to prevent transfusion-related GVHD. [235]

### *Role of Hematopoietic Growth Factors in Granulocyte Collection*

With the advent of hematopoietic growth factors, interest in the use of granulocyte infusions has increased. The number of granulocytes infused plays an important role in efficacy.[240] G-CSF priming of donors has been shown to increase the yield of neutrophils during apheresis. [241] G-CSF given every other day is equivalent to daily G-CSF dosing and is superior to prednisone alone to increase the number of granulocytes collected. [237] Clinical trials are under way to study the efficacy of G-CSF-stimulated granulocytes in the prevention and treatment of infections in neutropenic cancer patients.

## Clinical Use of Granulocyte Transfusions

### *Infection in Neutropenic Patients*

The optimal use of granulocyte infusion in the treatment of infection in neutropenic patients is unknown. Randomized studies of the efficacy of granulocyte transfusions given with intravenous antibiotics have been reported, but interpretation of these studies is difficult, as the number of granulocytes infused is relatively small.[235] Alloimmunization with antineutrophil antibodies also may be a substantial barrier. [242]

Few studies have examined the role of G-CSF–primed neutrophils in the prophylaxis and treatment of bacterial or fungal infections. Selection of patients is difficult, but criteria should include an ANC of fewer than 500 cells per $mm^3$, persistent documented bacterial or fungal infection despite adequate antibiotic or antifungal therapy, and no evidence of marrow recovery.

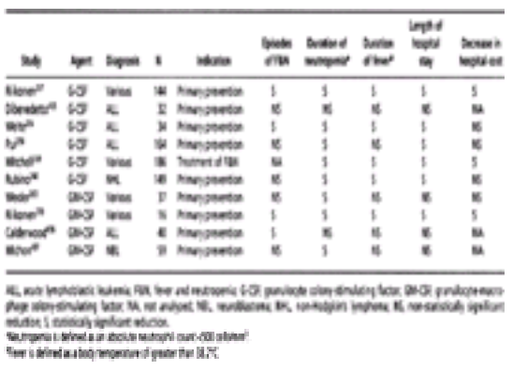
### *Adverse Events Related to Granulocyte Transfusions*

Transfusions of granulocytes in patients who have been alloimmunized to either HLA or neutrophil-specific antigens can result in fever and occasionally acute pulmonary symptoms, including chills, dyspnea, development of infiltrates seen on chest radiograph, chest tightness, acral cyanosis, and hypoxia. These episodes may take up to 12 hours to resolve. Concurrent administration of amphotericin B and granulocyte concentrates has been reported to cause particularly severe pulmonary reactions.[243] Separation of the two infusions by a minimum of 4 hours should circumvent this problem. [235]

## HEMATOPOIETIC COLONY-STIMULATING FACTORS

Improved survival in pediatric malignancies is due in large part to intensive chemotherapeutic regimens that now are better tolerated owing to improvements in supportive care. Children receiving high-dose chemotherapy are at increased risk of developing potentially life-threatening infections during periods of chemotherapy-induced neutropenia. The incidence and severity of these infections are related to the duration and severity of neutropenia. Methods used to prevent infection have included delay or reduction in chemotherapy dose, progenitor cell support, and use of prophylactic antibiotics. During the last decade, CSFs have been introduced into clinical practice, and the prophylactic use of these agents has been demonstrated to reduce the duration of neutropenia and the number of infections and hospitalizations.[244] CSFs usually are begun on the day after chemotherapy, but several recent studies have shown that CSF treatment may be delayed safely for several days after completion of a course of chemotherapy and can yield equivalent results. [244]

Although clinical benefit has been documented, the high cost of CSFs has led to concerns about their appropriate use. The American Society of Clinical Oncology (ASCO) has developed guidelines for the use of CSFs based on an expert multidisciplinary panel review of the available clinical data. Originally published in 1994 and updated in 1996, the most recent version was released in 2000. [245,246 and 247] In all versions, the panel recommended the prophylactic use of CSFs by patients in whom the expected incidence of chemotherapy-induced neutropenia is greater than or equal to 40%, after a prior episode of febrile neutropenia, or after high-dose chemotherapy with autologous progenitor stem-cell support. CSFs were found to be beneficial also in the mobilization of peripheral blood progenitor cells (PBPCs). The panel stated that although pediatric data are not conclusive, the guidelines recommended for adult patients generally are applicable to children as well. [246,247] A review of CSF use practices by members of the Pediatric Oncology Group indicates that pediatric oncologists use CSFs more commonly than do their adult colleagues and initial ASCO guidelines recommended. [248] Although much of the CSF use was dictated by protocol requirements, it was influenced also by physician preference and available data.[247] The higher perceived dose intensity and expected toxicity of pediatric chemotherapeutic regimens also appear to promote CSF use.[248] The 2000 ASCO guidelines make no new pediatric recommendations.[247] Further research is required to define more clearly the role of CSFs in children receiving chemotherapy and progenitor-cell transplantation. The results of selected randomized trials of white cell growth factors in pediatric patients are summarized in Table 40-6.



| Study | Agent | Diagnosis | N | Indication | Episodes of FEVA | Duration of neutropenia[a] | Duration of fever[b] | Length of hospital stay | Decrease in hospital cost |
|---|---|---|---|---|---|---|---|---|---|
| Kilmer[237] | G-CSF | Various | 144 | Primary prevention | S | S | S | S | S |
| DiBenedetto[238] | G-CSF | ALL | 32 | Primary prevention | NS | NS | NS | NS | NA |
| Meta[239] | G-CSF | ALL | 34 | Primary prevention | S | S | S | S | NS |
| Ky[240] | G-CSF | ALL | 104 | Primary prevention | NS | S | NS | S | NS |
| Kilmer[241] | GM-CSF | Various | 74 | Primary prevention | S | S | S | S | S |
| Calderwood[242] | GM-CSF | ALL | 40 | Primary prevention | S | NS | NS | NS | NA |
| Mitchell[243] | GM-CSF | NBL | 59 | Primary prevention | NS | S | NS | NS | NA |

ALL, acute lymphoblastic leukemia; FEVA, fever and neutropenia; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; NA, not analyzed; NBL, neuroblastoma; NHL, non-Hodgkin's lymphoma; NS, non-statistically significant reduction; S, statistically significant reduction.
[a]Neutropenia is defined as an absolute neutrophil count <500 cells/mm³.
[b]Fever is defined as a body temperature of greater than 38.3°C.

**TABLE 40-6. SUMMARY OF SELECTED RANDOMIZED TRIALS OF HEMATOPOIETIC GROWTH FACTORS IN PEDIATRIC PATIENTS**

### *Molecular and Cellular Physiology of Growth Factors*

Homeostatic mechanisms maintain the number of red blood cells, platelets, and mature myeloid and monocytic cells within a narrow range. Reductions in the numbers of these cells (e.g., as a result of chemotherapy) activate physiologic mechanisms that attempt to normalize the blood components. The CSFs can be divided into those that expand early hematopoietic progenitor cells (IL-3, IL-6, IL-11, stem-cell factor, and flt3 ligand) and those that are late-acting with biologic effects primarily limited to a single hematopoietic lineage (G-CSF, GM-CSF, and erythropoietin). However, the late-acting growth factors also may influence more than one hematopoietic lineage.[244]

### *Homeostatic Mechanisms*

Under normal conditions, serum levels of CSFs are fairly low, but they can increase markedly in response to specific stimuli, such as periods of stress (e.g., infection) and when the terminally differentiated cells regulated by the CSFs are substantially reduced. [244] Serum G-CSF levels appear to be controlled by changes in both the rate of G-CSF production and clearance. Lipopolysaccharides produced by pathogenic bacteria increase the rate of synthesis of G-CSF and other CSFs. Although normal serum G-CSF levels are approximately 25 pg per mL, concentrations of 1,000 pg per mL or higher can be observed in patients with severe infections [249] and after stem-cell transplantation.[250,251] Conversely, high neutrophil levels appear to increase CSF clearance. [252,253]

## Clinical Applications of Growth Factors

Three basic strategies are applied in the use of CSFs in the management of patients with malignancy. Primary prophylaxis is defined as the administration of a CSF in an attempt to prevent myelosuppression. Secondary prophylaxis involves the use of a CSF to prevent new episodes of myelosuppression or delays in the administration of subsequent cycles of chemotherapy in a patient who previously has experienced delays in therapy. CSF treatment is the use of CSFs to shorten the duration of an already established episode of neutropenia prior to the development of fever, as a component of the treatment of an episode of febrile neutropenia, or after a documented infectious complication has occurred.

### *Primary Prophylaxis in Patients after Chemotherapy*

#### Granulocyte Colony-Stimulating Factor

A variety of phase I and phase II studies in children having cancer and receiving intensive chemotherapy have documented that primary administration of G-CSF reduces the duration of neutropenia, lowers rates of neutropenic fever, decreases use of antibiotics, and diminishes the need for hospitalization as compared with historical control subjects who did not receive G-CSF. [244,254,255] Several larger randomized trials also have been completed in children having cancer and undergoing chemotherapy. Children with high-risk leukemia randomly assigned to receive G-CSF had a lower incidence of febrile neutropenia and culture-confirmed infection and a shorter duration of total antibiotic use as compared with those receiving placebo. [256] Another trial in children undergoing chemotherapy showed a reduction in the duration of neutropenia (4.8 days vs. 16.5 days), days of hospitalization (13 days vs. 65 days), and broad-spectrum antibiotic treatment (13 days vs. 95 days) for patients receiving G-CSF as compared to those receiving placebo. Two episodes of neutropenic fever occurred in patients in the G-CSF group, and ten took place in those in the placebo group.[257]

However, not all studies have shown a benefit from the use of G-CSF. In 164 children with acute lymphoblastic leukemia undergoing continuation chemotherapy and randomly assigned to receive either G-CSF or placebo, no significant difference was noted between the two groups in rate of hospitalization for febrile neutropenia (58% in the G-CSF group vs. 68% in the placebo group), event-free survival at 3 years (83% in both groups), or number of severe infections (five in patients in the G-CSF group vs. six in those in the placebo group). Patients treated with G-CSF did have shorter median hospital stays (6 days vs. 10 days) and fewer documented infections (12 vs. 27). The median total cost of supportive care was similar in those in the G-CSF and placebo-treated groups. [258] A Pediatric Oncology Group study also showed no significant benefit in a randomized trial of G-CSF versus placebo in children with T-cell leukemia and advanced-stage lymphoblastic lymphoma. [259] Another trial in 149 children and adolescents receiving chemotherapy for non-Hodgkin's lymphoma also showed no significant differences between the two groups in terms of febrile neutropenia, duration of neutropenia, and total costs of treatment. [260]

A beneficial effect of G-CSF on platelet levels has not been observed. In fact, several trials have shown that G-CSF-treated patients develop somewhat more severe thrombocytopenia in later cycles, perhaps as a result of higher chemotherapy dose intensity. [244] Amelioration of mucositis in association with G-CSF has been reported.[87] Conversely, in a trial of weekly chemotherapy for non-Hodgkin's lymphoma, patients who received G-CSF had more treatment delays for mucositis than did control subjects. This probably occurred because the G-CSF treated patients received more intensive treatment over the entire course of chemotherapy as a result of the lesser prevalence of neutropenia.[261] In conclusion, it appears that the use of G-CSF should be limited to pediatric patients who receive intensive chemotherapeutic regimens, as recommended in the ASCO guidelines. For malignancies in which available data do not demonstrate an improvement in survival with increasing dose intensity, consideration should be made to reduce chemotherapy doses rather then using a CSF. [247] The routine use of these costly agents after pulses of less myelosuppressive chemotherapy cannot be supported by the literature.

#### Granulocyte-Macrophage Colony-Stimulating Factor

Randomized trials of GM-CSF as primary prophylaxis of neutropenic fever usually have resulted in lessened duration or severity of neutropenia, but clinical benefits have not been as consistently positive as those observed with G-CSF. [244,255,262] Two prospective studies of children have been reported. In the first, GM-CSF prophylaxis was begun during the third treatment cycle of alternating vincristine, doxorubicin, and cyclophosphamide alternating with and ifosfamide plus etoposide for pediatric sarcomas.[263] Although GM-CSF reduced the depth and duration of the neutropenic nadir, the rates of neutropenic fever, hospital days, antibiotic requirements, dose intensity, and disease control were not affected significantly. Moreover, thrombocytopenia was more severe in children receiving GM-CSF, resulting in greater platelet and red blood cell transfusion requirements. [263] The other randomized trial of GM-CSF in children also documented a shortened duration of neutropenia for children receiving GM-CSF, but the period of thrombocytopenia was longer. [264]

### *Secondary Prophylaxis in Patients after Chemotherapy*

Currently, no randomized trials are assessing whether secondary prophylactic use of either G-CSF or GM-CSF can prevent new episodes of febrile neutropenia in pediatric patients with a prior episode, and encouraging results in adults are limited. In a randomized trial of G-CSF versus placebo in adults, patients on the placebo arm were crossed over to G-CSF during subsequent cycles if they had a fever in cycle 1. Patients receiving G-CSF had a shorter duration of neutropenia (median of 6.0 days vs. 2.5 days) and a reduction in the rate of neutropenic fever (100% vs. 23% after receiving G-CSF). Patients who continued to receive placebo had a median duration of neutropenia of 6 days, although the incidence of febrile neutropenia in the second cycle was only 5%. [265] Therefore, the routine use of G-CSF for secondary prophylaxis cannot be recommended.

### *Colony-Stimulating Factors as Therapy for Neutropenia*

CSFs sometimes are administered concomitantly with intravenous antibiotics in patients with febrile neutropenia. As the response rate of these patients to antibiotic therapy is high, the likelihood of detecting a therapeutic benefit of CSFs is minimal. The utility of CSF therapy, therefore, may have to be gauged in terms of improved quality of life using pediatric-specific quality-of-life instruments, indirectly by duration of hospital stay and antibiotic use, or reduced treatment costs.

A series of studies have examined the efficacy of initiating CSF therapy after neutropenia is identified during a chemotherapy cycle. Two relatively small, randomized trials failed to detect a clinical benefit for either G-CSF [266] or GM-CSF[91] in this setting. Another randomized study assigning afebrile neutropenic patients to either G-CSF or placebo showed that the median time to an ANC greater than 500 cells per $mm^3$ was significantly shorter for patients who received G-CSF (2 days vs. 4 days). In this study, no effect of G-CSF was seen on the rate of hospitalization, number of days in the hospital, duration of treatment with antibiotics, or number of culture-positive infections.[267] Therefore, administering CSFs to afebrile patients with neutropenia is unlikely to prove clinically valuable.

Several randomized controlled trials have evaluated either G-CSF, GM-CSF, or a combination of both agents as adjunctive treatment for patients with chemotherapy-induced neutropenia who already have fever.[244,255,262] In the largest of these trials, 216 patients were enrolled. Although median ANC recovery was statistically more rapid in patients in the G-CSF-treated group (3 days vs. 4 days), no significant difference was noted between the two groups as regards more clinically relevant parameters of fever duration, days of antibiotic use, duration of hospital stay, and mortality due to infection. [268]

In a double-blind study, pediatric patients who had neutropenia (ANC fewer than 500 cells per $mm^3$) and developed fever were randomly assigned to receive G-CSF (5 µg per kg per day) or placebo in addition to intravenous antibiotic therapy. Children randomly assigned to G-CSF had a shorter median hospital stay (5 days vs. 7 days) and fewer days of antibiotic use (5 days vs. 6 days) than did those receiving placebo. The 2-day reduction in hospital stay reduced the median cost by 29% per admission.[269] In a randomized study of 58 episodes of chemotherapy-induced febrile neutropenia in 40 children, the group given 5 µg per kg per day of GM-CSF

instead of placebo had a comparable slight reduction in hospital stay (9 days vs. 10 days) and antibiotic usage (7.0 days vs. 8.5 days). [270]

Other clinical trials evaluating CSF treatment for febrile patients with neutropenia have produced variable results, probably because of differences in patient characteristics, study design, and data analysis. In a randomized study of GM-CSF versus placebo in 107 adults, GM-CSF improved the response rate in terms of defervescence but not overall survival.[244] In a pediatric trial, GM-CSF therapy for febrile neutropenia after intensive chemotherapy shortened the mean duration of severe neutropenia from 9 days in the placebo group to 7 days in the GM-CSF treatment group. [263,271]

The ASCO guidelines state that because of the limited data regarding the efficacy of CSFs in afebrile patients with neutropenia, the use of CSFs in these patients is not recommended.[247] For febrile neutropenic patients as well, the routine initiation of CSF as an adjunct to antibiotic therapy is unnecessary. However, continuing G-CSF if started before the onset of febrile neutropenia is certainly warranted.

### *Chemotherapy Dose Intensity*

A number of preclinical studies and retrospective analyses have correlated chemotherapeutic efficacy with the dose intensity of the chemotherapy administered. Higher rates of response to antineoplastic agents have been related to delivery of full-dose chemotherapy combinations [272,273 and 274] or to overall dose intensity. Early phase I and phase II trials of both G-CSF and GM-CSF indicated that improvement in on-time, full-dose chemotherapy delivery was achieved with their use. [275,276] These results suggested that CSF prophylaxis may allow for increases in the dose intensity of chemotherapy, with consequent improvements in the antineoplastic effects of the cytotoxic drugs. A number of pediatric studies have evaluated chemotherapeutic regimens in which the doses of agents are escalated beyond those that can be given on time and with an acceptable incidence of febrile neutropenia without prophylactic use of CSFs. Regimens using even higher doses of cyclophosphamide (e.g., more than 4.0 g per $m^2$ per course) have been evaluated for neuroblastoma,[277] Ewing's sarcoma,[278] and other pediatric solid tumors.[279]

Another strategy for increasing the dose intensity of cytotoxic chemotherapy is to compress the interval between chemotherapy courses with CSF support. A randomized study of children with acute myelogenous leukemia demonstrated the efficacy of this approach.[280] Trials in adults employing the approach of rapid delivery of a moderately intensive chemotherapeutic regimen also have been successful in achieving enhanced chemotherapy delivery. [89,281,282,283,284 and 285]

Randomized trials of adult patients have shown no benefit in overall survival or disease-free survival for most tumors when the dose of chemotherapy was maintained and secondary prophylaxis with myeloid CSFs was instituted. The 2000 ASCO guidelines recommend that except for curable tumors or tumors for which data exist to maintain dose intensity, chemotherapy dose reduction should be considered after neutropenic fevers occur or severe or prolonged neutropenia is experienced after prior cycles.[247]

Many pediatric tumors are curable in a significant percentage of patients; accordingly, pediatric oncologists in practice are reluctant to reduce dose intensity as an alternative to CSF use. Indeed, in the Pediatric Oncology Group survey, chemotherapy dose reduction alone never was selected as a strategy to prevent febrile neutropenia for pediatric patients.[248] The ASCO guidelines recommend that use of CSFs to maintain dose intensity should be limited to clinical research protocols. [247]

### *Autologous Bone Marrow and Peripheral Progenitor Stem-Cell Rescue*

Randomized studies have evaluated the use of CSFs after autologous bone marrow rescue.[244,255,262] In general, neutrophil recovery was significantly hastened for patients receiving CSFs. One study demonstrated that G-CSF support resulted in a reduction of duration of grade 4 neutropenia, from a median of 20 to 13 days. [286] Randomized trials of G-CSF or GM-CSF prophylaxis after autologous BMT demonstrated significant effects on clinically relevant end points, such as duration of antibiotic usage and days in the hospital. In these trials, G-CSF use was associated with a significant reduction in duration of fever, a result that was not seen with GM-CSF use.[287]

Several small, retrospective studies of PBPC transplantation, including one study of children, found no significant benefit for postinfusion G-CSF in terms of either neutrophil or platelet recovery, raising the possibility that a larger number of infused progenitor cells obviates the beneficial effects of CSF therapy. [288,289] Randomized clinical trials have demonstrated a modest clinical benefit for G-CSF alone and for G-CSF plus GM-CSF in terms of more rapid neutrophil engraftment and shorter duration of hospitalization.[290]

On the basis of these data, the ASCO guidelines state that CSFs can successfully shorten the period of neutropenia and reduce infectious complications in patients undergoing high-dose cytotoxic therapy with autologous BMT.[247] Therefore, use of CSFs in this setting appears to be reasonable.

### *Allogeneic Bone Marrow Transplantation*

Neutrophil recovery usually has been enhanced with the use of either G-CSF or GM-CSF after allogeneic BMT. [244] No evident increase has been seen in GVHD, graft rejection, or relapse associated with CSF use in this setting. [286,291,292,293 and 294] Several studies have suggested a trend in favor of enhanced disease-free survival in CSF-treated patients. However, duration of hospitalization has not been altered significantly by administration of CSFs after allogeneic BMT. [292,293 and 294]

Pediatric data regarding the use of CSF prophylaxis after allogeneic BMT consist only of phase II trials compared to historical controls. In a small study, karyotypic analysis of recipient leukocytes in patients undergoing BMT from a donor of the opposite gender indicated that G-CSF allowed detection of donor karyotype 8 days faster than in controls.[295]

Based on this experience, the ASCO guidelines suggest a potential benefit to patients undergoing allogeneic BMT, but these data remain less conclusive than those for patients undergoing autologous BMT.[247] Therefore, routine use of CSFs after allogeneic transplantation cannot be recommended at the present time.

### *Engraftment Failure after Bone Marrow Transplantation*

In some patients who undergo high-dose therapy followed by stem-cell rescue, neutrophil engraftment does not occur, is delayed, or is lost after return of granulocytopoiesis. Patients who received T-cell–depleted grafts, whose donors are an HLA-C mismatch, whose graft is purged *in vitro* with chemotherapy, or who receive a low cell dose per kg of recipient body weight (e.g., umbilical cord blood graft recipients) are at particularly increased risk of primary or secondary graft failure. Mortality from infection in these patients is substantial, and this has been the impetus for studies of CSFs as a possible means to ameliorate this complication.

Most trials have evaluated the use of GM-CSF in patients who did not receive primary prophylaxis with a CSF and who failed to recover neutrophil counts by 3 to 4 weeks after autologous BMT. The largest of these studies demonstrated a significant reduction in death rates associated with the use of GM-CSF. [296] This study and other smaller trials have demonstrated neutrophil responses to GM-CSF administration in approximately one-half to two-thirds of such patients. However, interpreting these studies is difficult. Comparisons with historical controls, particularly in evaluating indirect end points, such as infectious mortality, have the strong potential for patient selection bias. Descriptive accounts of neutrophil recovery associated with CSF use are also uncertain. Quantifying the incremental benefit associated with GM-CSF use in these patients is rendered difficult by the extremely variable rate of spontaneous neutrophil recovery. On the basis of the existing data, the ASCO guidelines state that CSFs may have a role in assisting in the recovery of patients who experience delayed or inadequate neutrophil engraftment after progenitor cell transplantation.[247]

### *Mobilization and Collection of Peripheral Blood Progenitor Cells*

The collection and infusion of PBPCs as a means of hastening hematopoietic recovery after myeloablative chemotherapy are described in more detail in Chapter 16. Increasing experience is being gained in the use of PBPCs in the allogeneic setting, although they are used primarily for autologous transplant. PBPCs are collected by means of leukapheresis, are stored, and then are infused after the administration of myeloablative therapy. A total of 2.5 to 5.0 × $10^6$ $CD34^+$ cells per kg of recipient body weight usually are collected. Harvesting PBPCs without the use of chemotherapy or CSF priming requires multiple pheresis collections, as only small numbers of progenitors normally are present in the circulation. [297] Administration of nonablative chemotherapy with such agents as cyclophosphamide was found to cause a large increase in circulating PBPC numbers during hematologic recovery. Both GM-CSF and G-CSF stimulate release of PBPCs from the bone marrow into the peripheral blood. Peak yields usually are observed 4 to 8 days after CSF treatment alone, whereas peak PBPC numbers after administration of both

chemotherapy and CSF usually are noted shortly after recovery from neutropenia. A number of large historically or sequentially controlled trials provide convincing evidence that inclusion of CSFs in the mobilization regimen allows for collection of more PBPCs than are obtained from unstimulated donors or after hematologic recovery from chemotherapy alone.[244,255,262] In one randomized trial, 22 patients were assigned to receive or not receive G-CSF. Patients receiving G-CSF had a 2.5- to 5.5-fold increase in the numbers of mononuclear cells and PBPCs in their leukapheresis products. [298] Evidence also substantiates that CSF-assisted mobilization of PBPCs may reduce harvesting and posttransplantation supportive care costs. A randomized trial comparing the efficacy of different CSFs (G-CSF, GM-CSF, G-CSF combined with GM-CSF, and PIXY-321) in mobilizing PBPCs showed no difference between the various mobilization agents. The ASCO guidelines recommend the use of CSFs in the collection of PBPC.[247] The optimal dose of G-CSF with or without chemotherapy is under investigation, but a higher dose of G-CSF (10 µg per kg per day) may yield a greater content of $CD34^+$ progenitor cells in the PBSC product.

CSF-mobilized PBPCs are being evaluated also for use in the allogeneic transplantation setting. Potential advantages to the donor include less discomfort during the procedure and, in most cases, avoidance of general anesthesia.[299] Concerns have been raised about the use of CSFs in otherwise healthy donors, owing to the possible risks of secondary malignancies that have been associated with their use in congenital neutropenia, aplastic anemia, and other nonmalignant conditions (discussed in the section Potential of Colony-Stimulating Factors to Induce Malignancy ). Recipient benefits include faster hematopoietic reconstitution after transplantation and a reduction in the morbidity and mortality of the procedure. G-CSF-primed leukocytes might theoretically carry a greater risk of acute or chronic GVHD, as patients receiving PBPC would receive a dose of mature lymphocytes higher than that given with bone marrow. However, early experience suggests that CSF-mobilized PBPCs may provide rapid hematologic recovery without an appreciably greater incidence of GVHD. [299,300 and 301]

In children undergoing PBPC transplantation, pediatric-specific problems can be encountered. Unlike adults in whom large, peripheral intravenous catheters can be placed for PBPC collection, most children require a rigid central venous catheter to be placed to collect an adequate number of stem cells. Permanent, indwelling pheresis catheters can be placed at the beginning of therapy, thus avoiding surgery for the placement of a second central venous catheter, if transplantation is an option early in the treatment course. Other potential complications include the development of thrombocytopenia, [302] hypocalcemia secondary to the large volume of citrate anticoagulant in the circuit,[303] headache, nausea, and vomiting. Techniques for minimizing or managing these complications have been developed, and PBPC harvesting now is considered safe and feasible for infants and young children whose weight is more than 10 kg. [304] CSFs used in the harvesting procedure may alleviate some of the difficulties of collection in younger donors by reducing the number of pheresis collections necessary to harvest an adequate amount of PBPC for transplantation.[305,306]

### *Colony-Stimulating Factors as Antitumor Therapy*

#### Priming Effect of Granulocyte-Macrophage Colony-Stimulating Factor before or during Chemotherapy for Acute Myeloid Leukemia

*In vitro* evidence exists that myeloid leukemic cells have receptors for GM-CSF and that their proliferation and differentiation are supported by exposure to GM-CSF.[262] Recruitment of chemoresistant cells into more sensitive phases of the cell cycle was hypothesized to enhance the effect of chemotherapeutic agents. GM-CSF has been shown to increase the number of leukemia cells in S phase. In a randomized trial of 114 patients with newly diagnosed AML, patients were randomly assigned to receive chemotherapy alone or with GM-CSF starting 24 hours beforehand. [307] The overall remission rate was 79% in patients receiving GM-CSF, compared to 84% in controls. Similar studies in patients with AML showed a trend toward increase in disease-free survival; however, the use of GM-CSF during induction therapy of AML did not appear to have a significant impact on treatment outcome. [308]

#### Granulocyte-Macrophage Colony-Stimulating Factor as an Adjunct to Antitumor Vaccine Therapy

GM-CSF might be expected to enhance antitumor vaccine immunogenicity on the basis of its role as a mediator of proliferation, maturation, and migration of dendritic cells as well as induction of primary and secondary T-cell responses. [309,310 and 311] GM-CSF was administered as an adjunct to a melanoma vaccine in 20 patients with stage IV melanoma. Four patients had a complete or partial response, and four had stable disease. [312] GM-CSF isbeing investigated also as an adjunct to tumor vaccines in multiple myeloma.[313,314]

#### Granulocyte-Macrophage Colony-Stimulating Factor as an Adjunct to Antitumor Immunotherapy

GM-CSF has been shown to enhance slightly the cytotoxic activity of peripheral blood monocytes and lymphoctyes and to increase antibody-dependent cellular cytotoxicity.[315,316] The effect of GM-CSF on activated killer T-cell activity was evaluated in 20 patients with AML and undergoing autologous BMT. [317] In this study, activated killer cell function was enhanced by GM-CSF *in vitro*. The actuarial rate of relapse in the GM-CSF-treated group was 37.4%, as compared with 49.5% in controls ($p$ = .05). Twenty-four patients with metastatic renal cell carcinoma were treated with GM-CSF; one patient had stable disease, and the rest progressed. [318] GM-CSF has been studied also in combination immunotherapy. In one trial, GM-CSF and IL-2 were administered to 20 patients with metastatic renal cell carcinoma. No responses occurred among the 20 patients, although 1 had a partial response and 3 had stable disease. [319] In a trial of 20 patients with melanoma, GM-CSF was administered as adjuvant therapy with R24, a murine monoclonal antibody that mediates complement-dependent cellular cytotoxicity of melanoma tumor targets. Of six patients who received GM-CSF alone, three had no response, and three had progressive disease. Of the 14 patients who received GM-CSF and R24, 2 had a partial response.[320] In a phase II study of GM-CSF and chimeric anti-GD2 monoclonal antibody in patients with multiply recurrent neuroblastoma, 1 of 27 patients had a complete response, 3 had a partial response, and 2 had stable disease. [321] Randomized studies are required to determine whether GM-CSF is efficacious as an adjunct to antitumor immunotherapy.

### *Hematologic Disorders and Premalignant Disorders*

#### Myelodysplasia

CSFs have been evaluated in treating patients with refractory anemia, refractory anemia with an excess of blasts, refractory anemia with an excess of blasts in transformation, and chronic myelomonocytic leukemia.[262] However, the application of CSFs has been limited by theoretic concerns about their ability to stimulate the growth of myeloid leukemias (discussed in section Potential of Colony-Stimulating Factors to Induce Malignancy ). In five separate clinical trials, 38 of 45 patients who had myelodysplasia (MDS) and received GM-CSF had an improvement in their neutrophil counts. [322] In a randomized trial, 133 patients with MDS were randomly assigned to receive GM-CSF or placebo. GM-CSF use was associated with a significant reduction in major infections in association with increases in ANC. G-CSF likewise has been evaluated in patients with MDS. [323] G-CSF appears to cause more differentiation and less proliferation than does GM-CSF. In a large randomized trial in which 102 patients received G-CSF or placebo, G-CSF was associated with an increase in ANC and a decrease in infectious complications. [324]

#### Aplastic Anemia

Aplastic anemia is a heterogeneous disorder caused by absent or defective stem cells, microenvironmental defects, or immunologically mediated bone marrow suppression. CSFs have been investigated in the treatment of aplastic anemia, often in combination with immunosuppressive agents such as cyclosporine and antithymocyte globulin. Several case series have shown that CSFs alone may induce a complete or partial response in some patients. Patients with a baseline ANC of more than 200 cells per $mm^3$ appear to have a response rate to CSFs superior to that in patients with a lower ANC. [244]

#### Kostmann's Syndrome

Severe congenital neutropenia, or Kostmann's syndrome, is a disorder of impaired neutrophil differentiation and baseline neutrophil counts of fewer than 200 cells per $mm^3$. Bone marrow examination shows a maturation arrest at the promyelocyte stage.[325] Serum levels of G-CSF in such patients are normal or elevated. Several studies have demonstrated a remarkable increase in the neutrophil counts of almost all patients treated with G-CSF. The doses required to keep the ANC above 1,000 cells per $mm^3$ varied from 3 to 15 µg per kg per day or more of G-CSF.[326] A multicenter phase III study of G-CSF in 120 patients with severe chronic neutropenia, including Kostmann's syndrome, Shwachman-Diamond syndrome, and myelokathexis reported complete responses in 108 patients, partial responses in 4, and failure to respond in only 8 patients.[327]

### Other Congenital Neutropenic Disorders

Cyclic neutropenia is a rare disorder characterized by regular 14- to 28-day cyclic fluctuations in the numbers of neutrophils, monocytes, eosinophils, lymphocytes, platelets, and reticulocytes. Patients develop recurrent episodes of fever, mucosal ulceration, and occasionally life-threatening infections during the period of neutropenia. Studies have shown that the administration of G-CSF at doses of 3 to 15 µg per kg per day both reduced the nadir of the neutrophil counts and shortened the duration of the nadir. G-CSF therapy was shown also to reduce the number of infections during the neutrophil nadir. [327,328,329] and [330] Chronic idiopathic neutropenia is characterized by transient maturation arrest of neutrophil precursors in the bone marrow and in neutrophil counts below 1,500 cells per $mm^3$. G-CSF has been shown to increase the neutrophil count and reduce the number of infections and need for hospitalization in these patients, [331] even at extremely low doses.[332]

## Clinical Use of Colony-Stimulating Factors: Toxicity, Dosing, and Route of Administration

### *Toxicity*

### Granulocyte Colony-Stimulating Factor

The predominant side effect associated with the administration of G-CSF is medullary bone pain, which occurs in 15% to 39% of study subjects receiving approximately 5 µg per kg per day[244] and more frequently at higher doses. Bone pain most commonly is observed either shortly after the injection or during the time of neutrophil recovery and is associated with the peak of marrow proliferative activity. It can be relieved by analgesics, such as acetaminophen or ibuprofen. Splenomegaly also has been reported to occur. Although usually asymptomatic, reports of left upper quadrant pain consistent with splenic infarction and hypersplenism have been described. Infrequent adverse effects include vasculitis, acute febrile neutrophilic dermatosis (Sweet's syndrome), osteopenia, glomerulonephritis, rashes, bone marrow fibrosis, transient leukemia cutis in a patient with chronic myelogenous leukemia, MDS or leukemia, transient inverted chromosome 5q with excess blasts, and possible anaphylactic reactions. Anti–G-CSF antibodies have not been reported. Doses of more than 100 µg per kg per day of G-CSF have been given without dose-limiting toxicity.[244]

### Granulocyte-Macrophage Colony-Stimulating Factor

At doses of 0.3 to 10 µg per kg per day, GM-CSF has been associated with fever, chills, lethargy, myalgia, bone pain, anorexia, change in weight, generalized skin eruptions, flushing, and raised erythematous lesions at the subcutaneous injection site. [244] The first dose of GM-CSF may be followed within 3 hours by a characteristic reaction involving transient flushing, tachycardia, hypotension, musculoskeletal pain, dyspnea, nausea and vomiting, and arterial oxygen desaturation and is more common after intravenous administration than after subcutaneous administration. Patients who develop this syndrome appear to be at increased risk for recurrence if GM-CSF is restarted. GM-CSF doses of more than 20 µg per kg per day are not well tolerated. The major toxicities encountered were weight gain with fluid retention, pleural and pericardial inflammation and effusions, and venous thrombosis. [244]

### Toxicity Comparisons among the Colony-Stimulating Factors

A commonly held belief is that GM-CSF may be more toxic than G-CSF. The observed GM-CSF toxicities may result from the broader range of cells stimulated, with the consequential induction of cytokines such as IL-1, TNF-a, and IL-6, [333] or of inflammatory mediators, such as the leukotrienes.[334] Randomized trials comparing G-CSF and GM-CSF in patients receiving standard-dose chemotherapy indicate relatively few toxicities for either agent. Local reactions, generalized rashes, constitutional symptoms, fever, thrombocytopenia, and anemia seem more prominent with GM-CSF.[244] However, in a randomized trial comparing the two agents as therapy for febrile neutropenia, similar efficacy for both agents and few differences in toxicity were reported. [335] Another study that prospectively compared GM-CSF and G-CSF as therapy for afebrile neutropenia also noted no differences in systemic symptoms. [336] Reports from a randomized, blinded comparison of GM-CSF and G-CSF used with standard-dose chemotherapy indicated relatively modest toxicities due to either agent, with the only major difference being a higher frequency of grade 1 or grade 2 fever with GM-CSF.[337]

### *Potential of Colony-Stimulating Factors to Induce Malignancy*

Concerns have been raised about use of GM-CSF in patients with AML. GM-CSF promotes the *in vitro* proliferation of leukemic blasts and thus might lead to *in vivo* precipitation of relapse. However, numerous clinical studies have not shown a clinically detectable adverse effect of CSFs on stimulation of myeloid leukemic cell growth. The complete response and relapse rates of patients receiving CSFs usually have been the same as or better than those in control groups. [308] However, in one trial, patients who received GM-CSF had a statistically significant increase in the incidence of residual leukemia and a decrease in disease-free survival as compared to those in the control group.[338]

Reports of MDS or acute leukemia developing during the treatment of both pediatric and adult aplastic anemia patients with CSFs have raised concerns about long-term use of these agents. Evaluating the malignant potential of CSFs in aplastic anemia is difficult, because the risk of MDS and AML can be as high as 20% in patients treated with immunosuppressive therapy (cyclosporine and antithymocyte globulin) alone. [339,340] and [341] Three cases of monosomy 7 MDS transformed from aplastic anemia after continuous therapy with G-CSF have been reported. [342] A series of 167 children with aplastic anemia included 11 who developed MDS after treatment with immunosuppression and G-CSF.[343] The incidence of MDS or leukemia has been reported to be 47% ± 17% at 7 years in 62 children who were treated with immunosuppressive therapy and G-CSF.[343] In another study, MDS developed in only 1 of 47 patients treated with G-CSF alone, as compared with 4 of 18 patients who received either antithymocyte globulin or cyclosporine. In this analysis, the administration of G-CSF for more than 1 year was the most important predictive factor in the development of MDS.[344]

Several cases of monosomy 7–related MDS and AML have been reported in patients with Kostmann's syndrome (severe congenital neutropenia) treated long-term with G-CSF.[344,345,346,347] and [348] The historical risk of malignancy in patients with Kostmann's syndrome is unknown, because before CSFs, most patients succumbed to serious infections in infancy. In a cohort of 420 patients registered with the Severe Chronic Neutropenia International Registry, 220 of whom had received G-CSF for 8 or more years, only 16 cases of AML or MDS have been reported thus far.[254] No patient with cyclic neutropenia treated with CSFs has developed a secondary malignancy.[254] All the malignancies in the Registry report were associated with mutations in the gene for the G-CSF receptor. [349] In a review of 125 patients who received G-CSF for treatment of congenital neutropenia, aplastic anemia, and MDS, 4 developed fatal MDS or AML that was related to monosomy 7. [350] Although CSFs clearly have a therapeutic effect in these severe hematologic and premalignant disorders, patients so treated must be observed carefully for the development of MDS and leukemia.

### *Dosage and Route of Administration*

### Granulocyte Colony-Stimulating Factor

The optimal dose of G-CSF has not been established in all clinical settings. Studies of primary prophylaxis after outpatient chemotherapy in adults and children have demonstrated that approximately 5 µg per kg per day of G-CSF is effective in reducing the incidence of neutropenic fever. Although some phase I investigations have suggested that higher doses of G-CSF may produce more rapid bone marrow recovery, others have not been able to document such an effect. When G-CSF is given intravenously, it is diluted with albumin to protect the G-CSF from adsorption onto plastic materials and is given as a 15- to 30-minute infusion. No reported difference in efficacy has been cited between the intravenous and subcutaneous routes of administration. [244]

Intravenous and subcutaneous administration of G-CSF doses as low as 1.5 to 2.0 µg per kg per day may shorten the duration of neutropenia after chemotherapy.[351,352] and [353] Although one of these trials suggested that the subcutaneous route was more active, both routes showed efficacy. [351] Equivalent rates of fever and comparable patterns of neutropenia have been noted with doses of 2 and 5 µg per kg per day of G-CSF, [354] and preliminary findings from a very large randomized trial evaluating fixed-unit dosing of 300 or 480 µg total per day have implied that the lower dose is as efficacious as the higher. [355] Therefore, although a G-CSF dose of 5 µg per kg per day is reasonable and safe, available data suggest that lower G-CSF doses may provide similar benefit at lower cost. [246]

In the setting of BMT, the concern that higher G-CSF doses may be required to counter extreme myelosuppression has led to randomized comparisons of doses of

10, 20, and 30 µg per kg per day. Intravenous G-CSF produced enhanced neutrophil recovery after BMT [356] and high-dose chemotherapy for acute lymphoblastic leukemia (ALL)[357] with doses of 2, 5, 10, and 20 µg per kg per day; doses exceeding 5 µg per kg per day did not appear to provide an overt additional benefit. Although sequential evaluations of G-CSF doses as high as 24 µg per kg per day have not been able to link administration of higher doses definitively with enhanced PBPC yields,[358,359] G-CSF doses higher than 10 µg per kg per day often are used when G-CSF is employed as a single agent for PBPC mobilization. [299,300] and [301,360,361] Adose-response effect for PBPC mobilization has not been established clearly.

### Granulocyte-Macrophage Colony-Stimulating Factor

The best dosing data for GM-CSF are derived from the randomized licensing trial. In it, a 2-hour intravenous infusion at a dose of 250 µg per $m^2$ per day proved effective in decreasing the time to neutrophil recovery, shortening duration of hospitalization, and lessening antibiotic use if given after autologous BMT. [93] Much of what is known is based on phase I dose-ranging evaluations of GM-CSF prophylaxis after intensive chemotherapy that have suggested activity in the range of 250 to 750 µg per $m^2$ per day in small cohorts of patients.[362,363] Phase I pediatric data implied that doses of more than 500 µg per $m^2$ per day may provide greater clinical benefits,[364] but this information is highly susceptible to selection bias. A follow-up phase II trial employing 1,000 µg per $m^2$ per day of GM-CSF after intensive chemotherapy demonstrated improvements in neutrophil counts as compared to lower doses, but showed no clinical advantages. [365] Mobilization of PBPC with GM-CSF appears to be possible with conventional doses. In one study, subcutaneous administration of GM-CSF across a dose, but range of 125 to 500 µg per $m^2$ per day indicated no evident dose-related response in the mobilization of PBPC. [366]

The ASCO guidelines recommend that G-CSF be dosed at 5 µg per kg per day and GM-CSF at 250 µg per $m^2$ per day.[247] These agents can be administered subcutaneously or intravenously, as clinically indicated. Dose escalation of CSFs is not recommended. The guidelines recommend rounding the dose to the nearest vial size in larger children and adolescents.

### Initiation and Duration of Colony-Stimulating Factor Prophylaxis

The current recommendation is that a course of G-CSF begin 24 to 48 hours after completion of chemotherapy and continue through the period of granulocyte nadir until an ANC of at least 10,000 per $mm^3$ is achieved.[244] A number of studies have evaluated alternative methods of CSF prophylaxis, striving either to initiate CSFs earlier to maximize benefit or terminate prophylaxis as quickly as possible, thereby reducing costs. [367] Starting the CSF with chemotherapy raises the concern that the CSF may induce progenitor cell cycling that actually would enhance bone marrow sensitivity to chemotherapy. [143] Evidence from studies with both G-CSF and GM-CSF suggests that this concern may be more than hypothetical. Patients receiving CSF prophylaxis simultaneously with 5-fluorouracil [368,369] plus topotecan [370] or combination chemotherapy[266] appeared to have more profound neutropenia or depressed neutrophil recovery as compared with historical controls or with patients not treated with G-CSF and chemotherapy simultaneously. More convincing has been a trial in which patients receiving daily oral etoposide were assigned randomly to receive or not receive GM-CSF concurrently with the chemotherapy; GM-CSF–treated patients had a degree of myelosuppression significantly greater than that in patients receiving only etoposide.[371] Conversely, a study of adult patients with ALL in whom G-CSF was given simultaneously with repeated courses of cell cycle–active agents (cytarabine and 6-mercaptopurine) and cyclophosphamide found that neutropenia was moderated significantly by the G-CSF, compared with the outcome in controls who received chemotherapy alone.[372] At present, avoiding concurrent use of CSFs and chemotherapy seems prudent.

Because the neutrophil nadir usually is delayed by 5 to 7 days after administration of chemotherapy, consideration has been given also to delaying the initiation of prophylaxis with CSFs until the expected onset of severe neutropenia. Eighteen children were randomly assigned to early initiation of G-CSF therapy (24 hours after chemotherapy) or delayed initiation (5 days after chemotherapy). No differences were noted between the two groups in terms of infection, hospital days, and intravenous antibiotic use.[373] In another study, 72 courses of chemotherapy were given in a sequential cohort study. G-CSF was administered either 24, 48, 72, or 96 hours after chemotherapy. Patients who received G-CSF early (24 and 48 hours after chemotherapy) had a shorter duration of leukopenia as compared to that in patients who received G-CSF later (72 or 96 hours). However, no difference was seen in the duration of ANC below 500 cells per cubic or thrombocytopenia. [244] In a study of patients undergoing autologous PBPC collections, 30 received G-CSF immediately after the end of chemotherapy and 35 received the first G-CSF dose 3 to 4 days after the completion of chemotherapy. The study reported no statistically significant difference between the two groups in the median numbers of $CD34^+$ cells collected or the rate of failure to collect an adequate number of stem cells. [374]

The ASCO guidelines recommend starting G-CSF or GM-CSF between 24 and 72 hours after chemotherapy to provide optimal recovery. [247] Continuing the CSF until the occurrence of an ANC of 10,000 cells per $mm^3$ after the neutrophil nadir, as specified in the G-CSF package insert, is known to be safe and effective. However, a shorter duration of administration sufficient to achieve and sustain clinically adequate neutrophil recovery is a reasonable alternative, considering issues of patient convenience and cost.

## HEMORRHAGE

The body's chief defense against hemorrhage from large blood vessels is rapid deposition of an insoluble fibrin clot. This results from a complex interaction of circulating coagulant and anticoagulant proteins finely tuned to maintain hemostasis. If the system becomes unbalanced by infection, neoplasia, or complications of its treatment, hemorrhage or thrombosis may result.

### Disseminated Intravascular Coagulation

DIC is characterized by increased amounts of thrombin and plasmin in the circulation. This increase results in consumption of platelets, coagulation factors and inhibitors, hemolytic anemia, and secondary hyperfibrinolysis. Ultimately, DIC results in microthrombi formation and acute generalized bleeding. [375,376]

Screening laboratory tests indicative of DIC include a prolongation of the prothrombin time (PT) and the activated partial thromboplastin time (APTT) due to consumption and proteolysis of fibrinogen and other coagulation factors. Some patients may demonstrate shorter than normal PT and APTT values owing to circulating activated clotting factors. [375,377,378] Thrombocytopenia is a constant finding in DIC, resulting from shortened platelet survival. In addition, DIC may cause platelet dysfunction.[379] However, thrombocytopenia may be related also to the underlying disorder, particularly in cancer patients. Schistocytes often are seen on the peripheral blood film. Elevated fibrin degradation products (FDP) or fibrin split products almost universally are seen in DIC, but the levels may be influenced by the balance of procoagulant activity, fibrinolytic response and activity of the renal and macrophage mediated clearance mechanisms. D-Dimer is more specific but is less sensitive than FDP measurements.[375,377,378] Specific factor assays, antithrombin levels, and fibrinopeptide A measurements usually are not required in clinical practice unless administration of a specific replacement product is contemplated.

In children with cancer, DIC is seen predominantly with gram-negative septicemia. Laboratory evidence of DIC has been reported in 3% to 13% of patients with newly diagnosed pediatric acute leukemia. It is more common in AML, particularly the promyelocytic (M3) and monomyeloblastic (M5) subtypes, and in children with ALL and hyperleukocytosis, particularly with a T-cell phenotype. [380,381] DIC has been reported also in children with neuroblastoma and other solid malignancies, usually in the setting of diffuse metastatic disease or extensive primary tumors.[382,383]

Suppression or attenuation of the underlying cause of DIC remains the most crucial aspect of treatment. Excellent critical care, including meticulous correction of hypovolemia, hypoxia, and acidosis, is required. Blood products to replace the consumed platelets, coagulation factors, and inhibitors are indicated for intractable bleeding or in preparation for invasive procedures. [375,378] Replacement of factors with cryoprecipitate, FFP, or platelet concentrates does not appear to “fuel the fire” significantly by causing thrombosis in active DIC. [384,385]

Replacement therapy, if given, should be as specific as possible and usually is provided by FFP at a dose of 10 to 15 mL per kg body weight. Large volumes, up to 6 units per 24 hours, often are required in adults. [378] If this dosage does not result in cessation of bleeding or in a fibrinogen level of more than 0.5 g per L, cryoprecipitate, 10 units per 2 to 3 units of FFP, can be added. [375] Platelet transfusion should be considered for values of less than 20,000 per $mm^3$ or for major bleeding if the platelet count is less than 50,000 per $mm^3$.[375,378]

Heparin therapy for DIC is less widely recommended than previously, reflecting the absence of objective data demonstrating its benefit. Some physicians consider this agent useful to prevent the formation of thrombi and subsequent organ dysfunction caused by ischemia. Heparin should be considered only in DIC with overt thromboembolism or with extensive deposition of fibrin, such as in purpura fulminans, [378,386] chronic DIC, thrombosis often associated with adult cancers (Trousseau's

syndrome),[387] and perhaps in the coagulopathy associated with APML.[388]

APML (M3) frequently is associated with a distinct form of DIC. In such cases, a severe hyperfibrinolytic state and an activated coagulation system lead clinically to bleeding, but disseminated thrombi often are found at autopsy.[378,389] Induction treatment that includes all-*trans*-retinoic acid, which induces differentiation of myelocytes into neutrophils, rapidly normalizes fibrinogen concentration leading to amelioration of the bleeding diathesis, instead of worsening it as is seen with chemotherapy alone.[390] However, the thrombotic tendency due to persistent procoagulant activity seen in patients with APML who develop hyperleukocytosis may persist for several months.[391] Treatment with arsenic trioxide, a promising therapy for patients with relapsed or refractory APML, also appears to decrease FDP and D-dimer levels.[390] A low-dose constant infusion of heparin during induction chemotherapy formerly was believed to be of value, but today it usually is reserved for marked or persistent elevation of FDP or clinical thrombosis.[388]

Thus, for DIC with overt thromboembolism or extensive deposition of fibrin (as occurs in purpura fulminans), unfractionated heparin may be given at a low dose of 5 to 8 units per kg per hour as a continuous infusion.[378,392] Low-molecular-weight heparin also has been used in this setting, with equal efficacy and a decrease in bleeding.[393,394]

Antithrombin levels may be low in DIC, and infusion of antithrombin concentrates with or without heparin may be beneficial. The outcome of an ongoing randomized multicenter trial to administer high doses to patients with sepsis will help to determine the role of this agent in the treatment of DIC.[376,378,392] Similar trials of activated protein C concentrates are under way. Numerous other novel therapies for DIC, including the protease inhibitors gabexate and aprotinin, also are under evaluation.[376] Clinical use of these agents should be limited to investigational protocols at present.

## Specific Clinical Problems in Hemostasis

### *Liver Disease*

Patients with impaired hepatocellular function have a bleeding tendency, primarily originating from decreased synthesis of multiple blood coagulation factors in the liver. Children with cancer may develop severe hepatic dysfunction, hepatitis, or cirrhosis as a consequence of transfusion-related infection, hepatotoxicity of chemotherapy, biliary obstruction, or sepsis. A prolonged PT in this setting can be due to multiple causes, and the need for clotting factor replacement must be ascertained by measurement of coagulation factor levels. Although recommended management of a prolonged PT consists of FFP as treatment of hemorrhage or before invasive procedures, few data addressing efficacy are available.

### *Vitamin K Deficiency*

Vitamin K deficiency occurs infrequently in children with cancer and usually is due to diminished intake, decreased intestinal absorption, or suppression of bowel flora by broad-spectrum antibiotics (resulting in reduced synthesis of endogenous vitamin K). Without vitamin K to promote g-carboxylation of the glutamic acid residues of factors II (prothrombin), VII, IX, and X, these factors are unable to bind calcium and are inactive in the clotting cascade. Factor VII has the shortest half-life, so the PT becomes prolonged first. Vitamin K is required also for the function of the natural circulating anticoagulants protein C and protein S. Fibrinogen concentration and platelet counts usually are normal in vitamin K deficiency.

Therapy consists of oral or parenteral vitamin K (1 to 5 mg) daily for a minimum of 3 to 5 days. Oral vitamin K may be absorbed erratically, whereas intravenous therapy may be associated rarely with hypotension. Patients who fail to respond to vitamin K or who urgently require invasive procedures may be treated with FFP. Given the short half-life of factor VII (approximately 6 hours), aggressive support with FFP (10 to 15 mL per kg every 6 to 8 hours) often is necessary to produce a sustained reduction of the PT. Rarely does the PT shorten to less than 14 seconds.[377]

### *Massive Transfusion Syndrome*

Massive transfusion syndrome results from transfusion of large amounts of stored red blood cells over a short interval (usually hours) without concomitant transfusion of FFP or platelets. Initially, it was thought to be due to a “wash-out” of plasma clotting proteins and platelets.[377] More recently, the problematic diffuse microvascular bleeding in this syndrome was demonstrated to be due to a low platelet count.[395] Transfusion of a red cell volume equal to 1.5 times the blood volume or more over a period of hours may place a patient at risk. Treatment consists of laboratory assessment of the platelet count, PT, APTT, and FDPs with replacement by transfusion of the deficient components, usually platelets. In the setting of massive transfusion and bleeding, the platelet count should, if possible, be maintained at more than 50,000 per $mm^3$, owing to the functional platelet abnormalities that may occur also in this situation.[395,396]

### *Uremia*

Uremia is a paradigm of the entire coagulation system, predisposing to both bleeding and thrombosis. Bleeding, usually mucosal or with invasive procedures, is related to the degree of uremia.[397,398] Mechanisms that promote bleeding include quantitative and qualitative platelet defects resulting from contact with small and intermediate-weight dialyzable factors, from vitamin K deficiency, and from a circulating heparin-like anticoagulant.[397,398 and 399] Although uremic bleeding is partially correctable by hemodialysis, maintaining the hemoglobin at more than 10 g per dL may promote the formation of the primary platelet plug, the nidus of the clot.[400] The use of 1-deamino-8-D-argenine vasopressin (DDAVP) in standard doses may correct the bleeding time and allow invasive procedures if dialysis and adjustment of the hemoglobin do not.[401] Nephrotic syndrome and dialysis predispose to thrombosis through a variety of mechanisms, including increased levels of coagulation factors and decreased levels of antithrombin.[397,399]

### *Therapy for Hemorrhage*

Children with cancer and altered laboratory tests of hemostasis but no hemorrhage do not require treatment. FFP is used to treat coagulation disorders, but generally it should not be used as a volume expander or as prophylaxis of coagulation abnormalities.[19,402] FFP should be ABO-compatible with the patient's red blood cells. It requires 30 to 60 minutes to thaw in a manner that preserves the function of its coagulation factors.[19] The usual dose of FFP is 10 to 15 mL per kg administered over 1 to 2 hours as volume considerations allow. It may be repeated every 12 to 24 hours as needed to stop hemorrhage. Each unit of FFP contains on average 1 unit per mL of prothrombin and factors V, VII, VIII, IX, and X in a volume of 180 to 300 mL.[19,20] It can bestored frozen for 1 to 7 years, depending on conditions. Units can be held in quarantine until the donor returns for repeat testing after an interval longer than the window period for known viruses and the units can be shown to be seronegative. This approach to ensure the safety of transfused plasma has been used in the United States since September 1998.[230]

Treatment of plasma with a solvent-detergent (SD) process to inactivate lipid envelope viruses is another approach to producing plasma with a decreased infection risk. The production of SD plasma is accomplished by pooling 2,500 individual plasma donations, treating them with solvent and detergent, and repackaging the product in standardized 200-mL units. The contents are unchanged from single-donor units except that the procoagulant activity is reduced by 15% to 30%, proteins C and S by 20% to 40%, and large multimers of von Willebrand factor by 50% or more.[230,402] A unit of SD plasma costs two to five times as much as FFP.[403]

The large plasma pools necessary to render SD processing commercially feasible raise concern about transmission of nonenveloped viruses. The product does not transmit HIV-1 or HIV-2, HBV or HCV, HTLV-1 or HTLV-2, or HGV.[404] SD treatment is not effective against HAV,[230] parvovirus B19,[230] and the newly described liver disease–related TT virus.[405,406] Convenience and lack of knowledge that SD plasma is blood-derived also may lead to inappropriate use, just as it has with albumin.[230,402,403]

## THROMBOSIS

Thrombosis recently emerged as a significant problem in children with cancer. The most common sites of deep venous occlusion are the iliofemoral system in the legs and pelvis and the subclavian veins and superior vena cava in the chest. Arterial thrombosis is encountered as well.

### Predisposing Factors

The pathophysiology of thrombosis is complex, involving a number of acquired and underlying genetic alterations. First, as addressed in the discussion of DIC, an ill-defined hypercoagulable state exists in cancer patients of all ages. [407] Notably in children, this occurs with leukemia (especially with hyperleukocytosis or AMPL) or disseminated solid tumors.[380,381,382 and 383] Second, as discussed later, obstruction of flow in the upper venous system due to implanted central venous catheters predisposes to thrombosis.[408,409] Certain medications, particularly L-asparaginase, may further promote a prothombotic state. Finally, immobilization or obstruction of venous return due to massive adenopathy, hepatosplenomegaly, or bulky tumor may predispose children with cancer to development of a clinically significant clot.

Underlying genetic disorders predisposing to thrombosis may provide an added risk. Although inherited deficiencies of antithrombin, protein C, and protein S are uncommon, the factor V Leiden (factor V G1691A) mutation, prothrombin G20210A mutation, the TT677 genotype of methylenetetrahydrofolate reductase (MTHFR), and elevated lipoprotein(a) concentrations cumulatively affect more than 10% of the general pediatric population with stroke. [410] That inherited thrombophilias may contribute to thrombosis in certain populations was suggested by the European cooperative group finding that 67% of pediatric patients with ALL and thrombosis—but only 21% of ALL patients overall—had a genetic risk factor. [411] Further, no patient with other forms of pediatric leukemia, lymphoma, or solid tumors and thrombosis had a genetic risk factor.[411] This group also recently reported that 22 of 289 children (11%) with ALL treated on the Berlin-Frankfurt-Münster 90 and 95 protocols developed deep venous thrombosis. Some 27 of 58 patients (46.5%) with at least one pro-thrombotic risk factor developed thrombosis as compared to 5 of 231 (2%) of patients without any risk factors.[412] Although arterial thrombosis may occur as well, also secondary to indwelling catheters, these events are not nearly as common as those involving large veins. [413]

Diagnosis of venous thrombosis in the lower extremities is best made by compression duplex Doppler ultrasonographic examination. Although line studies involving instillation of contrast into the implanted device can disclose obstruction at the tip or interruption of the catheter, contrast venography is required for definition of thrombi in the upper venous system. This test involves injection of a small amount of contrast material into an antecubital vein followed immediately by fluoroscopy or plain film images of the chest.

#### *Central Lines*

Early in their treatment, children with cancer frequently have a central venous catheter placed for ease of infusion of fluids, chemotherapy, and blood products. Small thrombi occluding the tip of the catheter are thought to be prevented by regular heparin flushes, although this preventative strategy is increasingly questioned. [414] Larger thrombi may occlude the lumen and lead to inability to withdraw blood. Catheters also alter the flow of blood and cause endothelial injury that predisposes to thrombosis by their very presence.

The most common form of deep venous thrombosis in children with cancer is stenosis or occlusion of veins in the upper venous system, including the superior vena cava and subclavian, bracheocephalic, and jugular veins. Such thrombi may occur shortly after catheter insertion and result acutely in superior vena cava syndrome (e.g., facial swelling and cyanosis, distended neck veins, swelling of the upper arm). [415] More commonly, thrombi are detected by difficulty in accessing the catheter, a prominent pattern of distended veins on the chest wall and neck, and gradual swelling of the extremity distal to the obstruction. [408,409] Pulmonary embolism, with fatal sequelae, has been reported.[408,409] A recent prospective study of the prevalence of upper venous system thrombosis in children with cancer and had implanted venous catheters for 6 months or more showed that 50% of patients had a radiographically identified major thrombus involving the upper venous system with prominent collateral vessels. Most of the patients were asymptomatic.[416] Similarly, the European group noted a “clear-cut positive correlation” between thrombosis in children with ALL and the use of central lines. [412]

Treatment with either low-dose low-molecular-weight heparin[417] or mini-dose warfarin (1 mg per day in adults)[418,419] starting after catheter insertion has been demonstrated to decrease the incidence of thrombus development[418,419 and 420] or recurrence[420] in patients with cancer.

#### *L-Asparaginase*

Intensive therapy with L-asparaginase is used in most ALL treatment protocols in childhood. For more than two decades, combined hemorrhagic and thrombotic lesions involving the central nervous system accompanied by clinical stroke have been reported in 2% to 3% of children with ALL and receiving L-asparaginase during induction therapy.[412,421] Large thrombi in other veins, and more recently a high incidence of catheter-related upper venous system thrombosis, also have been reported in patients receiving repeated doses of L-asparaginase.[409,412]

This agent decreases antithrombin and plasminogen levels predisposing to thrombosis. [421,422,423 and 424] Protein C and protein S deficiency do not appear to play a role.[425] This agent has been associated also with significant lipid abnormalities and pancreatitis that may themselves have a role in the development of thrombosis. [426] Trials are under way to determine whether infusion of antithrombin concentrates during leukemia induction therapy reduces the incidence of this complication. FFP infusions, although often employed in the past, do not appear to be of value.

#### *Treatment*

No specific management recommendations exist for the treatment of thrombosis in children with cancer, and a full review of all options is beyond the scope of this chapter. A number of recent comprehensive reviews address various aspects of the problem.[427,428,429,430,431,432 and 433] Theapproach to management includes a decision about systemic thrombolysis with tissue plasminogen activator or streptokinase if the clot is large and recently formed versus instillation of urokinase or lower doses of tissue plasminogen activator into the catheter if only mild problems with aspiration from or infusion into the catheter are noted. Removal of the catheter, if present, is indicated for all but promptly resolving thrombi. The need to continue to treat the malignancy may require the cautious continuation of L-asparaginase along with anticoagulation. Further, the need for intrathecal administration of chemotherapy and anticipated thrombocytopenia with even moderate-dose chemotherapy may complicate the planning of anticoagulation.

Patients with acute symptomatic thrombi should receive anticoagulation with either low-molecular-weight heparin at therapeutic doses or conventional unfractionated heparin followed by warfarin. If instituted rapidly, this treatment may prevent the sequelae of thrombosis, such as post-phlebitic syndrome. [427] Treatment should be continued until the clot resolves or stabilizes and for an additional period (6 weeks to 6 months) to allow vessel healing. The need for therapy is less clear in patients who are found coincidentally or on the basis of minor symptoms to have obstructed catheters many months after catheter placement.

## CONCLUSION

The expanded use of hematopoietic growth factors, understanding of the potential complications of central line use, and safer blood products have improved the hematologic supportive care available to pediatric oncologists. Further investigations, including cost-benefit analyses with assessment of quality of life parameters, will be necessary to refine further the optimum care of children with cancer.

## NATURE OF THE IMMUNOCOMPROMISED HOST

Infections cause significant morbidity and mortality in children with cancer. Cancer itself, independent of its therapy, puts children at risk for serious infection. For example, leukemia can disturb normal immune function. Solid tumors can cause anatomic obstruction with subsequent infectious complications. Tumors can also lead to functional impairments (e.g., poorly coordinated swallowing in patients with brainstem tumors) that contributes to significant infectious risks.

The therapy for cancer involves three primary modalities: chemotherapy, surgery, and radiation therapy, each of which contributes to the risk of serious infections. A large proportion of the drugs used for cancer therapy are myelosuppressive and toxic to the mucosal epithelium, putting patients at risk for serious bacterial and fungal infections. Radiation therapy can cause local tissue breakdown and provide potential sites for focal infections. Surgery has inherent associated infectious risks made more substantial by the underlying immunosuppressed status of the child. In addition, stem cell transplantation carries with it a degree of immune suppression, both acute and chronic, that puts children at significant risk. The effects of host colonization, disruption of natural skin and mucosal barriers, presence of foreign bodies, and overall nutritional status of the patient further influence the risk for infection ( Fig. 41-1).

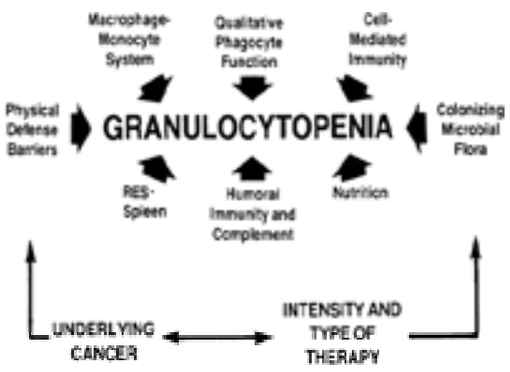

**FIGURE 41-1.** Interactions of the defense matrix that delineate the compromised host. RES, reticuloendothelial system.

It is important to recognize that there are variations among patients in the degree to which they are immunocompromised, the type of impairment, and, consequently, the types of infections to which they are susceptible. An understanding of the nature of the immune defects, the clinical presentation of common infectious syndromes, the likely pathogens, and the appropriate management of these situations is critically important for individuals providing medical care for these patients.

## INTEGUMENTARY BARRIERS, ALTERED MICROBIAL COLONIZATION, AND ENHANCED SUSCEPTIBILITY TO INFECTION

The skin and mucosal surfaces constitute the primary host defense against invasion by endogenous and acquired microorganisms. A complex arrangement of specialized cells of the skin and the respiratory, gastrointestinal (GI), and genitourinary mucosa protect the body from invading pathogens. For example, ciliated and mucus-producing cells of the respiratory tract, acid- and enzyme-producing cells of the GI tract, and bactericidal fatty acids and secretory immunoglobulins displayed by epidermal cells are specific adaptations that enhance defense against exogenous organisms.

Any factor that bypasses or disrupts the integumentary barrier can enhance susceptibility to infection. The integrity of this barrier may be disrupted by local tumor invasion or as a result of surgery, irradiation, or cytotoxic chemotherapy. Mucositis, for example, is an important feature of therapies that are toxic to the cells of the GI mucosa, rendering the patient vulnerable to infection by bacteria that reside in the GI tract. Many procedures, including fingersticks, venipunctures, bone marrow aspirations, and insertion of venous access devices, can also disrupt the integument and provide a nidus for colonization and the eventual dissemination of pathogens.

Mucosal and epithelial cells also contain specific and nonspecific receptors for the attachment or adherence of bacteria. The microbial ligands for these receptors are called adhesins. The attachment of a microbial pathogen to an epithelial surface receptor by means of adhesins is often the first step in the initiation of an infectious process.[1,2] In healthy persons, integumentary and mucosal attachment sites are populated with relatively innocuous “normal” flora, consisting predominantly of aerobic gram-positive and a variety of anaerobic organisms.[1,3] Within 24 hours of hospitalization, seriously ill patients undergo a change in their indigenous microflora toward one of aerobic Gram-negative organisms.[4,5] Why this change occurs is unclear, although underlying disease and exposure to antibiotics can promote changes in bacterial adherence and colonization.[6]

The organisms colonizing the patient are integrally related to the pattern of infections that ultimately occurs in the cancer patient. More than 80% of the microbiologically documented infections that occur in patients with acute myelogenous leukemia (AML) are caused by organisms that are part of the endogenous microflora, usually at sites at or near the source of infection. Approximately half of the responsible pathogens are acquired by the patient after the initial admission to the hospital.

### Cellular Immune Dysfunction

The effector cells of the immune response include polymorphonuclear leukocytes (PMNs), T lymphocytes, B lymphocytes, natural killer cells, peripheral blood monocytes, and fixed-tissue macrophages (including the cells of the spleen and reticuloendothelial system). The cells that are more severely affected by disease or therapy-mediated immune dysfunction are the PMNs, monocytes, and lymphocytes. The cells of the reticuloendothelial system are relatively less sensitive to the toxic effects of antineoplastic therapy and provide at least a rudimentary framework for the maintenance of nonclonal cellular immunity even in the face of profound cellular immunosuppression. Quantitative or qualitative abnormalities of the cellular aspects of the immune response predispose the patient to infections with a broad array of pathogens (Table 41-1).

### Polymorphonuclear Leukocytes

A critical determinant of susceptibility to most bacterial and fungal pathogens in patients receiving cytotoxic chemotherapy is the number of circulating neutrophils.

The more profound and protracted the granulocytopenia, the greater the likelihood of a serious infection. [7] Granulocytopenia may be secondary to the disease itself (e.g., acute leukemia or aplastic anemia) but is more commonly a consequence of cytotoxic chemotherapy or radiotherapy. The absolute level of granulocytopenia is a particularly important risk for infection; most bacteremias and bacterial pneumonias occur when the absolute neutrophil count is less than 100 cells per $mm^3$.

The second crucial determinant of outcome is the rate at which granulocyte numbers return to a "protective" level after the onset of fever. Neutropenia that persists, usually for more than 1 week, is associated with increasing risk for recurrent or new infections, both bacterial and fungal. On the other hand, those in whom no infection has been documented, who defervesce rapidly on empiric microbial therapy, and who resolve granulocytopenia within 1 week of the febrile episode are more likely to pursue an uncomplicated course. Even in the setting of a documented infection, rapid return of the granulocyte count (i.e., within 7–10 days) is usually predictive of a good outcome.

Finally, the rate at which the granulocyte count declines also contributes to the susceptibility to infection. A patient with aplastic anemia in whom the granulocyte count has decreased slowly over a period of weeks may be at lesser risk of a serious bacterial infection than is the patient with a similar degree of granulocytopenia induced within days by antecedent chemotherapy. However, the prolonged neutropenia associated with aplastic states predisposes to serious, often fatal fungal infections.

Qualitative abnormalities of neutrophil function may occur as a consequence of the underlying malignancy (especially acute leukemias) or secondary to antineoplastic therapy. For example, the neutrophils from patients with leukemia or lymphoma exhibit suboptimal chemoattractant responsiveness, bactericidal activity, and superoxide production.[8,9] Antineoplastic chemotherapy and radiotherapy also cause qualitative abnormalities of neutrophil function. [10,11] Deficiencies of neutrophil function iatrogenically induced by the administration of various medications (e.g., opiates, corticosteroids, antibiotics) may have a detrimental effect. [12] Patients with quantitative or qualitative defects of their PMNs are subject primarily to infections with bacteria and fungi. Gram-positive and gram-negative bacteria and invasive fungi (especially *Candida* and *Aspergillus*) are the most common pathogens.

### Lymphocytes

Disease- or treatment-induced abnormalities of lymphocytes can affect both the humoral (primarily B-cell–mediated) and the cellular (primarily T-cell–mediated) arm of the immune response. Certain malignancies, such as chronic lymphocytic leukemia or multiple myeloma, result in a significant alteration of the humoral limb of the immune response—that is, the ability to generate antigen-specific neutralizing antibodies against pathogens. [13,14] Patients with defects in humoral immunity are particularly susceptible to infections by encapsulated bacteria, especially *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*. Patients with Hodgkin's disease or non-Hodgkin's lymphoma have an impaired cellular immune response. Corticosteroids and radiotherapy can also contribute to lymphocyte dysfunction.[12,13,14,15] and [16] Patients receiving T-cell–depleted bone marrow transplants are particularly susceptible to viral pathogens, especially cytomegalovirus (CMV), although they may have a lower incidence of graft-versus-host disease. Furthermore, pathogens such as CMV that infect patients with altered cellular immunity can further suppress the host's defenses.[17,18] Patients with deficiencies of cellular immunity are prone to fungal, viral, and intracellularly replicating bacterial pathogens (e.g., *Listeria monocytogenes*, *Salmonella* sp.).

Depletion of helper T cells ($CD4^+$) is clearly induced by cytotoxic chemotherapy. Mackall and colleagues [19] have shown that although neutrophil, monocyte, and platelet numbers consistently recover to greater than 50% of pretreatment values after sequential cycles of therapy, lymphocyte numbers do not recover promptly, and lymphopenia may persist for many months after the completion of a chemotherapy regimen. The capacity for $CD4^+$ T-cell regeneration after chemotherapy seems to diminish with age, so that younger children have significantly greater recovery of T cells 6 months after chemotherapy than do young adults who have persistent, severe T-cell depletion. It appears that the thymus-dependent regeneration of T cells plays an important role in younger children, whereas older children and young adults have deficiencies in this pathway, perhaps as a result of the normal thymic involution that occurs with age. Prolonged T-cell depletion probably contributes to the development of opportunistic infections such as herpes zoster or *Pneumocystis carinii* pneumonia (PCP) during the months after chemotherapy.

### Spleen and Reticuloendothelial System

The spleen and fixed tissue cells of the reticuloendothelial system act as a mechanical filter and as an immune effector organ. The spleen is the principal organ involved in the production of antibodies to polysaccharide antigens, and it also filters out damaged cells and opsonin-coated organisms from the circulation. [20] Splenectomized patients are deficient in antibody production when challenged with particulate antigens, have decreased levels of immunoglobulin M (IgM) and properdin (a component of the alternate complement pathway), and are deficient in the phagocytosis-promoting peptide tuftsin. [21] Splenectomized patients are at increased risk for fulminant and rapidly fatal septicemia caused by encapsulated bacterial pathogens such as *S. pneumoniae, H. influenzae,* and *N. meningitidis*.[22]

### Other Factors Contributing to Immunocompromised States

Additional factors can exacerbate the immunocompromised state in a child with cancer. Alterations in central nervous system function or decreased levels of awareness, obstruction of a hollow viscus, and the depressed nutritive states common with malignancy can enhance susceptibility to infectious complications.

Obstruction of the biliary tree, GI or genitourinary tract, or respiratory passages by a primary or metastatic tumor mass can promote an infection by the organisms colonizing the site of obstruction. Similarly, diminution or obliteration of the gag reflex secondary to local neural infiltration or a decreased level of cognition markedly increases the risk of aspiration pneumonia. Aspirated pharyngeal organisms (most commonly gram-negative aerobes) can colonize, invade, and disseminate from a pulmonary source. The risk of aspiration pneumonia and subsequent disseminated infection is heightened by decreased mucosal clearance mechanisms and damage mediated by antineoplastic therapy.

The compromising effect of a malnourished state on immune function is well documented. [23] Although the precise effects of nutritional deficiencies in cancer patients have been difficult to elucidate, it is clear that nutritional deficiencies affect B and T lymphocytes, PMNs, mononuclear phagocytes, and complement system function.

## CARE OF THE FEBRILE CANCER PATIENT

### Definitions of Fever and Neutropenia

Fever (i.e., a temperature greater than 38 $^oC$) is common among children with cancer.[24] The production of fever in humans is a process mediated by the actions of several proinflammatory cytokines, primarily interleukin-1 (IL-1), tumor necrosis factor (TNF), and IL-6. These cytokines are produced by myriad cell types, although the monocyte-macrophage is their major source. They share a number of proinflammatory properties that inhibit bacterial replication, including the induction of fever, hepatic synthesis of acute phase reactants, activation of T and B cells, and metabolic changes such as mobilization of amino acids, decreases in serum iron and zinc, and increase in serum copper. By inducing the synthesis of other mediators, IL-1 and TNF also stimulate neutrophil, lymphocyte, and monocyte migration and activate mature neutrophil functions such as chemotaxis, phagocytosis, and killing of bacteria. IL-1 and TNF also appear to mediate the development of septic shock in humans. The overall effect of these activities is a unified host response against an infectious insult, with fever being an important by-product. [25]

Although fever in cancer patients is frequently caused by infection, noninfectious causes must also be considered. Pyrogenic medications (particularly cytotoxic agents such as bleomycin and cytosine arabinoside), blood products, allergic reactions, and the malignant process itself are potential sources of a febrile response. Nonetheless, in a granulocytopenic patient, fever may be the first and only sign of infection. [24,26] Other clinical signs and symptoms frequently indicative of an infectious process (i.e., pain, erythema, swelling) may be blunted or lacking. Alternatively, localized pain and signs of inflammation may occur in the absence of fever in a neutropenic patient. The physician must pay careful attention to these indicators of possible underlying infection in this situation and strongly consider antibiotic therapy even if there is not a febrile response.

Although the definition of granulocytopenia is somewhat arbitrary, most oncologists consider patients with an absolute granulocyte count (consisting of PMNs plus band forms) of 500 cells per $mm^3$ or less to be neutropenic. From a practical standpoint, patients whose absolute count is between 500 and 1,000 cells per $mm^3$ but falling because of antineoplastic therapy should be considered neutropenic.

### Pediatric versus Adult Patients

Pediatric cancer patients are different from their adult counterparts in multiple ways. These include the spectrum of oncologic diagnoses, the intensity of

chemotherapeutic regimens (with a larger percentage of children with cancer treated very intensely with the goal of curative therapy), and the incidence and severity of comorbid medical conditions preceding the diagnosis of cancer. In addition, the differences in prophylactic antimicrobial use, the percentage of patients with indwelling central venous catheters, the community exposures to infectious pathogens, and the maturation of the immune system may also be different based on age.

These differences between adult and pediatric patients affect the frequency and nature of episodes of fever and neutropenia. A review of results from four studies performed by the European Organization for Research on the Treatment of Cancer highlighted some of these differences. They reported that the sites of infection and spectrum of infecting organisms are different in children and adults. [27] Children more often do not have a clinically apparent site of infection and consequently have a higher rate of fever without a source. When a defined site is present, children were more likely than their adult counterparts to have upper respiratory tract findings. The overall incidence of bacteremia is similar; however, the rate of death during fever and neutropenia was 1% in children compared to 4% in adults.

**Evaluation of the Patient with Fever and Neutropenia**

The initial assessment of patients with fever and neutropenia has not changed significantly over the past three decades. A careful history and meticulous physical examination are extremely important. Neutropenic hosts have a decreased ability to manifest an inflammatory response, and thus even subtle signs and symptoms should be considered significant. Attention should be paid to areas at special risk in patients receiving cytotoxic therapy, such as the oropharynx, respiratory tract, perirectal area, central venous line sites, and any site of recent invasive procedures.

Blood cultures should be obtained from all lumens of central venous lines, when present, as well as peripherally. Other cultures should be obtained based on clinical suspicion (stool, urine, cerebrospinal fluid, central line site, or wound). [27] Routine serum chemistries should be obtained to ensure appropriate supportive care and safe administration of antimicrobials and other needed medications.

A chest radiograph should be considered in all patients. Although the yield of routine chest radiographs in asymptomatic neutropenic patients is small, the study should be performed in all patients with projected prolonged neutropenia because it provides an important baseline for comparison with later films, which may present only subtle indications of a pneumonic process. Other radiological studies may be helpful based on specific symptoms or physical examination findings.

After this evaluation, broad-spectrum antibiotics should be started promptly in all febrile neutropenic patients.

**Evaluation of the Afebrile Neutropenic Patient with Localizing Signs**

Granulocytes play an important role in the development of inflammatory responses to infection, and consequently, during neutropenia, inflammation may be markedly attenuated despite ongoing infection. Fever itself can be absent in some cases. The presence of infection may be detected only by attention to seemingly minor complaints from the patient or by subtle localized physical findings. It is critical that the physician takes these complaints or findings seriously and pursues them vigorously. The absence of fever in cancer patients with localizing signs does not mean that an underlying infection is controlled or insignificant. Abdominal pain, for example, may signify an evolving intra-abdominal infection (e.g., typhlitis), whereas erythema and tenderness along a subcutaneous catheter tunnel track usually indicate the presence of a deep soft tissue infection, even if the patient is afebrile. In these situations, it is most prudent to obtain cultures of blood and any other pertinent sites and then immediately to begin antibiotics directed against probable pathogens. Any delay in antibiotic therapy while awaiting the results of cultures allows for unchecked progression of infection in the neutropenic host.

**Risk Assessment in Cancer Patients with Fever and Neutropenia**

Traditionally, the empiric therapy for oncology patients with fever and neutropenia has involved admission to the hospital and administration of broad-spectrum intravenous (i.v.) antibiotics. [28] More recently it has become clear that not all patients with fever and neutropenia are at equal risk for significant morbidity or mortality from infection. [29,30,31 and 32] (The identification of a low-risk subset may allow for modifications of therapy in this group, with a goal of less therapy-related toxicity, an improved “quality of life” and decreased cost.)

A retrospective study performed by Talcott and colleagues [29] evaluated risk factors for serious medical complications and death during episodes of fever and neutropenia in adult oncology patients. A “high-risk” group was defined as those patients who were inpatients at the time of diagnosis with fever and neutropenia, or those presenting as outpatients with either concurrent comorbidity or uncontrolled cancer. The “low risk” group was, by exclusion, those patients presenting with fever and neutropenia as outpatients without comorbidity or progressive cancer. Importantly, the information required to stratify a patient as either high or low risk was available to the clinician at the time of the patient's presentation with fever and neutropenia. The medical course in the two groups was found to be significantly different. The rates of serious complications ranged from 31% to 55% in the high-risk group, compared to 2% in the low-risk group. Similarly, rates of death ranged from 14% to 23% in the high-risk group. No patients died in the low-risk group.

Prolonged neutropenia has been shown to be associated with worse outcome in patients with fever and neutropenia. [24,33] In a study by Wehl and colleagues, [34] those with neutropenia lasting greater than 5 days had an increased incidence of prolonged fever, need for antibiotic modification, and most important, death from infection. Predictions of duration of neutropenia, although not perfect, can be made by the clinician based on knowledge of the patient, his or her disease, and the treatment regimen used. In pediatrics, patients undergoing therapy for AML or Burkitt's lymphoma and those undergoing induction therapy for acute lymphoblastic leukemia (ALL) clearly have treatment-related prolonged neutropenia. Patients with solid tumors undergoing high-dose chemotherapy with stem cell rescue may also have long periods of neutropenia. In addition, patients with relapsed disease with bone marrow involvement also often have prolonged neutropenia.

Comorbidity at the time of presentation has been shown to be associated with adverse outcomes in several studies. [27,29,35] Comorbidity has been variably defined but usually includes signs and symptoms related to the acute infectious episode (e.g., hypotension, tachypnea, hypoxia, or chest radiograph changes) as well as noninfectious complications of therapy (e.g., mucositis requiring i.v. narcotics).

Other factors have also shown to be predictive of outcome in patients with fever and neutropenia. Rackoff and colleagues [36] found that the risk of bacteremia in pediatric oncology patients was associated with fever greater than 39 $^{o}$C and an absolute monocyte count of less than $0.1 \times 10^{9}$ per L at the time of presentation with fever and neutropenia. Klaassen and colleagues [37] found that patients with a presenting monocyte count of greater than $0.1 \times 10^{9}$ per L and without comorbidity or an abnormal chest radiograph were at low risk for significant bacterial infections. Other authors have formed a definition of low risk based on information gathered during a period of inpatient observation. Lucas and colleagues [35] retrospectively reviewed episodes of fever and neutropenia in pediatric oncology patients. It was found that those patients presenting without signs of sepsis, who were afebrile and had an absolute neutrophil count greater than 100 at 48 hours had a low risk of serious medical complication and could be considered for early discharge. In the patients admitted with fever and neutropenia, those with negative blood cultures, no or improved focal signs of infection, and evidence of bone marrow recovery were found to be low risk. [38,39 and 40]

Based on risk stratification, there is now evidence both in adults and pediatrics that oral antibiotic therapy in the subset of patients with low risk fever and neutropenia is safe and effective. [41,42 and 43] A placebo-controlled, randomized trial of in-hospital therapy with either i.v. ceftazidime or oral ciprofloxacin and amoxicillin/sulbactam in patients with low-risk fever and neutropenia showed the oral regimen to be both safe and effective. Outpatient therapy with i.v. antibiotics in low-risk febrile neutropenic oncology patients has also been shown to be feasible. [44,45 and 46]

Shifting therapy for low-risk fever and neutropenia in pediatric oncology patients to oral therapy in the outpatient setting should be evaluated by careful study before it becomes the standard of care. To make this shift possible, practitioners must have a validated system to accurately prognosticate a pediatric cancer patient's risk of serious complication or death from infection. The length of time of inpatient observation, if any, and design of outpatient follow-up needs to be determined to ensure the efficacy and safety of such regimens. In addition, the potential burden on patients and families, satisfaction with care in the inpatient versus outpatient settings, and cost, including level of reimbursement for services and out-of-pocket expenses for patients and their families need to be assessed.

**Evaluation of Febrile Non-Neutropenic Patients**

The evaluation of a febrile non-neutropenic cancer patient should include a careful history and physical examination. Bacterial cultures of the blood should be obtained. Patients with localized symptoms or signs should undergo the appropriate diagnostic procedures—for example, aspiration for culture and Gram's stain of accessible sites of cellulitis, stool cultures in patients with diarrhea, and lumbar puncture for patients with meningeal irritation. Patients who are non-neutropenic,

clinically well, without any identifiable focus of infection, and without an indwelling central venous catheter may be observed without empiric therapy. Patients with focal findings should receive appropriate therapy based on the site involved (e.g., amoxicillin for otitis, cephalexin for cellulitis). These individuals should be followed closely to assure that the infection responds appropriately.

Patients with indwelling venous access catheters (e.g., Hickman, Broviac) who become febrile, even if they are non-neutropenic, present a special problem. The incidence of infectious complications in patients with intravascular devices can be high with central-line associated bacterial bloodstream infections being of most concern. Blood cultures should be obtained from each port of a multilumen catheter and from at least one peripheral venipuncture site. The catheter exit site should be examined carefully for signs of erythema, tenderness, or discharge, and any discharge material should be cultured. If signs of infection or clinical instability are observed, an antibiotic regimen designed to cover the most commonly encountered line-related pathogens (i.e., *Staphylococcus aureus, Staphylococcus epidermidis*, and Gram-negative aerobes) should be initiated. A broad-spectrum third-generation cephalosporin (e.g., ceftriaxone) offers adequate initial coverage in the absence of an obvious tunnel infection. Antibiotics should be continued for a 48- to 72-hour trial. If the pre-antibiotic blood and catheter culture results are negative and no site of infection is determined, the antibiotics may be withdrawn, whether or not fever persists. This allows for a thorough evaluation of the cause of fever, without the confounding influence of antibiotics. If the cultures are positive, a full therapeutic course is necessary ( Fig. 41-2).

## INITIAL EMPIRIC TREATMENT OF THE FEBRILE NEUTROPENIC PATIENT

### General Considerations

The prompt initiation of empiric antibiotics when the neutropenic cancer patient becomes febrile has been the single most important advance in the management of the immunocompromised host. Before this policy was instituted, the mortality rate from gram-negative infections (especially with *Pseudomonas aeruginosa*, *Escherichia coli*, and *Klebsiella pneumoniae*) approached 80%.[47,48] With the widespread use of effective empiric antibiotics, the overall mortality rate has dropped to between 10% and 40% for infections caused by gram-negative bacteria.[49] What are the criteria for an empiric antibiotic regimen? Between 85% and 90% of pathogens that are documented to be associated with new fevers in immunosuppressed patients are bacteria.[24,50] Because gram-positive or gram-negative bacteria or both can be responsible, any empiric antibiotic regimen must cover a broad spectrum, provide high serum bactericidal drug levels, and be as nontoxic and as simple to administer as possible. These conditions have traditionally required the combination of two or more antibiotics. Several regimens, usually consisting of a cephalosporin, an aminoglycoside, and extended-spectrum penicillin, have been used.[49,51,52] However, no combination regimen has proved clearly superior to others. In practice, a number of options are available for the empiric management of the febrile neutropenic patient, the ultimate choice of which should depend on the predominant organisms, antibiotic sensitivity patterns, cost, and experience at the center in which the patient is being treated.

### Antibiotic Monotherapy

The development of third- and fourth-regeneration cephalosporins (e.g., ceftazidime and cefepime, respectively) and carbapenems (e.g., imipenem and meropenem) has provided alternatives to the more traditional aminoglycoside-containing combination regimens ( Table 41-2).[50,51,52,53] and [54] Several of these compounds are able to provide breadth of antimicrobial spectrum and high bactericidal levels when used as single agents. The use of antibiotic monotherapy for the empiric management of the febrile neutropenic patient is attractive because of the ease of administration, lower cost, and lesser toxicity of a single drug.

| Exit-site or pocket space infection with *Pseudomonas aeruginosa* or mycobacteria |
| Clinical deterioration with known positive blood cultures |
| Positive blood cultures for |
| *Staphylococcus aureus* |
| Viridans group streptococci |
| *Bacillus* sp. |

**TABLE 41-2. MANAGEMENT OF CENTRAL VENOUS CATHETERS IN PATIENTS WITH BACTEREMIA**

The first agent to undergo significant evaluation as monotherapy was ceftazidime. The efficacy of ceftazidime as a monotherapeutic regimen was supported by the results of a prospective randomized trial at the National Cancer Institute (NCI) in which ceftazidime monotherapy was compared with the combination of cephalothin, carbenicillin, and gentamicin for the initial empiric management of 550 episodes of fever and neutropenia.[51] Overall, the results demonstrated equivalent rates of success (i.e., survival of the patient through neutropenia, with or without antibiotic modifications of the initial regimen) between ceftazidime and the combination regimen. Significantly more modifications were required among patients randomized to ceftazidime, however, reflecting the need for anaerobic coverage in patients who developed necrotizing gingivitis or perirectal cellulitis, and the greater need for vancomycin for patients with documented gram-positive infections. Patients with documented infections more frequently required changes in antimicrobial therapy than did those with unexplained fever, but the need was the same (59%) for those receiving monotherapy or combination therapy. Subsequently, a large multicenter, randomized European study that compared treatment of 876 episodes of fever and neutropenia with either ceftazidime or piperacillin plus tobramycin confirmed the efficacy as well as the reduced toxicity of ceftazidime monotherapy over the combination regimen.[54] The majority of included patients had profound and prolonged granulocytopenia resulting from acute leukemia treatment or bone marrow transplantation, and even these patients responded equally well to combination and single-agent empiric therapy, as assessed by defervescence or eradication of infecting organisms. Those receiving ceftazidime alone experienced fewer adverse events, however.

Based on these results, many centers have adopted ceftazidime monotherapy as a standard of care for the initial management of the febrile neutropenic patient. Nonetheless, several concerns have been raised regarding the use of ceftazidime monotherapy.[55] First, the relative lack of activity of third-generation cephalosporins against gram-positive cocci, particularly *S. aureus* and some strains of a-hemolytic streptococci, prompted some investigators to advocate inclusion of vancomycin in the primary regimen.[56,57] Second, some have argued for the inclusion of an aminoglycoside in the initial regimen to maximize the activity against gram-negative pathogens and to decrease the emergence of resistant organisms.

The decision about appropriate empiric regimens must ultimately be individualized for each institution. Oncology centers have different patterns of microbial isolates

and antibiotic resistance, and this must be taken into account. The 1997 recommendations (currently under revision) from the Infectious Diseases Society of America (IDSA) acknowledge this fact and emphasize the need to tailor therapy to local patterns of infection and individual patient characteristics. [58] Nevertheless, it is clear that the initial empiric management of a febrile, neutropenic cancer patient may be accomplished with a single antibiotic such as ceftazidime or imipenem. Regardless of the regimen chosen, the clinician must recognize the indications for and use appropriately the modifications essential to ensure a successful outcome ( Table 41-3).

**TABLE 41-3. COMMONLY USED ANTIMICROBIAL AGENTS FOR PEDIATRIC CANCER PATIENTS**

The use of empiric vancomycin for patients with fever and neutropenia has received special attention. The recommendations from the IDSA *1997 Guidelines for the Use of Antimicrobial Agents in Neutropenic Patients with Unexplained Fever*[58] regarding the use of vancomycin are that it should "probably" be used as empiric therapy in institutions with high rates of gram-positive organisms leading to fulminant infections (i.e., *Streptococcus viridans*, methicillin-resistant *S.epidermidis*). Empiric vancomycin is also recommended for certain patient groups, including those with obvious serious central line infections, those receiving intensive chemotherapy leading to significant mucositis (specifically, high-dose cytarabine for AML), those who have received quinolone prophylaxis before their febrile episode, patients with known colonization with organisms treatable only with vancomycin, and patients presenting with hypotension. If no infection is identified, it is recommended that vancomycin be stopped after 3 or 4 days.

## Other Antibiotics Used to Manage Immunocompromised Patients

### *Carbapenems: Imipenem and Meropenem*

Imipenem and meropenem are members of the class of b-lactam antibiotics called carbapenems. Although their mechanism of bactericidal activity involves interference with bacterial cell wall synthesis, as does that of other b-lactam drugs (e.g., penicillins, cephalosporins), imipenem and meropenem uniquely possess the broadest antimicrobial spectrum of any currently available b-lactam antibiotic. In addition to their activity against gram-negative aerobes, including *P. aeruginosa* and the Enterobacteriaceae, imipenem and meropenem act against many gram-positive organisms (e.g., *S. aureus*, enterococci, some coagulase-negative staphylococci) and most anaerobic organisms.[59]

In a large, randomized trial at the NCI, imipenem monotherapy was found to be comparable to ceftazidime monotherapy for empiric coverage in febrile neutropenic adults and children. Overall success (i.e., survival through neutropenia, with or without modifications of the initial regimen) of more than 95% occurred in both monotherapy groups. Despite the broader spectrum of imipenem, however, modifications were required as frequently by those receiving that drug as it was by those receiving ceftazidime, except for fewer additions for anaerobic coverage with imipenem. [53]

Several drawbacks of imipenem therapy have been identified that limit its use. Nausea and vomiting are well documented adverse effects of imipenem; in the NCI trial, approximately one-third of febrile neutropenic patients receiving imipenem reported significant nausea, with approximately one-third of those requiring a switch to another antibiotic. In contrast, only 2% of ceftazidime recipients reported associated nausea. Also, an increased frequency of *Clostridium difficile* colitis was observed among imipenem recipients in the NCI study, presumably related to alterations in normal anaerobic bowel flora. This has not been a commonly reported effect but is one to be considered when treating patients undergoing multiple cycles of chemotherapy. Imipenem is also known to decrease the seizure threshold in seriously ill patients and in those with central nervous system pathology, and it should be avoided in these patients. [60]

The documented efficacy of imipenem in the initial management of fever and neutropenia allows its inclusion in the array of alternative therapies, but given its toxicities, a more precisely defined role for this drug may be as initial coverage in neutropenic patients who present with a source of anaerobic infection, such as a perirectal cellulitis, marginal gingivitis, or typhlitis. Imipenem should be used cautiously in the treatment of *P. aeruginosa*, because this organism can readily become resistant to imipenem during the course of therapy. It is recommended that serious infections caused by *P. aeruginosa* be treated with the combination of imipenem plus an aminoglycoside.[61]

Imipenem is impervious to destruction by amp-C chromosomal-mediated b-lactamases that are commonly produced by *Enterobacter*, *Citrobacter*, and *Serratia* sp. Treatment of infections caused by these pathogens by ceftazidime (or another b-lactam agent) may induce b-lactamase production and, accordingly, leads to therapeutic failures.[62] Because imipenem offers the advantage of b-lactamase stability as well as efficacy against most of these organisms,[63] it is an appropriate treatment for serious infections caused by *Enterobacter* and related species, or as empiric therapy in ill patients previously treated with multiple antibiotics, in whom the likelihood of resistant organisms is increased.

Meropenem is another broad-spectrum carbapenem antibiotic that shares many of the same *in vitro* antimicrobial properties of imipenem. Meropenem has been evaluated as an agent for empiric therapy of fever and neutropenia. It has the potential advantage over imipenem of less GI toxicity and does not have the effect of altering seizure threshold. A large trial that evaluated more than 1,000 episodes of fever and neutropenia compared monotherapy with meropenem versus combination therapy with ceftazidime and amikacin and showed that the two regimes are equally effective and both well tolerated. [64] In addition, there have been several smaller studies comparing meropenem to ceftazidime alone or to imipenem, with results suggesting equivalency. [65,66] *Stenotrophomonas maltophilia* is usually resistant to imipenem and meropenem. An oxidase-negative, gram-negative bacillus causing bacteremia in a febrile neutropenic patient who is already receiving imipenem is likely to be *S. maltophilia*. Trimethoprim-sulfamethoxazole (TMP/SMX) is the preferred antibiotic against *S. maltophilia*. Multidrug-resistant *P. aeruginosa* may also emerge during the course of carbapenem therapy.

### *Cefepime*

Cefepime is a potent, broad-spectrum, fourth-generation cephalosporin with enhanced activity against gram-positive and gram-negative aerobes, including some pathogens resistant to other cephalosporins. The toxicity profile includes mild GI symptoms and neurological side effects. Cefepime has been compared to ceftazidime, imipenem, and piperacillin/tazobactam in a series of relatively small trials evaluating monotherapy for fever and neutropenia. In each of these studies the regimens were not statistically different in terms of efficacy or toxicity. [67,68] and [69]

### *Piperacillin/Tazobactam*

Tazobactam is an irreversible b-lactamase inhibitor that has been paired with the extended-spectrum piperacillin to yield a broad-spectrum agent that is relatively stable and active in the presence of many of the common b-lactamases. Its spectrum includes many of the clinically important gram-positive and gram-negative aerobes and anaerobes. This agent has been evaluated, again in a series of small trials, in combination with aminoglycosides and as monotherapy. [68,69] and [70] Larger studies are required to evaluate this agent, particularly against *P. aeruginosa* and stably derepressed b-lactamase–producing gram-negative bacilli. Pending such studies, piperacillin/tazobactam is best used in combination with an aminoglycoside in febrile neutropenic children.

### *Fluoroquinolones*

The fluoroquinolones are a group of synthetic antibiotics that possess a broad spectrum of activity, including most aerobic gram-positive and gram-negative bacteria. Ciprofloxacin, norfloxacin, and ofloxacin were the initial family of quinolones developed. The use of trovafloxacin, a newer quinolone with a broader spectrum, including improved gram-positive coverage and antianaerobic activity, was restricted when postmarketing surveillance raised concerns regarding hepatic toxicity. Levofloxacin, another novel quinolone, has gained popularity recently. It has the advantages of excellent bioavailability, twice-daily dosing, and improved gram-positive coverage, including some species of penicillin-resistant pneumococci. Other novel quinolones, including gatifloxacin and moxifloxacin are in various stages of development.

The unique mechanism by which the quinolones exert bactericidal activity and inhibition of the DNA gyrase, responsible for supercoiling and packaging of bacterial DNA, is not shared by any other class of antibiotic. Because quinolones are structurally unrelated to the b-lactams or to any other antibiotic class, cross-resistance between the fluoroquinolones and other antibiotics is rare. Fluoroquinolones are usually active against multiresistant organisms; ciprofloxacin, for example, exhibits activity against many of the resistant gram-negative rods, including *P. aeruginosa, Serratia, Enterobacter*, and *Klebsiella* sp., that are responsible for serious infections in neutropenic and otherwise immunocompromised patients. Ciprofloxacin activity against streptococcal species, including a-hemolytic streptococci (e.g., *Streptococcus mitis, Streptococcus sanguis*) and *S. pneumoniae*, is often inadequate.[71] The newer quinolones have been developed in part to overcome this deficiency.

Because of the lack of reliable streptococcal coverage, ciprofloxacin is not useful as a single agent for empiric therapy in febrile neutropenic patients, but the addition of vancomycin or a penicillin to i.v. ciprofloxacin yields a regimen that compares favorably with more traditional combinations of a b-lactam plus an aminoglycoside.[72,73] Evaluations of levofloxacin as empiric therapy for fever and neutropenia are ongoing.

Experience with the fluoroquinolones in the pediatric population has been limited by evidence of joint toxicity in experimental juvenile animals.[74] Nonetheless, ciprofloxacin is being given with increasing frequency to children with cystic fibrosis who are colonized with strains of *P. aeruginosa* and to children with other refractory gram-negative infections. A report on more than 1,700 young patients who received ciprofloxacin therapy had only a few reports of transient arthralgias that resolved promptly on discontinuation of the drug.[75,76] Extensive physical and radiographic examination, including magnetic resonance imaging (MRI), of 12 children taking ciprofloxacin for 3 months revealed no evidence of joint toxicity in one study.[77] For children with cancer who are at risk for severe infections and in whom a very potent oral antibiotic would potentiate the possibility of outpatient therapy, the benefits of fluoroquinolone therapy in selected cases may be found to outweigh the risk of joint toxicity.

### *Linezolid and Quinupristin/Dalfopristin*

These two agents have been developed in response to the need for better therapy for gram-positive pathogens, especially in regards to the emergence of vancomycin-resistant pathogens.[78] Linezolid is an oxazolidinone with a unique mechanism of protein synthesis inhibition, inhibiting the initiation complex formation. Because of its unique mode of action, it does not exhibit cross-resistance with other antimicrobials. It has excellent oral bioavailability and can be administered either orally or parenterally. In addition, it has been shown to have a favorable toxicity profile. It is bacteriostatic against methicillin-resistant *S. aureus*, vancomycin-resistant *Enterococcus* sp., and penicillin- and cephalosporin-resistant strains of *S. pneumoniae.*[79,80]

Quinupristin/dalfopristin is a streptogramin antibiotic with activity against a spectrum of gram-positive organisms similar to that of linezolid.[81] The toxicity profile includes myalgias and arthralgias in approximately 10% of patients. In addition, peripheral venous infusion has been associated with local complications of pain, inflammation, and thrombophlebitis, and therefore it is recommended that it be administered via a central venous catheter. A concern with this agent is the fact that there is already reported resistance in some strains of *Enterococcus faecium* as well as staphylococci.

### *Aztreonam*

Aztreonam acts exclusively on gram-negative organisms, including *P. aeruginosa* (but not the non-*aeruginosa* pseudomonads), *Serratia, Enterobacter*, and other Enterobacteriaceae (e.g., *E. coli, Klebsiella*). The addition of an aminoglycoside to aztreonam is prudent in the treatment of serious *P. aeruginosa* infections. Because there is no gram-positive or anaerobic coverage, aztreonam should not be used as a single agent for empiric therapy in neutropenic or severely ill patients. Limited data indicate that the combination of aztreonam and vancomycin is effective for empiric coverage of febrile neutropenic cancer patients.[82]

A particular benefit of aztreonam is the apparent lack of antigenic cross-reactivity with the b-lactam antibiotics.[83] Aztreonam is most useful for patients with significant allergy to penicillin or other b-lactams in whom an antipseudomonal agent is desirable or required. The gram-negative spectrum and absence of renal toxicity allow the use of aztreonam as an alternative to aminoglycosides in certain instances.

## ANTIFUNGAL AGENTS

The armamentarium of systemically administered antifungal compounds has expanded from amphotericin B (AMB) as the only available drug to the new classes of antifungal imidazoles and triazoles, as well as lipid formulations of AMB. The antifungal and pharmacologic properties of these compounds, as they pertain to treatment of life-threatening mycoses in children, have been reviewed extensively elsewhere[84] and are summarized in the following section.

### Amphotericin B

AMB is the cornerstone of therapy in most critically ill patients with deeply invasive fungal infections. The principal mechanism of action of AMB, as of other polyenes, is the binding to ergosterol, the principal sterol present in the fungal cell membrane, which results in altered membrane permeability and causes leakage of sodium, potassium, and hydrogen ions. AMB also binds to a lesser extent to other sterols, such as cholesterol, which accounts for much of the toxicity associated with its usage. Oxidation-dependent AMB-induced stimulation of macrophages is another proposed mechanism of the chemotherapeutic effect of this polyene.

The pharmacokinetic profile of AMB in children differs from that in adults. Children older than 3 months have a smaller volume of distribution (less than 4 L per kg) and a faster clearance (greater than 0.026 L per kg per hour) than what is usually found in adults. The peak serum concentrations are significantly lower in approximately 50% of those obtained in adults receiving equivalent doses. There is a strong inverse correlation between patient age and total clearance of AMB, suggesting that higher dosages may be better tolerated in patients aged between 3 months and 9 years.

Acute or infusion-related toxicity of AMB is characterized by fever, chills, rigor, nausea, vomiting, and headache. Fever, chills, and rigors may be mediated by TNF and IL-1, cytokines that are released from human peripheral monocytes in response to the drug. These acute reactions may possibly be blunted by corticosteroids, acetaminophen, aspirin, other nonsteroidal anti-inflammatory drugs, or meperidine. Corticosteroids should be used only in relatively low dosages (e.g., hydrocortisone, 0.5 to 1.0 mg per kg). Meperidine in low doses (0.2 to 0.5 mg per kg) interdicts development of rigors; acetaminophen may decrease fever but appears to have little effect on rigors. Aspirin should be avoided in thrombocytopenic patients.

Nephrotoxicity is the most significant dose-limiting adverse effect of AMB; it may be classified as glomerular or tubular. The clinical and laboratory manifestations of glomerular toxicity include a decrease in glomerular filtration rate and renal blood flow, as evidenced by azotemia. Tubular toxicity is manifested as the presence of urinary casts, hypokalemia, hypomagnesemia, renal tubular acidosis, and nephrocalcinosis. Hypomagnesemia may be more profound in patients with cancer who develop a divalent cation-losing nephropathy associated with cisplatin. Azotemia is usually reversible, and renal function usually returns to normal levels after cessation of therapy. However, return to pretreatment levels may take several months in some cases. Administration of sodium in the form of normal saline, initially at 2 to 3 mEq per kg every 24 hours to a maximum of 4 to 6 mEq per kg every 24 hours, is often effective in preventing or attenuating the development of azotemia, possibly through inhibition of tubuloglomerular feedback. However, sodium loading requires close monitoring of patients to avoid hypernatremia, hyperchloremia, metabolic acidosis, and pulmonary edema. Furthermore, sodium loading does not ameliorate, and may indeed aggravate, hypokalemia.

Among the important drug interactions with AMB is the renal toxicity caused by aminoglycosides and cyclosporin during administration of AMB. Acute pulmonary reactions (hypoxemia, acute dyspnea, and radiographic evidence of pulmonary infiltrates) have been associated with simultaneous transfusion of granulocytes and infusion of AMB. Although some investigators have disputed the causality of AMB in such reactions, a rational approach is to separate the infusions of AMB and

granulocytes by the longest possible time period.

**Lipid Formulations of Amphotericin B**

Three carefully engineered lipid formulations of AMB have been approved in North America and Western Europe: a small unilamellar vesicle formulation of liposomal AMB (LAMB or AmBisome), AMB lipid complex (ABLC or Abelcet), and AMB colloidal dispersion (ABCD, Amphotec, or Amphocil).[85] Liposomal nystatin is an investigational compound. Based on open-label compassionate release and randomized studies, ABLC was the first lipid formulation approved in the United States by the Food and Drug Administration (FDA) in November 1995 for both children and adults. ABLC, 5 mg/kg per day i.v., in an emergency compassionate release protocol, was found to be active in treatment of immunocompromised pediatric patients with refractory mycoses and those with intolerance to conventional AMB.[86] This study found little dose-limiting nephrotoxicity of ABLC. A phase I-II study of ABLC in children with hepatosplenic (chronic disseminated) candidiasis found that the compound administered at 2.5 mg per kg for 6 weeks was effective, had no dose-limiting nephrotoxicity, and appeared to reach steady state plasma pharmacokinetics by 7 days.[87] A phase I-II study of the safety, toleration, and activity of LAMB in persistently febrile neutropenic pediatric oncology patients has recently been completed.

The introduction of lipid formulations has been an important advance in improving the therapeutic index of AMB. Because toxicity is the major dose-limiting factor of this drug, lipid formulations have been developed to reduce toxicity and permit larger doses to be administered. Although classically considered as liposomal formulations of AMB, the investigational and clinically approved formulations of AMB have a wider diversity of lipid structure. Liposomes (defined as phospholipid bilayers of one or more closed concentric structures) and other lipid formulations have been used as vehicles for AMB with encouraging results. The lipid formulation may provide a selective diffusion gradient toward the fungal cell membrane and away from mammalian cell membrane. The lipid composition, molar ratio of lipid, and liposomal size all play a role in toxicity.

Although associated with less nephrotoxicity, lipid formulations may confer their own patterns of toxicity. For example, the multilamellar lipid formulation of AMB induced reversible hypoxemia, pulmonary hypertension, and depression of cardiac output during infusion.[88] Infusion-related toxicity also may be seen with ABCD, ABLC, and LAMB. Unfortunately, the relatively greater expense of the lipid formulations of amphotericin B limits their broader use as less toxic alternatives to conventional AMB. We consider that the most appropriate use for the lipid formulations of AMB in pediatric oncology is for treatment of invasive fungal infections that are refectory to conventional therapy or for intolerance of conventional antifungal therapy. A lipid formulation of amphotericin B is also appropriate as initial empiric therapy or in definitive therapy for proven mycoses in high-risk patients receiving concomitant nephrotoxic agents (e.g., cyclosporine), those with preexisting renal impairment, those with an anticipated course of protracted neutropenia during which dose-limiting nephrotoxicity may ensue.[89]

**Flucytosine**

The mechanisms of action, pharmacokinetics, safety, antifungal properties, and clinical utility of flucytosine (5-fluorocytosine, or 5-FC) have been reviewed elsewhere.[90] 5-FC is most frequently used as an adjunct to AMB therapy. This combination was originally proposed because of the observation that AMB potentates the uptake of 5-FC by increasing fungal cell membrane permeability. Two mechanisms of action have been reported for 5-FC: 5-fluoro-deoxyuridylic acid monophosphate competitive inhibition of thymidylate synthase and 5-fluorouracil disruption of protein biosynthesis. Because of rapid emergence of resistant strains, 5-FC is used in treatment of candidiasis, aspergillosis, cryptococcosis, or other opportunistic mycoses only in combination with AMB.

Because it is a low molecular weight, water-soluble compound, orally administered 5-FC is absorbed from the GI tract rapidly and almost completely, providing excellent bioavailability. There is negligible protein binding in serum and excellent tissue penetration, including cerebrospinal fluid, with a volume of distribution that approximates that of total body water. Because 5-FC is almost completely filtered unchanged by the kidney, a decline in glomerular filtration rate results in an increase in serum concentrations of 5-FC and a higher risk of toxicity. Dose-dependent bone marrow suppression is the most serious toxicity associated with administration of 5-FC. GI side effects, such as diarrhea, nausea, and vomiting, are the most common symptomatic side effects, occurring in approximately 6% of patients. Abnormal elevation of hepatic transaminases has also been reported in approximately 5% of patients receiving the drug. Conversion of 5-FC to 5-fluorouracil by GI flora may account for most of these toxicities. These adverse effects may be controlled by close monitoring of the serum concentrations and adjustment of the dose to maintain peak serum concentrations between 40 and 60 mg per L. Because 5-FC is used in combination with AMB, the conventional dosage of 150/per kg per day is not recommended in most patients. Instead, 100 mg/kg per day is a preferable starting dose in patients with normal renal function. As the glomerular filtration rate decreases as a result of AMB, the 5-FC dosage is reduced to less than 100 mg/kg per day in three to four divided doses. However, some children may have unusually high clearance rates and require doses of 150 mg/kg per day or more.

**Antifungal Azoles**

The antifungal azoles include imidazoles (clotrimazole, miconazole, and ketoconazole) and triazoles (itraconazole and fluconazole). Clotrimazole and miconazole are available in topical applications. The parenteral formulation of miconazole is no longer available. The use of ketoconazole has been generally supplanted by itraconazole and fluconazole in the pediatric oncology setting. Thus, only fluconazole and itraconazole are discussed here.

The antifungal azoles are synthetic compounds that demonstrate less toxicity than AMB, have flexibility for oral administration, and have comparable efficacy against certain infections. The antifungal azole agents function principally by inhibition of the fungal cytochrome P-450 enzyme lanosterol 14a-demethylase, which is involved in the synthesis of ergosterol.

***Fluconazole***

Fluconazole is a water-soluble meta-difluorophenyl bis-triazole and is available in both oral and parenteral formulations. Fluconazole has been shown to be effective against infections caused by *Candida* sp., *Cryptococcus neoformans*, and other fungi in patients with neoplastic diseases, human immunodeficiency virus (HIV) infection, and other immunocompromised states.

Fluconazole is a relatively small molecule with rapid absorption and excellent bioavailability. Fluconazole is only weakly bound to serum proteins (12%). The concentration–time curves of orally and parenterally administered fluconazole are almost superimposable. Fluconazole exhibits linear plasma kinetics and is only slightly metabolized. In the setting of renal impairment, the dosage of fluconazole is adjusted to reflect glomerular filtration. A 50% reduction of dosage is recommended in patients with a creatinine clearance of 21 to 50 mL per min, and a 75% reduction in those with a clearance of less than 21 mL per min. Oral absorption of fluconazole does not depend on a low intragastric pH, feeding, fasting, or mucosal integrity.

A study conducted at the NCI and Children's National Medical Center found that the plasma half-life of fluconazole in children aged 5 to 15 years was substantially reduced in comparison with the half-life in adults (17 hours in children versus reports of 27 and 37 hours in adults).[91] In light of this more rapid clearance of fluconazole, life-threatening fungal infections in children are treated with 12 mg per kg in two divided doses (assuming normal renal function) to approximate the dosage equivalency in adults, as defined pharmacokinetically by the area under the concentration–time curve.

Fluconazole penetrates well into cerebrospinal fluid.[92] This distribution property results in cerebrospinal fluid to serum concentration ratios of between 0.5 and 0.9, increasing to between 0.8 and 0.9 in the setting of meningeal disease. Fluconazole has been well tolerated with very few dose-limiting side effects in different pediatric populations. Nausea, other GI symptoms, and elevated hepatic transaminases occur infrequently and are usually reversible. Fluconazole does not appear to affect the synthesis of steroid hormones.

The drug interactions of fluconazole in principle are similar to those of other azoles. For example, fluconazole has been reported to precipitate phenytoin toxicity because of inhibition of metabolism, thus warranting monitoring of phenytoin concentrations during coadministration of fluconazole. Concentrations of cyclosporine may be increased, and the effects of warfarin may be potentiated.

***Itraconazole***

Itraconazole, although structurally similar to ketoconazole, has a broader spectrum of antifungal activity, less toxicity, a longer plasma half-life, and the capacity to penetrate into brain tissue. The spectrum of itraconazole includes *Candida* sp., *C. neoformans*, *Trichosporon* sp., *Aspergillus* sp., dematiaceous molds, and the endemic dimorphic fungi, including *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Coccidioides immitis*, and *Paracoccidioides brasiliensis*. Despite this extended

spectrum and greater safety profile, itraconazole has limited bioavailability. Itraconazole is soluble only at low pH, as in the normal gastric milieu. There is wide intersubject variation in the plasma concentration curves of itraconazole, particularly in patients receiving intensive cytotoxic chemotherapy, oral antacids, or $H_2$ receptor–blocking agents.

Plasma levels of itraconazole are substantially decreased by antacids and by $H_2$ receptor–blocking agents (i.e., cimetidine or ranitidine) because of elevated gastric pH, which impairs absorption of the drug. This erratic bioavailability compromises the role of itraconazole in neutropenic patients, particularly those with chemotherapy- or radiotherapy-induced mucosal disruption.

Interpatient variation in absorption of itraconazole is improved by incorporation of the molecule into cyclodextrin. The cyclodextrin formulation of itraconazole is approved for treatment of mucosal candidiasis. Higher dosages of hydroxypropyl cyclodextrin itraconazole required to treat deeply invasive infections such as aspergillosis, however, may cause GI distress in some patients due to the cyclodextrin formulation, thereby necessitating the use of capsules. Thus, plasma concentrations of itraconazole should be monitored in treatment with patients with deeply invasive mycoses to assure adequate bioavailability.

Attainment of adequate plasma concentrations is critical for optimal antifungal effect of itraconazole. [93] Because itraconazole is highly protein bound (greater than 99%), with only 0.2% available as free drug, concentrations in body fluids equivalent to body water, such as saliva and cerebrospinal fluid, are negligible. Tissue concentrations, however, including those of the central nervous system, are two to five times higher than those in plasma, and they persist for longer, explaining the efficacy of the drug despite low plasma concentrations. Itraconazole is extensively metabolized by the liver to hydroxy-itraconazole, which also possesses intrinsic antifungal activity. Less than 1% of the active drug, and approximately 35% of the inactive metabolites, are excreted in the urine. Because the primary route of excretion is the biliary tract, no adjustment of dosage is necessary in patients with renal impairment.

Itraconazole has properties of drug interaction with cyclosporin, rifampin, phenytoin, phenobarbital, antihistamines, coumadin, and oral hypoglycemic agents. Important drug interactions between itraconazole and other agents can prolong the plasma half-life of cyclosporin, which may lead to cyclosporin-induced nephrotoxicity. Consequently, serum cyclosporin levels should be closely monitored, and dosages of cyclosporin should be adjusted in patients receiving itraconazole. Itraconazole's inhibition of the metabolism of antihistamines such as terfenadine and astemizole may lead to widening QT intervals and cardiac ventricular arrhythmias, including torsade de pointes. The serum concentrations of itraconazole may be markedly decreased with concomitant administration of drugs that induce hepatic microsomal enzymes, such as rifampin and phenobarbital. Caution should also be exerted in the coadministration of traconazole with vinca alkaloids, coumadin, and oral hypoglycemic agents, because the increased concentrations of these drugs may cause increased neuropathy, prothrombin time, and hypoglycemia, respectively.

Itraconazole is well tolerated with long-term use. Itraconazole has a relatively low incidence of hepatic toxicity (less than 5%). Most of the reported adverse reactions are transient; they include GI disturbances, dizziness, and headache, and no adverse effect on steroidogenesis.

A parenteral formulation of itraconazole in hydroxypropyl cyclodextrin solution has recently become available. This encouraging development obviates the problems of bioavailability and tolerance of the oral formulations. There are, however, limitations to the use of this new parenteral formulation. Due to the potential nephrotoxicity of the vehicle, use of the command is not approved beyond 2 weeks. The formulation is supplied only in 200-mg bags that cannot be combined for use in higher dosages. More data are required in understanding the use of the hydroxypropyl cyclodextrin solution of itraconazole in treatment of invasive mycoses.

The role of combination antifungal therapy with AMB and antifungal triazoles is controversial but frequently arises in the management of the patient with refractory aspergillosis, when the combination of AMB plus itraconazole is contemplated. Because there are clinical and experimental data demonstrating antagonism of antifungal activity when amphotericin is combined with an azole, the safety and efficacy of combination therapy are most appropriately determined from a clinical trial. To date, limited data exist from a recently completed multicenter clinical trial of fluconazole versus fluconazole plus AMB in non-neutropenic patients with candidemia.

New classes of antifungal agents also have recently been introduced into clinical trials. These include second-generation triazoles (voriconazole, posaconazole, and ravuconazole) and echinocandins [caspofungin (MK0991), FK463, and V-echinocandin (LY303366)]. The second-generation triazoles have expanded antifungal spectra and potent *in vitro* and *in vivo* antifungal activity. Voriconazole and ravuconazole are formulated for both oral and parenteral administration. Echinocandins are cyclic lipopeptides that inhibit 1,3-b- D-glucan synthase activity, resulting in inhibition of fungal cell wall biosynthesis. The current generation of echinocandins has activity against *Candida* sp., *Aspergillus* sp., and *P. carinii*; however, they do not have activity against *C. neoformans.* The echinocandins are formulated only for parenteral administration.

## ANTIVIRAL AGENTS

The herpesviruses, including herpes simplex virus (HSV), CMV, and varicella-zoster virus (VZV), commonly cause infections in immunocompromised patients. Often acquired early in childhood, these viruses cause acute infections and are then maintained indefinitely in a state of latency, within dorsal root ganglia in the case of HSV and VZV, and probably within monocytes in the case of CMV. It is thought that latent herpesviruses are held in check and prevented from frequent reactivation by the presence of effective cellular immune function. Immunosuppression, as a consequence of either cancer chemotherapy or the underlying malignancy itself, permits reactivation of herpesvirus replication. Reactivation of viral replication from latency may be detected simply as asymptomatic shedding of virus, or it may manifest as invasive disease. Herpes stomatitis, localized or disseminated zoster, and interstitial pneumonitis are the most common clinical manifestations of HSV, VZV, and CMV reactivation, respectively. Several important antiviral agents have become standard components of the antimicrobial armamentarium over the last decade, and others have been added more recently.

In addition to the herpes viruses, common respiratory viruses have been increasingly recognized as significant pathogens in cancer patients. Respiratory syncytial virus (RSV), parainfluenza, and influenza have been associated with significant morbidity and mortality, particularly in patients with leukemia and those undergoing bone marrow transplantation. Agents used for the prevention and treatment of these infections are discussed below.

### Acyclovir

Acyclovir was the first widely used antiviral agent, and it has become an essential element in the supportive care of children and adults with cancer. Acyclovir is a guanine nucleoside analog that, when triphosphorylated, is selectively recognized by viral DNA polymerase as a nucleotide. Acyclovir triphosphate acts as an inhibitor of herpesvirus DNA polymerase and stops viral DNA synthesis. Because of low affinity for cellular DNA polymerases, acyclovir triphosphate has an excellent therapeutic ratio. The selective antiviral action of acyclovir and other similar compounds is caused by preferential phosphorylation (i.e., activation of the drug) by the virus-encoded thymidine kinase enzyme.

Acyclovir is effective for prophylaxis and treatment of both primary infections and reactivations of HSV types 1 and 2 in immunocompromised patients. [94,95] It is used prophylactically in seropositive persons who are undergoing intensive therapy or bone marrow transplantation. There is also evidence that it prevents reactivations of VZV and CMV in bone marrow allograft recipients who receive it prophylactically, although acyclovir itself has no therapeutic efficacy against established CMV disease.[96] Treatment of localized zoster using i.v. acyclovir in immunocompromised patients prevents dissemination and reduces mortality from visceral VZV. [97] In immunocompetent children with chickenpox, oral acyclovir marginally reduces the duration of symptoms, but i.v. acyclovir remains the standard of care in those who are immunocompromised. The i.v. doses of acyclovir required to treat VZV disease (500 mg per $m^2$ every 8 hours) are double those used for HSV therapy (250 mg per $m^2$ every 8 hours), because VZV is relatively less sensitive to the drug. Acyclovir is associated with very few adverse effects, although high i.v. doses should be given with adequate hydration to avoid renal toxicity.

### Ganciclovir

Ganciclovir is a deoxyguanine nucleoside analog, and although it is active against the all of the herpesviruses affecting immunocompromised patients (HSV, VZV, and CMV), it is much more potent than acyclovir against CMV. Ganciclovir, like acyclovir, requires activation through phosphorylation, and the triphosphate form of the drug interferes with viral DNA synthesis. The significant myelotoxic effects of ganciclovir preclude its routine use to treat HSV or VZV. It is used almost exclusively for treatment and prevention of disease caused by CMV. For invasive CMV disease (i.e., retinitis, colitis, pneumonitis), ganciclovir induction therapy at 5 mg per kg twice daily (b.i.d.) for 2 to 4 weeks is often followed by a prolonged maintenance therapy period, especially in patients with persistently impaired immune systems [e.g., patients with the acquired immunodeficiency syndrome (AIDS)].

### Foscarnet

Unlike acyclovir and ganciclovir, foscarnet does not require phosphorylation to become active. It directly inhibits the DNA polymerases of the herpesviruses. The unique function of foscarnet has made it particularly useful for the treatment of infections caused by HSV and VZV that have become resistant to the standard nucleoside analogs. Typically, these resistant viruses have, by mutation, lost the viral thymidine kinase activity that normally activates acyclovir and ganciclovir. Foscarnet has assumed an important role as a highly effective treatment for mucocutaneous lesions of chronic zoster and HSV, often associated with resistant viruses, and for CMV retinitis in patients with AIDS, in whom it may confer a slight survival advantage over ganciclovir therapy. [98] The potential benefits of the drug must be balanced against the inconvenience of foscarnet administration, which is solely by the central venous route and is on a daily basis, usually over several hours. In addition, significant renal toxicity, with decreased glomerular filtration and rising creatinine, is seen in most patients receiving foscarnet.

### Famciclovir and Valaciclovir

Famciclovir and valaciclovir are very similar to acyclovir in their structure and activity. However, each has a pharmacokinetic profile that allows for less frequent oral dosing for treatment of HZV. Twice-daily dosing of famciclovir or thrice-daily dosing of valaciclovir has clear advantages for the patient when compared with the five times daily oral acyclovir dose that is recommended for immunocompetent adults. Both agents appear to be as efficacious as acyclovir in these patients. As yet, there have been no published studies of these drugs in immunocompromised children, although there is no reason to believe that these agents would be any less effective than acyclovir. They are attractive antibiotics because of their excellent pharmacokinetic profiles and less cumbersome dosing schedules.

### Sorivudine

Sorivudine, or BVaraU, is a synthetic deoxythymidine nucleoside analog with *in vitro* activity against VZV that is approximately 1,000-fold greater than that of acyclovir *in vitro*. It is orally available, and pharmacokinetics in adults favor once-daily dosing. In a study of adult patients with HIV and zoster, oral sorivudine administered once a day compared favorably to oral acyclovir administered 5 times per day in terms of the rate of cutaneous healing. [99] Sorivudine has a significant drug-drug interaction with the chemotherapy medication, 5-fluorouracil, with concomitant administration putting individuals at significant risk for severe myelotoxicity. [100] Because of this serious drug interaction, sorivudine has not been licensed in the United States.

### Ribavirin

Ribavirin is a synthetic virostatic nucleoside with antiviral properties *in vitro* against a variety of RNA and DNA viruses. It is a small-particle aerosol usually given in a dose of 20 mg per mL in 300 mL of distilled water nebulized in an oxygen hood, tent, or mask over 12 to 18 hours for every 24-hour period. Shorter-duration therapy with high-dose aerosolized ribavirin appears to be efficacious and is more convenient. [101] Ribavirin is associated with few side effects; nausea, headache, and bronchospasm occur at low frequency. Accumulated data have suggested that health care workers are not at significant risk for adverse effects with the minimal exposure that occurs during care of a child receiving aerosolized ribavirin, although pregnant women are advised to avoid areas in which ribavirin therapy is administered because of concerns about the uncertain teratogenic potential of the drug in humans. [102]

The use of ribavirin for treatment of RSV pneumonia was originally studied in infants with severe disease. The efficacy of this drug has shown mixed results, with some studies showing improvement in overall severity of illness [103] and others showing no difference [104,105] or worse outcome in the ribavirin-treated group. [106] The ambiguity of the data prompted the American Academy of Pediatrics to change its recommendation from ribavirin “should be used” to “may be considered” for selected infants and young children at high risk for serious disease. [107] These include children with chronic lung disease, congenital heart disease, prematurity, and those who are immunosuppressed.

The mortality rate from RSV pneumonia in adults undergoing therapy for AML and in bone marrow transplant patients is high. [108] The data regarding the efficacy of ribavirin therapy in these patients is somewhat limited and is based primarily on reports of on-case series compared to historical controls. [109] There is a suggestion from the data that the early initiation of ribavirin therapy, often given in conjunction with immune globulin, may have some beneficial effect.

Intravenous ribavirin in conjunction with interferon alpha-2b is now the standard of care for patients with chronic hepatitis C infection. [110] This combination has been shown to increase sustained response rates to 40% in those individuals who are treatment naive and to 50% in those who have relapsed after initially responding to interferon alone. Response is dependent to some degree on viral genotype, with 60% of those individuals with genotype non-1 having sustained responses compared with 30% in those individuals with genotype 1. [111] This therapy is unfortunately associated with significant side effects, most notably flulike symptoms from the interferon and dose-related hemolytic anemia from ribavirin, making it intolerable for a subset of patients.

### Synergis and Respiratory Syncytial Virus Immune Globulin

Synergis is a monoclonal antibody directed at the F glycoprotein of RSV, a surface protein highly conserved among RSV isolates. It was licensed by the FDA in 1998 for the prevention of RSV in premature infants and in those with chronic lung disease. It is given monthly during the RSV season at a dose of 15 mg per kg, administered intramuscularly. With this regimen it was shown in a randomized, placebo-controlled trial involving 1,502 patients with chronic lung disease who were younger than 24 months or in patients with a gestational age less than 35 weeks and were younger than 6 months that prophylaxis during the RSV season decreased hospitalization, intensive care unit days, and severity of disease. [112] RSV can be a serious pathogen in oncology patients, especially in those with acute leukemia and those undergoing bone marrow transplantation. However, to date there are no data in the utility of this agent for prophylaxis in these patient groups.

RSV immune globulin is blood product prepared from donors selected for high titers of RSV neutralizing antibodies. The range of RSV antibody titer is 1:2,400 to 1:8,000, whereas unselected immune globulin usually has anti-RSV antibody titers of less than 1:1,000. It was licensed by the FDA in 1996 also for the prevention of RSV pneumonia in premature infants and for those with chronic lung disease. It is given once a month at a dose of 750 mg per kg i.v. Similar prophylaxis studies were performed and undertaken for synergism with similar results. Again, however, there are no data evaluating this agent for prophylaxis in oncology patients.

There has been some evaluation of RSV immune globulin for therapy for RSV disease. In a study of infants with RSV pneumonia there was no difference in outcome. [113] There are a number of small case series in adult oncology and bone marrow transplant patients using RSV immune globulin in combination with ribavirin for the treatment of severe lower tract disease, with a suggestion of improved outcomes over historical controls. [109,110]

### Amantadine and Rimantadine

Amantadine and rimantadine both have activity against influenza A but not against influenza B at clinically relevant doses. They appear to inhibit the uncoating of the viral RNA within host cells, ultimately blocking viral replication. Both drugs are well absorbed orally and are usually well tolerated, with no serious organ toxicities. The most common side effects of amantadine and rimantadine are mild GI discomfort, including loss of appetite and nausea. However, amantadine is associated with central nervous system effects such as nervousness, lightheadedness, difficulty concentrating, and insomnia, particularly in older adults. Rimantadine causes fewer central nervous system effects.

Both drugs have proved effective for prophylaxis and treatment of influenza A infections in immunocompetent patients, and there are reported successes of amantadine in immunocompromised patients with influenza A pneumonia. Although the improvements in symptoms and in viral shedding that are seen in patients treated with amantadine or rimantadine are better than those seen with aspirin or placebo treatment, they are modest, and there have been no trials in immunocompromised patients or in patients with life-threatening influenza A. [115] Wild-type viruses are usually susceptible to both drugs, but resistance (and cross-resistance) emerges rapidly when they are used clinically. Resistant influenza A virus has been isolated from children receiving rimantadine treatment and in family members receiving postexposure prophylaxis. [116] This finding is of concern, and for this reason it is suggested that simultaneous therapy and prophylaxis in the same household be avoided. Amantadine doses of 2.2 to 4.4 mg per kg b.i.d. up to 150 mg per day are suggested for young children (aged 1 to 10 years), and older children may receive 100 mg b.i.d. for prophylaxis or treatment of influenza A.

### Oseltamivir and Zanamivir

Oseltamivir and zanamivir are potent and specific neuraminidase inhibitors. *In vitro* each has been shown to have activity against both influenza A and B. Oseltamivir is administered orally, whereas zanamivir is administered intranasally. When administered early in the course of influenza A or B infection, both agents have been shown to decrease the duration of illness and the severity of symptoms.[117,118 and 119]

To date, the evaluation of the efficacy of these agents in immunocompromised individuals has not been reported. Given the data in immunocompetent individuals, it is not unreasonable to consider these agents for prophylaxis of high-risk patients with significant exposures. Zanamivir has been studied in children older than 5 years, with similar results in terms of efficacy and tolerability as those found in adult studies.[120] Oseltamivir has not been evaluated in pediatric patients.

## ANTI–*PNEUMOCYSTIS* PNEUMONIA AGENTS

There are a number of agents in common usage for the prophylaxis and treatment of PCP. Much of the data on their efficacy have been evaluated in patients with AIDS; however, there is also a substantial amount of data in oncology and bone marrow transplant patient populations.

### Trimethoprim-Sulfamethoxazole

In 1977 Hughes et al. demonstrated that prophylaxis with TMP/SMX was highly effective in preventing PCP in high-risk oncology patients.[121,122] The use of PCP prophylaxis has since become a routine part of the management of most childhood cancers. The recommended prophylactic regimen is TMP/SMX with 150 mg TMP per $m^2$ per day and 750 mg per $m^2$ per day of SMX given orally in divided doses b.i.d. during 3 consecutive days per week. Most oncology patients are able to tolerate TMP/SMX; however, side effects including bone marrow suppression and rash sometimes make alternative therapy necessary.

### Dapsone

Dapsone is a synthetic sulfone that has been shown to be effective in the treatment and prevention of PCP.[123] It acts through the inhibition of folic acid synthesis in susceptible organisms. For prophylaxis it is administered at a dose of 2 mg per kg per day. Adverse effects include rash, anemia, methemoglobinemia, agranulocytosis, and hepatic dysfunction. Dapsone has been recommended in the 1997 *USPHS/IDSA Guidelines for the Prevention of Opportunistic Infections in Persons with Human Immunodeficiency Virus* as the PCP prophylaxis for those patients unable to tolerate TMP-SMX.[124]

### Pentamidine

Pentamidine, in its aerosolized form, is another agent that has been studied extensively in both children and adults with HIV as a prophylactic agent for PCP. It has been shown to be an effective regimen when administered at a dose of 300 mg via Respirgard inhaler (Marquest, Englewood, CO) monthly. In small children it is often considered difficult to administer this drug because of the mechanics of the inhaler therapy. It has, however, been shown to be feasible, at least in a study situation, in children as young as 4 months.[125] Intravenous pentamidine has only undergone limited evaluation as a preventive regimen and was associated with a significant number of adverse drug reactions.[126]

### Atovaquone

Atovaquone is a 1,4-hydroxynapthoquinone with broad anti-protozoal activity, including proved efficacy against *P. carinii*. It has been shown to be and effective agent in treating PCP.[127,128] More recently, atovaquone was shown to be as effective as dapsone for PCP prophylaxis in patients with AIDS who were intolerant of TMP-SMX. The side effect profile of atovaquone is favorable, with the most common adverse effect being mild upper GI symptoms and diarrhea.

The drug is significantly more bioavailable in suspension form and therefore is routinely given in that form. Pharmacokinetic studies have been completed in children[129] suggesting dosing of children aged 0 to 3 months and older than 24 months at 30 mg per kg per day and for those aged 3 to 24 months, 45 mg per kg per day. It is dosed once daily. One drawback of atovaquone is that it is significantly more expensive than other oral agents when used for prophylaxis.

## MANAGEMENT OF UNEXPLAINED FEVER IN THE NEUTROPENIC PATIENT

### Duration of Antibiotic Therapy

Once antibiotics have been started empirically, there is the question of how long to continue them if a site of infection has not been defined. Low-risk patients do well if antibiotics are continued until the granulocyte count recovers to approximately 500 cells per $mm^3$.[24] Alternatively, there is increasing evidence that antibiotics may be discontinued in these low-risk patients if their neutrophil counts are rising, even though they have not risen above 500 cells per $mm^3$.[38] In a prospective study of 131 children with fever and neutropenia hospitalized for i.v. antibiotic treatment, 70 had their antibiotics discontinued and were discharged after they met the following criteria: afebrile for 24 hours, appeared clinically well, had negative cultures for a least 48 hours, exhibited control of local infection, and had evidence of bone marrow recovery for at least 1 day, as measured by rising absolute neutrophil or PMN count or platelet count. Only 1 of the 70 children required readmission for recurrent fever, whereas six of eight patients were inadvertently discharged without signs of marrow recovery and required readmission. Substantial savings in hospital costs were estimated for early discharge patients, and this approach is a reasonable option for those patients who fit specific low-risk criteria.[39] However, these guidelines do not apply to high-risk patients who remain neutropenic for more than 1 week and who do not demonstrate evidence of bone marrow recovery. Stopping antibiotic therapy too early can lead to clinical deterioration in patients who remain granulocytopenic, particularly if they are persistently febrile.

The management of the high-risk subset of patients with prolonged neutropenia was addressed in a series of prospective clinical studies that stratified them according to whether they had defervesced after the initiation of broad-spectrum antibiotics or remained persistently febrile ( Fig. 41-3).[33] Among patients who had defervesced on therapy, 41% again became febrile within 3 days of stopping antibiotics on day 7; new bacterial isolates from those with documented infections were sensitive to the antibiotics that had been withdrawn. No subsequent infections were observed among patients who continued antibiotics, however.

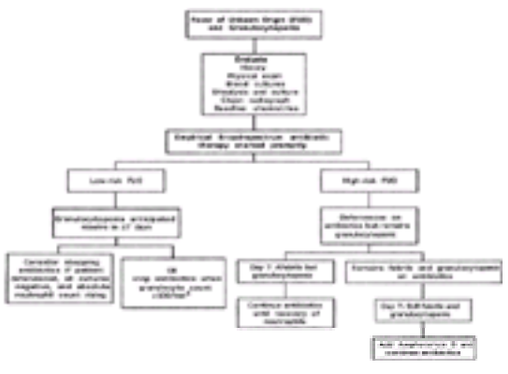

**FIGURE 41-3.** Algorithm for the initial management of the child who has unexplained fever and neutropenia. (See text for details.)

### Empiric Antifungal Therapy

The situation is more complicated for patients who remain persistently granulocytopenic and febrile despite antibiotic therapy. In a randomized clinical trial, we observed that 56% of patients with unexplained fever who remained febrile after receiving empiric antibiotics developed complications within 3 days of stopping therapy.[130] Of these, 38% became hypotensive. Simply continuing antibiotics in the face of persistent fever and granulocytopenia was also not satisfactory, however, because 31% of these patients eventually developed invasive fungal infections. These fungal infections were probably related to continued antibiotic therapy and

protracted granulocytopenia.

The background and rationale for the empiric use of an antifungal compound are based on several lines of reasoning. First, antemortem diagnosis of invasive fungal disease is difficult in an immunocompromised host. Second, withholding antifungal therapy pending a definitive diagnosis may allow dissemination to occur before the institution of therapy. Third, the outcome of a fungal infection in an immunocompromised patient is improved by early institution of therapy. Fourth, it is possible to identify patients who are at greatest risk for invasive mycoses. Neutropenic patients who remain febrile despite a 4- to 7-day trial of broad-spectrum antimicrobial therapy are particularly prone to fungal disease. [131] The use of empiric antifungal therapy would be expected to provide a dual benefit: the suppression of the fungal overgrowth that inevitably accompanies broad-spectrum antimicrobial therapy and the early treatment of subclinical, localized mycotic disease.

A prospective, randomized trial performed by the European Organization for Research on Treatment of Cancer corroborated the benefit of empiric AMB therapy for persistently febrile neutropenic patients. In that study, there were six documented fungal infections, four of which were fatal, among 64 patients who did not receive antifungal therapy, compared with only one fungemia and no deaths among 68 patients treated empirically with amphotericin (0.6 mg per kg per day or 1.2 mg per kg every other day) on or after day 4 of broad-spectrum antibiotic therapy. [132]

The point at which antifungal therapy was initiated varied in these studies. The arbitrary designation of day 7, used in the NCI trials, avoids the overuse of antifungal agents in patients who are slow to defervesce with empiric antibiotics and those who recover their granulocyte counts before day 7. Despite theoretical and clinical evidence substantiating the efficacy of empiric antifungal therapy, the toxicity of AMB limits the utility of empiric use of this compound. Less toxic alternatives are desirable.

A multicenter study, therefore, investigated whether liposomal AMB may be used instead of conventional AMB for empiric antifungal therapy in a randomized, double-blind trial design of LAMB versus conventional AMB in neutropenic children and adults with persistent fever despite broad-spectrum antibiotics. [133] Among 687 randomized patients, the composite success rate was equivalent (50% LAMB vs. 49% AMB) and independent of administration of antifungal prophylaxis or use of colony-stimulating factors. Comparable responses were observed in LAMB versus AMB, respectively, for survival rate (93% vs. 90%), resolution of fever during neutropenia (58% vs. 58%), and premature withdrawal of study drug due to toxicity or lack of efficacy (14% vs. 19%). There were fewer proved breakthrough fungal infections in patients treated with LAMB versus AMB [11 (3.2%) vs. 27 (7.8%) ($p$ = .009)]. There were fewer ($p$£.01) infusion-related fevers (17% vs. 44%), chills/rigors (18% vs. 54%), and cardiorespiratory events (dyspnea, hypotension, tachycardia, hypertension, and hypoxia; 13.1% vs. 45.6%) for LAMB versus AMB, respectively. There also was reduced ($p$ <.001) nephrotoxicity in patients treated with LAMB (19%) versus AMB (34%). Thus, this study conduced LAMB was equivalent to AMB in therapeutic success for empiric antifungal therapy in neutropenic patients, but superior in reducing proven treatment-emergent fungal infections, infusion-related toxicity, and nephrotoxicity.

For patients who remain neutropenic, antifungal therapy should be continued until the resolution of granulocytopenia. Persistence or recrudescence of fever should prompt a meticulous investigation for nonfungal infectious causes (e.g., bacterial or viral superinfections) or for a fungus that is resistant to doses of AMB given for empiric coverage (e.g., *Aspergillus* sp., *Trichosporon*, *Fusarium* sp., *Pseudallescheria boydii*, and *Scedosporium* sp.). Patients who develop a documented fungal infection should be treated with higher dosages of AMB or be enrolled onto emergency compassionate release of an investigational antifungal compound.

As lipid formulations of AMB are more costly than conventional AMB, targeting the highest-risk patients who may benefit from empiric AMB is important. Such patients include those with preexisting renal insufficiency, concomitant nephrotoxic agents, and anticipated protracted neutropenia. A recent pharmacoeconomic analysis investigated the impact of nephrotoxicity on total cost of hospitalization and the cost/benefit ratios of AMB and LAMB. [134]

## EVALUATION AND MANAGEMENT OF DOCUMENTED INFECTIONS

### Bacteremia

Approximately 10% to 30% of all febrile neutropenic cancer patients are bacteremic at presentation. [47,51] In the low-risk subgroup, the rate is consistently less than 10%.[36,37] Until the late 1970s, gram-negative aerobic organisms (especially *P. aeruginosa, E. coli*, and *K. pneumoniae*) were the most frequently isolated pathogens. Subsequently, the pattern of infections has shifted, and gram-positive bacteria are now isolated more often than gram-negative bacteria at most cancer centers. It is hypothesized that this shift is secondary to increased used of indwelling central venous catheters, fluoroquinolone prophylaxis, and high-dose chemotherapy induced oral mucositis.

The gram-positive pathogens most commonly isolated include *S. aureus, S. epidermidis, Streptococcus* sp. (including a-hemolytic streptococci), and *Enterococcus* sp. Species of *Corynebacterium* (e.g., *C. jekeium, C. diphtheriae*, and *C. equi* ) and *Bacillus* sp. are less frequently isolated and tend to occur in patients with long episodes of granulocytopenia or those with indwelling vascular access devices, respectively. [135] *E. coli, K. pneumoniae*, and *Enterobacter* sp. are now the most frequently isolated gram-negative bacilli, although more resistant species (e.g., non- *aeruginosa* pseudomonads, and *Serratia marcescens*) are occasionally encountered.

Resistance patterns in pathogens isolated from febrile neutropenic patients have emerged as a significant challenge. *Enterococcus* sp. that are resistant to vancomycin, ampicillin, aminoglycosides, or all of these, have been increasingly noted in recent years and are associated with high mortality in immunocompromised patients.[136,137] Someisolates of viridans streptococci are resistant to penicillin and cephalosporins and, therefore, require vancomycin for therapy. *S. pneumoniae* isolates with either intermediate- or high-level penicillin resistance are now relatively common in many parts of the United States. This is of special concern for immunocompromised individuals at high risk for pneumococcal septicemia—for example, asplenic patients and patients post–bone marrow transplantation with chronic graft-versus-host disease. In addition, gram-negative bacilli resistant to quinolones or cephalosporins are an increasing problem at some institutions.

In general, the morbidity and mortality rates associated with infections with gram-positive bacteria, especially the coagulase-negative staphylococci, are lower than those caused by gram-negative pathogens. An important exception is bacteremia caused by a-hemolytic streptococci, most commonly *S. mitis* and *S. sanguis*. Alpha-hemolytic streptococcal sepsis may cause sudden onset of hypotension, with progression in approximately one-fourth of cases to a syndrome that can include shock, respiratory failure due to adult respiratory distress syndrome, acute renal failure, and neurologic manifestations. Palmar erythema and subsequent desquamation may also be a feature of this syndrome. Although there is considerable variability between centers of mortality related to viridans streptococcal sepsis, the median death rate is approximately 10%.[138] The antecedent administration of high-dose cytosine arabinoside is a strongly correlative risk factor for the development of a-hemolytic streptococcal sepsis.[139] A number of other distinct risk factors have been associated with this syndrome, including the presence of mucositis, the administration of antacids or $H_2$-blockers, and prophylactic treatment with TMP-SMX or fluoroquinolone antibiotics, both of which allow for breakthrough growth of a-hemolytic streptococci.[47,140]

The most important therapeutic intervention for patients ultimately shown to be bacteremic is the prompt initiation of empiric antibiotic treatment at the time of the patient's presentation with fever and neutropenia. Necessary modifications of the initial regimen should be based on the antimicrobial sensitivity pattern of the bloodstream isolate (Table 41-3) while maintaining broad empiric coverage.

### Catheter-Associated Bacteremia

With the increased use of indwelling venous access devices, catheter-associated bacteremic episodes have become more frequent. [141] The strict diagnosis of a catheter-related versus non–catheter-related bacteremia is often difficult. Positive blood cultures drawn through a venous catheter can be considered to have arisen from one of three possible sources: colonization of the line from external sources (skin and catheter hub), hematogenous seeding of the catheter from internal sources and, rarely, contaminated infusions (e.g., platelets with bacterial contamination). Evidence of catheter-related infection as opposed to bacteremia from other sources includes a greater number of colony-forming units per mL of blood from cultures of the central line compared with simultaneous peripheral cultures and positive catheter tip cultures when the line is removed for presumed infection.

The majority of patients with fever and neutropenia and a central line–associated bacteremia do not need to have their catheters removed [142]; however, there are certain clinical situations and infectious pathogens that require line removal for cure of infection. *S. aureus* catheter-related bacteremia can generally be treated without line removal.[143] Patients with vancomycin-resistant enterococcal infections often require catheter removal for cure. Certain pathogens that are sensitive to therapy (e.g., some *Bacillus* sp.) require catheter removal to cure the infection. Patients with polymicrobial catheter-related bacteremia and those with candidemia

should have their catheters removed.

Most catheter-associated infections caused by coagulase-negative staphylococci can be controlled without removal of the catheter. [141] In addition, many gram-negative catheter infections can be treated with i.v. antibiotics and without removal of the catheter. In patients with double- or triple-lumen catheters, the antibiotic infusions should be rotated among each of the catheter lumens. If blood cultures remain positive despite 48 hours of appropriate antimicrobial therapy, the catheter should be removed. In addition, removal of the catheter should be considered when there is recurrent bacteremia with the same organism after an appropriate course of therapy.

### Local Catheter Infections

Local catheter infections include exit-site infections, pocket space abscesses or cellulitis, and tunnel infections. Purulence or cellulitis at the catheter exit site, without associated bacteremia, is evidence of a local exit site infection. Warmth, redness, and tenderness are highly suggestive of an infectious etiology, although at times this can be due to inflammation from local irritation or mechanical trauma. Exit site infections can often be managed conservatively with local care with or without systemic antibiotics. Usually these can be managed without catheter removal; however, if *Pseudomonas* is cultured from the site catheter removal may be required.

Pocket space infections present with fluctuance around the subcutaneous catheter hub, often with inflammation or cellulitis of the overlying skin. Tunnel infections are characterized by spreading cellulitis in the subcutaneous tissues along the tunnel tract of long-term i.v. catheters. Unlike exit-site infections, these infections are often associated with serious local morbidity and systemic infection. The pathogens involved are most commonly gram-positive cocci; however, gram-negative bacilli, including *Pseudomonas* as well as *Mycobacterial* sp., are also reported. These infections are best managed by rapid removal of the catheter and treatment with i.v. antibiotics.

### Ear Infections

Children with cancer may develop the same infectious problems as immunocompetent patients. For example, otitis media may follow a viral upper respiratory illness. Clinical findings suggesting an ear infection range from the classic complaints (e.g., ear pain, drainage, fever, irritability) to minimal symptomatology (e.g., slight tympanic erythema) in profoundly neutropenic children. Although the most likely pathogens are identical to those isolated from an immunocompetent host (e.g., *S. pneumoniae*, *H. influenzae*), neutropenic patients are also susceptible to gram-positive or gram-negative bacteria that may have colonized the oropharynx and nasopharynx.[144] Therefore, broad-spectrum antibiotic coverage is necessary unless a specific pathogen has been identified. Patients should receive 10 to 14 days of therapy. Children with anatomic alterations (e.g., radiation damage) of the external or middle ear or eustachian tube are particularly susceptible to recurrent infectious episodes.

Although mastoiditis has become uncommon, immunosuppressed patients, particularly those with an anatomic abnormality of the middle ear, are at risk for the development of mastoiditis. In addition to the usual bacterial pathogens associated with this disorder, individuals with prolonged neutropenia are at risk for fungal mastoiditis, which often requires surgical management for cure. [145] Patients should undergo appropriate evaluation, including computed tomography (CT) scans of the involved area, particularly if they have symptoms or signs (e.g., localized erythema, swelling, tenderness) referable to the mastoid.

### Sinusitis

In the immunocompetent or non-neutropenic child bacterial sinusitis is most commonly caused by *S. pneumoniae, H. influenzae,* and *Moraxella catarrhalis*.[146] *S. aureus*, gram-negative aerobes (including *P. aeruginosa*), and anaerobic bacterial species can also be found, although more with obstruction of the sinuses by tumor (e.g., nasopharyngeal carcinoma, Burkitt's lymphoma, rhabdomyosarcoma) are especially at risk for acute or chronic sinusitis.

Fungal pathogens (e.g., *Aspergillus* sp*., Candida albicans, Mucor*) are particularly worrisome causes of sinusitis in the immunocompromised host. Patients with acute leukemia or other disorders associated with long periods of neutropenia (e.g., aplastic anemia) are especially prone to fungal sinusitis. [144,147] The diagnosis of acute sinusitis is usually suggested by complaints of facial pain, local tenderness, and (assuming a patent outlet and an adequate granulocyte count) purulent nasal drainage. With involvement of the ethmoid sinus, edema of the eyelids and excessive tearing may also be observed. In young children, a nonproductive cough and fetid breath may indicate a sinus infection. In an immunosuppressed patient, however, many of the classic symptoms and signs may be absent, and a high index of suspicion must be maintained, particularly in a persistently febrile, granulocytopenic patient receiving broad-spectrum antibiotics. Any sinus tenderness or even minimal complaints of nasal stuffiness in a neutropenic child should be pursued with conventional radiographs or, preferably, a CT scan and a detailed nasopharyngeal examination, because even subtle findings on physical examination (e.g., minimal crusting on nasal turbinate) may be indicative of an invasive fungal lesion.

In children older than 1 year, radiologic examination of the sinuses is useful for diagnosis. The findings of sinus opacity, an air-fluid interface, or mucosal thickening strongly correlate with acute infection. In patients with chronic sinusitis, radiographic findings are less helpful because of the persistence of abnormalities related to the chronic infection. Serial CT or MRI scans may prove helpful in the immunosuppressed patient with chronic sinus disease because they are more sensitive and more specific than plain radiographs. [148] Specifically, these imaging techniques can facilitate detection of the bony erosion that is common to the indolent fungal pathogens.

Therapy must be tailored to the clinical situation. Acute sinusitis in a non-neutropenic patient is best managed with amoxicillin plus clavulanic acid (Augmentin) or TMP/SMX.[149] For neutropenic patients, broad-spectrum antimicrobial therapy is necessary. Decongestants are an essential adjunct to antimicrobial therapy to provide drainage of the sinuses. If a neutropenic patient with sinusitis does not improve after 72 hours of treatment, aspiration or biopsy of the sinus should be performed. For patients with chronic or recurrent sinusitis, particularly those with a local tumor mass or damage secondary to radiotherapy, an antral window may be necessary to allow adequate drainage.

The diagnosis and treatment of fungal sinusitis in neutropenic patients remain difficult, and the definitive diagnosis depends on histopathologic documentation of tissue invasion. A high level of clinical suspicion is the key to making the diagnosis. Plain radiographs often appear normal even though CT or MRI scans reveal the presence of extensive disease. Patients with prolonged neutropenia in whom fever and mild symptoms of nasal congestion or bleeding develop should undergo such scanning to identify invasive fungal disease. Fungal sinusitis caused by *Aspergillus* or *Rhizopus* sp. can progress to the rhinocerebral syndrome, with invasion through the cribriform plate and into the central nervous system. Early institution of AMB therapy is imperative. Surgical débridement of involved tissue is often required in an effort to remove necrotic and inflammatory material. Even with these aggressive therapeutic maneuvers, a successful outcome depends on the recovery of an adequate granulocyte count.

## INFECTIONS IN THE RESPIRATORY TRACT

Infections of the respiratory tract are among the most common complications in the immunosuppressed cancer patient. Colonization of the upper airway provides a ready source of pathogenic species in direct proximity to the lower respiratory tract. Altered mucosal and humoral immune mechanisms (e.g., subnormal ciliary function, decreased secretory immunoglobulins) provide for less effective clearance of aspirated organisms, and the absence or suboptimal functioning of the phagocytic effector cells (e.g., PMNs, pulmonary macrophages) permits establishment of a local infection and frequently hematogenous dissemination of the organisms.

One of the principal problems in managing pulmonary infiltrates in an immunocompromised host is the number of infectious and noninfectious causes that must be considered, including progression of the underlying malignancy, drug reactions, emboli, and hemorrhage secondary to vascular erosion or severe thrombocytopenia. The most practical approach for the evaluation of an immunocompromised patient with a pulmonary infiltrate is to categorize patients according to the anatomic distribution of the infiltrative lesion (i.e., localized or diffuse) and the granulocyte count (i.e., neutropenic or not). This classification permits rapid evaluation, identification of likely pathogens, and prompt institution of appropriate therapy to optimize the chance for a successful outcome ( Fig. 41-4).

**FIGURE 41-4.** Algorithm for the management of the child with a pulmonary infiltrate.

### Diagnosis of Pneumonia in the Immunocompromised Patient

Pulmonary infections in immunocompromised individuals can progress rapidly to respiratory failure, and therefore, initial evaluation needs to be performed expeditiously. The extent to which a specific etiology for the pulmonic process is investigated will often depend on the clinician's judgment of the immune status of the patient and his or her degree of illness.

The initial evaluation of the child with suspected pneumonia should include a chest radiograph, blood cultures, hematologic indices, pulse oximeter reading (or arterial blood gases in more critical situations), and collection and examination of available culture material. Sputum is usually not available in granulocytopenic patients. Nasopharyngeal aspirates, particularly for viral pathogens, including respiratory syncytial virus, parainfluenza, influenza, and adenovirus can be useful.

Further radiographic evaluation with a CT scan may provide information regarding the pattern and extent of disease that may not be evident on plain film alone. [150] It is important to remember, however, that the radiographic presentation may be extremely variable for any given etiology and that the differential diagnosis of most radiographic findings remains broad.

Flexible bronchoscopy can provide evidence for a specific diagnosis in immunocompromised patients with pneumonia. The yield of bronchoscopy depends on the clinical situation and the extent of prior therapy. [151] Bronchoalveolar lavage (BAL) can yield a specific diagnosis in approximately 80% of cases of PCP, whereas it is significantly less sensitive for fungal infections or bacterial infections in patients who have received prior antibiotic therapy. In a series of 89 bone marrow transplant patients with pulmonary complications of unclear etiology, approximately 50% had a diagnosis made by BAL, including findings of infectious (PCP, bacterial, CMV, RSV) and noninfectious (diffuse alveolar hemorrhage) causes. [152] Transbronchial biopsy may increase the diagnostic yield in some situations; however, this procedure is limited in very small children by the size of the equipment required.

Transthoracic needle biopsy can be useful for the assessment of disease that is focal and in the periphery of the lung parenchyma. Thoracoscopic lung biopsy can provide excellent pathologic samples as well as an ability to visualize superficial lesions, but it is limited in small children by the size of the instruments required. Open lung biopsy remains the gold standard for the diagnosis of pulmonary pathology. Open biopsy allows for sampling of an affected area and can obtain more tissue for pathological analysis. In patients not responding to appropriate empiric antimicrobial therapy with a nondiagnostic workup, an open lung biopsy is often indicated.

### Localized Pulmonary Infiltrate in a Non-Neutropenic Patient

The common causes of a localized pulmonary infiltrate in a non-neutropenic cancer patient are similar to those in an immunocompetent child. Common bacterial, viral, and mycoplasmal organisms are most frequently isolated (Table 41-4), and therapeutic considerations are similar to those for an immunocompetent child. Non-neutropenic patients who are receiving immunosuppressive therapy (including corticosteroids) are also at risk for unusual pathogens, including *Mycobacterium tuberculosis*, atypical mycobacteria, *Nocardia asteroides*, *Legionella* sp., *Aspergillus* sp., *C. neoformans*, *Chlamydia* sp., and certain endemic mycoses such as *H. capsulatum* and *C. immitis*.

**TABLE 41-4. MODIFICATIONS OF INITIAL ANTIMICROBIAL REGIMEN FOR FEBRILE NEUTROPENIC CANCER PATIENTS**

Specific mycobacterial identification is especially important to distinguish atypical isolates (particularly *Mycobacterium kansasii* or *Mycobacterium avium-intracellulare*) from true *M. tuberculosis*. Children with documented drug-sensitive *M. tuberculosis* should receive 9 to 12 months of therapy with at least two effective antituberculosis agents (e.g., isoniazid and rifampin). However, it is critical to consider the possibility of multidrug-resistant strains of tuberculosis, particularly in patients who live in areas where those strains are endemic. [153]

A less common but nevertheless important pathogen to consider as the cause of localized pneumonia in an immunosuppressed child is *Legionella*. *Legionella* sp. are commonly found in water sources and may be found in the hospital environment, leading to nosocomial acquisition. *Legionella* pneumonia in immunosuppressed pediatric patients is heralded by abrupt onset of nonspecific symptoms such as fever, malaise, anorexia, lethargy, and headache. A nonproductive cough develops in most patients; chest pain, dyspnea, diarrhea, and neurologic symptoms may be prominent features. [154,155] A lobar, patchy, alveolar infiltrate is most common, although diffuse infiltrates may occur. [156] A definitive diagnosis of *Legionella* pneumonia is made by culture of the organism from respiratory secretions. The urinary antigen test is specific only for *Legionella pneumophila* type 1, which causes 80% of cases. [157] Other rapid tests for diagnosis of *Legionella* infection (direct fluorescent antibody stain, DNA probe) lack the sensitivity and specificity of culture. Erythromycin (40 to 50 mg/kg per day, maximum of 4 g) given for 3 weeks is the treatment of choice, with addition of rifampin for seriously ill patients.

*Nocardia*, particularly *N. asteroides*, may also present as a localized pulmonary infiltrate, although miliary and microcavitary patterns have been described in cancer patients. [158] Approximately 30% of patients with a pulmonary infection caused by *N. asteroides* also have cutaneous infection and central nervous system involvement (usually brain abscesses). Diagnosis depends on positive cultures or histopathologic demonstration of tissue invasion by the organisms. TMP/SMX (15 mg per kg per day TMP) for 6 months is the most practical therapy. The mortality rate of disseminated disease remains at approximately 30%.

Noninfectious causes for a localized pulmonary infiltrate in a non-neutropenic patient should also be considered, including progression of the underlying malignancy, an atelectatic segment of lung (potentially caused by compromise of the airway by adjacent tumor), pulmonary hemorrhage, and a localized reaction to a chemotherapeutic agent (particularly methotrexate, cyclophosphamide, or bleomycin), although drug reactions are more commonly manifested as diffuse interstitial

pulmonary processes.

**Localized Pulmonary Infiltrate in a Neutropenic Patient**

An array of opportunistic pathogens must be considered in the neutropenic patient with a localized infiltrate, including those noted in the non-neutropenic patient. Any gram-positive or gram-negative organism as well as a variety of fungal, parasitic, and viral pathogens can be responsible ( Table 41-4). Bacterial pathogens predominate in patients with neutropenia lasting less than 14 days. Patients with longer periods of neutropenia and those in certain clinical settings (e.g., allogeneic bone marrow transplantation) are more prone to develop a fungal (e.g., *Aspergillus*) or viral (e.g., CMV) infection. Unless the clinical presentation suggests otherwise, it is appropriate to initiate a 48- to 72-hour trial of broad-spectrum antibiotics before proceeding to an invasive diagnostic procedure. If the patient has stabilized or improved by 72 hours, a 10- to 14-day course of treatment is necessary. If the patient has not stabilized or improved, a BAL or open lung biopsy should be performed.

The most frequently encountered cause of a localized pulmonary infiltrate in the patient with protracted neutropenia is a fungal pneumonia, particularly if the patient already is receiving broad-spectrum antibiotics.[159,160] *Aspergillus* sp. are most often responsible, although *P. boydii*, *Fusarium* sp., *Trichosporon beigelii*, and the Zygomycetes (e.g., *Rhizopus* sp.) may also play a role.[161,162] Occasionally, *Candida* sp. (especially *C. albicans* and *C. tropicalis*) may cause hematogenous or primary pulmonary candidiasis.[163] Other fungi, including *H. capsulatum*, *C. immitis*, and *C. neoformans*, can also cause focal pneumonia in neutropenic patients receiving corticosteroids, although infections with these organisms are more commonly manifested as a diffuse or nodular pulmonary pattern.[164] The clinical, laboratory, and radiographic features of fungal pathogens are indistinguishable from those of other pulmonary processes, and definitive diagnosis depends on microbiologic or histopathologic confirmation in specimens obtained from transbronchial or open lung biopsy.

The incidence of pulmonary infections caused by *Aspergillus* sp. has increased in recent years and has been observed in clusters in certain hospitals.[162,165,166] The most common scenario is that of a profoundly and persistently neutropenic patient who develops a localized, progressive pulmonary infiltrate while receiving broad-spectrum antibiotics. Infections caused by *Aspergillus fumigatus* and *Aspergillus flavus* are the most common, presumably initiated by inhalation of airborne conidia. Because of the tendency for *Aspergillus* sp. to invade blood vessels, a necrotizing bronchopneumonia is characteristic, with the possibility of life-threatening hemoptysis. Disseminated aspergillosis occurs in approximately 30% of the cases, with involvement of the central nervous system, liver, kidneys, skin, and spleen. Despite this propensity for widespread disease, blood cultures are almost never positive.

Diagnosis of aspergillosis by noninvasive measures remains suboptimal, although positive culture of sputum or BAL specimens from a patient with long-term fever and neutropenia and a progressive infiltrate is highly associated with *Aspergillus* pneumonia. A definitive diagnosis still requires histologic confirmation or a positive BAL culture obtained in a clinically relevant setting.

Control of *Aspergillus* pneumonia requires an early diagnosis and prompt intervention. Therapy is provided by AMB at 1.0 to 1.5 mg per kg per day. Invasive pulmonary aspergillosis can develop in patients who are receiving empiric AMB at 0.5 to 0.6 mg per kg per day or lipid formulation of AMB for persistent fever and prolonged neutropenia. Higher dosages of AMB (1.0 to 1.5 mg per kg per day) or lipid formulation of AMB (greater than or equal to 5 mg per kg per day) are required to contain aspergillosis in this setting. Even with potent pharmacologic intervention, the most important prognosticator of a successful outcome is recovery from neutropenia. Subsequent cycles of chemotherapy-induced neutropenia may result in recrudescence of *Aspergillus* pneumonia unless antifungal therapy is continued during these periods of immunosuppression.

Lipid formulations of AMB offer the potential of treating sinopulmonary aspergillosis with higher dosages and less nephrotoxicity. These compounds may be particularly important in patients receiving concomitant nephrotoxic agents, such as aminoglycosides, cyclosporin, and foscarnet.

Other filamentous fungi, such as *P. boydii, Fusarium* sp., dematiaceous molds, and the Zygomycetes, especially *Rhizopus* sp., can cause pulmonary infiltrates that are similar to those associated with *Aspergillus*.[167,168] These organisms may also cause sinus infections and the rhinocerebral syndrome. Diagnosis requires documentation of tissue invasion. Therapy consists of AMB (1.0 mg per kg per day) and, if appropriate, aggressive surgical débridement. Nevertheless, treatment results remain poor unless granulocyte recovery ensues.

**Diffuse Pulmonary Infiltrates in a Cancer Patient**

Diffuse pulmonary infiltrates can be caused by bacterial, viral, fungal, or protozoal pathogens; the probability of having a specific pathogen is influenced by whether the patient is neutropenic (Table 41-4). A non-neutropenic patient with a diffuse pulmonary infiltrate is unlikely to have a bacterial or fungal process; however, both groups of patients are at risk for severe infection from *Pneumocystis pneumoniae* and various viral pathogens.

One of the most commonly encountered infections in this setting is PCP.[121] This infection is thought to result from a reactivation of latent cysts, because almost all normal children possess detectable antibody to the organism. However, patient-to-patient transmission has been suggested by reports of nosocomial clusters of cases.[169] It is also possible that certain chemotherapeutic regimens predispose patients to interstitial infiltrates caused by *P. carinii*.

Patients with *Pneumocystis* pneumonia most commonly present with fever, a nonproductive cough, tachypnea, and hypoxemia. The time course of the symptoms ranges from a chronic, indolent course (characteristic of patients with AIDS) to an acute, fulminant presentation, more common in pediatric oncology patients.[170] Rales are not usually detectable on auscultation. Radiographic examination usually reveals bilateral diffuse interstitial infiltrates, often originating at the hilum and extending peripherally. Rarely, the chest radiograph is atypical, ranging from normal to a lobar or nodular infiltrate. Pleural effusions are rare.

Diagnosis of *Pneumocystis* pneumonia requires demonstration of cysts or trophozoites in pulmonary material from patients with a clinically compatible course. In patients with AIDS (including children), positive specimens may readily be obtained from induced sputum samples stained with toluidine blue O, a modified Giemsa stain, or with monoclonal antibodies to human *Pneumocystis* organisms. The sensitivity of sputum examination in an HIV-infected patient population has increased from initial reports of 55% with the routine stains to as high as 92% with monoclonal antibody stains detected by indirect immunofluorescence. A specificity of almost 100% has been reported from experienced laboratories.[171,172] In cancer patients, *Pneumocystis* organisms may not be as abundant as in patients with AIDS.[173] The diagnosis of *Pneumocystis* pneumonia in an immunosuppressed cancer patient can sometimes be made by monoclonal staining techniques on induced sputum, and this should be the first diagnostic approach whenever possible.[170] The demonstration of cysts, however, may require BAL or, in some cases, open lung biopsy.

In clinical situations in which the likelihood of *Pneumocystis* pneumonia is great, examination of induced sputum is a reasonable first step in older children. If the specimen is not attainable or if there is a negative result, it is best to continue on to a BAL while initiating an empiric course of TMP/SMX. A response to TMP/SMX may not be apparent for 4 to 5 days, although stabilization or slight improvement in alveolar air exchange usually occurs within 72 to 96 hours. Patients who do not respond should be given pentamidine at a daily dose of 4 mg per kg i.v. Pentamidine has been associated with myriad toxicities, including metabolic and hematologic abnormalities, pancreatitis, hypotension, and nausea and vomiting. Evidence from the adult AIDS population suggests that atovaquone or dapsone plus TMP may be acceptable alternatives to TMP/SMX or pentamidine in patients with mild or moderate disease.[174,175]

The early use of adjunctive steroids has been shown to improve the outcome in adult patients with AIDS with moderate or severe *Pneumocystis* pneumonia, defined by a room air arterial partial pressure of oxygen equal to 70 mm Hg or less, or an alveolar-arterial gradient greater than 35 mm Hg on presentation. Decreases in respiratory failure and death rates were observed among patients who received steroids with standard antiprotozoal therapies, compared with those who did not receive steroids.[176,177] Based on this information, the practice of initiating a short course of steroids in children with moderate or severe *Pneumocystis* pneumonia has been adopted by many pediatricians, although the optimal dose and duration of steroid therapy in children have not been defined. The recommendation for adults is for 40 mg prednisone (or the equivalent steroid) b.i.d. for the first 5 days of treatment, 40 mg once daily for the next 5 days, and then 20 mg once daily for 11 days, for a total treatment course of 21 days. A roughly estimated equivalent for children is 1 mg per kg b.i.d. for the first 5 days, 1 mg per kg daily for the next 5 days, and 0.5 mg per kg daily for the remainder of a 14- to 21-day course of therapy.

*Mycoplasma pneumoniae* can cause diffuse pulmonary infiltrates and severe disease in immunocompromised children. Evaluation of BAL fluid by polymerase chain reaction (PCR) for mycoplasma can be diagnostic. Often an empiric course of azithromycin is warranted until definitive diagnosis can be made.

Viruses are an important cause of diffuse interstitial infiltrate in non-neutropenic patients. Before routine prophylaxis and strategies for “preemptive therapy” (see below) CMV pneumonitis was a common cause of viral pneumonia after allogeneic bone marrow transplantation. CMV pneumonitis has also been seen in a very small percentage of patients after autologous bone marrow transplantation.[178] The most frequent causes of CMV infection and subsequent disease are reactivation of latent

virus in seropositive patients and acquisition of CMV from donor marrow in seronegative patients. CMV pneumonitis most often occurs between day 30 and day 100 after allogeneic bone marrow transplantation, coinciding with the period of highest risk for the development of acute graft-versus-host disease. Radiographically, CMV pneumonitis is characterized by diffuse bilateral linear or nodular infiltrates, although it is occasionally represented by a unilateral consolidation or a single nodule. [179]

The use of CMV antigenemia assays as well as CMV PCR has allowed for the rapid diagnosis of CMV infection. Routine screening during the period of highest risk, for example with twice weekly CMV antigen assays, has proved a highly effective strategy to prevent invasive disease. Detection of CMV or antigen in blood buffy coat post–bone marrow transplantation is a sign of CMV reactivation that is highly predictive of impending invasive disease. Such findings should prompt the institution of a treatment course with ganciclovir. Ganciclovir therapy has significant toxicity, primarily causing granulocytopenia, which much be monitored carefully. Alternative therapy can be accomplished with foscarnet.

The diagnosis of CMV pneumonia can be made by isolating CMV from bronchoalveolar fluid in the proper clinical setting and demonstrating either CMV antigen or nucleic acid in alveolar macrophages or compatible tissue pathology. Until recently, CMV pneumonitis has been associated with an extremely high mortality (greater than 85%) despite the use of a variety of antiviral and immunotherapeutic agents. Combined therapy with ganciclovir and i.v. immune globulin (pooled or CMV hyperimmune) has markedly improved survival to more than 50% in allogeneic bone marrow transplantation patients with CMV pneumonitis. [180,181] Despite the limited enrollment and uncontrolled nature of these trials, the dramatic results have led to an acceptance of the ganciclovir and immune globulin combination as a standard of care for patients with CMV pneumonitis. Whether i.v. immunoglobulin is a useful adjunct to ganciclovir for CMV pneumonitis or even colitis in other types of patients is less clear.

Other herpesviruses, VZV and HSV, can also cause diffuse pneumonitis. These viruses, however, rarely cause isolated pulmonary disease but instead are associated with visceral dissemination from dermatomal or cutaneous disease.

RSV can cause severe lower respiratory tract disease with a high mortality rate, especially in patients undergoing therapy for AML or bone marrow transplantation. [108,109] RSV usually can be diagnosed rapidly using a direct immunofluorescent antibody stain performed on a nasal wash specimen.

Although no randomized controlled studies have addressed the utility of ribavirin in immunocompromised cancer patients, it may be appropriate to extrapolate from existing data in other pediatric populations that suggests that there may be a benefit of this therapy. [103,104,106] There is anecdotal evidence from several small case series reports that adult bone marrow transplantation and acute leukemia patients with lower tract RSV respond favorably to ribavirin aerosol in addition to therapy with i.v. immunoglobulin or RSV immune globulin. [109,114] Survival appeared to be improved particularly if the drug was administered early in the course of infection.

Adenovirus, parainfluenza virus, influenza, and human herpesvirus type 6 have been described as causes of interstitial pneumonitis in pediatric cancer patients. All of these entities cause diffuse interstitial pneumonitis and are also associated with a high rate of mortality. [182,183]

**Infections of the Gastrointestinal Tract**

The GI tract is frequently a source of infection in the neutropenic patient. The GI mucosa is in direct contact with the external environment. Normally, it acts as a mechanical barrier, but it can be disrupted by tumor invasion or by damage from chemotherapy or radiotherapy. The mucosal ulceration induced by these treatments offers a potential site for bacterial, fungal, and viral colonization, invasion, and infection. The normal microbial balance of the GI tract is also altered by serious illness, mechanical factors (e.g., surgery, altered motility), hospital exposures, and antimicrobial therapy, further contributing to colonization and potential infection.

**Infections of the Oral Cavity**

The most common mucosal infection encountered in the immunosuppressed cancer patient is thrush, a superficial oral infection caused by *C. albicans*. The lesions usually appear as whitish plaques with slightly raised indurated borders. This infection is easily controlled in most cases by topical antifungal agents, such as clotrimazole troches. If there is no response to topical therapy, fluconazole at doses of 50 to 100 mg per day has proved highly effective for the treatment of oropharyngeal candidiasis. [184] Despite their relatively benign appearance and ease of control, superficial fungal infections may serve as a nidus for systemic dissemination and contribute to poor nutrition.

HSV is the most common viral pathogen isolated from mucosal lesions. Clinically, the lesions usually appear as clear vesicular eruptions, frequently in clusters or “crops” on an erythematous base, either periorally or intraorally. However, intraoral lesions may be nondescript, are often ulcerative, and can be confused with the stomatotoxicity usually attributed to chemotherapy. Diagnosis may be confirmed by rapid shell vial culture (requiring 24 to 48 hours) or may be made presumptively by the identification of multinucleated giant cells (positive Tzanck preparation) or by a positive fluorescent-antibody reaction. Unlike the self-limited and relatively innocuous presentation in an immunocompetent host, herpetic stomatitis may be a serious complication in an immunosuppressed patient. The severity of the local tissue involvement, inflammation, and eschar formation has deleterious consequences, causing discomfort and also serving as a nidus for bacterial superinfections. Acyclovir (750 mg per $m^2$ per day divided every 8 hours) is the preferred treatment because of its infrequent toxicity, ease of administration, and documented efficacy in reducing the duration of viral shedding and shortening the time to healing. [185] HSV-seropositive patients undergoing bone marrow transplantation or induction regimens for acute leukemia should receive prophylactic acyclovir, orally or parenterally, to prevent HSV reactivations.

If the patient does not have specific local or systemic indications of infection, management of mucosal ulceration should be directed toward symptom management. There is no evidence that maintenance of oral hygiene reduces the incidence or severity of oral mucositis induced by chemotherapy, although it is probably beneficial with regard to reduction of infectious complications.

Periodontal disease (including gingivitis and periodontitis) is especially problematic among adults, and the incidence of periodontal disease in the general population increases with age. However, periodontal disease may be found among pediatric cancer patients and is related to the adverse effects of the antineoplastic therapy on the host defense mechanisms normally operative in the oral mucosa. Gingivitis is an inflammation of the superficial structures of the mucosal epithelium, and periodontitis describes an involvement of the supportive structures of the teeth. A prospective study of 38 febrile patients receiving therapy for acute myeloblastic leukemia revealed a 32% incidence of oral infections. [186] The periodontium was the most common site, and cultures of infected sites revealed mixed aerobic and anaerobic flora. [187] The presence of marginal or necrotizing gingivitis, characterized by an erythematous periapical gingiva, is caused by anaerobes and should be treated with specific anti-anaerobic agents such as clindamycin, metronidazole, or imipenem.

**Esophagitis**

Clinically significant esophagitis may result from infectious or noninfectious causes. A syndrome clinically identical to infectious esophagitis occurs in patients who have received extensive chest wall or mediastinal irradiation, or it may result from the severe mucosal toxicity that is associated with certain chemotherapeutic regimens.

Infectious esophagitis most commonly occurs among neutropenic patients. Patients most often present with subacute onset of retrosternal burning chest pain and odynophagia. Fungal, viral, and bacterial organisms can all cause an infectious esophagitis in the immunocompromised host. [188,189]

The occurrence of infectious esophagitis in a non-neutropenic patient is rare. In non-neutropenic patients, esophagitis is most commonly caused by chemical irritation of the distal esophagus by refluxed gastric contents, as may be associated with chemotherapy-induced emesis. These patients are best managed with judicious use of antacids, histamine antagonists, or omeprazole. If the non-neutropenic patient has persistent esophageal discomfort, esophagoscopy with brushings for culture and biopsy should be performed. In non-neutropenic patients with AIDS, herpetic or *Candida* esophagitis is the most common infection.

Chemotherapy-induced mucositis, neutropenia, mediastinal radiation, and gastroesophageal reflux are important risk factors for esophageal candidiasis. Concomitant infections caused by HSV, CMV, and bacteria may coincide with or precede esophageal candidiasis. The absence of oral lesions cannot be used to discount the presence of esophageal candidiasis. Esophagoscopy with mucosal biopsy is the most definitive method for establishing a diagnosis, but it may not be feasible, practical, or safe in many children and is not recommended in those who are neutropenic. Accordingly, an empiric approach is often warranted in children with suspected esophageal candidiasis. Initial therapy with oral fluconazole is often effective; however, failure to symptomatically respond promptly is an indication for empiric AMB. Furthermore, the resolution of symptoms does not necessarily signify the eradication of esophageal candidiasis in granulocytopenic patients, and

therapy should continue until the resolution of the neutropenia. Persistent symptoms may indicate the presence of another infectious process, such as HSV, CMV, or bacterial esophagitis. If the patient has persistent symptoms after 48 hours of i.v. AMB, an empiric course of acyclovir (750 mg per $m^2$ per day, given at 8-hour intervals) is reasonable, because the second most likely pathogen (or co-pathogen) is HSV. If the patient responds, acyclovir should be given for 7 days. If symptoms do not improve, esophagoscopy and biopsy should be pursued if feasible.

**Intra-Abdominal Infections**

The clinical presentation of even common intra-abdominal processes such as appendicitis or infectious diarrheal syndromes can be altered by granulocytopenia and compounded by complications of cancer or its treatment. For example, obstructive lesions may be caused by primary or metastatic cancer; cholangitis or a conjugated hyperbilirubinemia may be caused by extrahepatic biliary obstruction by tumor; and chronic abdominal pain or diarrheal syndromes may be secondary to bowel wall infiltration by malignant disease or infection.

Intra-abdominal complaints must be expeditiously evaluated with a thorough physical examination, including a judiciously performed rectal examination. Repetitive rectal examination must not be performed in the neutropenic patient, because bacteremia and local infection may result. Appropriate studies include routine hematologic and serum chemistry values, amylase, total and direct bilirubin, and flat and upright abdominal radiographs. Additional diagnostic procedures such as abdominal or pelvic ultrasound, CT, or MRI should be pursued in the appropriate settings. Invasive diagnostic or radiographic procedures such as barium enema and endoscopy should be avoided in the neutropenic patient.

Typhlitis is a necrotizing infection of the cecum restricted almost entirely to cancer patients. Typhlitis most commonly occurs in association with prolonged granulocytopenia in patients with acute leukemia, although any granulocytopenic patient is at risk. Patients most often present with subacute or acute onset of right lower quadrant abdominal pain, which frequently becomes generalized over several hours, with fever, diarrhea, and prostration. The etiologic agents responsible for typhlitis include anaerobes and gram-negative bacillary organisms, especially *P. aeruginosa*. *Clostridium* sp., including *C. difficile*, may also be responsible. Optimal management initially involves supportive care, including nasogastric suction, adequate fluid replacement, and adjustment of antimicrobial therapy to cover resistant gram-negative and anaerobic species. The most sensitive diagnostic radiographic technique is CT or MRI, which should be performed in all neutropenic patients with right lower quadrant pain for prompt diagnosis.[190] Aggressive surgical intervention to resect necrotic bowel may be beneficial for a subset of patients, and the timing of such intervention is critical. Criteria that have been proposed for sending a patient to surgery are persistent GI bleeding after resolution of neutropenia; thrombocytopenia and clotting abnormalities; evidence of free intraperitoneal perforation; clinical deterioration requiring support with vasopressors or large volumes of fluid, suggesting uncontrolled sepsis; and development of symptoms of an intra-abdominal process, in the absence of neutropenia, which would normally require surgery.[191,192]

**Other Abdominal Infections**

An infrequently encountered clinical syndrome is peritonitis and bacteremia caused by *Clostridium*. Patients with clostridial peritonitis classically have a fulminant clinical course with fever, tachycardia, abdominal wall ecchymoses and crepitance, and significant hemolysis.[193] *Clostridium perfringens* and *Clostridium septicum* are the organisms most frequently isolated. Serious infections with *Clostridium* (especially *C. septicum*) can occur in the absence of fever and should be considered in the afebrile neutropenic patient with abdominal pain. A less fulminant bacteremic syndrome caused by *Clostridium tertium* has also been described in granulocytopenic children with acute leukemia who received broad-spectrum antimicrobial therapy for long periods.[194] Most *Clostridium* isolates are sensitive to the penicillins, cephalosporins, and clindamycin, with the exception of *C. tertium*, which requires vancomycin therapy.

Colitis has long been associated with the administration of clindamycin, ampicillin, and broad-spectrum b-lactam antibiotics. *C. difficile*, a normal component of intestinal flora in approximately 3% of healthy adults, has been isolated as the causative agent in most cases.[195] The symptomatic disease is related to *C. difficile* colonization of the gut after some perturbation of the normal gut flora, followed by overgrowth and toxin production by the organism.[196] In cancer patients, antineoplastic agents and antibiotics contribute to the alteration of intestinal flora and increase the risk of *C. difficile* colitis. Patients classically present with acute generalized abdominal pain, fever, leukocytosis, and watery or mucoid foul-smelling diarrhea. A high index of suspicion is necessary because of the occurrence of similar abdominal symptoms in cancer patients receiving chemotherapy or periabdominal radiation. Cancer patients with diarrhea with or without fever and abdominal pain should be evaluated with routine stool cultures and a *C. difficile* toxin assay. Toxin production, not just a culture positive for *C. difficile*, is necessary for diagnosis, because as many as 42% of hospitalized patients receiving antibiotics are culture positive but not toxin positive.[197]

Treatment of documented *C. difficile*–associated colitis is accomplished with either oral vancomycin or metronidazole. The use of vancomycin as first-line therapy is discouraged because of concern about emergence of resistant gram-positive organisms. There is a 10% to 20% rate of relapse, although most patients respond to a second course with the same or alternative therapy. Some patients have repetitive episodes of *C. difficile* diarrhea with each cycle of chemotherapy. *C. difficile* may be nosocomially transmitted, and patients who are culture and toxin positive should be placed on enteric precautions.

An infrequently encountered clinical problem is a hyperinfection syndrome caused by the intestinal nematode *Strongyloides stercoralis*.[198] The clinical syndrome of fever, nausea, vomiting, diarrhea, and abdominal pain is caused by invasion and ulceration of the GI mucosa by the filariform larvae. Chemotherapy is thought to promote the maturation of these larvae from a quiescent rhabditiform stage. Polymicrobial sepsis may accompany the intestinal invasion, presumably as a result of the ulcerated mucosa. Overwhelming pulmonary and meningeal involvement has been described in immunocompromised patients. Diagnosis requires demonstration of the larvae in feces or duodenal fluid and should be sought in patients who have resided in subtropical climates or endemic regions. Treatment of asymptomatic infestation is accomplished with thiabendazole (25 mg per kg b.i.d. for 2 days) or ivermectin, 200 µg per kg. Ivermectin has evolved as the preferred drug with efficacy comparable to that of thiabendazole but with less toxicity. Immunocompromised patients with the hyperinfection syndrome should be treated for 2 to 3 weeks, although the mortality rate remains high despite such long-term treatment.[199] Due to its long half-life, ivermectin may be used on days 1, 2, 13, and 14 of a 2-week treatment cycle.

**Hepatic Infections**

Hepatitis may be caused by a variety of infectious agents, including those that infect the liver primarily (e.g., hepatitis A, B, C, and the delta agent) and those that infect secondarily (e.g., HSV, CMV, Epstein-Barr virus, coxsackie B virus, adenovirus, toxoplasmosis, *C. albicans*). In addition, many chemotherapeutic agents and other medications that immunocompromised cancer patients may be receiving are associated with noninfectious hepatitis. In addition to the morbidity (e.g., fever, nausea, emesis, arthritis, arthralgia) and deaths directly attributable to hepatitis, significant alteration in hepatic function can affect the pharmacokinetics of antineoplastic agents and other medications and should be taken into consideration when dosing drugs.

Hepatitis C virus (HCV) is now well-recognized as the predominant cause of classic transfusion-associated non-A, non-B hepatitis.[200,201] More recently it has been recognized as a significant issue for long-term survivors of childhood cancer. In one study of cancer patients who had been transfused between 1961 and 1992, 6.6% were found to be infected with HCV.[202] At the time of infection most cases are subclinical but can be characterized by fatigue and hepatomegaly with elevated or fluctuating levels of aminotransferases. Incubation is approximately 8 weeks, with the onset of symptoms, if any, typically occurring 5 to 12 weeks after exposure. Approximately 85% of patients infected with HCV develop chronic infection.[111] Of those with chronic hepatitis, 20% to 25% develop cirrhosis, and 2% to 9% die due to complications of cirrhosis or hepatocellular carcinoma.

Persistent antihepatitis C antibody is usually but not always found in patients with chronic disease, whereas those with the acute, self-limited illness may have only a transient rise in antibody titers. The development of antibody after hepatitis C exposure is usually delayed, with a mean interval of approximately 20 weeks and occasionally much longer. Late serologic testing is therefore essential for the diagnosis of chronic hepatitis C.[203] All patients positive for HCV antibodies by enzyme immunoassay or by recombinant immunoblot assay should be tested for HCV RNA by PCR. In addition, the viral genotype should be determined, as this information may impact therapy.[110]

Some patients with chronic HCV infection can be effectively treated with a combination of interferon and ribavirin. The decision of who and when to treat is based on a number of factors, including severity of disease, concurrent comorbidity and preexisting contraindications to ribavirin or interferon. There have been two large randomized, controlled trials of combination therapy in patients with documented HCV infection and persistently elevated transaminases, and without significant coexisting medical conditions or decompensated hepatic cirrhosis. In both studies patients had improved outcomes with combined therapy compared to monotherapy.[204,205] In these studies the overall rate of sustained response for the combination regimen was 64% to 69% in patients with genotype 2 and 3 and 28%

for those with genotype 1. The combination regimen has significant side effects that required medication discontinuation in 8% to 19%.

Hepatitis B may result in acute or chronic infections, including chronic active hepatitis, chronic persistent hepatitis, and asymptomatic carrier states. The incidence of hepatitis B was previously as high as 10% to 20% among cancer patients, but with the introduction of effective prophylactic measures, particularly widespread use of hepatitis B vaccine and efficient screening methods to detect infected donors, the number of patients affected has fallen dramatically. Immunosuppressive therapy may increase the likelihood of development of a chronic carrier state among patients infected with hepatitis B, making it important to know the patient's hepatitis status before initiating antineoplastic therapy. In addition, an acute hepatic failure syndrome may result from acute infection in an immunosuppressed patient. [206,207] Lamivudine is licensed for the therapy of hepatitis B in adults, but there are no data available for use in children.

The delta agent, an incomplete RNA virus, requires prior infection or coinfection with the hepatitis B virus to manifest clinically. Therefore, hepatitis caused by the delta agent occurs only in three circumstances: as a superimposed infection in a patient with active hepatitis B, as an acute hepatitis in a chronic hepatitis B carrier, and as a chronic infection in a chronic hepatitis B carrier. Coinfection with hepatitis B and delta virus can produce a more fulminant or severe hepatitis than can infection with hepatitis B alone. In the United States, the incidence of delta virus is low and will presumably decrease further as hepatitis B incidence diminishes with widespread vaccination efforts. [208,209]

Several viruses may involve the liver secondarily as part of a more widespread systemic infection. The Epstein-Barr virus, CMV, HSV, VZV, rubella, rubeola, mumps, adenovirus, and coxsackie B virus have been associated with hepatic enzyme elevations. The hepatic dysfunction attending these secondary infections is usually self-limited and less severe than that associated with primary viral hepatitis. However, fulminant hepatic necrosis, coma, and death have been described with several of these agents (especially HSV, CMV, and VZV) in the immunocompromised host. Patients with acute hepatitis caused by HSV or VZV should receive acyclovir, and those with CMV hepatitis may require ganciclovir or foscarnet.

All cancer patients with clinical or biochemical evidence of hepatitis should undergo a serologic evaluation to attempt to characterize the etiologic agent. Serum tests for hepatitis B surface antigen, antibodies to hepatitis A (IgM and IgG), and hepatitis B core antigen (IgM and IgG) can identify patients with hepatitis A or B. Repeated testing for the development of antibody to hepatitis C over a period of weeks to months may be required to diagnose this infection, in addition to evaluation by PCR for HCV RNA. Patients with a negative antibody screen for all of these viruses can have hepatitis caused by an agent other than the classic hepatitis viruses or a noninfectious cause. In addition to viral infection, hepatic enzyme elevation or hyperbilirubinemia can occur with bacterial sepsis, fungal infection of the liver (especially *Candida* or *Aspergillus*), or toxoplasmosis.

**Hepatic Candidiasis**

A syndrome referred to as *hepatic candidiasis* occurs in patients recovering from a long period (usually more than 7 days) of neutropenia. [210,211] It is characterized by the presence of bull's-eye lesions in the liver on ultrasound or CT scan ( Fig. 41-5). These lesions are not apparent in patients who are neutropenic but rather become recognizable at the time of neutrophil recovery. Patients have persistent fever after recovery from an episode of neutropenia, frequently with right upper quadrant discomfort, nausea, and increased serum alkaline phosphatase. The lesions are granulomas and consist of an inner core of necrosis (in which the yeast and pseudohyphae can be found) surrounded by a ring of inflammatory cells and an outer ring of fibrosis. These imaged lesions change over time and with treatment and resolution may become calcified, an important end point of therapy.

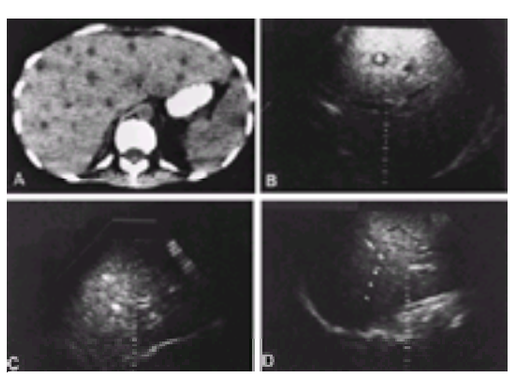

**FIGURE 41-5. A:** Computed tomography scan of the liver shows numerous rounded areas of decreased attenuation compatible with the diagnosis of hepatic candidiasis. This is a nonspecific finding. **B:** Ultrasound examination in the same patient shows the typical bull's-eye lesion of candidiasis characterized by a central echogenic nidus surrounded by a radiolucent halo. This is seen early in the natural history of the disease. **C:** The radiolucent halo is now less obvious than in **(B)**. This illustrates the variable appearances of candidal abscesses on ultrasound studies at different times in the same patient. **D:** Later in the course of the disease, the microabscesses become denser (*arrow*). Note the acoustical shadow posterior to the lesion, caused by attenuation of the sound beam ( *arrowheads*). (From Thaler M, Bader J, O'Leary T, Pizzo PA. Hepatic candidiasis in immunocompromised patients. Ann Intern Med 1988;108:88–100, with permission.)

The pathogenesis of hepatic candidiasis is one of chronic disseminated candidiasis—that is, the liver as well as the spleen, kidneys, lungs, brain, eyes, and other tissues may be infected by antecedent candidemia. Blood cultures may be negative before the diagnosis of hepatic candidiasis and are almost invariably negative on recovery from neutropenia. The diagnosis is based on a high index of suspicion and should be confirmed with liver biopsy. Hepatic tissue may be obtained by a small midline open incision in children and by laparoscopy in adults. These procedures in our experience are well tolerated in patients with hepatic candidiasis. Splenic lesions may be the only apparent abscesses on CT scan. On laparoscopy or biopsy, however, the liver in these cases is usually found to be infected by small lesions below the threshold of CT scan detection. MRI scans with gadolinium contrast may reveal lesions that are not otherwise visible on CT scans. The detection of the *Candida* enolase antigen and D-arabinitol in blood has been used as an adjunctive tool for diagnosing invasive candidiasis, including hepatic candidiasis, with encouraging results. [212,213]

Hepatic candidiasis poses a therapeutic challenge. Long courses of treatment are necessary, with the average duration of AMB administration approximately 6 to 12 months. The addition of 5-FC may further enhance antifungal activity if the kidney or CNS is involved. Current experience with lipid formulation of AMB indicates that it is effective in the treatment of hepatosplenic candidiasis, with curative total doses of drug being delivered in a much shorter time and with fewer side effects than those that have been seen with conventional AMB. [87] Experimental data and several encouraging reports suggest that fluconazole has significant efficacy in the treatment of hepatosplenic candidiasis in patients in whom AMB has not controlled the infection or who have had serious AMB-related toxicities. [214,215] and [216] Failures of fluconazole in this setting have also been described, however, suggesting that caution should be exercised until definitive clinical trials are performed. A reasonable approach is to treat children initially with AMB and 5-FC and, after the patient is afebrile or has response of lesions to change therapy to fluconazole at 12 mg per kg in two divided doses. AMB lipid complex would be indicated in children refractory to or intolerant of AMB or fluconazole.

Whether patients with hepatosplenic candidiasis should continue to receive antineoplastic therapy, which may cause neutropenia with the risk for progressive hepatosplenic involvement or breakthrough fungemia, can be a major dilemma. We have found that this infection in patients with cancer can be treated successfully under careful observation through repeated courses of chemotherapy-induced neutropenia without progression of hepatosplenic candidiasis or breakthrough fungemia. [217]

**Perianal Cellulitis**

The overall incidence of perianal cellulitis has decreased in recent years, presumably because of the early use of empiric antibiotics when granulocytopenic patients become febrile. Nonetheless, the risk for perianal cellulitis remains, especially for patients in the high-risk category, those with chronic (more than days) and profound (less than 100 cells per $mm^3$) granulocytopenia. Predisposing factors include perirectal mucositis caused by chemotherapy or localized radiotherapy, hemorrhoids, anal fissures, and any type of rectal manipulation (e.g., barium enema, anoscopy, sigmoidoscopy). Accordingly, constipation should be avoided, because passage of hard stool promotes the formation of anal fissures and increases the risk of perianal infection.

The most common pathogens in perianal cellulitis are aerobic gram-negative bacilli (e.g., *P. aeruginosa, K. pneumoniae, E. coli*), enterococci, and bowel anaerobes. Because of the involvement of anaerobic organisms, antibiotic coverage must include a specific antianaerobic agent such as clindamycin or metronidazole in addition to broad-spectrum aerobic coverage. Therapy should start at the first complaints of tenderness. Additional supportive measures include sitz baths three or four times daily, stool softeners, a low-bulk diet, and avoidance of unnecessary rectal manipulation, especially repetitive digital examinations. Surgical intervention should be restricted to cases that demonstrate the development of an abscess or progressive involvement of the ischiorectal fossa despite optimal antimicrobial therapy. [218,219]

## INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

### Shunt and Reservoir Infections

Children with intraventricular shunts and Ommaya reservoirs are at highest risk for central nervous system infection. The responsible pathogens are most commonly those colonizing the adjacent skin: coagulase-positive and coagulase-negative staphylococci, *Corynebacterium* sp., and *Propionibacterium acnes*; rarely, they are gram-negative bacilli. [220,221] Patients may be totally asymptomatic, in which case the diagnosis may be made by noting cerebrospinal fluid cultures repetitively positive for the same organism, or patients may have fever, headache, increased intracranial pressure, and meningismus. Most patients with Ommaya reservoir infections can be treated successfully without the need to remove the device, although this may require a combination of intrathecal and i.v. therapy. [221]

### Meningitis

Infectious meningitis in cancer patients is rare but associated with significant morbidity and mortality. [222,223] Meningitis in cancer patients can be subtle in presentation. Children with cancer presenting with fever and signs or symptoms of CNS dysfunction should be promptly evaluated. Radiographic evaluation, most commonly with a head CT scan with contrast, should be preformed if there is concern for a potential focal process. Evaluation of cerebrospinal fluid should include aerobic culture and Gram's stain, cryptococcal antigen determination, fungal culture, and cytologic analysis, in addition to the routine studies such as cell count and differential, protein, and glucose.

In a retrospective series of 40 pediatric cancer patients with meningitis, it was found that the most common risk factor was recent neurosurgical manipulation, associated with 65% of the cases.[224] Of the patients that were neutropenic, most presented with fever and altered mental status but without meningismus. The pathogens causing infection were similar to those that are commonly associated with bacteremia in this patient population, including gram-positive organisms ( *S. epidermidis*, a-hemolytic *streptococci, Enterococcus*), gram-negative organisms (*E. coli, K. pneumoniae, P. aeruginosa*), and fungi (*C. albicans* and *Aspergillus*). The primary risk factor for death related to meningitis was neutropenia at presentation.

### Encephalitis

A variety of viral, bacterial, parasitic, fungal, and rickettsial agents can be associated with encephalitis or encephalomyelitis. The relative prevalence of the various etiologic agents is altered in different populations of immunodeficient patients. For example, patients with humoral immune abnormalities, especially hypogammaglobulinemia, may have a chronic encephalitis caused by poliovirus or echovirus. [225,226] Patients with abnormalities of cell-mediated immunity more often have encephalitis caused by measles.[227] Although HSV reactivation is common during cancer chemotherapy, herpes encephalitis does not appear to be more common in immunosuppressed patients.[228] Encephalitis caused by Epstein-Barr virus, CMV, or VZV also occurs sporadically but may be more common among patients with AIDS.

Patients with encephalitis or encephalomyelitis commonly present with signs of meningeal irritation (e.g., fever, headache, nuchal rigidity) and evidence of altered mentation. Confusion may progress to stupor and finally to coma. Focal neurologic signs and seizures are relatively common. Cerebrospinal fluid examination may demonstrate a pleocytosis (10 to 2,000 cells per $mm^3$), with a predominance of mononuclear cells. An increased number of erythrocytes has been reported with HSV encephalitis. Protein levels are usually elevated, and the glucose characteristically remains within the normal range except for a decreased level in mumps infection.

For the cancer patient with focal neurologic deficits or altered mentation, it is important to separate infectious, metabolic, toxic, and neoplastic causes. CT scan or MRI of the brain may help in some instances, especially if a focal lesion is visualized, but specific diagnosis of encephalitis in an immunocompromised patient is often difficult. Acute and convalescent serum antibody titers against herpesviruses, echoviruses, and the less common arboviruses should be measured. Specific cerebrospinal fluid antibody may be detected in cases of mumps, HSV, or VZV. However, increasing experience with the technique of PCR to detect viral DNA in cerebrospinal fluid may supplant some of these older and less precise diagnostic procedures. In the past, the diagnosis of HSV encephalitis required a brain biopsy, but more recently, the application of PCR to cerebrospinal fluid has allowed for prompt and highly specific diagnosis, with excellent correlation to brain biopsy results. treatable central nervous system infection that can present as an encephalitis in an immunosuppressed child or as a mass lesion in the patient with AIDS is caused by the obligate intracellular parasite *Toxoplasma gondii*.[229] Toxoplasmosis may represent newly acquired or reactivated infection and is rarely limited to the central nervous system, usually occurring in concert with fever, lymphadenopathy, hepatitis, pneumonia, myocarditis, and pericarditis. The cerebrospinal fluid typically manifests a mononuclear pleocytosis, elevated protein, and a normal glucose concentration. A battery of serologic tests is available for the diagnosis of toxoplasmosis, but most of these are limited in their applicability to the immunosuppressed patient because of suboptimal antibody responses. Definitive diagnosis requires demonstration of the parasite within tissue sections.

Standard treatment of active toxoplasmosis is pyrimethamine combined with sulfadiazine, with the addition of folinic acid to reduce pyrimethamine-induced myelotoxicity. For immunodeficient patients, therapy should be continued for 4 to 6 weeks after the resolution of all clinical symptoms and signs. The combination of high-dose i.v. clindamycin with the usual doses of pyrimethamine appears to be a useful alternative for treatment of toxoplasmosis in patients who are unable to tolerate sulfa-based drugs. Other agents combined with pyrimethamine, such as atovaquone, dapsone, or a newer macrolide, may also be effective. [230]

### Brain Abscesses

The important differential diagnosis in a cancer patient with evidence of a focal lesion within the central nervous system is between metastatic or primary malignancy and a brain abscess. Predisposing factors for brain abscess include a contiguous infected site (e.g., otitis, sinusitis, dental abscess), a history of penetrating cranial trauma, congenital cardiac disease, bacterial endocarditis, and pulmonary infection. In addition to the usual aerobic and anaerobic bacteria responsible for abscesses in immunocompetent patients, fungal and nocardial species are particularly prone to cause disease in immunosuppressed patients. These infections are usually associated with pulmonary infiltrates.

Early evaluation and specific diagnosis are crucial in the management of brain abscess, because effective antimicrobial or neurosurgical therapy is available. Diagnosis is commonly made by radiographic demonstration of a localized mass and followed by an open or closed procedure to aspirate or resect the localized lesion.

## INFECTIONS OF THE GENITOURINARY TRACT

The genitourinary tract is infrequently the source of infection in the immunocompromised child. However, local obstruction resulting from tumor, neurologic dysfunction mediated by spinal cord compression or medications (e.g., vincristine, narcotics), and local therapeutic maneuvers (e.g., radiotherapy, surgery, bladder catheterization) can predispose cancer patients to genitourinary infection. Most commonly, gram-negative aerobic bacilli (e.g., *E. coli, Klebsiella* sp.,*Proteus* sp., *P. aeruginosa*) or enterococci are the causative agents.

In a neutropenic patient, urine culture of a single organism should prompt antibiotic intervention whether or not the patient is symptomatic. The presence or absence of leukocytes in the urine must not be relied on as a diagnostic criterion in the neutropenic patient.

Differentiation between colonization and tissue invasion is particularly difficult for fungal pathogens. Fungal colonization is especially prevalent among patients with indwelling urinary catheters and those receiving broad-spectrum antimicrobial therapy. Unlike the typical situation with bacterial pathogens, in which clinical signs and symptoms are apparent, fungal invasion of the genitourinary tract may be insidious. The repetitive isolation of a particular fungal species (usually *C. albicans, Candida tropicalis*, or *Candida glabrata*) in association with fever, deteriorating renal function, or, rarely, flank pain should prompt the institution of systemic AMB. Heavily

colonized bladders or superficial bladder infections manifested by persistence of positive urine cultures despite removal of predisposing factors may be effectively treated by fluconazole, which is highly concentrated in the urine.

Adenovirus, particularly type 11, and polyomavirus (BK virus) have been associated with hemorrhagic cystitis in bone marrow transplant recipients. Bladder pain and gross hematuria may occur suddenly and can be very difficult to control. The occurrence of aggressive adenovirus nephritis causing renal failure and ultimate mortality has been described as well. Urinary tract infections may be localized, but in some cases they precede a disseminated adenovirus infection. Detection of virus as well as defining serotype is possible by PCR. [231] Case reports of successful control of adenoviral and polyomavirus hemorrhagic cystitis with i.v. ribavirin, vidarabine, and ganciclovir have yet to be confirmed by larger studies. [232,233,234 and 235]

## INFECTIONS OF THE CARDIOVASCULAR SYSTEM

Cardiovascular infections are relatively uncommon among cancer patients, probably because of the early institution of broad-spectrum antimicrobial therapy. However, cancer patients who have predisposing factors for a cardiovascular infection, such as dental abscess, a history of i.v. drug abuse, or congenital cardiac anomaly, are at risk. Endovascular infections are more likely with the increased use of indwelling venous access catheters. Although gram-positive bacterial species (e.g., *Enterococcus*, viridans or b-hemolytic streptococci, *S. aureus*) most commonly cause endovascular infections, aerobic gram-negative bacilli and fungi may also cause disease. These latter pathogens are particularly difficult to eradicate, and morbidity and mortality remain discouragingly high.

The clinical manifestations of endocarditis in the immunosuppressed patient are similar to those in an immunocompetent patient. Nonspecific complaints of fever, chills, malaise, fatigue, night sweats, and weight loss are common, but these complaints are nondescript, and the degree of diagnostic specificity that may be ascribed to them is slight. In most instances, the diagnosis must be made on the basis of the physical and laboratory evaluations. The numerous physical stigmata of endocarditis (e.g., heart murmurs, splinter hemorrhages, Roth's spots, splenomegaly) should be sought, but the diagnosis is confirmed by the isolation of an organism from multiple blood cultures.

The complications of endovascular infection in immunocompromised patients are similar to those described for patients without cancer. Valvular insufficiency resulting in congestive heart failure, emboli, and renal failure is the most serious. Fungal endocarditis is particularly likely to cause large-vessel embolization. [236] Patients with *Candida* or *Aspergillus* endocarditis are treated with valve replacement and AMB.

Therapy must be directed at the specific pathogen. The isolation of *S. aureus* or *S. epidermidis* from multiple blood samples, even if the patient has an indwelling catheter, is not a sufficient criterion for prolonged antibiotic therapy unless a valvular infection can be confirmed. A standard 10- to 14-day course of therapy suffices for these patients.[141]

## INFECTIONS OF THE SKIN

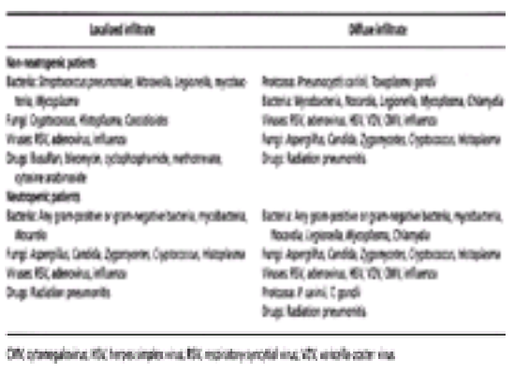
The skin can be infected primarily or in association with bacteremia (e.g., *P. aeruginosa*, *Aeromonas hydrophila*, *S. marcescens*), fungemia (*Aspergillus*, *Candida*, *Trichosporon*, *Fusarium*, and *Cryptococcus*), or viremia (e.g., HSV, VZV, and CMV). Skin lesions may permit the early diagnosis of an established infection, and new lesions should be aspirated or biopsied and the material stained (e.g., Gram's stain, wet mount, and methylene blue) and cultured. If the lesions are vesicular, the base should be scraped, smeared on a glass slide, and submitted for a direct fluorescent antibody test to detect HSV or VZV. Alternatively, a Tzanck preparation may be performed to look for the multinucleated giant cells that are characteristic of these viral infections.

Primary varicella is a significant concern for the child with cancer, because the mortality rate in untreated patients ranges from 7% to 20%, usually owing to visceral dissemination to the liver, lung, and central nervous system. [237] Severe abdominal pain, back pain, or evidence of inappropriate antidiuretic hormone secretion may herald multisystem involvement, indicating the need for prompt use of acyclovir. [238] High doses of i.v. acyclovir (500 mg per $m^2$ every 8 hours) are indicated for the treatment of primary varicella or herpes zoster in very immunosuppressed patients. [239]

Scabies infestation may present as papules, excoriations, or vesicles located particularly in the interdigital spaces and on the palms, soles, face, neck, and scalp. A severe variant of scabies, Norwegian or crusted scabies, occurs in immunodeficient patients and is characterized by widespread, hyperkeratotic, crusted lesions. These lesions contain heavy burdens of mites and their eggs, and Norwegian scabies is highly contagious. Lindane 1% lotion has been the standard treatment for scabies, although it is not recommended for young children because it is cutaneously absorbed and may cause neurologic side effects. Permethrin 5% cream is poorly absorbed and may be more effective than lindane, so it is recommended for children. The antiparasitic agent, ivermectin, has been shown to be highly effective in curing both routine cases and Norwegian scabies after a single oral dose; the simplicity and efficacy of this therapy may preclude use of the topical agents. [240]

## PREVENTION OF INFECTION IN CHILDREN WITH CANCER

In a multitude of clinical trials investigating the efficacy of various measures to prevent or reduce infection, the most important antiinfective measure identified has been the simplest: careful hand washing practices.[241,242] Several approaches have been taken to decrease the acquisition of new organisms or to suppress those already colonizing the cancer patient (Table 41-5). However, no method has stood out as singularly effective and each has both promise and problems.



CMV, cytomegalovirus; HSV, herpes simplex virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus

**TABLE 41-5. CAUSES OF PNEUMONIA IN CANCER PATIENTS**

### Preventing the Acquisition of New Organisms

Because most of the organisms responsible for infections in patients with cancer are derived from the endogenous flora, and almost half of this flora is acquired from the hospital environment, much attention has been directed toward preventing the acquisition of potential pathogens. Inanimate objects within the hospital environment (e.g., faucet aerators, showerheads, respirators, plants, and floors) are reservoirs of pathogenic organisms. Although epidemiologic studies have for the most part investigated nonimmunocompromised patients, they do suggest that transmission from inanimate sources usually requires a human vector. Therefore, the most efficacious intervention that can be performed is adherence to strict hand washing precautions. The easiest way to enforce such a policy is to educate the child and parents to disallow contact with anyone who has neglected to wash his or her hands.

A second maneuver to decrease the acquisition of new organisms is to maintain a cooked diet during periods of granulocytopenia, with avoidance of fresh fruits and vegetables and unprocessed dairy products, because these foods are naturally contaminated with gram-negative bacteria, especially *K. pneumoniae*, *E. coli*, and *P. aeruginosa*.[243,244]

Environmental sources can contribute to fungal (especially *Aspergillus*) and bacterial (*Legionella*) colonization and infection. In medical centers in which *Aspergillus* is

a significant problem, special air filtration systems such as high-efficiency particulate air filters (HEPA filters) or water purification systems may be helpful.

Although the technique of reverse isolation has often been used, it does not significantly reduce the acquisition of new organisms in an environment in which hand washing techniques are strictly followed. There is no compelling reason to enforce this policy, particularly because the extra expense, time consumption, and inconvenience are not balanced by a beneficial effect. [245,246]

Total protective isolation is a comprehensive regimen designed to reduce the patient's endogenous microbial burden while preventing the acquisition of new organisms (Table 41-5). A sterile environment is created in a clean-air room with constant positive-pressure airflow. It is maintained by an aggressive program of surface decontamination and sterilization of all objects that enter the room and by an intensive regimen to disinfect the patient, including oral nonabsorbable antibiotics, skin antiseptics, antibiotic sprays and ointments, and a low-microbial diet. The total protective environment does reduce the number of infections in profoundly granulocytopenic patients. It is expensive, however, and because of the improvement in treating established infections, it does not offer a survival advantage to patients. Total protective isolation is not necessary for the routine care of cancer patients. Modifications of the approach are used, on occasion, for patients undergoing allogeneic bone marrow transplantation and for patients who are likely to experience periods of 30 or more days of profound neutropenia. [246]

## PROPHYLACTIC ANTIBIOTICS

### Antibacterial Prophylaxis

Because the GI tract is the source of many of the pathogens causing microbiologically defined infections, investigators initially evaluated the efficacy of reducing the endogenous GI flora with oral nonabsorbable antibiotics (e.g., vancomycin, gentamicin, polymyxin B, nystatin, framycetin, colistin). This technique has not been especially valuable because the agents used are unpalatable and poorly tolerated, making compliance a significant problem, especially among patients receiving emetogenic chemotherapy. Equally disturbing has been the emergence of resistant bacterial strains among patients receiving aminoglycoside-containing regimens. Therefore, prophylactic regimens aimed solely at reducing the total endogenous GI flora cannot be recommended. [247]

A modified technique is selective decontamination of the GI tract with antibiotics that preserve the anaerobic flora while reducing the aerobic bacteria. This approach is based on experimental data showing that preservation of the anaerobic flora of the GI tract provides colonization resistance against aerobic and fungal organisms.[248,249] The most commonly investigated agent for selective decontamination has been TMP/SMX. Early trials of this drug in children and adults demonstrated a reduction in all infections and in bacteremic episodes. Many follow-up clinical trials have yielded conflicting results, however, perhaps because of variability in study design, nonuniform patient populations, and failure to monitor compliance properly. The potential for reduction in infectious morbidity and mortality must be balanced against two important adverse effects observed with the prophylactic use of TMP/SMX: the prolongation of granulocytopenia and the emergence of resistant organisms. Successful selective decontamination of the GI tract requires excellent patient compliance and close microbiologic monitoring to adjust the antimicrobial regimen properly for resistant or newly emerging species. Strict compliance with the oral regimens is often difficult, however, and surveillance cultures are costly in time and money.[250,251,252,253 and 254]

The fluoroquinolone antibiotics are attractive for oral prophylaxis because of their bioavailability, excellent tolerability, and broad spectrum. These agents have been widely used in adult oncology patients but are not generally used for prophylaxis in children because of concern of cartilage toxicity with long-term exposure. In adults, comparative studies have shown no advantage of the oral quinolones over more traditional regimens of infection prophylaxis such as for prevention of infection. [255,256] Moreover, none of the studies of antibacterial prophylaxis has demonstrated a reduction in mortality caused by infection. Further, prophylaxis with fluoroquinolones is not recommended by the IDSA.

### Antifungal Prophylaxis

Because of the increasing incidence of invasive mycoses in immunocompromised hosts, antifungal prophylaxis also has been extensively studied. The topic of antifungal prophylaxis in neutropenic patients has been reviewed in detail elsewhere. [257] Orally administered andtopically applied nystatin, AMB, miconazole, and clotrimazole, as well as systemically absorbed ketoconazole, fluconazole, and itraconazole have all been evaluated as prophylactic antifungal agents in neutropenic patients. Most prophylactic regimens have been aimed at reducing invasive infections caused by *Candida* sp. and, by virtue of the antifungal activity of the agents used, would not be expected to have a significant impact against *Aspergillus* or filamentous fungal pathogens. Data from laboratory studies of fluconazole were particularly compelling for the use of fluconazole for prevention of invasive candidiasis in neutropenic hosts. [258]

Several randomized, placebo-controlled studies demonstrated that the prophylactic administration of fluconazole to recipients of allogeneic bone marrow transplant recipients reduced the incidence of both disseminated and mucosal candidiasis. [258,260] These and other studies using prophylactic antifungal regimens observed a shift in the colonization pattern of fungal organisms, usually toward more resistant fungi. [261] The prophylactic regimens may eradicate the susceptible fungi while permitting overgrowth and ultimate invasion by more resistant species, including *C. glabrata*, *Candida krusei*, *Candida parapsilosis*, *Aspergillus*, and other filamentous species of fungi. Fluconazole is most beneficial in prevention of disseminated candidiasis in the neutropenic allogeneic bone marrow transplant recipient. The decision to use fluconazole or other prophylactic antifungal agents in other patient populations depends on the institution, the cytotoxic regimen used, and the patient. [262]

### Antiviral Prophylaxis

Several antiviral agents can be used for selective prophylaxis. Amantadine has proved prophylactic activity against influenza A (although not against influenza B) in school children treated with 100 mg per day, and it is likely to be similarly efficacious in the immunocompromised host. [263] It may be particularly useful if given to a susceptible immunocompromised individual for a prolonged period during an influenza A outbreak or during “flu season.” Rimantadine has equivalent protective efficacy but is associated with fewer central nervous system effects than is amantadine. Postexposure prophylaxis of family members is also effective with both drugs, although it is recommended that simultaneous prophylaxis and treatment of influenza A be avoided within a household so that resistant virus strains do not become a significant problem.[264] The use of the newer neuraminidase inhibitors in immunocompromised patients as prophylactic agents has not yet been studied.

Acyclovir, given orally or i.v., is effective prophylaxis against reactivations of HSV in seropositive bone marrow transplantation patients and in those undergoing intensive chemotherapy for acute leukemia.[265,266] Doses ranging from 250 mg per $m^2$ i.v. every 8 hours to 5 mg per kg i.v. every 12 hours, and oral doses of 400 mg given three times daily are effective in preventing reactivation of HSV in seropositive individuals. Although acyclovir is therapeutically less active against VZV or CMV, prophylactic acyclovir given to bone marrow transplant recipients may nonetheless decrease the occurrence of zoster and invasive CMV disease during the posttransplant period.[267,268]

Acyclovir-resistant strains of HSV have been recognized with increasing frequency, particularly in patients with HIV infection. In bone marrow transplantation patients and in those with HIV infection, resistant HSV is associated with indolent disease, characterized by the persistence of low-grade, chronic mucocutaneous lesions that may be painful and refractory to routine or even high-dose acyclovir therapy. The clinical presentation of resistant HSV infection is preceded by a prolonged continuous or intermittent course of acyclovir, such as a prophylactic regimen. Discontinuation of acyclovir often allows the reemergence of a sensitive virus strain from the mixed pool of latent virus. Refractory lesions may be responsive to foscarnet. [269]

Ganciclovir prophylaxis can reduce the frequency of invasive CMV disease in patients who have received bone marrow transplants. The marked myelosuppressive effects of ganciclovir are problematic for most patients, however, making it an unattractive routine prophylactic agent. Targeting of those who are at highest risk for severe CMV disease has yielded the practice of “preemptive” ganciclovir therapy—that is, treatment of patients who have evidence of CMV reactivation in surveillance assays (CMV antigenemia, CMV PCR). This approach has been shown to effectively suppress CMV culture positivity in most patients and, accordingly, it is associated with dramatically fewer cases of invasive CMV disease. [270,271]

### *Pneumocystis* Prophylaxis

Successful prophylaxis for PCP was originally described in high-risk oncology patients. [121] In the 1980s PCP emerged as the most common opportunistic infection in individuals with AIDS. Most large studies of prophylactic regimens since that time have been undertaken in the HIV population, with results then abstracted for use in other immunocompromised groups.

The decision to administer antimicrobial prophylaxis to oncology patients should be based on underlying disease and the type and intensity of immunosuppressive therapy. The reported incidence of PCP in patients before the routine use of prophylaxis was 22% to 43% in children with ALL, 25% in patients being treated for rhabdomyosarcoma,[121] 16% of those having undergone a bone marrow transplant[272] and 27% of those children with severe combined immunodeficiency syndrome. In some centers almost half of the cases of PCP occur in patients with solid tumors.[273] In addition, patients with brain tumors receiving significant doses of corticosteroids are also at risk.[274]

There are several effective regimens and the choice between them often depends on the patient's tolerance of their various side effects. TMP-SMX, b.i.d for 3 days per week should in general be considered the first-line regimen.[275] For patients who can tolerate this regimen, the failure rate is near zero.[276] The use of TMP-SMX is limited, however, in a significant number of individuals by rash, neutropenia, and GI symptoms. The overall rate of treatment-limiting adverse reactions is variably reported but is estimated at approximately 19 per 100 patient years.[276]

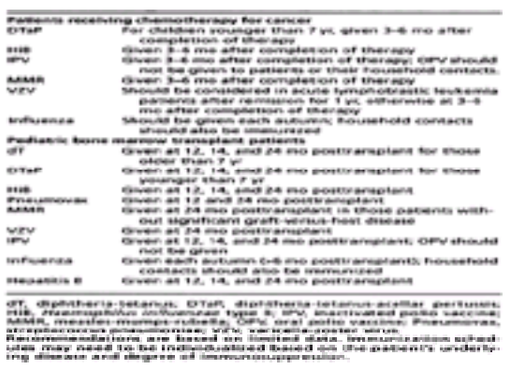
Dapsone administered at a dose of 2 mg per kg per day (with a maximum dose of 100 mg per day) is also effective therapy. The rate of reported failure of prophylactic dapsone ranges from 0% to 21%.[123] The side effects of dapsone include rash, anemia, methemoglobinemia, agranulocytosis, and hepatitis. The incidence of treatment-limiting adverse reactions is estimated to be similar to that of TMP-SMX.

Aerosolized pentamidine administered monthly is also effective therapy, having a comparable failure rate to dapsone.[276] Its primary side effect is bronchospasm at the time of administration. The use of aerosolized pentamidine is often limited in very young children because of technical and compliance issues. Intravenous pentamidine has not undergone sufficient study as a prophylactic regimen to allow it to be recommended.

Atovaquone has been shown to be as effective as dapsone in a single large trial of adult patients with HIV who were intolerant of TMP-SMX.[277] In addition, in patients not already receiving dapsone at the time of randomization it was better tolerated. The most common adverse events include upper GI symptoms and diarrhea. Pharmacokinetic studies have been performed in children with HIV giving rise to dosing recommendations of 30 mg per kg per day in children aged 1 to 3 months and older than 24 months and 45 mg per kg per day for those aged between 3 and 24 months. These doses were chosen to attain a serum level of 15 µg per ml, which in adult patients is associated with therapeutic success of greater than 95%.[129]

## IMMUNIZATION

Immunizations are an important part of the care of healthy children. The routine vaccination schedule is often disrupted for younger children undergoing therapy for cancer. No universally accepted recommendations for immunizing children undergoing therapy for cancer exist, but some general guidelines can be applied ( Table 41-6). The American Academy of Pediatrics and the Centers for Disease Control and Prevention regularly publish updated guidelines regarding immunization practices in healthy and immunocompromised patients.[278,279] In considering reasonable vaccine strategies, information about the host's risks for infection need to be balanced with the safety and efficacy of each vaccine in this population. Two main concerns have to be considered: (a) will the patient be able to mount (or maintain) an antibody response, and (b) could the vaccine itself (in the case of attenuated live organisms) cause disease?[280]



| | |
|---|---|
| **Patients receiving chemotherapy for cancer** | |
| DTaP | For children younger than 7 yr, given 3–6 mo after completion of therapy |
| HIB | Given 3–6 mo after completion of therapy |
| IPV | Given 3–6 mo after completion of therapy; OPV should not be given to patients or their household contacts. |
| MMR | Given 3–6 mo after completion of therapy |
| VZV | Should be considered in acute lymphoblastic leukemia patients after remission for 1 yr, otherwise at 3–6 mo after completion of therapy |
| Influenza | Should be given each autumn; household contacts should also be immunized |
| **Pediatric bone marrow transplant patients** | |
| dT | Given at 12, 14, and 24 mo postransplant for those older than 7 yr |
| DTaP | Given at 12, 14, and 24 mo postransplant for those younger than 7 yr |
| HIB | Given at 12, 14, and 24 mo postransplant |
| Pneumovax | Given at 12 and 24 mo postransplant |
| MMR | Given at 24 mo posttransplant in those patients without significant graft-versus-host disease |
| VZV | Given at 24 mo posttransplant |
| IPV | Given at 12, 14, and 24 mo posttransplant; OPV should not be given |
| Influenza | Given each autumn (>6 mo posttransplant); household contacts should also be immunized |
| Hepatitis B | Given at 12, 14, and 24 mo posttransplant |

dT, diphtheria-tetanus; DTaP, diphtheria-tetanus-acellular pertussis; HIB, Haemophilus influenzae type b; IPV, inactivated polio vaccine; MMR, measles-mumps-rubella; OPV, oral polio vaccine; Pneumovax, streptococcus pneumoniae; VZV, varicella-zoster virus.
Recommendations are based on limited data. Immunization schedules may need to be individualized based on the patient's underlying disease and degree of immunosuppression.

**TABLE 41-6. IMMUNIZATIONS IN PEDIATRIC CANCER PATIENTS**

### Live Virus Vaccines

Measles-mumps-rubella is a live virus vaccine that is contraindicated in patients undergoing active chemotherapy. In the early development of the vaccine one of eight children vaccinated with the Edmonton b strain measles vaccine died of the disease. Immunization has been shown to be safe and is recommended for patients with ALL after completion of therapy, with the usual waiting period of 3 to 6 months to allow for T-cell reconstitution. It has been recommended that patients having completed therapy for Hodgkin's disease not be vaccinated given their prolonged T-cell deficits.[281] Household contacts can be safely vaccinated because transmission of the vaccine virus does not occur.[278] The risk associated with wild-type measles is considered to be higher than the risk for vaccine-related complications.[282,283]

Oral polio vaccine is a live virus vaccine that is contraindicated in immunocompromised patients and their household contacts.[278] In activated polio vaccine can be used safely during treatment for nonimmunized patients. Reimmunization after the completion of therapy with inactivated polio vaccine is generally recommended.[281]

The varicella vaccine is potentially the most extensively studied vaccine in immunocompromised children. Varicella vaccine is now universally recommended for healthy individuals in early childhood and for susceptible older children and adolescents. It is not contraindicated in household contacts of immunosuppressed individuals.[278] The use of varicella vaccine has been studied extensively in children with ALL, and it has been shown to be safe with the most common toxicity being a mild rash occurring in 50% of those treated.[284] The efficacy of the vaccine has been shown in the degree of protection from acquiring the disease from household contacts, with 14% developing mild disease and complete protection from severe varicella. There has been concern about herpes zoster in immunocompromised vaccinees, but it has been shown that leukemic vaccinees are less likely to develop zoster than are comparable children with leukemia who had wild-type infection.[284,285] Passive immunoprophylaxis either with varicella zoster immune globulin within 96 hours of exposure or regular infusions of gamma globulin may be indicated in the child at high risk.

### Live Bacteria Vaccines

The only common live bacterium that potentially could be used in a childhood immunization schedule is the bacillus Calmette-Guérin (BCG) vaccine. Although not used in the United States, it is still recommended in more than 100 countries worldwide.[278] Because disseminated bacillus Calmette-Guérinitis can occur in immunocompromised children, it is generally contraindicated in that population.[286,287,288] and [289]

### Inactivated Bacteria, Inactivated Viruses, Polysaccharide-Protein Conjugates, and Toxoids

Diphtheria-pertussis-tetanus vaccine has been evaluated in young infants with neuroblastoma and in children receiving maintenance therapy for various malignancies, and these children have been shown to mount adequate responses.[290,291] It has been suggested that children should be given this vaccine at scheduled times even while undergoing active therapy. The alternative approach is to immunize at the end of therapy. To decrease the risk of seizures (a special concern in children with brain tumors or preexisting seizure disorders) it is currently recommended that all children should receive the acellular form of the pertussis component (DtaP).

Patients with ALL as well as those with Hodgkin's disease, treated at a time when splenectomy was routine, have been shown to be at a higher risk for invasive

pneumococcal and *H. influenzae* type B disease.[292,293 and 294] Pneumococcal infection contributes significantly to the morbidity and mortality of pediatric HIV infection.[295,296] The polysaccharide pneumococcal vaccine is only moderately immunogenic when studied in oncology or transplantation populations. Evaluation of the newer pneumococcal vaccines needs to be carried out in children with cancer; however, it is currently recommended that patients who are expected to be functionally or anatomically asplenic should receive pneumococcal vaccine.

The *H. influenzae* type B conjugate vaccines have been tested in children who were on treatment or who had completed treatment for ALL, as well as in children with HIV infection. The responses were not normal, but those that did respond had protective antibodies that were measurable for 12 months. [292,297,298] Although the data are not definitive, some authors recommend the vaccination of *all* immunosuppressed individuals with pneumococcal, *H. influenzae* type B, and meningococcal vaccines.[279,281]

The efficacy of the influenza vaccine in patients undergoing cancer therapy is controversial. In the pediatric age group it was shown in a small retrospective study of patients with ALL that immunization decreased the incidence of influenza infection compared to nonimmunized controls. [299] Despite the lack of definitive data, it is generally recommended that all immunocompromised children and their household contacts receive yearly influenza vaccines before flu season. [279]

## GRANULOCYTE TRANSFUSIONS

In the 1970s there was significant interest in the use of granulocyte transfusions for the treatment of patients with severe infections and neutropenia. Support for this modality waned as results from studies revealed mixed efficacy and occasional severe toxicity.

Between 1972 and 1982 there were a number of randomized controlled studies published evaluating the efficacy of granulocyte transfusions. Some studies showed a clinical benefit for the neutrophil transfusion group compared to controls, [300,301 and 302] some showed no overall benefit but efficacy in certain subgroups of patients, [303] and some reported no benefit.[304] On further analysis of these studies, one potential explanation for the varying results was the use of varying cell dose, with studies using higher doses showing efficacy and those using a smaller cell dose (i.e., less than 0.4 to 0.5 × $10^{10}$ PMNs transfused) being less effective.[305]

Recent technical advances, with the possibility of collecting significantly larger numbers of PMNs per pheresis, have made a reevaluation of this modality of interest.[306,307] It is estimated that an adequate cell dose for a single granulocyte transfusion should be greater than 1 × $10^{10}$ PMN cells.[308] Previously, the collection of adequate numbers of cells from normal donors proved to be difficult, even with corticosteroid stimulation. More recently, the use of granulocyte colony-stimulating factor (G-CSF) to mobilize granulocytes in normal healthy donors has been shown to be safe and effective, allowing for the collection of significantly more PMN cells per cycle of pheresis.[309,310]

Cell collection techniques have also dramatically improved. Cell collection is now done by centrifugation as opposed to filtration. The process of filtration has been shown to activate neutrophils and lead to smaller cell yields and higher rates of toxic reactions, presumably related to activated white blood cells, whereas centrifugation yields higher numbers of cells with potentially less infusion-related toxicity.

The use of “matched” donors has been suggested as an important factor in granulocyte transfusion efficacy. [306] There is evidence that alloimmunization to HLA antigens decreases cell recovery in the recipient and may also correlate with the incidence of transfusion reactions. [311,312] There is clearly a need for further randomized controlled trials to reevaluate efficacy and safety of this modality given the progress made in pheresis and transfusion medicine. Studies using adequate cell dose and matching techniques are imperative.

## CYTOKINES

The development of cytokines for adjunctive therapy in oncology patients was greeted with great enthusiasm. The potential ability of the colony-stimulating factors (CSFs) to attenuate the marrow toxic effects of cancer chemotherapy, radiotherapy, and bone marrow transplantation was hoped to have a large impact on infectious morbidity and mortality. CSFs have come to have an important role in the care of the oncology patient, although it is clear that they should be used judiciously to maximize medical benefit, limit potential toxicity, and be cost-effective.

The two cytokines that have undergone the most intense study for their potential to decrease the infectious morbidity of chemotherapy are G-CSF (filgrastim) and granulocyte-macrophage-CSF (GM-CSF; sargramostin). G-CSF promotes the proliferation and maturation of neutrophilic precursors and the function of mature neutrophils. GM-CSF additionally enhances the number and function of cells of the monocyte-macrophage lineage. There are limited data comparing the two agents directly in terms of their relative efficacy and toxicity, [313] which in general are considered similar. The recommended use of a given agent varies, primarily based on the indication for which it was developed. [314]

The doses of the two agents are 5 µg per kg per day for G-CSF and 250 µg per $m^2$ per day for GM-CSF. The use of higher doses has not been associated with improved clinical outcome.[315,316] The exception to this is in the setting of donor stimulation for peripheral blood stem cell pheresis, in which there may be an advantage to the use of 10 µg per g per day of G-CSF.[317,318,319 and 320] In either setting, rounding the dose to the closest vial size is likely to save costs without detriment to the patient. The CSFs should be administered subcutaneously but may also be given i.v.

In 1994 the American Society for Clinical Oncology (ASCO) published the first set of recommendations for the appropriate use of growth factors based on an extensive review and analysis of the relevant literature. [314] These recommendations were updated in 1997.[321]

### Primary Prophylaxis: Use of Colony-Stimulating Factors in the Prevention of Fever and Neutropenia

The use of CSFs for primary prevention involves their administration immediately following a course of myelotoxic chemotherapy in an attempt to decrease the depth and duration of neutropenia and the associated risk of infection.

There is evidence from a number of studies that the use of CSFs in patients receiving significantly myelotoxic chemotherapy can reduce the incidence of fever and neutropenia. In addition, for patients receiving prophylactic CSF, the duration of neutropenia, antibiotic administration, and hospitalization may be shortened.[322,323,324,325,326 and 327] Results regarding the effect of incidence of documented infection have been more variable. Importantly, no study to date has shown a significant effect of disease-free or overall survival.

The use of G-CSF as primary prophylaxis for patients undergoing less aggressive chemotherapeutic regimens with a low incidence of fever and neutropenia is of unclear medical or economic benefit. If the number of patients receiving the cytokine injections far exceeds those who would potentially experience any beneficial effects, the expense of the growth factor and the discomfort of daily injections in all patients could offset the advantage to a few patients.

The ASCO guidelines recommend the use of CSF for primary prophylaxis if the anticipated rate of fever and neutropenia for a given chemotherapeutic regimen is greater than 40%.[321] This degree of myelosuppression and associated fever is relatively rare in adult oncology, but may be more common in pediatrics, in which dose-intensive therapy is common. In addition to those groups of patients with anticipated high rate of fever and neutropenia, there may be individuals who may benefit from primary prophylaxis, such as patients who have received extensive prior chemotherapy or radiation therapy to their pelvis or spine and are therefore expected to have more significant myelotoxicity from any given regimen.

End points for G-CSF discontinuation have varied according to different protocols, but the goal should be to maintain the peripheral leukocyte count at protective levels until the intrinsic bone marrow activity is sufficient to independently achieve these levels. Although investigators have targeted total leukocyte counts of 10,000 cells per mL as a stopping point for cytokine administration, lower end points are being explored to improve the cost-effectiveness of this intervention.

A survey of clinicians in the Pediatric Oncology Group indicated that CSFs are used for primary prophylaxis more commonly in children than in adults. [328] This was in part due to the fact that, unlike their adult counterparts, the majority of pediatric patients are on clinical research protocols that often require or suggest growth factors use.

### Secondary Prophylaxis: Use of Colony-Stimulating Factors in Patients with a Prior Episode of Fever and Neutropenia

The restriction of CSF administration to patients with a history of a prior episode of fever and neutropenia may provide a more select patient population that may benefit from CSFs. In addition, this strategy may avoid their use, and associated toxicities and costs, in a group of patients for which they would provide limited or no benefit. The ASCO recommendations encourage chemotherapy dose adjustment for subsequent cycles of therapy for patients that have developed fever and neutropenia on a prior cycle unless there is evidence that maintaining dose intensity is beneficial to patient outcome. If maintaining dose intensity is important, CSFs should be considered for secondary prophylaxis. Interestingly, in the Pediatric Oncology Group survey of practicing pediatric oncologists, dose modification was rarely selected as a mode of secondary prophylaxis and conversely, CSF use was common.[328]

### Tertiary Prophylaxis: Use of Colony-Stimulating Factors in Patients with Known Neutropenia but without Fever

There have been two small studies and one large trial of the initiation of CSFs at the time of a patient's diagnosis with neutropenia. [329],[330] and [331] Although the number of days of neutropenia was shortened, there was no measurable clinical benefit in terms of days in the hospital, days of antibiotic therapy, or documented infections. Given these data it is recommended that CSFs not be routinely initiated for patients presenting with neutropenia alone.

### Use of Colony-Stimulating Factors for the Adjunctive Treatment of Fever and Neutropenia

There have been a series of prospective, randomized, controlled trials [332],[333],[334],[335],[336],[337],[338] and [339] addressing the question of whether administration of G-CSF or GM-CSF as adjunctive therapy to antibiotics, beginning at the time of diagnosis of fever and neutropenia, has beneficial effects on patient outcome. In general, as in the use in other circumstances, CSFs have been shown to decrease the duration of neutropenia and have variable effects on days of fever, days of antibiotic administration, and days of hospitalization. There was no measurable impact on infection-related mortality. In terms of cost savings, the use of CSFs in this situation has also shown mixed results, with some studies showing reduced costs,[333],[339] whereas others showed increased costs in the CSF-treated groups.[334],[335] and [336] The ASCO recommendations are that CSFs not routinely be initiated as adjunctive therapy for the patient presenting with fever and neutropenia. [321]

There may be a group of high-risk febrile neutropenic patients for which the initiation of CSFs may be of benefit. This may include a group with profound or prolonged neutropenia, patients with prior severe infections, or in elderly or debilitated patient groups. There is not sufficient data to date to assess whether the use of CSFs at the time of fever and neutropenia in these situations is clinically beneficial.

### Use of Colony-Stimulating Factors in Documented Infections in Immunocompromised Hosts

G-CSF and GM-CSF can enhance antimicrobial activity of granulocytes and monocytes *in vitro*. Accordingly, they may augment microbicidal activity of these effector cells in the immunocompromised patient and may therefore be useful as adjuncts to antimicrobial agents in the treatment of ongoing infections. Although there are some data from animal models to suggest a survival benefit of CSFs given during septic episodes, one small clinical study in leukemic children showed no benefit to the delayed addition of G-CSF at the time of documented sepsis.[340],[341] Based on current therapy recommendations, it is most likely that patients who are at highest risk for sepsis will already be receiving CSF prophylaxis during neutropenia.

### Use of Colony-Stimulating Factors in Stem Cell Transplantation

Both G-CSF and GM-CSF have been shown to significantly accelerate neutrophil recovery after autologous and allogeneic bone marrow and peripheral blood stem cell transplantation.[342],[343],[344],[345],[346],[347] and [348] The effects on the incidence of fever or documented infections, antibiotic usage, or duration of hospitalization have been more variable. Furthermore, these cytokines do not augment platelet recovery, which remains a significant problem for transplant recipients. Nonetheless, CSFs are used as part of most immediate posttransplant regimens for their impact on shortening the duration of neutropenia. Whether they affect long-term outcomes, such as graft failure or survival, is still not apparent. Generally, cytokine therapy is continued until engraftment is documented and an adequate circulating neutrophil count has been observed on successive days. The doses, routes, and schedule of administration are similar to those used in chemotherapy-induced neutropenia. In selected circumstances, it may be reasonable to consider the use of a hematopoietic growth factor in patients who are slow in neutrophil engraftment or who demonstrate an inadequate recovery after autologous or allogeneic transplantation. [321]

## FUTURE DIRECTIONS

With the evolution of new cancer therapies there will continue to be new challenges in the assessment and management of infections in children with cancer. The use of novel chemotherapeutic agents, such as monoclonal antibodies and anti-angiogenic agents will provide new challenges in the assessment of their impact on the child's immune function and the associated infectious complications.

In addition to novel chemotherapeutic agents, there are numerous new antimicrobial agents in the process of development. These drugs will need to be evaluated not only for safety and efficacy but also for cost-effectiveness and ease of administration. It is critical that as new drugs are developed, knowledge about their appropriate use in children is obtained.

Further understanding of the components and function of the immune system in the “normal” host and how it is affected by cancer and its therapy will continue to inform the best clinical care. Understanding risk factors for infection, the spectrum of clinical presentations of infectious disease in different hosts, and the appropriate use of diagnostic tests and therapeutic agents will continue to be challenges in the care of the child with cancer.

# NUTRITIONAL SUPPORTIVE CARE

LORI J. BECHARD
ORLY ESHACH ADIV
TOM JAKSIC
CHRISTOPHER DUGGAN

## INTRODUCTION

The high prevalence of undernutrition in adult [1,2] and pediatric[3] cancer patients has been appreciated for decades and continues to be documented. [4,5] Although the prognostic significance of malnutrition among patients with cancer is controversial, [6,7] it is generally accepted that nutritional support is an important component of medical therapy (Table 42-1). Indeed, because of the unique nutritional needs of pediatric patients, [8] including energy needs for growth and development, randomized, controlled studies have been difficult to perform concerning this inherently vital supportive therapy. Parents of children with cancer are quite concerned about issues of appetite and other gastrointestinal symptoms, even when death is imminent.[9] The frequent use of complementary and alternative dietary supplements among families with cancer also underlines the importance that patients attach to nutritional therapy. [10] This chapter reviews the definitions, epidemiology, etiology, and practical therapy of nutritional problems of the pediatric cancer patient.

**TABLE 42-1. RATIONALE FOR NUTRITION SCREENING AND INTERVENTION IN PEDIATRIC CANCER PATIENTS**

## DEFINITION OF CANCER CACHEXIA

Cachexia has been classically defined as a severe state of malnutrition characterized by anorexia, weight loss, muscle wasting, and anemia. [11,12] In its broader sense, cancer cachexia has also been used to describe a variety of metabolic phenomena, including hypoalbuminemia, hypoglycemia, lactic acidosis, hyperlipidemia, impaired hepatic function, glucose intolerance with insulin resistance, elevated gluconeogenesis, skeletal muscle atrophy, visceral organ atrophy, and anergy. [13]

More recently, Roubenoff and colleagues[14] have proposed that the terms *wasting*, *cachexia*, and *sarcopenia* be considered as three distinctly defined entities ( Table 42-2). *Wasting* is defined as involuntary weight loss and is found in patients with anorexia nervosa, cancer, advanced human immunodeficiency virus infection, and marasmus. *Cachexia*, in contrast, is defined as involuntary loss of fat-free mass in the setting of minimal or no overall weight loss. This type of malnutrition can be seen in some patients with cancer, as well as in those with critical illness and early human immunodeficiency virus infection. In this scenario, patients of normal weight can still be malnourished due to reduced lean body mass. Because a decline in lean body mass has important functional and prognostic significance, even in the setting of stable or increasing weight, this type of malnutrition is important to identify. *Sarcopenia* refers to the involuntary loss of muscle mass that occurs with aging.

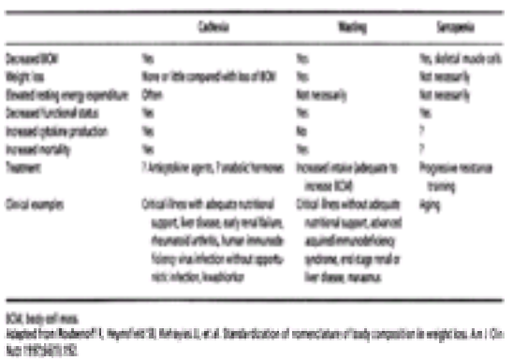

**TABLE 42-2. PARADIGMS OF WEIGHT LOSS/BODY COMPOSITION CHANGES IN ILLNESS**

The pattern of weight loss and changes in body composition in patients with illness are important to consider, because differential loss of body fat versus fat-free mass implies a different etiology and prognosis of malnutrition. For example, prolonged fasting in the absence of metabolic perturbation (as can be seen in adolescents with anorexia nervosa) leads to a predictable decrement first in body fat, then in body protein stores. [15] In these cases, energy repletion is usually successful with the provision of adequate energy, protein, and micronutrients.

In contrast, weight loss in the setting of cancer, infection, or other metabolic stress is composed of both fat and fat-free mass. [16] Because the energy density of fat-free mass is lower than that of fat, the body's use of lean body mass as an energy and amino acid source can lead to weight loss that can be quite profound and rapid. It is this loss of fat-free mass that is of significance, because loss of lean body mass is associated with important functional changes such as loss of strength, decreased immune function, decreased pulmonary function, increased disability, and death. [17,18,19,20 and 21]

More important, the provision of nutritional support to these patients may not be adequate to reverse the catabolic effects of the underlying condition. In the early days of parenteral nutrition (PN) use, it was hypothesized that aggressive PN could overcome the catabolism of cancer and other critical illnesses [22]; however, this has not proved to be the case. Instead, a more realistic appreciation for the limitations of nutritional support has emerged. [23] The utility and indications for PN in the pediatric cancer patient are reviewed in the following sections.

## EPIDEMIOLOGY

The occurrence of wasting among cancer patients is determined by host susceptibility, tumor type and location, and anticancer regimen. Because during infancy and adolescence there are increased energy needs for growth, children in these age groups are at increased risk of malnutrition. Other patients at higher risk of malnutrition are those with advanced disease and metastatic solid tumors, and those needing protracted chemotherapy ( Table 42-3). A striking example of malnutrition is the diencephalic syndrome in which a hypothalamic tumor presents with severe weight loss in the setting of a normal appetite. [24,25]

| |

J Parenter Enteral Nutr 1990;14(3):315; and Rickard K, Grosfeld J, Coates T, et al. Advances in nutrition care of children with neoplastic diseases: a review of treatment, research, and application. J Am Diet Assoc 1986;86:1666.

**TABLE 42-3. RISK FACTORS FOR MALNUTRITION IN PEDIATRIC CANCER PATIENTS**

In contrast, most patients with low-risk acute lymphoblastic leukemia (ALL), those with nonmetastatic solid tumors, and patients in remission are generally able to maintain a normal weight. It should be noted, however, that weight loss may be considered the final step in a long process of nutritional perturbation in patients with cancer and, as such, may not be a sufficiently sensitive marker for malnutrition. For example, one study of prepubertal children with low-risk ALL followed body weight and lean body mass over time (as measured by sum of four skinfold measurements and bioelectrical impedance). Although body weight in the cancer patients was no different than age- and sex-matched controls, lean body mass declined substantially with the use of chemotherapy. [26] Thus, mere reliance on body weight to document normal nutritional status may lead to an underestimate of the prevalence of lean body mass depletion.

## ETIOLOGY AND PATHOPHYSIOLOGY

It is axiomatic that patients with weight loss exhibit reduced dietary intake, malabsorption or maldigestion of foods, or altered energy and nutrient needs. The challenge of nutritional care of pediatric cancer patients is that all three mechanisms may be at play, so that the clinician's diagnostic and therapeutic tools must be broadly considered.

In brief, weight loss or gain is due to energy imbalance, which ensues when energy intake differs from total energy expenditure (TEE). TEE, in turn, is considered to be the sum of several components of the energy equation. That is, in a steady state,

$$\text{Energy intake} = \text{TEE} = \text{REE} + E_{activity} + E_{growth} + E_{losses} + \text{SDA}$$

where

REE = resting energy expenditure (an estimate of basal metabolic rate),

$E_{activity}$ = energy needs for activity,

$E_{growth}$ = energy needs for normal growth,

$E_{losses}$ = energy needs for obligatory losses in urine and stool,

SDA = specific dynamic action of food, the energy needs for digestion and absorption

Weight loss occurs when any of the components of TEE are higher than expected and are not matched by a compensatory increase in energy intake. Weight gain occurs when energy intake exceeds TEE. Although an increase in energy intake is the most common reason for overweight, reduction in energy of activity has also been implicated in the development of obesity.[27]

### Decreased Nutrient Intake

Many studies have confirmed the clinical impression that cancer patients, especially when undergoing chemotherapy or radiotherapy, ingest lower amounts of nutrients than do age-based standards[28]; these dietary changes, therefore, place them at risk of negative energy balance and micronutrient deficiencies. For example, more than two-thirds of teenagers with ALL were found to be consuming less than 80% of the recommended dietary allowance for energy. [26]

There are multiple reasons for decreased nutrient intake. One is the well-known occurrence of circulating cytokines, including tumor necrosis factor alpha (formerly called cachectin), that induce anorexia. [11] The effects of proinflammatory cytokines have been studied as the etiology of multiple metabolic phenomena of cancer and its treatment and are more fully considered below.

Another important reason for decreased nutrient intake is anorexia and other gastrointestinal side effects of chemotherapy and radiotherapy. Mucosal damage is generally dose related, with increased risk of mucosal toxicity with high-dose induction therapy, escalating dosage patterns, continuous infusion (versus bolus doses),

and combination chemotherapy treatments. High-dose chemotherapy and total body irradiation as conditioning for bone marrow transplantation (BMT) often produce painful oral mucositis that can reduce nutritional intake for days to weeks. Other gastrointestinal side effects of cancer treatment include esophagitis and enteritis with malabsorption and diarrhea; these are more fully described in Chapter 39 and Chapter 44. Taste perception has also been shown to be altered in cancer patients receiving chemotherapy, with an increasing sensitivity to bitter tastes; this phenomenon may lead to reduced food intake, and may make the use of oral supplements difficult.

Psychological factors are also important to consider in evaluating the reasons behind inadequate dietary intake. Depression-related anorexia is probably underappreciated as a cause. Appetite and feeding behaviors are inherently complicated activities of all children, and this behavior can obviously be affected by the onset of illness and its treatment, as well as the psychosocial impact that cancer has on the child and family. The nature of cancer medical care is such that parents often feel that they are relinquishing much of their usual caregiving behavior to the medical and nursing staff. Some parents understandably cling to the provision of food and nutrients as a critical part of parenting; indeed, the terms *nutrition*, *nursing*, and *nurture* all share the same Latin root. Occasionally, such strong feelings concerning food and dietary intake can cause conflict between parent and child and be counterproductive to the goal of optimal nutrition.

### Changes in Energy Expenditure: Resting Energy Expenditure

Although decreased nutrient intake is common in cancer, anorexia alone cannot wholly explain the common development of malnutrition because some patients maintain an excellent intake but still suffer progressive weight loss. Therefore, it is not surprising that much research has focused on the possible role of increased energy expenditure of cancer patients in trying to explain cancer cachexia. Unfortunately, although studies have been performed for more than 50 years on this topic,[29,30] and [31] the issue has not been consistently resolved.

In brief, earlier studies suggested that the energy needs of rapidly dividing cells of the tumor increased the basal metabolic demands of the host from 20% to 90% over predicted needs. Because basal energy needs account for a substantial portion of total energy needs, any increment in basal energy requirements could clearly result in energy imbalance. More recent data have confirmed that hypermetabolism can occur but not in all patients at all times. In a large cohort study, Knox and colleagues[32] studied 200 adult cancer patients using the technique of indirect calorimetry, a noninvasive bedside measure of REE, the clinical estimate of basal metabolic rate.[33] Their subjects had solid organ malignancies, such as tumors of the gastrointestinal, gynecologic, or genitourinary tracts. They found that one-third of patients was hypometabolic (REE was less than 90% of predicted levels), one-fourth was hypermetabolic (REE greater than 110% predicted), and the remaining 40% had normal REE (between 90% and 110% predicted). Older subjects, those with longer duration of disease, and underweight patients tended to have higher REE measurements. Others have reported that tumor type may play a role in effecting energy expenditure. Patients with lung cancer have been reported to have an increased REE, but those with gastric and colon cancer showed no change. [34]

In children, there have been fewer studies of this issue. An infant with diencephalic syndrome was found to have a strikingly increased TEE, as measured by the doubly labeled water technique.[35] Stallings and colleagues[36] measured REE in nine patients with ALL and found that patients with a higher tumor burden (elevated white blood cell count, organomegaly) had an increased REE. A study of 26 patients with ALL or solid tumors in remission showed no evidence of an increased REE when compared to age- and sex-matched healthy controls.[37]

### Changes in Energy Expenditure: Energy of Activity

As noted above, total energy requirements include energy needed for physical activity. Recent studies have shed light on this part of the energy equation in pediatric cancer patients. An interesting population of children with cancer whose energy balance has been studied are those with ALL. Although generally well nourished on presentation, some children with ALL actually become obese.[38] Reilly and colleagues[39] studied 20 preadolescent children with ALL with doubly labeled water, a technique which reliably measures TEE in free-living individuals. [40] Compared to healthy controls matched for age, sex, and body composition, children with ALL had significantly lower TEE than did controls by an average of 282 kcal per day. Most of this reduction was due to reduced physical activity of the patients. A similar study, using a combination of indirect calorimetry and ambulatory heart rate monitoring to measure basal metabolic rate and TEE, also concluded that ALL patients have lower levels of energy expenditure for activity. [41] The implications of these findings for obesity prevention in ALL survivors, as well as children at large, may be significant.

## ALTERATIONS IN MACRONUTRIENT METABOLISM

Children with cancer manifest changes in carbohydrate, lipid, and protein metabolism. The pattern of macronutrient use in malignancy is markedly different than that evident with starvation. The tumor itself seems to impose a pattern of perturbations that lead to catabolism; however, the extent of this response is variable. This may be due to the heterogeneity of tumor types and sizes, variant treatment protocols, and differences in baseline nutritional status. A general understanding of these alterations is, however, useful in anticipating potential metabolic complications as well as planning nutritional therapy.

### Carbohydrate

The changes seen in carbohydrate metabolism that are associated with malignancy generally consist of glucose intolerance, increased gluconeogenesis (the conversion of amino acid carbon skeletons to glucose),[42] and increased Cori cycling (the hepatic conversion of lactate to glucose). [43] Glucose intolerance in cancer patients is at least partially due to the presence of insulin resistance. [44,45] and [46] This has been demonstrated with various tumors by documenting decreased glucose uptake under steady states of hyperinsulinemia induced during glucose clamp studies. The augmented conversion of lactate to glucose may be secondary to increased lactate production by selected tumors. Overall, the enhanced production of glucose provides the tumor with a substrate that is readily metabolized under both aerobic and anaerobic conditions.

### Lipid

Lipid metabolism is also affected by cancer. Alterations include increases in free fatty acid turnover, free fatty acid oxidation, glycerol turnover, and lipolysis. Lipogenesis is reduced. A lipid mobilizing factor has been isolated from the urine of cachectic cancer patients and shows bioactivity with isolated murine adipocytes. [47] As may be expected, these changes are accompanied by a marked loss of body fat that can occur early in the evolution of the malignancy. [48] Children with ALL and widespread solid tumors tend to have elevated triglycerides as do children in remission treated with L-asparaginase.[49] The provision of glucose does not seem to resolve the high rates of fatty acid and glycerol turnover evident in weight-losing cancer patients. [50] Treatment with chemotherapy is associated with decreased fat use in children newly diagnosed with ALL.[36]

### Protein

Another salient derangement of macronutrient metabolism accompanying cancer is the presence of protein catabolism. Hypoalbuminemia is common, whereas the synthesis of acute phase proteins remains high.[51] Some tumors, such as hepatocellular cancer, manifest very high rates of protein turnover and increased protein degradation.[52] An increase in muscle protein breakdown mobilizes amino acids that may afford tumor growth as well as fuel gluconeogenesis. This increased protein breakdown in pediatric cancer patients may be related to falling levels of insulin-like growth factor and insulin-like growth factor binding proteins. [53] In other patients, decreased skeletal muscle protein synthesis seems to be of primary importance.[54] Although the mechanism remains uncertain, a net loss of skeletal muscle protein is a common finding with malignancy and is particularly problematic in the growing child.

### Cytokines

Proinflammatory cytokines commonly associated with cancer cachexia include tumor necrosis factor a (TNF-a), interleukin (IL)-6, IL-1, and interferon g. These cytokines are secreted by macrophages and lymphocytes and may represent the host response to cancer. TNF-a was first identified as a mediator of cachexia in an animal model of infection.[55] In humans, the acute administration of TNF-a produces effects associated with cancer cachexia, including increased fatty acid turnover, elevated glycerol turnover, and increased whole-body protein turnover. [56] Not all patients with cancer cachexia have detectable levels of TNF-a; hence, a paracrine or autocrine mechanism of action may be responsible. Other factors also seem to be involved with the catabolic response to cancer. Circulating IL-6 levels are generally elevated in cancer patients and transfection of the IL-6 gene into nude mice does engender cachexia. [57] As with TNF-a, the precise mechanism of action of IL-6 is unknown. The metabolic roles of IL-1 and interferon g are less well characterized in tumor models; however, as with TNF-a and IL-6, they appear to inhibit lipoprotein

lipase and hence facilitate lipolysis. Various medications with cytokine inhibitory properties, such as pentoxifylline and megestrol acetate, are being evaluated as possible therapies for cancer cachexia.[58]

## CLINICAL ASSESSMENT OF NUTRITIONAL STATUS

The assessment of a child with cancer includes standard elements of a nutritional evaluation: history of past and present illness, review of dietary intake, physical examination, and anthropometric measurements. Attention should also be directed to the significance of body composition changes, as well as a review of pertinent laboratory measures.

### History

A detailed medical history is essential to the nutritional evaluation of a patient. Perhaps the most important historical aspects are the type and stage of the tumor, the intensity of the planned antitumor therapy, and the presence or absence of remission. As noted above, there are important risk factors for the development of malnutrition in cancer patients (Table 42-3).[8]

Nutritional history should include (a) elicitation of current symptoms of cancer and its therapy and their effect on nutrient intake, absorption, and retention; (b) past history, including past growth data; previous antitumor therapy, and its effects on nutritional status; (c) developmental status, with special attention to milestones of feeding skills and swallowing function; (d) known or perceived food allergies or intolerances; (e) medications, with special attention to those with gastrointestinal side effects (Table 42-4); (f) family history, parental heights, and sibling growth patterns; and (g) social history, food preferences/beliefs, and food availability.

| Category | Examples | Side effects |
|---|---|---|
| Chemotherapy | Busulfan | N&V, mucositis, hepatic (high dose) |
| | Cyclophosphamide | N&V, altered tastesmell |
| | Cytarabine | N&V, mucositis, diarrhea |
| | Dactinomycin | N&V, mucositis, hepatic, diarrhea |
| | Doxorubicin | Severe mucositis, N&V, diarrhea |
| | L-Asparaginase | Pancreatitis, hepatic, hyperglycemia, altered tastesmell |
| | Melphalan | N&V, mucositis, diarrhea |
| | Methotrexate | Mucositis, diarrhea, hepatic |
| | Vincristine | Neurotoxicityileus |
| Corticosteroids | Prednisone, dexamethasone | Hyperglycemia, fluid and salt retention, muscle wasting |
| Antibiotics | Augmentin, erythromycin, clindamycin | Diarrheastomach cramps |
| Narcotics | Codeine, morphine | Ileus |
| Radiation | Total body irradiation, focal irradiation | Mucositis, radiation enteritis (depending on site) |

N&V, nausea and vomiting.

**TABLE 42-4. GASTROINTESTINAL SIDE EFFECTS OF TREATMENTS USED IN PEDIATRIC ONCOLOGY**

The ability of children to eat at their appropriate developmental level may affect the nutritional adequacy of their diet. Anorexia, mucositis, and other effects of cancer treatment may interrupt the normal progression of feeding skills in infants and young children. Once arrested, the development of these skills may be difficult to restore. Poor swallowing and chewing abilities lengthen the time required to complete a meal and thus may lead to inadequate consumption of many required nutrients. Children may refuse to eat their preferred foods due to adverse associations or other impairments and thus may self-restrict their intake.

A thorough diet history obtained from the patient or caregivers may be analyzed to detail the nutritional intake of the child with cancer. A 24-hour dietary recall, which is the most rapid dietary intake method, can be easily incorporated into the general history and physical examination. Problems of recall bias, and under- or overreporting of intake have been noted,[59] however.

A prospective food diary, in which a subject measures and writes down all intake for 3 to 7 days, may be the most reliable and valid clinical tool for evaluating nutritional intake. Proper interpretation of these diet records requires consultation with a qualified dietitian. The nutritional composition of these foods is often determined by using one of the common nutritional databases, often with the use of proprietary software.[60] An average daily intake of energy, macronutrients, and micronutrients can then be calculated and compared with published reference data. Prospective diet records should generally be performed while the patient is feeling well, free of the effects of acute illness, and should include at least one weekend day in school-age children.

### Physical Examination

The physical characteristics of a child with cancer may suggest the presence of nutritional problems. Indeed, the predisposition of chemotherapy to affect tissues of rapid turnover (e.g., hair and gastrointestinal mucosa) mirrors the symptoms of deficiency of a wide range of nutrients (e.g., stomatitis with some B vitamins, alopecia with biotin deficiency). Careful inspection and palpation of subcutaneous fat and muscle stores are particularly important in the physical examination, because deficits of these two components of body stores are common in malnutrition.

The general physical examination may show edema as a result of low concentrations of circulating albumin. This can be a subtle finding with only mild hypoalbuminemia. Edema may actually mask progressive muscle wasting and loss of lean body mass. Hypoalbuminemia may be due to poor liver function related to tumor or treatment, inadequate protein intake, or nutrient losses in excess of intake.[61] Painful mouth or esophageal sores caused by mucositis can negatively impact a child's oral intake and thus be an impetus to consider nutritional support.[62] Alopecia and stomatitis, commonly associated with chemotherapy, can also be caused by vitamin or mineral deficiencies.[63] Children who have limited activity due to impairment by disease or treatment side effects may experience changes in appetite or satiety. Recognition of significant changes in the physical examination is a valuable clue to the overall nutritional assessment of children with cancer.

### Anthropometrics

Weight and height measured over time are the mainstays of nutritional monitoring and evaluation.[64] When compared to age- and sex-appropriate standards, these data can provide objective measures of nutritional status and provide the most information for the least inconvenience and cost. Indications for intensified nutritional assessment and monitoring based on weight and height measures are listed in Table 42-5. Weight should be measured daily in the hospital setting and at each office visit for outpatients. Weight of infants should be recorded to the nearest gram with the child wearing no clothes or a diaper. In older children, shoes and heavy clothing should not be worn, and the scale should be accurate to the nearest 0.1 kg. Length should be measured on a length board with a tape measure attached and a moveable footboard. Children older than 2 years should be measured with a stadiometer while standing erect. Height/length measurements should be recorded to the nearest 0.1 cm. Accurate technique is critical to the validity of the measures; detailed methodologies are outlined elsewhere.[65,66] Length should be measured every 1 to 3 months in infants, and at least yearly for older patients. Measurements should be plotted on the National Center for Health Statistics (NCHS) growth curve and compared to established norms for age and sex, and the corresponding percentile should be determined. Updated reference curves have recently been published by the NCHS of the Centers for Disease Control and Prevention at http://www.cdc.gov/growthcharts/.

| Criteria | Risk |
|---|---|
| Height for age below tenth percentile | Chronic malnutrition |
| Height velocity <5 cm/yr after 2 yr of age | |
| Weight for height (<10 yr) below tenth percentile | Acute malnutrition |
| Weight velocity <1 kg/yr (prepubertal) | |
| Weight for age (>10 yr) below tenth percentile | |
| Weight velocity (peak) <1 kg/6 mo (pubertal) | |
| Weight for height (<10 yr) above ninetieth percentile | Obesity |
| Weight for age (>10 yr) above ninetieth percentile | |

Adapted from Motil KJ. Sensitive measures of nutritional status in children in hospital and in the field. Int J Cancer 1998;11(Suppl):2.

**TABLE 42-5. INDICATIONS FOR NUTRITIONAL ASSESSMENT**

The most widely used anthropometric screening criteria for malnutrition in children are those of Waterlow ( Table 42-6).[67] These criteria recognize that children who are underweight may be either short and well proportioned (so-called stunted) or truly underweight for their height (so-called wasted). Wasted children have an acute deficit of body mass and have a variety of functional deficits (e.g., decreased muscle strength, impaired immune function, and decreased organ mass). The incidence of weight and height deficits in children with cancer has been reported to be quite high, depending on the severity and type of cancer and its treatment. [8]

| | Degree of malnutrition | | | |
|---|---|---|---|---|
| Criteria | 0 (normal) | 1 (mild) | 2 (moderate) | 3 (severe) |
| Weight-for-height (% expected) | 90–110 | 80–90 | 70–80 | <70 |
| Height-for-age (% expected) | ≥95 | 90–95 | 85–90 | <85 |
| | Degree of obesity | | | |
| | 1 (overweight) | 2 (obese) | 3 (morbid) | |
| Weight-for-height (% expected) | 110–120 | 120–140 | >140 | |

Adapted from Metil KJ. Sensitive measures of nutritional status in children in hospital and in the field. Int J Cancer 1998;11(Suppl):2; and Waterlow J. Classification and definition of protein-calorie malnutrition. BMJ 1972;3:566.

**TABLE 42-6. ANTHROPOMETRIC CRITERIA FOR THE DIAGNOSIS OF MALNUTRITION AND OBESITY IN PEDIATRIC CANCER PATIENTS**

Due to the increased incidence of obesity in children in industrialized countries [68] and the predisposition of some pediatric cancer patients to become obese, it is equally important to screen for overweight. This can be done by calculating the weight-for-height percent standard. An increasingly used anthropometric index is body mass index (BMI),[69] which is a reasonable measure of body fatness. Children with BMIs greater than the eighty-fifth percentile for age and sex are termed *overweight*, and those with BMIs greater than the ninety-fifth percentile are obese. Reference values for BMIs are available [70] and are included in the 2000 NCHS growth curves.

### Arm Anthropometrics

Arm anthropometrics are an inexpensive, noninvasive, and widely accepted technique for estimating body composition against established normal values. Mid-arm circumference is measured with a nonstretchable flexible tape at the midpoint between the acromion and the olecranon with the arm flexed at a 90-degree angle. Triceps skinfold is measured on the back of the arm at this same point with a caliper exerting a constant pressure of 10 g per $mm^2$. With these two measurements, the mid-arm muscle area can be calculated:

$$\text{MAMA} = \left(\frac{\text{MUAC} - \text{BTSF}}{4\pi}\right)^2$$

where

MAMA = mid-arm muscle area ($cm^2$),

MUAC = mid–upper arm circumference (cm),

TSF = triceps skinfold (cm),

p = 3.1416

Percentiles and standards for comparisons for triceps skinfolds and mid-arm muscle area are available [71] and may indicate the presence of malnutrition when weight or height is unavailable or invalid.

A study of 16 boys with newly diagnosed cancer revealed no significant deviation from normal with respect to weight, height, and weight for height. When comparing the mid-arm circumference, triceps skinfold, and subscapular skinfold to normal values, however, significant reductions were found in the patients with cancer. [72] This and other studies suggest that arm anthropometrics may be more sensitive indicators of undernutrition than are weight and height.

### Measures of Body Composition

Anthropometric measurements may be confounded by technique, inaccuracy of equipment, lack of patient cooperation, and discrepancies between weight and protein energy reserves. Lean body mass is the metabolically active component of the body. It would be ideal, therefore, to characterize weight by some measure of lean body mass to accurately assess the need for or response to nutritional intervention. [72] Patients with solid tumors before reduction or excision are particularly susceptible to inaccurate weight measurements. In a study of 19 children with malignant solid tumors, regional ultrasonography of the femoral quadriceps muscle was more sensitive than anthropometrics and measurements of visceral proteins in detecting reduced muscle protein reserves compared to age- and sex-matched controls,[73] suggesting the need for further analysis of body composition in assessing nutritional status.

Bioelectrical impedance is an inexpensive and increasingly available method of assessing body composition. The technique relies on the principle that fat-free mass, being composed of water and ions, conducts an electrical charge faster than does fat mass. [74] Lean body mass, therefore, has a lower resistance to current. Reactance, a measure of cell membrane capacitance, is also measured by bioelectrical impedance and together with resistance can be used to measure total body water, both intra- and extracellular. Fat-free mass is calculated using assumptions about its water content.

Dual-energy X-ray absorptiometry (DEXA) is becoming increasingly more available for clinical use. DEXA is able to measure lean body mass, fat mass, and bone mass, thereby accounting for any abnormalities in bone-mineral density. [75] Specifically, DEXA scanning determines bone mineral content, bone mineral density, and total body bone mineral content. Some instruments assess total body bone mineral content, nonbone lean tissue, and fat, thereby providing body composition information using a three-compartment model. A number of studies have compared measurements of fat mass with DEXA versus results obtained from underwater weighing (hydrodensitometry),[76] and the correlations between the methods have generally been high. Unlike hydrodensitometry, DEXA also measures the composition of particular body parts, thus allowing one to compare visceral and subcutaneous adiposity. The ultimate applicability of DEXA scanning to human body composition and nutritional assessment is still evolving. [77]

### Laboratory Evaluation

Although laboratory evaluation of the pediatric cancer patient is commonly performed to assess the hematologic and metabolic response to cancer and its treatment, the clinician should also monitor nutritional status with selected biochemical parameters. Serum electrolytes and mineral concentrations are commonly deranged during treatment of cancer, especially when nephrotoxic agents are used. A specific metabolic emergency termed *tumor lysis syndrome* occurs when the tumor mass is suddenly reduced with initial chemotherapy. The massive cell lysis can lead to life-threatening electrolyte abnormalities, as discussed in detail in Chapter 39.

Biochemical parameters used for nutritional assessment include visceral protein levels. These proteins synthesized by the liver are often used to assess nutritional status, because decreased levels presumably reflect a reduced supply of amino acid precursors or decreased hepatic and other visceral protein mass. Blood concentrations of these proteins, however, are dependent on their rates of synthesis, degradation, and escape from the circulatory system. Serum proteins are also affected by infectious or catabolic processes. The concentrations of positive acute phase proteins (e.g., C reactive protein, ferritin, ceruloplasmin) are increased in infectious or other catabolic illnesses, whereas negative acute phase proteins (e.g., albumin, prealbumin, transferrin, and retinol binding protein) are decreased in these circumstances.

Albumin is the most abundant serum protein, making up nearly 5 of the 10 grams per deciliter of total protein in the serum. It is the least expensive and easiest protein to measure, and therefore is the most commonly used biochemical marker to assess protein status. Because more than half of body albumin is extravascular (primarily in skin and muscle), maintenance of normal serum levels can occur from mobilization of these stores despite prolonged energy or protein inadequacy. Combined with a long half-life of 20 days, these factors make serum albumin a relatively insensitive marker of nutritional status. Hypoalbuminemia is not necessarily diagnostic of malnutrition; it can occur in situations of decreased synthesis (e.g., liver disease, age older than 70 years, malignancy), increased losses (e.g., nephrosis, protein-losing enteropathy, burn injuries), or increased losses to extravascular spaces (e.g., acute catabolic stress with capillary leak syndrome). Fluid overload can also dilute albumin concentrations, and bed rest can decrease levels by 0.5 g per dL.

Prealbumin is another visceral protein, named because of its proximity to albumin on an electrophoretic strip. Prealbumin circulates in plasma in a 1:1 ratio with retinol-binding protein. Its short half-life (2 days) and high ratio of essential to nonessential amino acids make it a good measure of visceral protein status, more sensitive than albumin as a measure of nutritional recovery. Studies have shown prealbumin to correlate well with nitrogen balance, [78,79] and it is likely the best available serum marker of nutritional status. Similar to albumin, concentrations fall with an acute phase protein response or liver disease. Levels increase with renal failure.

In a study of 170 children with an assortment of cancers, albumin and prealbumin levels were significantly lower on presentation in patients than in controls, whereas the acute phase indicator C-reactive protein was elevated. After 6 months of chemotherapy, however, the C-reactive protein levels were comparable in the groups but the visceral protein levels were still lower in those with cancer. [80] This suggests that even though the acute phase response is responsible for some alterations in visceral protein levels, cancer patients still have poorer visceral protein nutrition than do controls.

It may also be helpful to assess vitamin and mineral nutriture, particularly in the patient on total enteral or parenteral nutritional support. At the time of diagnosis, the effect of tumor burden on metabolic processes may be profound, as demonstrated by laboratory analysis. In a study of 40 children with ALL, more than 70% had low plasma 1,25-dihydroxy vitamin D levels, 73% had low osteocalcin levels, and 64% had hypercalciuria at the time of diagnosis. This is an indication of the effect of leukemia on vitamin D metabolism and bone turnover. The use of steroids and nephrotoxic agents may worsen hypercalciuria, putting patients at a greater risk for osteopenia fractures. Excessive renal losses of magnesium during treatment with these medications were also demonstrated, with only 50% of patients able to maintain normal serum magnesium levels despite parenteral supplementation. [81]

Antioxidant nutrients, including vitamins A and E, beta-carotene, zinc, and selenium have also been studied. Children with a variety of cancers had lower concentrations of retinol, beta-carotene, vitamin E, and zinc before treatment compared to controls but were not significantly different than controls after treatment. When separated by diagnosis, however, zinc concentrations in patients with central nervous system tumors and malignant bone tumors were persistently lower after 6 months of treatment. [80]

Zinc deficiency was also found to be common in children after BMT. Nineteen of twenty-eight children developed biochemical zinc deficiency at a median of 7 ays posttransplant. Zinc blood levels were positively correlated with serum concentrations of alkaline phosphatase, a zinc-dependent enzyme. [82]

## NUTRITION INTERVENTION TECHNIQUES

The method of nutrition support chosen is based on the clinical assessment and the child's nutrient requirements. [83] Some children may require minor alterations to their oral diet; others may require specialized enteral or parenteral support. There is increasing evidence that enteral support is a less expensive, safer, and effective way of nourishing the child with cancer than PN. [84,85] Patients and their family members should, of course, be included in the discussion of nutrition options, with accurate depiction of the risks and benefits of the possible methods of nutrition support given the patient's current situation.

When treating the malnourished child, it is imperative to consider the manifestations of refeeding the body in a starved state. A profound hypophosphatemia, in particular, can characterize the rapid cellular influx of nutrients during the anabolic phase following starvation. Severe metabolic complications may be avoided by the slow advancement of macronutrients over a period of days to weeks, as well as close laboratory monitoring of electrolytes, glucose, and minerals.

### Oral Feeding

Modifications to the oral diet for pediatric oncology patients include reduced bacteria, [86] texture changes, adjustments to electrolyte or mineral content, and calorie supplementation. Although the efficacy of low-bacteria diets to reduce infections has not been proved, some centers continue to use them routinely, particularly in the BMT setting. General principles of cautious food safety should be followed for any immunocompromised child ( Table 42-7).

| |
|---|
| Wash hands well before and after preparing and eating meals. |
| Do not share food with others. |
| Avoid foods from street vendors, salad bars, and shared bins of foods in grocery stores. |
| Wash raw foods well before eating. |
| Cook meat until well done. |
| Avoid raw eggs. |
| Keep foods at temperatures <40°F or >140°F to minimize growth of bacteria. |
| Clean all preparation items thoroughly before and after use to avoid cross-contamination. |
| Keep refrigerated leftovers for no more than 3 d. |

Adapted from Bechard L. Oncology and bone marrow transplantation. In: Hendricks K, Duggan C, Walker W, eds. Manual of pediatric nutrition. Hamilton, Ontario: B.C. Decker, 2000.

**TABLE 42-7. SANITARY FOOD PRACTICES FOR IMMUNOCOMPROMISED PATIENTS**

Children with mucositis may better tolerate a soft diet. A diet high in magnesium or potassium may be useful for the child with excessive urinary losses of minerals due to chemotherapies or antibiotics. Most commonly, however, calorie supplementation is required to assist with weight gain or weight maintenance during cancer treatment. This can be accomplished with usual foods or in combination with commercial supplemental drinks, bars, or calorie additives. Techniques for increasing oral energy intake are listed in Table 42-8.

| |
|---|
| Loss of appetite |
| Offer small frequent feedings (6-8 meals or snacks per day). |
| Encourage nutrient-dense beverages between meals. |
| Offer favorite nutritious foods during treatment-free periods to prevent learned food aversions. |
| Nausea and vomiting |
| Feed 3 to 4 h before therapy that typically causes nausea and vomiting. |
| Offer small amounts of cool foods and encourage slow eating; avoid strong odors. |
| Offer clear liquids between meals; using a straw in a covered cup may facilitate sipping. |
| Mouth sores |
| Serve soft or pureed bland food or liquids. |
| Add butter, gravy, sauce, or salad dressing to moisten foods. |
| Avoid highly seasoned or hard, rough foods. |
| Altered taste perception |
| Use stronger seasonings; avoid excessively sweet foods. |
| Offer salty foods (e.g., hot dogs, pizza, canned pasta). |
| Try new flavors of foods. |

Adapted from Bechard L. Oncology and bone marrow transplantation. In: Hendricks K, Duggan C, Walker W, eds. Manual of pediatric nutrition. Hamilton, Ontario: B.C. Decker, 2000.

**TABLE 42-8. STRATEGIES FOR IMPROVING ORAL INTAKE DURING CANCER TREATMENT**

Some children, particularly long-term survivors of cancer with activity limitations, may be aided by the instruction of moderate-calorie and low-fat diet principles when obesity is a concern (Table 42-9).

| |
|---|
| Aim for fitness |
| Aspire to a healthy weight. |
| Be active each day within personal limitations. |
| Build a healthy base |
| Follow the eating guidelines of the food guide pyramid. |
| Eat a variety of whole grains, fruits, and vegetables each day. |
| Choose sensibly |
| Select a diet low in saturated fat and cholesterol. |
| Keep total fat intake <30% of calories. |
| Limit sugary foods and beverages. |
| Choose and prepare foods with less salt. |

**TABLE 42-9. HEALTHY EATING GUIDELINES FOR CHILDHOOD CANCER SURVIVORS**

## Enteral Feeding

If children are unable to meet their nutrient needs orally, tube feedings should be considered as a means of preserving or obtaining optimal nutritional status. Nasogastric tubes have been used with success in many pediatric oncology patients. In 21 children newly diagnosed with cancer, nasogastric tube feedings were given in addition to volitional oral intake. After 16 weeks of feedings, weights increased significantly. [87] Another study using nasogastric feedings in children after BMT demonstrated improved weight gain in 21 patients, compared to eight children receiving dietary counseling alone. There was a positive correlation between increases in weight and mid-arm circumference and the duration of enteral feedings. However, eight of the 21 patients stopped feedings after 10 days due to vomiting or diarrhea. Six of these patients were then switched to PN support.[88] These studies suggest the feasibility of nasogastric feeding as a method of nutrition support for pediatric cancer patients, although clearly some patients will be unable to tolerate the required volumes to support their nutritional requirements, particularly in the BMT setting.

Gastrostomy tube feedings are generally considered to be more cosmetically acceptable and comfortable than nasogastric feedings, while still providing the same advantages over PN. The use of surgically placed or percutaneous endoscopic gastrostomy feedings in pediatric cancer patients has been examined by several groups (Table 42-10).

| Reference | Number of patients | Type of tube | Complications | Weight changes |
|---|---|---|---|---|
| [illegible] | [illegible] | PEG | No major; 77% of patients experienced minor complications, including leakage of gastric juice and superficial wound infections | +2.3 standard deviation score of weight for age |
| [illegible] | [illegible] | 12 PEG, 2 surgical | 1 systemic infection; 9% of patients experienced minor complications, including skin inflammation, local infection, bleeding, and feeding intolerance | 82% achieved or maintained ideal body weight |
| [illegible] | [illegible] | PEG, surgical | 1.53 episodes of infections per 1,000 days of use compared with 5.0 episodes per 1,000 days for total parenteral nutrition | All gained or maintained weight |

PEG, percutaneous endoscopic gastrostomy tube

**TABLE 42-10. GASTROSTOMY FEEDINGS IN CHILDREN WITH CANCER**

The use of tube feedings for pediatric cancer patients can initiate weight gain and improved nutritional status with limited risks. Although some patients may ultimately require parenteral support due to gastrointestinal intolerance, the use of enteral nutrition substantially reduces the amount and duration of PN required, thus reducing the risks and costs with which it is associated.[84,85,89,90]

Nutritionally complete formulas for oral supplementation or tube feeding are available for a variety of ages and conditions. Most pediatric cancer patients will tolerate intact protein, 1-kcal-per-mL formulas, either orally or via tube feeding ( Table 42-11). On rare occasions, a specialized formula for tube feeding may be indicated. Formulas with an elemental (free amino acids) or semi-elemental (small peptides) base are available, primarily for the purpose of protein allergy or intolerance. Medium-chain triglycerides are also used in many formulas intended for patients with fat malabsorption. An abundance of defined formula diets are available for varying conditions and ages.

| Formula | Manufacturer | Flavors | Designed for ages |
|---|---|---|---|
| Boost | Mead Johnson Nutritionals | Chocolate, chocolate mocha, chocolate raspberry, vanilla, strawberry, strawberry banana | Teens and adults |
| Ensure | Ross Products | Vanilla, chocolate, strawberry, butter pecan, coffee | Teens and adults |
| Nutrabics | Nestle | Vanilla, chocolate, strawberry | Teens and adults |
| Ordercal | Mead Johnson Nutritionals | Vanilla | Children aged 1–10 yr |
| Pedisure | Ross Products | Vanilla, chocolate, strawberry, banana cream | Children aged 1–10 yr |
| Nutren Junior | Nestle | Vanilla | Children aged 1–10 yr |
| Resource Just for Kids | Novartis | Vanilla, chocolate, strawberry | Children aged 1–10 yr |

Note: Review manufacturer information.

**TABLE 42-11. INTACT PROTEIN FORMULAS FOR ORAL OR TUBE FEEDING**

## Parenteral Feeding

When the gastrointestinal tract is nonfunctional or unavailable, nutrients may be infused via central venous catheters. Peripheral venous lines may also be used temporarily to provide a nutrient solution with less than 900 mOsm per L, usually 10% dextrose and 1.5% to 2% amino acids. PN has been widely used in the oncology population due to the cytotoxic effects of many treatment regimens. Most chemotherapy regimens commonly cause some degree of nausea and vomiting. Radiation therapy, when directed to gastrointestinal organs, also causes cell damage that may impair digestive or absorptive function. High-dose chemotherapeutic regimens and total body irradiation, used in preparation for BMT, may cause a severe mucositis and enteritis, making significant oral or enteral intake difficult for many patients to achieve for several weeks.

The value of PN in cancer patients has been questioned; in fact, its routine use in adults undergoing chemotherapy has been discouraged due to the risks of infectious complications.[91] BMT, however, is one of the few clinical situations in which PN has demonstrated benefit. In a study of 22 patients receiving prophylactic PN compared to age- and diagnosis-matched historical controls, engraftment occurred significantly sooner in patients receiving prophylactic PN; there was no significant difference in overall clinical outcome. [92] In a subsequent prospective trial, patients were randomized to receive either PN or a 5% dextrose solution with additives for 1 week before and 4 weeks after transplantation. Although engraftment was not different among the two groups, overall survival, time to relapse, and disease-free survival were significantly better in the group receiving PN. [93] This study was instrumental in making PN an integral part of supportive care to BMT patients.

Since the publication of these studies, however, and with the exception of studies of glutamine (Gln) supplemented PN (see the section Glutamine and Other Experimental Nutrients in Pediatric Cancer), there have been relatively few well-designed trials to further advance the science of nutrition support in cancer patients. For instance, one group evaluated the effect of PN on visceral protein levels in children undergoing BMT and reported that concentrations of albumin and prealbumin rose significantly from day 0 until the end of PN administration. However, all subjects received the same PN regimen and no control data were presented. [94]

Some published studies in adults may shed light on the role of PN in the BMT setting, with the caveat that the significance of these data in children is difficult to assess due to the substantial differences in physiology and metabolism between adults and children. A study of adults with acute myelogenous leukemia examined the need for PN based upon three indications: severe malnutrition, a 7- to 10-day period of minimal oral intake, or weight loss of more than 10%. Patients receiving a mismatched BMT had the greatest incidence of PN use (92%), whereas only 35% of patients needed PN during consolidation courses. The authors concluded that PN was not required for all patients undergoing intensive cytotoxic therapy. [95] A study of 28 adults undergoing BMT compared the effects of a high nitrogen (330 ± 60 mg N per kg per d) PN solution versus a standard nitrogen (267 ± 44 mg N per kg per d) PN solution. [96] Caloric intake was kept constant. With the exception of nitrogen balance (better in the high-nitrogen-intake group), no clinical or metabolic differences were observed. This study underlines that fact that the severe catabolism of BMT conditioning cannot be reversed simply by providing higher protein intake.

In contrast, an interesting study of 15 adults evaluated the impact of reducing parenteral energy and protein intake after BMT. [97] Ten consecutive patients received 150% of estimated basal energy expenditure and 1.4 grams of protein per kg body weight and five subsequent patients received only 100% of estimated basal energy expenditure and 0.8 grams protein per kg body weight. No oral intake was allowed during the study; lipid emulsion was infused twice weekly to prevent essential fatty acid deficiency. The group receiving reduced amounts of energy and protein had significantly higher serum albumin levels, less hyponatremia, and less hyperkalemia compared to the group receiving higher amounts of energy. Nitrogen balance was similar in both groups. The results suggest the possibility of more efficient nitrogen utilization with a decrease in calories and protein, as well as improved metabolic homeostasis; further investigation of these results is warranted.

The use of lipids in PN has been questioned with regard to infectious risk and immunosuppressive effects. Clinical and metabolic effects of a lipid-based PN (80% nonprotein calories) versus a glucose-based PN (lipid free) were analyzed and suggested a lower incidence of lethal acute graft-versus-host disease and hyperglycemia in the lipid-based PN group. No significant differences in survival, time to engraftment, incidence of infections, or rate of relapse were seen. [98] This implies the possibility that intravenous (i.v.) lipids, due to their immunosuppressive effects, may have an effect on the severity of graft-versus-host disease. More research, particularly in children, is warranted.

When indicated, PN in children should be initiated according to the guidelines shown in Table 42-12. Goals of parenteral nutrients will be based on estimated requirements for age and nutritional assessment. Fluid requirements and venous access must also be considered in formulating the PN prescription. Electrolytes are added in accordance with usual requirements; pediatric multivitamin and trace element preparations are generally used as well.

| Nutrient | Start with | Advance by | Goal |
|---|---|---|---|
| Dextrose | 3-4 mg/kg/h | 2-3 mg/kg/h | 8-18 mg/kg/h |
| Amino acids | 1 g/kg/d | 0.5-1.0 g/kg/d | 1.5-3.0 g/kg/d |
| Lipids | 1 g/kg/d | 0.5-1.0 g/kg/d | 1-3 g/kg/d |

**TABLE 42-12. INITIATION OF PARENTERAL NUTRITION IN CHILDREN WITH CANCER**

The risks of PN can be significant, and include infections, hepatotoxicity, suppression of oral intake, and metabolic abnormalities. Most children undergoing aggressive cancer treatment will require indwelling central venous catheters for chemotherapy, but it has been demonstrated that the use of PN increases the risk of infectious complications by 2.4-fold in children receiving chemotherapy who have central access devices in place. [99] The specific role of i.v. fats in increasing infectious complications was evaluated in a randomized trial of more than 500 children and adults undergoing BMT. There was no increased risk of bacteremia or fungal infections in those receiving standard amounts of i.v. lipids (25% to 30% of energy) versus those receiving only 6% to 8% of energy as fat. [100]

Many of the medicines used in oncologic treatment can cause liver injury. The use of PN, alone or in combination with these medicines, may cause biliary dysfunction or steatosis.[101] Another potential risk of PN administration is the generation of peroxide compounds, which may have harmful effects in neonates and others with immune dysfunction or reduced antioxidant defenses.[102] Covering PN bags and i.v. tubing with opaque plastic coloring may reduce this effect. [103]

PN may also cause early satiety and decreased oral intake. In a randomized controlled trial of children and young adults after BMT, outpatient PN delayed resumption of oral intake by 6 days as compared to 5% dextrose hydration. The clinical outcome of both groups was not significantly different. [104] Nausea and vomiting have been linked with children receiving PN at home.[105] Metabolic derangements are also associated with PN. Over- or underhydration, electrolyte imbalance, hyperglycemia, and hypoglycemia are among the most common concerns.[106]

Although the weight of evidence still seems to support a role for PN in selected pediatric cancer patients, close monitoring of laboratory values and clinical condition in addition to the specifics of the PN prescription are necessary to prevent complications ( Table 42-13).

| Parameter | Hospitalized patients on parenteral nutrition | Hospitalized patients on oral/tube feeding | Outpatients on parenteral nutrition | Outpatients on oral/tube feeding |
|---|---|---|---|---|
| Weight | Daily | Daily | Weekly | Monthly |
| Height | Monthly | Monthly | Monthly | Monthly |
| Head circumference (<36 mo) | Weekly | Weekly | Monthly | Monthly |
| Arm anthropometrics | Monthly | As indicated | Monthly | As indicated |
| Intake/output | Daily | Daily | Daily to weekly | Weekly to monthly |
| Electrolytes, glucose | Daily | Weekly | Weekly | Monthly |
| Blood urea nitrogen, creatinine | Weekly | Weekly | Weekly | Monthly |
| Calcium, phosphorus, magnesium | Daily to weekly | Weekly | Weekly | Monthly |

## GLUTAMINE AND OTHER EXPERIMENTAL NUTRIENTS IN PEDIATRIC CANCER

The significant metabolic and nutritional ramifications of cancer and its therapy have led investigators to evaluate whether the addition of various nutrients may improve clinical outcomes. Some of these trials have used nutrients in high, or pharmacologic, doses; the terms *nutraceuticals* and *nutritional pharmacology* have been coined to describe this use of nutritional therapy. [107]

The amino acid Gln is an example of such a nutrient. Owing to its importance as a fuel source for rapidly turning-over cells, [108] and the demonstration that Gln may reduce amino acid efflux from muscle in catabolic postoperative patients, [109] many studies have been performed to evaluate the clinical efficacy of Gln-supplemented nutrition. Studies have documented a role for Gln in ameliorating the mucosal atrophy seen in prolonged states of PN, [110,111] in the healing of gastrointestinal mucosa after damage from radiotherapy or chemotherapy, [112,113] in improving gut and systemic immune function, [114] and in reducing episodes of bacterial translocation [115,116] and clinical sepsis. [117,118]

Table 42-14 provides an overview of clinical trials of Gln in oncology patients; it is worth noting that the majority of these have been performed in adults. The possibility that the unique metabolic and nutritional requirements of children with cancer may respond differently to Gln supplementation has not been well addressed.

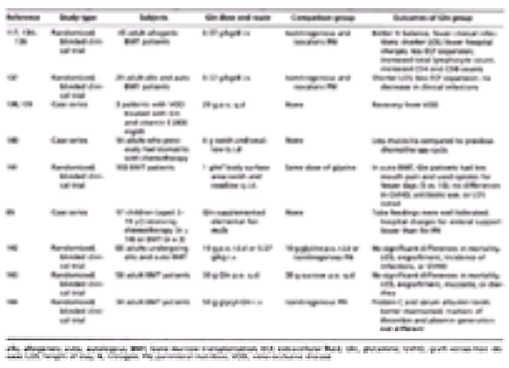

**TABLE 42-14. SUMMARY OF CLINICAL TRIALS OF GLUTAMINE IN THE NUTRITIONAL THERAPY OF PATIENTS WITH CANCER**

## NUTRITIONAL CONCERNS OF LONG-TERM SURVIVORS OF CHILDHOOD CANCER

Most nutritional issues during cancer treatment are associated with weight loss or poor growth, but there is a notable risk of obesity in adults who survive pediatric cancers. As many as half of childhood leukemia survivors in one study became obese young adults. [38] This incidence may be related to the impact of therapy on final adult height. A cohort of BMT survivors, engrafted before or at the onset of puberty, had a significant decrease in final height compared to pretransplant height standard deviation scores. However, most of the patients achieved a height considered to be normal. [119] A study of 33 childhood leukemia survivors followed for a median of 16.2 years found that 36% were obese. All patients had reduced height standard deviation scores during treatment; however, only patients who received cranial radiation with chemotherapy (versus chemotherapy alone) had reductions in final adult height. [120] It has also been postulated that a reduction in physical activity and thus a change in body composition of leukemia survivors may explain the subsequent onset of obesity. [41] A recent report found an alarming incidence of insulin resistance (52%) among 23 long-term survivors of BMT. [121] Unquestionably, complications of oncologic treatment including obesity and insulin resistance need further evaluation and attention. Children should be taught healthy diet principles and acceptable activity options for weight maintenance and control when malnutrition is not a concern (Table 42-9).

## CONCLUSION

The nutritional care of children with cancer is ongoing from the time of diagnosis to many years after treatment. Because children must be expected to continue acceptable growth during extended treatment courses as well as after therapy, serial nutritional assessments should be performed with appropriate actions taken. Malnutrition should not be accepted as an unavoidable consequence of cancer or its therapy. Likewise, every effort should be made in the prevention of obesity in long-term cancer survivors. Extensive nutritional intervention and counseling can assist with the supportive care of the pediatric cancer patient. A multidisciplinary approach considering the quality of life of each child should be used.

# SYMPTOM MANAGEMENT IN SUPPORTIVE CARE

CHARLES B. BERDE
AMY LOUISE BILLETT
JOHN J. COLLINS

## INTRODUCTION

A diagnosis of cancer evokes immediate fear for patients and their families, in part because cancer is a potentially fatal disease but also because cancer and its treatment are commonly associated with pain, nausea, and other distressing symptoms. Pediatric oncologists have a primary role in symptom management for children with cancer and should reassure patients and their families that relief of distressing symptoms is feasible in most situations.

In this chapter, we summarize aspects of the management of common symptoms, including pain, nausea and vomiting, pruritus, sedation, sleep disturbance, fatigue, dyspnea, dysphoria, constipation or ileus, and urinary retention. In many cases, these symptoms may be interconnected, or treatment of one symptom may exacerbate another. Treatment of symptoms should not proceed in isolation but rather in the context of the patient's overall clinical situation. In some circumstances, treatment of one symptom may cause or exacerbate another symptom, as with sedation or nausea from opioids given to relieve pain. Assessment of the relative contributions of multiple symptoms to the patient's overall quality of life and sense of well-being is essential.

In the United States, the consensus conference on the management of pain in childhood cancer created guidelines for the management of disease- and treatment-related pain and established pain management as a standard of care for these children. [1] The global application of the principles of pain management and palliative care in children with cancer, including the application of the World Health Organization's (WHO) analgesic ladder ( Fig. 43-1), has been a major initiative of the WHO Cancer Unit. A monograph outlining symptom management and palliative care for children is available from the WHO or from the U.S. Cancer Pain Relief Committee.[2]

## PAIN MECHANISMS: IMPLICATIONS FOR TREATMENT

Nociception, or the sensation of tissue injury or inflammation, is an important biologic function that alerts an individual to potential or ongoing injury and prompts the avoidance or limitation of further injury. Lack of protective sensation can lead to a variety of medical complications, including compartment syndromes or decubitus ulcers. Conversely, other types of pain (e.g., metastatic cancer, migraine) often carry no protective significance.

The neural mechanisms underlying nociception have been extensively reviewed, and the reader is referred to other sources for detailed descriptions. [3,4] Nociceptors in deep and superficial tissues can be activated by chemical, thermal, or mechanical stimuli to send afferent impulses through thinly myelinated A-d fibers or unmyelinated C fibers. Primary afferents synapse in the dorsal horn of the spinal cord. Secondary fibers then convey impulses rostrally through a number of tracts, especially the anterolateral spinothalamic tracts. Descending control systems modulate and inhibit pain perception. Endogenous opioids, serotonin, and norepinephrine all appear to be involved in these descending pain-inhibiting systems.

Clinicians and researchers have long observed the lack of correlation between the extent of tissue injury and the intensity of pain or suffering. The experience of pain is subjective and, as such, is modulated by developmental, familial, situational, emotional, and other factors. Assessment of the extent to which one or more of these modulating factors require specific interventions is critical.

*Nociceptive pain* refers to pain associated with intact neurons detecting and transmitting impulses associated with tissue injury or inflammation. The term *neuropathic* pain refers to pain associated with abnormal excitability in peripheral or central neurons. Neuropathic pain may persist even after tissue injury or inflammation have subsided. Neuropathic pain often is described as burning, shooting, or stabbing in character, and it often is associated with paresthesias. The term *allodynia* refers to a condition in which pain can be elicited by normally nonpainful stimuli, such as light stroking of the skin. In the absence of acute inflammation of the skin, allodynia generally implies the existence of an underlying neuropathic condition.

## ASSESSMENT OF PAIN IN CHILDREN WITH CANCER

The experience of pain is known to others only secondhand, and all methods of assessment and measures are imperfect. A distinction commonly is made between *pain assessment*, which involves broad-based clinical hypotheses about the pathophysiology of the pain and its impact on the physical and psychosocial functioning of the patient, and *pain measurement*, which refers to formal scales that assess pain intensity or quality. The management of a child with cancer or treatment-related pain requires ongoing assessment, which in turn requires ongoing measurement of pain to establish the success or failure of treatment strategies.

### Clinical Assessment of Pain

In clinical practice, the measurement of pain contributes to overall assessment of the patient. As the diagnosis and staging of cancer in a child are being established, reports of pain demand a thorough clinical assessment. This assessment is initiated when the practitioner takes seriously the child's report of pain and avoids the common tendency to dismiss or minimize such symptoms that are not easily explained. A medical history is obtained, and the characteristics of the pain are established, including the location, quality, radiation, and relieving and exacerbating factors. Previous opioid use and specific difficulties with opioids should be documented. The history should assess psychological and social factors that may influence the experience of pain. A complete physical examination, followed by appropriate investigations, should seek to establish the cause of the pain. Treatment for the primary cause should be implemented and appropriate analgesia prescribed.

### Measurement of Pain

Pain measures involve one or more of three types of information: self-report (e.g., Visual Analog Scales, [5,6] color analog scales,[7] Faces,[8] Oucher,[9] Poker Chip Tool[10]) behavioral observation,[11] and physiologic measurement. Self-report measures generally are used for children older than 6 years; behavioral scales generally are used in the preverbal and cognitively impaired child. The subsequent discussion is limited to the use of these measurement scales in pediatric cancer pain.

#### *Self-Report Measures*

Patients' reports are the most useful source of information in most circumstances. *Intensity* is the dimension of pain most frequently assessed through self-report measures, although some measures assess qualitative and affective dimensions as well.[12,13] Visual analog scales have been used most commonly for adolescents and adults. These scales usually are presented in the form of a 100-mm line and have two anchors at scale's extremes, the numbers at one end represent no pain, whereas the numbers at the other end represent the worst pain possible. Visual analog scales have useful psychometric properties and are widely used to assess analgesic efficacy. To use these scales, children must be able to interpret the pain using the descriptors and numerals and to understand the concept of proportionality. Visual analog or similar scales have been used successfully by investigators studying acute procedural pain in children with cancer. [14,15]

A number of scales have been developed to extend self-report measurement to younger children, particularly those aged 4 to 8 years. Several scales involve showing the child a series of cartoon faces[8] or photographs[9] that express increasing degrees of distress. Face scales have been used successfully in studies of acute procedural pain in children with cancer.[15] Color analog scales use increasing color intensity to represent increasing pain intensity; they are also useful in the 4- to 8-year-old group.[7,16]

#### *Behavioral Observation*

Behavioral observations are most widely used among children who are cognitively impaired or are too young to use self-report measures. These often include observation of facial expressions, limb movements, crying, and related behaviors. In patients with persistent pain, behavioral observation may underrate pain intensity when compared with self-report.[17] Frequently, children lie immobile in bed, not because they are comfortable but because of severe incidental pain related to movement. Conversely, behavioral scales may overrate pain in the setting of brief procedures and may measure fear or anxiety in addition to pain. Some investigators describe these scales as *distress scales* rather than pain scales, regarding distress as some combination of pain, fear, and anxiety.

The Observational Scale of Behavioral Distress[18] and the Procedure Behavior Checklist (PBCL)[19] are observational scales created to assess procedural pain in children with cancer. Psychometric study has replicated the correlation of the Observational Scale of Behavioral Distress with other measures of pain and distress; however, correlation with physiologic measures may be unstable and in the low range. Validity data of the PBCL indicate that behaviors on the PBCL represent various combinations of pain and anxiety, depending on circumstances and the individual patient, but anxiety tended to be represented more consistently than pain. In addition, behaviors on the PBCL were related more strongly to observer than to patient ratings. The purpose of these measures has been to quantify the occurrence, intensity, and range of a child's pain during traumatic procedures. A novel approach for behavioral observation researchers is to focus on child and adult distress and coping behaviors and, thereby, to discover the processes by which a child's distress may be modified by adult interactions. [15]

Gauvain-Piquard et al.[20] designed a behavioral observation scale to be used in the assessment of tumor-related pain in children between the ages of 2 and 6 years. The 17 items in the scale assessed pain, depression, and anxiety. Some items on this scale lacked operational definitions, which reduced interrater reliability.

#### *Physiologic Measures*

Heart rate, blood pressure, and respiratory rate often increase with increasing pain and decrease in response to analgesics. Although useful, these measures may be confounded by other processes unrelated to pain, including anxiety, hypoxemia, hypovolemia, and fever. Autonomic measures may be the only signs of pain in the intensive care patient receiving neuromuscular blockade; absence of movement does not ensure unconsciousness or comfort. Physiologic signs may habituate in the setting of chronic pain.

## PATHOPHYSIOLOGY OF TUMOR-RELATED PAIN IN CHILDHOOD CANCER

Tumor commonly causes pain from involvement of bone, viscera, and nerves. Visceral stretch, compression, or ischemia activates nociceptive endings that evoke pain. Visceral pain typically is more poorly localized than is somatic pain. Animal studies have demonstrated primary visceral afferents that discharge maximally only to apparent noxious stimuli and have small myelinated or unmyelinated axons.

Mechanisms that may cause pain from bone metastases include stimulation of nerve endings in the endosteum by chemical agents released from the destroyed bone tissue, such as prostaglandins, bradykinin, substance P, or histamine; stretching of the periosteum; fractures; and tumor growth into surrounding nerves and tissues. [21] The periosteum is more sensitive than bone marrow and cortex.

Mechanisms for persistent neuropathic pain after damage to peripheral tissues have been reviewed.[22,23] They include deafferentation-induced hyperactivity of dorsal horn pain transmission cells, loss of central inhibition by loss of myelinated primary afferents, ectopic impulse generation in damaged nociceptive primary afferents, sympathetic efferent activation of damaged or intact primary afferents, and changes in autonomic reflexes. Systematic evaluation and consideration of the neurologic mechanisms that underlie patterns of referral and pain quality should be encouraged. [24]

## EPIDEMIOLOGY OF CANCER PAIN IN CHILDHOOD

Since Farber et al.[25] described the use of folic acid antagonists in the treatment of childhood leukemia, survival from childhood cancer has dramatically improved.

Improvement in survival has resulted from the evolution of multimodal treatment regimens. Since the development of multimodal treatment, the epidemiology of pain associated with childhood cancer has changed from a predominantly tumor-related to a predominantly treatment-related pattern.

At diagnosis and during the early treatment phase of childhood cancer, tumor-related pain predominates. Miser's study [26] of children with non–central nervous system malignancy at the National Cancer Institute found that 62% of the children studied presented to their practitioner with a report of pain before the diagnosis of cancer and that the pain had persisted for a median of 74 days before treatment was begun. The duration of pain experienced by patients with metastatic disease was not longer than that for patients without metastases. After initiation of cancer therapy, most children had resolution of pain related to their tumors; only the rare patient experienced persistent pain. Pain persisted for a median of 10 days after the institution of cancer therapy. Children with hematologic malignancies had a shorter duration of pain after initiation of treatment than did children with solid tumors.

We have accrued little information about the epidemiology of pain related to pediatric brain or spinal cord tumors. Children with brain tumors present to their practitioners with symptoms consistent with raised intracranial pressure, including headache, or with abnormal neurologic signs (see Chapter 27). A retrospective review of children with spinal cord tumors at the Children's Memorial Hospital in Chicago showed that most children with spinal cord tumors do present to their practitioners with pain.[27] Metastatic spinal cord compression is unusual at diagnosis and is more likely to occur later in a child's illness. Back pain, more often than abnormal neurologic signs or symptoms, is the initial presenting sign of spinal cord compression in children. [28]

As the treatment evolves, treatment-related rather than tumor-related causes of pain predominate. [29,30] Possible causes of treatment-related pain include mucositis, phantom limb pain, infection, antineoplastic therapy–related pain, postoperative pain, and procedure-related pain (e.g., needle puncture, bone marrow aspiration, lumbar puncture, and removal of central venous line).

Tumor-related pain frequently recurs in patients at the time of relapse and during the terminal phase of an illness. Palliative chemotherapy and radiotherapy, depending on tumor type and sensitivity, sometimes are instituted as modalities of pain control for terminally ill pediatric patients with malignancy. Severe pain in terminal pediatric malignancy occurs more commonly in patients with solid tumors metastatic to spinal nerve roots, nerve plexus, or larger peripheral nerves, or with spinal cord compression.[31]

## SYNDROMES OF PEDIATRIC CANCER PAIN

### Treatment-Related Syndromes

#### *Mucositis*

The optimal management of pain related to cancer chemotherapy and radiation-induced mucositis is not established. A national survey of U.S. hospitals indicated a wide variation in the prophylaxis and management of oral mucositis in the adult population and lack of a consistent approach to pain management despite National Institutes of Health guidelines. [32] Therapy for mucositis has included topical therapies, either singly or in combination, including saline, sodium bicarbonate, hydrogen peroxide, nystatin, viscous lidocaine, dyclonine, as well as systemic therapies, especially opioids and systemic antifungal agents. Hospitals vary greatly in their choice of treatments for mucositis. Hospitals frequently have second- and third-line regimens for the management of mucositis, including opioids, but no consistent pattern can be identified.

The mucositis that occurs after conditioning for bone marrow transplantation is more intense and prolonged than that associated with routine chemotherapy. The pain of mucositis in transplantation patients typically is continuous, with exacerbation during mouth care, swallowing, and on awakening. Even when treated with opioids, the patient may have pain that can preclude talking, eating, and swallowing. [33] For patients with severe mucositis, parenteral opioids are appropriate, administered as either a continuous infusion or patient-controlled analgesia (PCA). Data are emerging regarding the safety and efficacy of PCA in the setting of mucositis pain after bone marrow transplantation in children.[33,34,35] and [36] In some studies, PCA produced better analgesia than did continuous infusions or nurse-administered intermittent dosing,[35] whereas in other studies, analgesia was equivalent [37] but, almost invariably, patients receiving PCA achieved either equivalent or better analgesia despite using less opioid than patients who received the drug by infusion or nurse-administered intermittent dosing. A randomized comparison of PCA morphine, hydromorphone, and sufentanil found similar analgesia in most respects, although a higher percentage of patients in the sufentanil group failed to achieve adequate analgesia, whereas morphine was the preferred choice in terms of fewest side effects.[38] Sufentanil developed tolerance to twice the degree of morphine or hydromorphone.

Some centers use topical agents, including local anesthetics, for analgesia in patients with mucositis. The upper limit for repeated dosing for oral mucosal lidocaine is not established; a single dose of lidocaine 2% (5 mL, swished, not swallowed) resulted in safe plasma concentrations. [39] Some practitioners still have concerns that topical anesthesia may extend to supraglottic and glottic structures, thereby creating a predisposition to aspiration of secretions. The incidence of this complication after oral mucosal lidocaine use is unknown.

#### *Graft-Versus-Host Disease*

The gastrointestinal manifestation of acute graft-versus-host disease (GVHD) may be associated with severe abdominal pain. After mucositis, GVHD is the next most common cause of pain subsequent to allogeneic bone marrow transplantation. Pain due to GVHD frequently requires the administration of opioids. [34]

#### *Phantom Limb Pain*

Phantom sensations and phantom limb pain are common among children after amputation of an extremity for cancer. The incidence and severity of phantom pain in children tend to decrease with time after amputation.[40,41] Evidence appears to demonstrate that preoperative pain in the diseased extremity may be a predictor for subsequent phantom pain.[40] One study suggested that prior treatment with chemotherapy increased the risk of phantom pain after subsequent amputation. [42] In some studies in adults, preoperative regional anesthesia appeared effective in preventing phantom pain, [43,44] whereas in other studies, no preventive effect could be demonstrated.[45] Differences in results may relate to the study design and to the method of regional anesthesia, drug choice, and the duration of interruption of afferent inputs to the spinal cord. Tricyclic antidepressants and calcitonin [46] have undergone positive clinical trials for phantom limb pain.

Although traditionally opioids were regarded as ineffective for phantom pain, a recent study found useful analgesic effects in a subset of patients. A preliminary report appears to confirm the common impression that early and frequent use of a limb prosthesis may reduce the duration and severity of phantom pain. [47]

#### *Infection*

Pain is commonly associated with infection in the child with cancer and usually is associated with an acute illness. Common causes of pain due to infection in the immunocompromised child include perioral, perirectal, and skin infection (particularly at sites of intravenous access). Resolution of pain usually is associated with resolution of the infection, and primary therapy should be directed at treatment of the infection.

Acute herpes zoster commonly is associated with pain. Unlike in adults, in children, herpes zoster infection is rarely associated with post-herpetic neuralgia. A small subgroup of children and adolescents, however, develop severe burning pain and skin hypersensitivity that persists years after herpetic infections. Growing evidence from adult studies points to a reduction in the incidence of post-herpetic neuralgia after early treatment with antiviral agents. [48,49] In adults, treatment for post-herpetic neuralgia includes tricyclic antidepressants [50,51]; anticonvulsants (including gabapentin) [52]; topical, regional, and systemic local anesthetics; opioids; and epidural injection of local anesthetics and corticosteroids. A recent study reported benefit from spinal administration of corticosteroids. [53]

#### *Antineoplastic Therapy–Related Pain*

Peripheral venous injection of chemotherapy (e.g., leucovorin, thiotepa) may be associated with local pain at the time of injection. After injection of chemotherapy into a peripheral vein, thrombophlebitis occasionally develops. Intrathecal chemotherapy has been associated with arachnoiditis and meningeal irritation syndrome (i.e.,

headache, nuchal rigidity, fever, nausea, and vomiting).

Extravasation of antineoplastic agents is becoming less problematic in the treatment of cancer in children because of the increased use of central venous lines and intravenous access devices. Children who do not have these devices are at risk for extravasation. This is a particular danger for antineoplastic agents that have vesicant or irritant properties. Vesicants, when extravasated, produce local necrosis, and irritants produce burning or inconsequential inflammation without necrosis. A long-term pain management problem may be associated with painful vincristine neuropathy. Although in most children with cancer this usually is a self-limiting condition, it may, in some cases, cause severe pain that requires treatment with strong opioids, anticonvulsants, or antidepressants.

As new antineoplastic agents become available for the treatment of childhood cancer, the practitioner must be aware of the possibility of new pain syndromes arising. The monoclonal antibody 3F8 is an antiganglioside agent being explored as a novel agent for the treatment of stage IV neuroblastoma. The infusion of this agent has been associated with severe abdominal and limb pain in children, despite opioid administration. Infusion of this antibody into rats produces an acute painful peripheral neuropathy. In the rodent model, both gabapentin and intravenous lidocaine appear effective. [54]

### *Postoperative Pain*

The management of postoperative pain in the child with cancer is similar, in many respects, to the management of postoperative pain in a patient without malignancy, as has been reviewed elsewhere. Nonetheless, some features in postoperative care are unique to the child with cancer. In a patient who was receiving opioids preoperatively, the daily dose of opioids should be calculated, and this dose should be used as a baseline to which additional opioids are added for the purposes of postoperative pain control. Because this principle is commonly ignored in postoperative care, oncology patients often are dramatically undermedicated. Opioid requirements can be very high in children undergoing extensive thoracic, abdominal, pelvic, or extremity cancer resections.

We have been informed of several incidents in which pediatric oncology patients were distressingly aware intraoperatively during anesthesia due to selection of a nitrous oxide–opioid–relaxant-based anesthetic technique that did not sufficiently take into account the patients' increased opioid requirements (Charles B. Berde, *unpublished observations*). Unless contraindicated by severe hemodynamic instability, oncology patients should receive sufficient depth of anesthesia with inclusion of volatile or intravenous anesthetic agents to diminish as much as possible the likelihood of intraoperative awareness. Even among children with severe doxorubicin (Adriamycin) cardiotoxicity, sufficient doses of sedative-hypnotic agents can be incorporated into the anesthetic plan.

### *Procedure–Related Pain*

#### Needle Puncture

Needle puncture often is required in cancer treatment for obtaining blood specimens, administering intravenous or intramuscular chemotherapy (e.g., asparaginase), or obtaining access to implanted intravenous access devices. Needle procedures are a major source of distress for children. Children must be adequately prepared before their first needle puncture to minimize their fear and anxiety. This preparation commences with the practitioner working with a child's parents to obtain an insight into the child's coping style, to explain to them the nature of the procedure, and to enlist their support. An age-appropriate explanation to the child should follow, with consideration of a particular child's previous experience and coping style. [55]

A variety of topical treatments have been used to provide analgesia for needle procedures. Skin cooling with ice or fluorocarbon coolant sprays has been used with some success. The eutectic mixture of local anesthetics (EMLA) has become a useful method of topical anesthesia before venipuncture, venous cannulation, lumbar puncture, and accessing of subcutaneous central venous ports. [56,57] EMLA has proven safe, with low plasma concentrations of local anesthetic and a negligible risk of methemoglobinemia. Although it provides no analgesia for structures deep to the dermis, EMLA can help to lessen the pain of subsequent deeper infiltration with local anesthetic. Skin cooling and EMLA can produce vasoconstriction, [58] which may occasionally make venous cannulation more difficult. More commonly, though, these procedures reduce distress sufficiently to facilitate cannulation, thereby outweighing the potential disadvantage of vasoconstriction. The depth of penetration of this anesthesia increases in proportion to the duration of the application of EMLA. [59] Although 60 minutes is the commonly recommended application span before a procedure is undertaken, a longer application period is recommended for more distressing procedures. In addition, application for 3 hours or longer tends to produce vasodilation, [58] rather than vasoconstriction, probably due to a combination of direct actions on subdermal vascular smooth muscle tone and conduction blockade at sympathetic terminals in subdermal arterioles. To achieve the benefits of 3-hour application in outpatients, application of EMLA at home before coming to clinic is advised.

Several other topical local anesthetics also appear to be effective. A formulation of tetracaine (amethocaine; Ametop) is available in many countries (although not in the United States). This tetracaine formulation provides faster onset of cutaneous analgesia than does EMLA [60,61] and showed better efficacy in some studies. [61,62] Tetracaine has the advantage of inciting vasodilation at all times after application, which may facilitate identification of veins for venipuncture or venous cannulation. Liposomal lidocaine formulations have become available in the United States, and these too appear to provide rapid onset of cutaneous analgesia. [63]

EMLA and other forms of topical anesthesia are very useful, and their application should be encouraged, but they should not be promised as a panacea to relieve all needle-related pain. If venipuncture is unsuccessful at sites treated with EMLA, it may be necessary to perform subsequent attempts at untreated sites.

#### Lumbar Puncture

The pain related to lumbar puncture is caused largely by puncture of the skin by the spinal needle or by contact with bone if the needle fails to pass directly through the interspace. Although the dura is a pain-sensitive structure, patients only rarely experience pain as the dura is punctured or as intrathecal medication is instilled. EMLA or other topical anesthetics may be applied before the subcutaneous administration of local anesthesia. Equally important factors in the distress of lumbar puncture for children are the required body position and the necessity to remain still until the procedure is complete. For children who are unable to comply voluntarily, a variety of cognitive and behavioral techniques, conscious sedation, or even general anesthesia may prove beneficial. Hip flexion facilitates needle placement. Conversely, despite common practice, neck flexion is irrelevant to the degree of flexion or extension of the lumbar spine, and is not necessary. In infants, neck flexion may predispose to airway obstruction, particularly if sedatives are administered.

Occasionally, lumbar puncture may produce a sustained cerebrospinal fluid leak, leading to low intracranial pressure and so-called spinal headache. The epidemiologic pattern of postdural puncture headache in children with cancer has been examined in recent studies. [64] Dural puncture headache is not rare among children receiving diagnostic lumbar puncture, with an incidence of 11%, 9%, and 8% in three studies. [64,65] and [66] Headaches occurred at a similar frequency among toddlers, school-age children, and adolescents. [64]

The treatment of this headache, if it occurs, is accomplished with simple analgesics, adequate hydration, and a recumbent position. In refractory cases, an epidural blood patch (i.e., the injection of autologous blood in the epidural space) may be required to alleviate this symptom. [67,68] For a child with a history of severe postdural puncture headache who requires subsequent lumbar punctures, consideration should be given to use thin (24- to 27-gauge) spinal needles with modified noncutting tips. An extensive body of literature addressing the subject of adults receiving spinal anesthesia indicates that these needles substantially reduce the likelihood of spinal headache in surgical and obstetric patients. [69] Use of these needles entails a learning curve. Withdrawal of cerebrospinal fluid is much slower with narrow needles and may require gentle syringe aspiration. Measurement of cerebrospinal fluid pressure probably is less reliable through these narrow needles.

#### Bone Marrow Aspiration

The pain related to bone marrow aspiration results from the insertion of a large needle through the periosteum of the posterior superior iliac spine or other sites and from the unpleasant sensation experienced at the time of suctioning of the marrow. The latter pain is not alleviated by the administration of local anesthetic. The almost universal distress of children undergoing bone marrow aspiration was documented previously. [70,71] Conscious sedation, [72] general anesthesia, and a variety of cognitive-behavioral interventions (including guided imagery, relaxation, and hypnosis) [73] have shown some effectiveness in alleviating pain and distress in this setting. [74] No single method can be advocated over another, because the choice depends on the patient's age, preference, previous experience with the procedure, and temperament and on the availability of services. For example, a 12-year-old child who is an excellent hypnotic subject and who experiences severe nausea or dysphoria with sedation or general anesthesia may prefer hypnosis to pharmacologic measures. Conversely, a 3-year-old child who has had traumatic experiences

with previous procedures may fare better with a brief general anesthetic.

Propofol, either alone or in combination with opioids, has emerged as a useful short-acting intravenous general anesthetic for pediatric oncologic procedures, [75] particularly for children with indwelling central venous access. Alternatives for children with difficult or distressing intravenous access include inhalation general anesthesia, sedation using 50% nitrous oxide by inhalation, [76] oral administration of midazolam and ketamine,[77] or oral transmucosal fentanyl citrate (OTFC).[78]

In a study of patients undergoing bilateral iliac bone marrow harvest, unilateral bupivacaine infiltration around the periosteum reduced pain scores for 3 days relative to the ratings for the contralateral side.[79] When bupivacaine is injected in this setting (maximum dose 2.5 mg per kg), the practitioner must take extra care to avoid the uncommon but serious occurrence of inadvertent injection directly into the marrow through a previous needle hole in the cortex. Systemic uptake of local anesthetic from the marrow is very rapid (analogous to intraosseous drug administration in resuscitation), leading to the potential for severe cardiac depression and convulsions.

### Removal of Central Venous Lines

The increasing use of tunneled central venous lines in children with cancer has created the need for sedation or for brief general anesthesia during the lines' removal. Common practice at our institution calls for anesthesiologists to administer propofol through the line prior to the procedure and then to maintain anesthesia with inhalation agents as needed.

### Other Sources

The spectrum of colony-stimulating factor–related toxicities in children is similar to that reported in adults, but the effects may occur less frequently. The predominant side-effect associated with administration of filgrastim (G-CSF) or sargramostim (GM-CSF) is medullary bone pain, and this effect is dose-related. The pain associated with myeloid growth factors usually responds to non-opioid analgesics, although opioids may be required for some patients.

### Tumor-Related Syndromes

Aside from the predominance of treatment-related pain, a number of children experience pain related to tumor, despite the initial response of their pain to treatment. Miser[79] found that one-third of the pain experienced by patients in the hospital setting was tumor-related pain, but less than 20% of the pain experienced by outpatients was caused by tumor.

Direct tumor involvement of bone, hollow viscera, or nerves is a common cause of pain in adult patients with cancer. Such tumor involvement commonly results in somatic, visceral, and neuropathic pain, respectively. Somatic pain is typically well localized and is frequently described as aching or gnawing. Examples of somatic pain include pain associated with primary or metastatic bone disease or postsurgical incisional pain. Visceral pain results from the infiltration, compression, distention, or stretching of thoracic and abdominal viscera by primary or metastatic tumor. This pain is poorly localized but often is described as deep, squeezing pressure and may be associated with nausea, vomiting, and diaphoresis, particularly when acute. An example of visceral pain is pain associated with liver tumor, either primary (e.g., hepatoblastoma) or metastatic (e.g., neuroblastoma). Neuropathic pain most commonly results from tumor compression or infiltration of peripheral nerves or the spinal cord. Chemical- or radiation-induced injury also may result in this sort of pain. The clinical features of pain resulting from neural injury include abnormal or unfamiliar unpleasant sensations (dysesthesias), pain evoked stimuli that are normally innocuous, such as light touch of the skin (allodynia), pain felt in a region of a sensory deficit (anesthesia dolorosa), and pain characterized by burning or electrical quality or paroxysmal brief shooting component.

### Pain Syndromes Unrelated to Treatment or Tumor

The pediatric oncology patient is just as prone to pain unrelated to the tumor or its treatment (e.g., trauma, migraine, nonspecific abdominal pain) as is any child in the general pediatric population. Diagnosis generally occurs after causes related to the tumor or its treatment are excluded. Acute appendicitis in children with leukemia and other malignancies may present a diagnostic dilemma and is associated with a high diagnostic error rate. [80]

### Chronic Pain as a Management Problem for the Long-Term Survivor of Cancer

As the survival for children with cancer improves, practitioners must be alert to the potential for chronic pain management problems to arise as a consequence of treatment. There is considerable literature about the potential physical and psychological late effects of childhood cancer treatment but little about chronic pain as a consequence of treatment.

At the Pain Treatment Service of the Children's Hospital of Boston, patients who are long-term survivors of childhood cancer and who have chronic pain management problems often are seen. A variety of problems have been encountered in these patients, including chronic abdominal pain of uncertain cause, causalgia of the lower extremity, phantom limb pain, chronic lower extremity pain due to a mechanical problem with an internal prosthesis, avascular necrosis of multiple joints, neuralgia and mechanical pain due to failure of bony union after tumor resection, and post-herpetic neuralgia. A number of these patients require chronic opioid therapy as part of their pain management strategy.

## PSYCHOLOGICAL INTERVENTIONS AND OTHER NONPHARMACOLOGIC APPROACHES TO PAIN MANAGEMENT

Preparation of the child, including a description of the steps of a given procedure and of the sensations experienced, is perhaps the most common intervention for children about to undergo invasive medical procedures. The rationale for this intervention is that coping with unexpected stress is difficult and more anxiety-provoking than is coping with anticipated or predictable stress. [79] It is helpful to perform procedures in a quiet, calm environment conducive to reducing stress and anxiety, in a location separate from the child's room.

Nonpharmacologic methods of pain control in children include a variety of techniques that are categorized as physical (e.g., massage, heat and cold stimulation, electrical nerve stimulation, acupuncture), behavioral (e.g., exercise, operant conditioning, relaxation, biofeedback, modeling, desensitization, art and play therapy), or cognitive (e.g., distraction, attention, imagery, thought stopping, hypnosis, music therapy, psychotherapy), according to whether the intervention is focused on modifying an individual's sensory perception, behaviors, or thoughts and coping abilities.

Complementary and alternative treatments are widely used by children with cancer, often without the knowledge of their physicians. Physicians should include questions about use of these treatments in a patient's medical history. Because these techniques are so widely used, a need exists for properly controlled studies to define safety and efficacy.[82] Placebo effects are highly prevalent, and study design issues can be complex.

Cognitive-behavioral techniques are most commonly used for the pediatric cancer patient to decrease distress and enhance a child's ability to cope with medical procedures. The decision to use a psychological or pharmacologic approach (or both) depends on the practitioner's knowledge of and skill with the procedure, an understanding of the child, and the expectations of pain and anxiety for that particular child undergoing a specific procedure. Choosing which nonpharmacologic method to use is based on factors such as the child's age, behavioral factors, coping ability, fear and anxiety, and the type of pain experienced.

The effectiveness of hypnosis in the reduction of pain and anxiety during bone marrow aspiration and lumbar puncture in children has been confirmed by several reports.[73,83] Similarly, the role of distraction techniques in reducing children's distress during procedures has been examined by several investigators and has been shown to be effective. Distraction was less effective for younger children in one study. [84] Another study enlisted the support of parents and showed a reduction in the children's behavioral distress and a lowering of the parents' anxiety. [15] Several investigators have examined and demonstrated the effectiveness of cognitive-behavioral interventions comprising multiple components, including preparatory information, relaxation, imagery, positive coping statements, modeling, and behavioral rehearsal.[85,86]

Cognitive-behavioral approaches have a distinct advantage in that learning them for one situation may be generalized to their use in another situation. For example, a child who learns relaxation training and guided imagery to manage needle procedures then may apply this method to managing headache, dyspnea, nausea, or other symptoms.

## ANALGESIC MEDICATIONS

### Nonopioids: Acetaminophen, Aspirin, and Nonsteroidal Antiinflammatory Drugs

Acetaminophen is the nonopioid analgesic used most commonly in children. It inhibits prostaglandin synthesis primarily in the central nervous system and lacks the sedative effects that characterize opioids. Acetaminophen provides, at most, a minimal antiinflammatory effect, unlike nonsteroidal antiinflammatory drugs (NSAIDs), which inhibit peripheral cyclooxygenases. Acetaminophen lacks the peripheral side effects of gastritis and inhibition of platelet function found with aspirin and NSAIDs. There is a potential for hepatic and renal injury, but this is extremely uncommon with therapeutic doses. [87] Acetaminophen has antipyretic action and may be contraindicated in circumstances in which it is important to monitor a fever. Pediatric dosing of acetaminophen is based on the dose-response relation for antipyretic effects, because proper dose-response studies for analgesia are limited. Oral dosing of 15 mg per kg every 4 hours appears to be safe. Although rectal dosing generally is avoided in oncology patients, recent studies suggest that rectal absorption is inefficient and that single rectal doses of 30 to 40 mg per kg can be given without generating excessive plasma concentrations.[88]

Aspirin and NSAIDs often are contraindicated in pediatric oncology patients, who commonly are at risk for bleeding due to thrombocytopenia. Aspirin's effects are a greater concern because aspirin's irreversible inhibition of platelet function persists for many days after the drug is cleared, in contrast to the reversible inhibition seen with NSAIDs, which terminates as the drug is cleared. In a comparative study of aspirin and ibuprofen in children with juvenile rheumatoid arthritis, the drugs were equally efficacious, but the dropout rate because of side effects was significantly higher in the aspirin group. [89] In selected children with adequate platelet number and function, NSAIDs may be extremely helpful analgesics, alone and in combination with opioids. It is a common misperception that NSAIDs are specifically effective for bone pain, but a meta-analysis of NSAID use for pain relief in adult cancer patients found no basis for a specific effect on bone versus visceral or other pains. [90]

Choline magnesium salicylate (Trilisate) and related nonacetylated salicylates are widely recommended because of reports of minimal effects on platelet function in adults.[91] However, clinicians should view these data with some caution, because the studies do not include patients with severe thrombocytopenia. The safety of choline magnesium salicylate is not established for patients with active bleeding or a platelet count of fewer than 20,000 cells per cubic millimeter.

A new class of NSAIDs, the cyclooxygenase-2 (COX-2) inhibitors, have been developed to target a specific isoenzyme (found predominantly in leukocytes, peripheral nerves, and the central nervous system) that is involved in generation of prostanoids, which contribute to pain and inflammation. [92] COX-2 inhibitors exert minimal inhibition of COX-1, which makes them less prone to cause gastritis [93,94] or platelet dysfunction.[95] The two COX-2 inhibitors currently available in the United States, celecoxib and rofecoxib, have not undergone pediatric clinical trials. We make use of these drugs off-label for children with specific indications. It is likely that after further study, these agents will assume an important role in pain management for children with cancer. One study examined bleeding time; *in vitro* platelet aggregation to collagen, arachidonate, or a thromboxane receptor agonist; and serum thromboxane $B_2$ concentrations in normal volunteers randomized to receive celecoxib, placebo, or a traditional NSAID, naproxen.[95] For all the preceding end points, naproxen increased *in vivo* and *in vitro* measures of bleeding diathesis as compared with placebo, whereas celecoxib showed no differences as compared with the placebo group. We were unable to identify studies of *in vitro* or *in vivo* hemostasis among patients with moderate or severe degrees of thrombocytopenia receiving COX-2 inhibitors.

### Weak Opioids: Codeine

The distinction between weak opioids and strong opioids in the WHO analgesic ladder is a matter of dose as well as choice of agent. In pediatrics, codeine is the most commonly used agent among the weak opioid class. Although codeine sometimes is accused of having a “ceiling effect,” evidence for this is lacking. The practical limitation on escalated dosing of codeine is that side effects increase with dosing greater than 2 mg per kg. Codeine typically is administered to pediatric patients in oral doses of 0.5 to 1.0 mg per kg every 4 hours. Codeine is largely a prodrug; it is O-demethylated to morphine as the active agent. Recent pharmacogenetic studies have demonstrated that 4% to 14% of subjects lack the hepatic enzyme functions for conversion of codeine to morphine; in these subjects, codeine is largely ineffective as an analgesic. [96,97] Thus, if a patient obtains little analgesia with codeine, clinicians should not hesitate to substitute a different opioid.

Oxycodone may also be used as a weak opioid in lower doses (e.g., 5 mg for adolescents), but dose escalation is highly effective, and no evidence of a ceiling effect exists.

So-called weak opioids are practical in a situation in which opioids are needed immediately by a patient who is far from the prescribing physician and requires a prescription issued by telephone to the pharmacy. In some locations in the United States, telephone prescribing of combinations of acetaminophen with codeine (e.g., Tylenol 3 or 4) or hydrocodone (e.g., Vicodin) is permitted, but telephone prescription of strong opioids is prohibited. Some pharmacies will allow opioid prescriptions to be faxed for patients who are in palliative care.

In some countries, legal barriers to the prescribing of mixed agonist-antagonist opioids or opioids with preferential action at k receptors are less restrictive than those for standard μ-opioid agonists. The k-agonist buprenorphine may have a useful role for children in countries having limited availability of morphine. [96] Aside from availability issues, indications for use of mixed agonist-antagonist opioids or opioids with preferential action at k receptors in children are few at present. Mixed agonist-antagonists frequently produce somnolence or dysphoric reactions in adults, and they may evoke withdrawal symptoms in patients who have been receiving μ-opioid agonists.

### Strong Opioids: Morphine, Hydromorphone, Fentanyl, Meperidine, and Methadone

For moderate to severe pain, μ-opioid agonists are indicated. The starting dosage schedule for the opioids commonly used in pediatric patients is shown in Table 43-1. Morphine is the most widely used strong opiate and is a proper first choice in most circumstances. It may be administered by the oral, rectal, intravenous, subcutaneous, epidural, intrathecal, or intraventricular route. Morphine has significant first-pass metabolism in the liver after oral dosing, and an oral-to-parenteral ratio of approximately 3:1 commonly is recommended. The major metabolite of morphine, morphine-6-glucuronide, produces considerable analgesia and side effects comparable to morphine with chronic dosing.[98,99] A typical starting dose for immediate-release oral morphine in opioid-naive subjects is 0.3 mg per kg every 4 hours. Morphine-6-glucuronide may accumulate and exacerbate sedation in patients with renal insufficiency, because it requires renal clearance. Because morphine clearance is delayed in the first 1 to 3 months of life, [100] starting doses in very young infants should be reduced by approximately 50% on a per-kg basis relative to dosing recommended for older children.

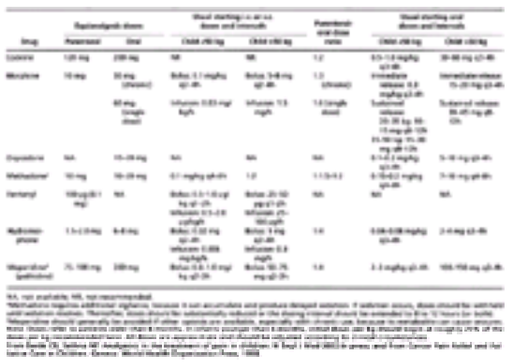

**TABLE 43-1. OPIOID ANALGESIC INITIAL DOSAGE GUIDELINES**

Sustained-release preparations of morphine and oxycodone are available. They permit oral dosing at intervals of twice or three times daily. In a study of children with cancer, sustained-release morphine given twice daily produced greater fluctuations in plasma concentrations than was anticipated, supporting the recommendation that the drug be administered three times daily.[101] Crushing slow-release tablets produces immediate release of the drug, which limits their use for children who are

unable to swallow pills. Sustained-release oral suspensions of morphine are under investigation.

Hydromorphone is an opioid available for oral, intravenous, subcutaneous, epidural, and intrathecal dosing. Hydromorphone commonly is used in adults if there are dose-limiting side effects from morphine. Adult studies indicate that hydromorphone is five to eight times as potent as morphine. A double-blind, randomized, cross-over comparison of morphine to hydromorphone using PCA in children and adolescents with mucositis after bone marrow transplantation showed that hydromorphone was well tolerated and had an approximate potency ratio of 5:1 relative to morphine in this setting. [36] Hydromorphone is convenient for subcutaneous infusion if a high-potency, high-concentration agent is desired to limit infusion volumes, because it is commercially available in 10-mg-per-milliliter solutions and can be prepared in concentrations up to 50 mg per milliliter if needed. The metabolites of hydromorphone are under investigation.

Fentanyl is a synthetic opioid that is approximately 50 to 100 times more potent than morphine, depending on whether infusion or intravenous single-dose comparisons are used. Fentanyl has a very rapid onset after intravenous administration because of its high lipid solubility and rapid entry into the brain. Its duration of action after intravenous bolus administration is much shorter than that for morphine. These features make fentanyl especially useful for brief noxious procedures, for which rapid onset and short duration are useful. Fentanyl may also be used for continuous infusion for selected patients with dose-limiting side effects from morphine, especially pruritus. Although the central mechanisms of pruritus can be activated by fentanyl, less peripheral excitation of itching may ensue with this drug because of less histamine release from fentanyl than with morphine.

The high lipid solubility of fentanyl permits two novel routes of administration: transdermal and oral transmucosal (OTFC). Transdermal administration using a patch permits sustained analgesic effect for selected patients who are unable to tolerate oral opioids. [102] It should not be used in opioid-naive patients and should not be used in patients with rapidly changing pain intensity. OTFC produces a rapid onset of effect and bypasses first-pass hepatic clearance. Schechter et al. [78] described the successful use of oral transmucosal fentanyl for sedation or analgesia for bone marrow biopsy or aspiration and lumbar puncture. Vomiting appears less frequent among pediatric oncology patients than among patients receiving OTFC for sedation prior to surgery.

Meperidine is a synthetic opioid that has been used for procedures and postoperative pain, although it has no advantages over morphine for the latter. A major drawback to the prolonged use of meperidine is that its major metabolite, normeperidine, can cause dysphoria, excitation, and convulsions, particularly in patients with impaired renal clearance. Meperidine is an acceptable alternative to fentanyl for short painful procedures; its duration of action is shorter than that of morphine. Meperidine in low doses (0.25 to 0.5 mg per kg intravenously) is uniquely effective among the opioids for treatment of rigors after the infusion of amphotericin or blood components.

Methadone is a synthetic opioid that has a prolonged duration of action owing to slow hepatic metabolism. In a single parenteral dose in opioid-naive subjects, its potency is similar to that of morphine. It is absorbed efficiently after oral administration, with an oral to parenteral ratio of approximately 1.5 to 2:1. Methadone clearance is variable, with elimination half-lives ranging from 6 to 36 hours. In children undergoing surgery, methadone produced more prolonged analgesia than morphine.[103]

In the past, titration of methadone has been regarded as difficult, and it has been commonly observed that patients converted from a regimen of other opioids to methadone developed delayed somnolence. This outcome often was ascribed to the variability in methadone pharmacokinetics. Although kinetic factors play some role, recent studies have identified additional biologic bases for difficulties in conversion of other opioids to methadone.

Methadone is supplied as a racemic mixture. The L-isomer is a standard μ-opioid, whereas the D-isomer (and, to a lesser extent, the L-isomer) acts as an antagonist at the NMDA subgroup of excitatory amino acid receptors.[104,105] NMDA receptor antagonists have been shown to prevent and partially reverse the development of tolerance to μ-opioids.[105] The implications of this are twofold: First, the potency ratio of methadone to morphine and other opioids depends on the preexisting degree of opioid tolerance. If methadone is given to opioid-tolerant subjects, it acts much more potently than it would in opioid-naive subjects. Second, dosing of opioid-tolerant subjects according to tables derived for opioid-naive subjects will produce overdoses. Ripamonti et al. [106] have examined conversion ratios from morphine to methadone in adults and derived a regression formula based on previous daily oral morphine dosing. Our opinion is that the conversion ratios derived from adult studies by Ripamonti et al. should be used as an approximate starting point for children in lieu of more specific pediatric data.

Because of these factors, frequent patient assessment is key to safe and effective use of methadone. If the patient becomes comfortable after initial doses, the dose should be reduced or the interval extended to reduce the likelihood of subsequent overdosage. If a patient becomes oversedated early in dose escalation, the recommendation is to stop dosing (rather than simply to reduce the dose) and to observe the patient until he or she exhibits increased alertness. Although as-needed dosing is discouraged for most patients with cancer pain, some clinicians find it a useful way to establish a dosing schedule for methadone. Methadone is especially convenient as a long-acting medication in patients who are unable to swallow slow-release morphine tablets whole, because its prolonged duration depends on delayed clearance, and it remains a long-acting agent when administered by elixir or crushed tablets. Methadone is inexpensive, but availability is limited in some pharmacies because of its historical association with opioid addiction treatment programs. Methadone's action as an NMDA antagonist may also increase its effectiveness in certain patients with neuropathic pain. Patients with neuropathic pain who do not respond well to dose escalation of other μ-agonists should be considered for a trial of methadone.

## Routes and Methods of Opioid Administration

### *Oral Administration*

Oral administration of drugs is the first choice for most patients. Oral dosing is generally predictable and inexpensive, and it does not require invasive procedures or technologies. Practical strategies for helping children with medications have been discussed elsewhere. [107] Oral dosing is not feasible in some children with severe unrelieved nausea or ileus or in the occasional child who is rendered uncooperative by extreme fear, delirium, or respiratory distress.

### *Intravenous Administration*

Intravenous administration has the advantage of rapid onset, titrated dosing, complete bioavailability, and constant effect when infusions are used. The main drawback is the need for intravenous access, which is limited in some patients but readily available in the large subgroup of pediatric oncology patients having central venous lines in place. Typical starting intravenous morphine infusion rates are 0.03 to 0.04 mg per kg per hour beyond the first 3 months of life, and 0.015 mg per kg per hour in younger infants.[108,109]

### *Subcutaneous Administration*

For children with poor intravenous access who require parenteral opioids, a convenient alternative is the use of continuous subcutaneous infusions of morphine or hydromorphone.[110] A small catheter or butterfly needle (27-gauge) may be placed under the skin of the thorax, abdomen, or thigh, the site being changed every 3 to 5 days, as needed. Solutions are concentrated so that infusion rates do not exceed 1 to 3 mL per hour, although some centers have used higher rates. The subcutaneous route can also be used for intermittent dosing or for PCA. [111] Needle placement can be made less noxious by prior use of EMLA cream. Pain at the injection site can be diminished by mixing one part lidocaine 1% (10 mg per milliliter) with nine parts opioid solution (lidocaine infusion rates should not exceed 1.5 mg per kg per hour). Intravenous and subcutaneous infusions can be made more convenient for the home by use of small portable infusion pumps. Most of these pumps are equipped with a PCA bolus option as well as a continuous infusion mode. Intramuscular dosing should be avoided in most circumstances, because it is painful and does not permit titrated dosing or infusion.

### *Patient-Controlled Analgesia*

PCA is a method of opioid administration involving a device, usually computer-controlled, that permits the patient to administer small bolus doses within set time limits. Table 43-2 outlines the advantages of PCA in pediatric patients. As noted earlier, PCA has been used very successfully for the management of prolonged oropharyngeal mucositis pain in adolescents. In one study, PCA and staff-controlled continuous-infusion morphine delivery were compared in a randomized, controlled trial in adolescents during oropharyngeal mucositis pain after bone marrow transplantation. The PCA group required less morphine, experienced less sedation, and had less difficulty concentrating, but they benefited from analgesia equivalent to that achieved by the group receiving staff-controlled continuous-infusion morphine.[37]

| |
|---|
| Permits titrated dosing to compensate for individual variation in pharmacokinetics or pharmacodynamics and pain intensity |
| Permits the patient to exercise control and diminish anxiety |
| Permits the patient to balance analgesia against side effects |
| Diminishes sedation |
| Is safe, well accepted |

**TABLE 43-2. ADVANTAGES OF PATIENT-CONTROLLED ANALGESIA IN PEDIATRIC PATIENTS**

PCA allows appropriately selected children control over their analgesia, which can be timed with routine mouth care and other causes of incidental mouth pain. It also allows children to choose a balance between the benefits of analgesia and the side effects of opioids. It is a standard of care at the Children's Hospital of Boston to institute patient-controlled opioid analgesia in appropriately selected children once topical measures and intermittent parenteral intravenous opioids have failed to produce adequate analgesia. In postoperative use, PCA is widely used successfully by children older than 6 years. Anecdotal experience suggests that some children between the ages of 4 and 6 years who become medically sophisticated during cancer treatment can use PCA successfully but, in this group, the risk of inadequate analgesia is higher, owing to failure of the patients to associate pain relief with pressing the button device on the PCA pump to administer opioid. We employ a basal infusion along with PCA-administered doses in most oncology patients.

### *Parent- and Nurse-Controlled Analgesia*

The use of parent-controlled analgesia or nurse-controlled analgesia has been somewhat more controversial. These two methods of analgesia administration permit caregivers to provide incremental, titrated dosing to patients who are unable to dose themselves, whether because of age, cognitive or motor impairment, or severe debilitation. The safety of PCA has been thought to derive from the fact that, when a patient becomes sedated, he or she stops pushing the PCA button device. When other caregivers are charged with pushing the button, this safety factor is removed. In practice, nurse-controlled analgesia has had a very good safety record and has been widely accepted in pediatric centers worldwide, largely for inpatients after surgery or for patients with cancer.

We make frequent use of parent-controlled analgesia in palliative care of children at home. In these circumstances, children generally are opioid-tolerant, which reduces the risk of hypoventilation, and parents have become experienced at judging their child's pain and clinical status. Conversely, parent-controlled analgesia has resulted in a significant number of cases of severe hypoventilation and several deaths among opioid-naive postoperative patients. In review of some of these cases, it appears that patients had risk factors that were inadequately appreciated, there was no formal program for parent education, and patient monitoring was sparse. In one published series of pediatric postoperative patients receiving either nurse-controlled analgesia or parent-controlled analgesia, hypoventilation requiring naloxone was not rare; because all patients were monitored, no adverse outcomes occurred.[112] Parents who will be operating a parent-controlled analgesia device should receive instruction in the aspects of pain assessment, the effects of opioids, and dose titration. They should have a support system that permits immediate telephone availability of clinicians with whom they can confer about dosing. Because in most cases the terminally ill child ultimately will die at home, parents must be reassured in advance that the cancer, not their dosing of opioids to allow comfort, is the cause of their child's demise.

### Opioid Dose Escalation, Opioid Switching, and Incomplete Cross-Tolerance

The effective opioid dose for treatment of cancer pain is extremely variable, and dosing should be titrated based on analgesia and side effects. The WHO analgesic ladder (Fig. 43-1) presents an algorithm for the prescription of analgesics in the setting of cancer pain, in which analgesia is prescribed in a step-wise manner, ranging from simple analgesics for mild pain to strong opioids for intense pain.

*Tolerance* refers to the progressive decline in potency of an opioid with continued use, such that increasingly higher doses are required to achieve the same analgesic effect. When tolerance to a particular opioid develops, cross-tolerance to other opioids may be incomplete. *Physical dependence* is a physiologic state characterized by withdrawal (i.e., abstinence syndrome) after discontinuation of the opioid. Initial manifestations of withdrawal include yawning, diaphoresis, lacrimation, coryza, and tachycardia. Addiction is a psychological and behavioral syndrome characterized by drug craving and aberrant drug use.

Patients and parents often are reluctant to increase dosing because of a fear that tolerance will make opioids ineffective at a later date. They should be reassured that tolerance in the great majority of cases can be managed by simple dose escalation, use of adjuvant medications, or perhaps by opioid switching in the setting of dose-limiting side effects. No justification exists for withholding opioids to save them for a later time of need. Some parents may fear that administration of opioids to their child will cause the child subsequently to become a drug addict. The incidence of opioid addiction was examined prospectively in 12,000 hospitalized adult patients who received at least one strong opioid. Only four cases of subsequent addiction in patients without a prior history of drug abuse were documented. These data suggest that iatrogenic opioid addiction is an exceedingly uncommon problem.[113]

Traditionally, opioids are regarded as interchangeable in terms of the development of tolerance and the ratio of analgesia to side effects. Cases were described that seemed to exhibit two novel features: incomplete cross-tolerance when switching from one opioid to another, and markedly different efficacy or ratio of analgesia to side effects with different opioids.[114] These phenomena warrant further study. If intolerable side effects are found with dose escalation of one opioid, it is reasonable to try another opioid. Foley[115] recommended reducing to 50% of the equianalgesic dose when switching from an opioid with a short half-life to another in the same category. As noted earlier, transition from another opioid to methadone in particular should be undertaken with caution, and even lower starting doses of methadone should be used.[106] Patients who have been switched from a short half-life opioid to a long half-life opioid require close observation. The development of progressive somnolence may indicate the need to reduce the dose or frequency of administration. Table 43-1 demonstrates the potency of the various opioids relative to morphine. Clinical examples of opioid dose calculation and conversion for treating pediatric cancer pain are given in Table 43-3.

**TABLE 43-3. CLINICAL EXAMPLES OF OPIOID DOSE CALCULATION AND CONVERSION FOR PEDIATRIC CANCER PAIN**

### *Pain Associated with Advanced Cancer in Childhood*

Among adults with cancer, rapid opioid dose escalation is most commonly attributed to tumor spread rather than rapidly progressive tolerance.[116] The opioid requirements and dose escalation were examined for a cohort of 199 children who died of malignancy at Boston's Children's Hospital and the Dana-Farber Cancer

Institute from 1989 to 1993, a time during which the WHO program was more consistently applied. [31] Twelve patients(6%) required greater than 100-fold escalation over starting values or greater than 3 mg per kg per hour of intravenous morphine equivalent. This rapid dose escalation occurred most commonly in the final weeks of life (Fig. 43-2) and among patients with solid tumors metastatic to the spine, central nervous system, or major nerve plexus. Maximum opioid dosing ranged from 3.8 to 518 mg per kg per hour of intravenous morphine equivalent. The maximum infusion rate (exceeding all previously published reports) occurred in an infant with an isolated metastasis in the periaqueductal gray matter, a brainstem site linked to mediating analgesia and defense reactions. [117]

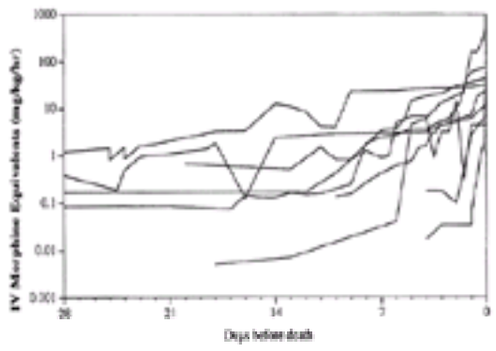

**FIGURE 43-2.** Logarithmic escalation of dose for pediatric patients with terminal malignancies who require massive doses of opioids. (From Collins JJ, Grier HE, Kinney HC, Berde CB. Control of severe pain in children with terminal malignancy. J Pediatr 1995;126:653, with permission.)

Standard dosing of opioids adequately treats most cancer pain in children; however, a significant number of pain episodes related to cancer require more extensive management. Of the 12 patients in our series, [31] eight required extraordinary measures (i.e., epidural or subarachnoid infusion and sedation) to achieve adequate analgesia. The clinical course of care derived from the management of these patients with intractable pain during the terminal phase of their illness is shown in Figure 43-3.

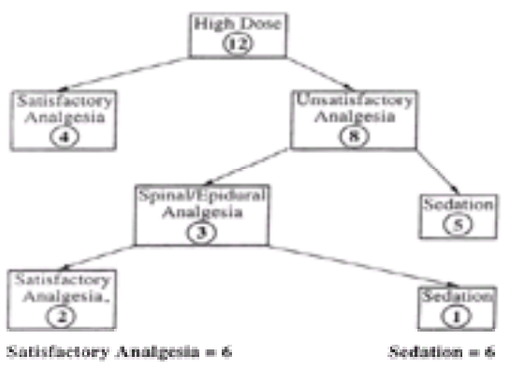

**FIGURE 43-3.** The clinical course of 12 pediatric patients requiring high-dose opioid therapy for terminal malignancies. Circled numbers represent the number of patients in each category. Ultimately, analgesia was satisfactory in six patients. (From Collins JJ, Grier HE, Kinney HC, Berde CB. Control of severe pain in children with terminal malignancy. J Pediatr 1995;126:653, with permission.)

The choice of sedation as a method of analgesia generally assumes that there is no acceptable means for providing analgesia with preservation of alertness. We strongly recommend continuing high-dose opioid infusions along with sedative-hypnotics in these circumstances, to avoid situations in which the patient has unrelieved pain but inadequate clarity of sensorium to communicate about his or her pain. The ethics of providing sedation in the terminally ill is discussed elsewhere.[118] A retrospective survey of parents after the death of their child due to cancer indicated that a high percentage of children experienced delays or incomplete effectiveness in achieving relief of pain and other symptoms. [119]

### *Treatment of Opioid Side Effects*

All opioids can potentially cause the same constellation of side effects. However, the constellation experienced by individual patients receiving different opioids may not be the same. Children do not necessarily report all side effects (e.g., constipation, pruritus) and should be asked specific questions. The assessment of analgesic effectiveness includes an assessment of opioid side effects. Tolerance to sedation, nausea and vomiting, and pruritus often develop within the first week after commencing opioids. One uncommon side effect of opioids is the onset of dreams that usually are described as vivid in quality, although not necessarily frightening. A change of opioid may be required if this is distressing to the child. Table 43-4 outlines management strategies for common opioid side effects.

**TABLE 43-4. MANAGEMENT OF OPIOID SIDE EFFECTS**

## Invasive Approaches to Pain Management

### *Anesthetic Approaches*

Several techniques are used extensively for adult cancer patients who experience inadequate relief with massive dose escalation or who experience intolerable side effects with the use of opioids and adjuvant medications. The most widespread invasive technique for adults in the United States involves epidural or subarachnoid infusions of opioids and local anesthetics. [120],[121] and [122] Experience with children is much more limited, but preliminary experience in several centers suggests that selected use of a spinal infusion may be helpful.

Based on experience with epidural and subarachnoid infusions among 12 children and adolescents with cancer, [123] we recommend the following modifications of

technique for children relative to common adult practice:

- Adults commonly receive placement of epidural and spinal catheters while they are awake or with minimal sedation. This is an entirely unnecessary source of distress, and we advocate placement of epidural and subarachnoid catheters in children under effective sedation or general anesthesia. Positioning of catheters should be confirmed by fluoroscopy and contrast injection at the time of placement, whenever feasible, to verify proper positioning and to confirm that the access of medications to the intended sites of action is not occluded by spinal metastases.
- Although many adults obtain an adequate ratio of analgesia to side effects with opioids alone, children and adolescents invariably require some local anesthetic along with an opioid to achieve optimal effects. Morphine, fentanyl, and hydromorphone have commonly been used via the epidural route in children.
- Catheters should be tunneled at the time of initial placement for improved skin care and maintenance.
- Because local anesthetics usually are needed and their cephalocaudad spread is limited, particularly by the epidural route, optimal placement of catheters is at or above the appropriate dermatomal level of the patient's major sites of pain. For pain predominantly above the umbilicus, we prefer placement of thoracic epidural catheters. For pain predominantly below the umbilicus, we prefer lumbar subarachnoid catheters to give the greatest flexibility in local anesthetic dose escalation.
- With spinal analgesia, particularly using local anesthetics, requirements for systemic analgesia vary widely. Patients may become sedated from minimal systemic opioids because of the reduction of afferent stimuli, or they may experience withdrawal from rapid reduction of systemic opioids. Dosing must be individualized on the basis of clinical signs.
- Maintaining a route for rescue medication, including intravenous boluses, and for planning of dose escalation of spinal medications is essential. Some patients will need additional systemic opioid analgesia or anxiolytics for the management of terminal air hunger.

Neurolytic blockade using agents such as phenol or alcohol is used most widely for adults with visceral malignancy, such as celiac plexus blockade for pancreatic cancer[124] or hypogastric plexus blockade for pelvic malignancies.[125] Neurolytic blockade is used rarely in children, although we found celiac plexus blockade useful for a child with hepatoblastoma that was unresponsive to treatment.[126] Specialists with experience in pediatric regional anesthesia and cancer pain management should be consulted if anesthetic techniques are considered for children with widespread cancer pain.

### *Neurosurgical Approaches*

The use of neurodestructive procedures in adults with cancer pain has diminished as our facility with systemic opioids and adjuvants has improved and as spinal infusion of opioids and local anesthetics has become available. Experience with neurodestructive procedures in children is extremely limited. In an earlier era when opioids were used less effectively, Matson[127] described his experience with effective use of cordotomy in children, but whether these cases could have been managed effectively by current pharmacologic approaches remains unclear.

A discussion of the considerations for neurosurgical approaches to pain in children is given elsewhere.[128] These authors describe several cases of decompressive laminectomies that relieved refractory pain for patients with acute cord compression. Considerations for surgery, irradiation, or medical therapy of cord compression must be individualized. An algorithm for the management of back pain and spinal cord compression in adults has been proposed by Portenoy.[129]

The choice of invasive methods of pain management in patients with terminal malignancy should be made judiciously, with a consideration of the wishes of the patient and family. For example, if opioid escalation is limited by somnolence or confusion despite addition of a stimulant, a primary consideration is whether the patient wishes to remain alert. Some children prefer somnolence during their terminal course. In this situation, escalation of opioids and anxiolytics may be preferable to an invasive procedure. Other children wish very strongly to have alertness along with comfort, and an invasive method of analgesia may then be appropriate.

## Adjuvant Agents

The term *adjuvant analgesic* describes a heterogeneous group of drugs that have a primary indication other than pain but are analgesic in some painful conditions.[130] Common classes of drugs that have been used as adjuvant analgesics include antidepressants, anticonvulsants, neuroleptics, psychostimulants, antihistamines, corticosteroids, centrally acting skeletal muscle relaxants, and associated drugs. These agents are commonly, but not always, prescribed with primary analgesic drugs.

### *Antidepressants*

The use of tricyclic antidepressants for the treatment of chronic pain in adult patients was first reported in 1960.[131] Subsequently, tricyclic antidepressants have been used for a variety of pain conditions, including post-herpetic neuralgia,[51] diabetic neuropathy,[132] tension headache,[133] migraine headache,[134] rheumatoid arthritis,[135] chronic low back pain,[136] and cancer pain.[137] Tricyclic antidepressants may be useful as an adjuvant analgesic in patients with neuropathic pain caused by tumor. The mechanism of action of tricyclic antidepressants as analgesics and the method by which they may potentiate morphine analgesia have been reviewed elsewhere.[138,139]

Despite the lack of controlled trials on the use of tricyclic antidepressant drugs as adjuvant analgesic agents in the unwell pediatric population, guidelines for the choice and management of antidepressants as adjuvant analgesics in children have been outlined by Heiligenstein and Gerrity.[140] These guidelines include the premise that

- It is reasonable to prescribe when shown to be effective in adults.
- NSAIDs or opioids should be tried first, except in deafferentation pain.
- The choice usually is made on the basis of side effect profile (in patients with insomnia and pain, consider a sedating compound at bedtime).
- A baseline complete blood count, electrolyte assay, liver enzyme profile, and electrocardiogram (to exclude Wolff-Parkinson-White syndrome or other cardiac conduction defect) should be performed.[141]

Because children metabolize these agents more efficiently than do adults, some psychiatrists employ a twice-daily regimen of tricyclic antidepressants, often with a larger dose at night than in the morning. Our preference for most ambulatory patients is to use only nighttime dosing. Indications for blood levels include confirmation of compliance and confirmation that optimization of dosage has occurred before the drug's use is discontinued. A titration electrocardiogram is recommended for long-term use or if standard dosages are exceeded, as asymptomatic electrocardiographic changes can occur.[142]

The anticholinergic and sedating side effects of amitriptyline may be a significant problem for some patients. A change to a tricyclic drug with fewer sedating or anticholinergic side effects (e.g., nortriptyline, desipramine) is an option. Amitriptyline is available in a parenteral preparation, and use of this route of administration in children has been described elsewhere.[143]

Common causes for insomnia in children with cancer include unrelieved pain, anxiety, and depression. If pain is a cause of sleep disturbance, a prescription of a larger dose of opioid at bedtime or the use of sustained-release preparations (e.g., MS-Contin) or slowly metabolized opioids (e.g., methadone, levorphanol) can diminish the chance of nighttime awakening from pain. Otherwise, our preference is to treat most sleep disturbances with small doses of a tricyclic antidepressant or with the tetracyclic antidepressant trazodone. We discourage the prolonged use of benzodiazepines for sleep disturbance, because with chronic use, they disrupt sleep cycles, produce tolerance and dependence, and can exacerbate daytime somnolence and confusion.

### *Psychostimulants*

The analgesic effects of amphetamines are believed to be mediated by central and descending spinal inhibitory pathways. Descending noradrenergic and serotoninergic spinal inhibitory pathways may play a role in the analgesic action of methylphenidate.[144] Psycho stimulants have multiple potential benefits as adjuvant drugs in pain management. Dextroamphetamine potentiates opioid analgesia in postoperative adult patients.[145] Methylphenidate counteracts opiod-related sedation[146] and cognitive dysfunction[147] in advanced cancer patients and may allow dose escalation of opioids in cancer patients who have somnolence as an opioid-limiting side effect.[148] Yee and Berde[149] reported on the safety, efficacy, and tolerability of dextroamphetamine and methylphenidate in a retrospective review of 11 children receiving opioid for a variety of indications, including cancer pain. Somnolence was reduced without significant adverse side effects.[149] Prescription of methylphenidate should be preceded by consideration of its potential side effects, which include anorexia, insomnia, and dysphoria.

### *Corticosteroids*

Corticosteroids mediate their analgesic activity in the setting of cancer pain by a variety of mechanisms, including antiinflammatory effects, reduction of tumor edema and, potentially, reduction of spontaneous discharge in the injured nerve. [150] Most studies examining the role of steroids in the setting of cancer pain have evaluated adults. Steroids have a role to play in the setting of bone pain due to metastatic bone disease, [151] cerebral edema due to primary or metastatic tumor,[152,153] epidural spinal cord compression[154] and, possibly, neuropathic pain. [155] Although the optimal type and dosage of corticosteroids for various indications have not been adequately studied, dexamethasone often is used because of its high potency, longer duration of action, and minimal mineralocorticoid effect.

### *Anticonvulsants*

Anticonvulsants are effective for many forms of neuropathic pain. Although traditionally used for lancinating or paroxysmal neuropathic pain, they also are useful for many forms of constant burning pain or for conditions with severe allodynia. [156] Carbamazepine has been used effectively for lancinating pain due to cancer. Phenytoin, clonazepam, and valproate may have similar effects. The mechanism of action of anticonvulsants in controlling lancinating pain is unknown but is presumed to be related to reducing paroxysmal discharges of central and peripheral neurons. [157]

In recent years, gabapentin has emerged as the most commonly used anticonvulsant for neuropathic pain. In comparison with the agents listed earlier, this anticonvulsant is associated with a reduced risk of hematologic, hepatic, or autoimmune complications. Controlled trials have demonstrated analgesic effects in adults with diabetic neuropathy and post-herpetic neuralgia. The dose response and maximum tolerated dose of gabapentin vary widely. Our general approach is to begin with a first day of very low doses administered twice daily (e.g., 50-mg morning dose and 100-mg evening dose for adolescents; 25- and 50-mg doses for younger children). (The smallest capsules are 100 mg, so the contents are dissolved in juice and a fraction of the volume is administered.) If the drug is tolerated, dosing is continued on a three-times-daily schedule with larger evening doses than daytime doses, and is escalated on a daily basis by 50% until one of three end points is reached: (a) analgesia is achieved, (b) side effects (sedation, changes in memory or cognition, mood changes) become bothersome, or (c) dosing reaches roughly 50 to 60 mg per kg per day.

A number of other new anticonvulsants are under investigation for neuropathic pain, including topiramate, lamotrigine, and pregabalin. Information on pediatric use of these agents is limited, and their use has largely been confined to treatment of refractory epilepsy.

### *Neuroleptics*

Phenothiazines and butyrophenones are largely indicated as antiemetics rather than as analgesics. In some cases, neuroleptics given to patients in pain may reduce their ability to interact and verbalize their pain rather than reduce the intensity of the pain experience. Evidence for an analgesic effect for most of the neuroleptics is scant.

The phenothiazine methotrimeprazine appears to be analgesic in the setting of adult cancer pain. [158] It may be useful as an adjuvant analgesic in the patient with advanced cancer should not be considered a substitute for opioid analgesia. The mechanism by which methotrimeprazine produces analgesia and its role as an adjuvant agent in pediatric cancer pain are unclear.

### *Radionuclides*

One case report indicated the potential role of [ $^{131}$I]-meta-iodobenylguanidine ([ $^{131}$I]MIBG) in painful bone disease related to disseminated neuroblastoma. [159] Administration of [$^{131}$I]MIBG occurred on three separate occasions and allowed cessation of opioids subsequent to the administration of this agent. The side effects of [$^{131}$I]MIBG were thrombocytopenia and cystitis. The use of other radionuclides for painful metastatic bone disease in adults has been reported. [160]

## NAUSEA AND VOMITING

The intensification of both chemotherapeutic and radiotherapeutic programs has resulted in both increased efficacy in and increased toxicity to cancer patients. Nausea and vomiting, which are experienced by almost all cancer patients, are among the most troublesome and debilitating side effects. Nausea (the feeling of the imminent need to vomit) and vomiting (the forceful expulsion of gastric contents) are not the self-limiting symptoms commonly associated with other disease states. Rather, they are severe and often prolonged symptoms associated with numerous unpleasant sequelae ranging from wound dehiscence to dehydration that necessitates hospitalization. Without effective prophylaxis, these symptoms become debilitating, and patients are physically incapable of receiving further chemotherapy or are so psychologically distressed that they or their parents may refuse subsequent treatments.

During the last two decades, major advances have led to better, although still imperfect, control of nausea and emesis. These advances stem from improved understanding of the physiology of nausea and vomiting, the development of the 5-hydroxytryptamine subtype 3 (5-HT $_3$) receptor antagonist class of antiemetics, and improved differentiation of anticipatory, acute, and delayed symptoms. Despite these advances, nausea and vomiting remain the first and third most distressing side effects of chemotherapy in adults and continue to occur in most adult and pediatric patients. [161,162 and 163]

### Physiology of Vomiting

Vomiting is mediated by the vomiting center located in the medullary lateral reticular formation. [164] This center receives afferent input from five main sources:

1. Chemoreceptor trigger zone (CTZ)
2. Vagal and sympathetic afferents from the viscera
3. Midbrain receptors that detect changes in intracranial pressure
4. Labyrinthine apparatus, which detects motion and position
5. Higher central nervous system structures (e.g., the limbic system)

The vomiting center, in turn, activates a series of efferent pathways, which include phrenic nerves to the diaphragm, spinal nerves to abdominal musculature, and visceral nerves to the stomach and esophagus. These efferent pathways respond to the centrally mediated stimulation in the vomiting center and act to induce actual vomiting.

### *Chemotherapy-Induced Vomiting*

Chemotherapeutic agents may induce vomiting either by stimulation of the vomiting center itself or via direct or indirect stimulation of the CTZ. The CTZ, a distinct medullary center located in the floor of the fourth ventricle in the vicinity of the area postrema, activates the vomiting center to produce nausea and vomiting. The CTZ has no autonomous capability to produce vomiting.

Animal studies of CTZ ablation suggest that chemotherapeutic agents induce nausea and vomiting by CTZ stimulation. [165] Participation of the forebrain and peripheral mechanisms has also been demonstrated.[166] However, major species differences exist. Thus, one can only infer the site of action in human beings by extrapolation from animal studies and by clinical observations. Several findings suggest that the action of chemotherapeutic agents on the CTZ is indirect: First, it appears unlikely that the CTZ would have a unique receptor for each drug. Second, vagotomy and sympathectomy abolish cisplatin-induced vomiting in the ferret. [167] Third, transfer of whole plasma, plasma filtrates, and blood from dogs and cats with cisplatin-induced vomiting fails to induce vomiting in the recipient. [168] Current evidence suggests that neuronal afferents activated by chemotherapeutic agents increase neural input to the CTZ. This hypothesis is supported by animal experiments in which denervation of the vagal and sympathetic afferents prevents chemotherapy- and radiation-induced emesis. [166,167] Whether chemotherapeutic agents act on the gastrointestinal tract wall to release a humoral or neuronal signal or act directly on vagal afferents is under investigation.

Our understanding of the neurochemistry of vomiting has improved but remains incomplete. [169] We now know that serotonin (5-HT) receptors, particularly subtype 3

receptors (5-HT$_3$), play a role in the mediation of chemotherapy-induced nausea and vomiting. Selective antagonists of 5-HT $_3$ receptors are potent antiemetics. Enterochromaffin cells in the gastrointestinal tract are major producers of serotonin, and studies in ferrets have demonstrated that cisplatin-induced emesis can be prevented with depletion of body serotonin stores.[170] Human studies have shown a rise in serotonin metabolites in the urine after administration of cisplatin.[171] This rise correlates with the onset and intensity of emesis. 5-HT $_3$ receptors are located throughout the human brain, including a high concentration in the area postrema, where the CTZ is located.[172] Injection of 5-HT$_3$ receptor antagonists into the area postrema inhibits cisplatin-induced emesis in the ferret.[173] 5-HT$_3$ receptors are present in vagal afferent fibers, and activation by serotonin leads to an increased firing rate in these fibers.[174] In addition, metoclopramide, which previously was known to act on dopaminergic receptors, now has been shown to act on serotonin receptors as well.[175] Whether the predominant clinical effect of 5-HT $_3$ receptor antagonists is central, on receptors in the area postrema, or peripheral, on receptors in the gastrointestinal tract wall or vagal afferents, remains unclear.

Recent work suggests that substance P, a neuropeptide found in the gastrointestinal tract and central nervous system, may play a role in mediating emesis from a number of stimuli. Substance P antagonists, which antagonize the neurokinin-1(NK $_1$) receptor, inhibit vomiting in animals from a number of stimuli, including radiation and chemotherapy.[176,177,178,179,180 and 181] These NK$_1$ receptor antagonists are effective antiemetics when administered with the emetogenic treatment or when administered after the first emesis has occurred.[179,181] In ferrets, regular administration of an NK$_1$ antagonist inhibits vomiting after cisplatin administration more effectively than does ondansetron.[182] Hence, in the near future, NK$_1$ receptor antagonists may be developed as effective antiemetics, particularly for delayed emesis.[183,184,185 and 186]

### *Radiation-Induced Vomiting*

Radiation-induced nausea and vomiting appear to be mediated through both CTZ and peripheral mechanisms.[187] Total-body, cranial, and abdominal radiation are all emetogenic, particularly the latter.[188,189 and 190] The role of serotonin in emesis induction is suggested by the findings that higher urine serotonin metabolite levels have been correlated with more emetogenic radiation and that 5-HT $_3$ receptor antagonists are effective in controlling radiation-induced emesis.[190,191]

### *Disease-Induced Vomiting*

Nausea and vomiting result from various sequelae of cancer. Metastatic disease may produce tumor exudate or sloughing of tissue, which in turn produces toxic central effects. Abnormally high or low intracranial pressure, stretching of the capsule of an organ, inflammation of the gastrointestinal tract (gastritis or gastroenteritis), or gastrointestinal obstruction may also initiate nausea and vomiting. The exact mechanisms of symptoms are not clearly defined for these states. However, some of these states can respond to both surgical and pharmacologic intervention. Opioid-induced vomiting and opioid-induced ileus leading to vomiting are common among patients at all stages of illness. Opioids produce nausea and vomiting by both brainstem and direct enteral afferent mechanisms.

## Clinical Presentation

Great variability occurs in symptom presentation, intensity, time to onset, and duration. Some of this variability can be predicted from the specific treatment modalities used, but great variability among patients in response to identical regimens also exists. Symptoms include nausea, retching, and vomiting and tend to occur in a cyclic fashion if not properly treated early in therapy. Retching is identical to vomiting in that the same physiologic mechanisms are occurring, but gastric contents are not expelled. Clinically, retching often is perceived by the patient to be more debilitating than vomiting, because the abdominal musculature can be significantly strained and no relief is achieved. *Acute* symptoms occur during the first 24 hours after administration of chemotherapy. *Delayed* nausea and vomiting occur 24 to 120 hours after emetogenic treatment. Almost all patients experience delayed symptoms after cisplatin administration; nearly half do so after moderately emetogenic treatment.[192,193 and 194] Three-fourths of adult patients experience delayed emesis on the third to fourth days after cisplatin administration.[195] *Anticipatory (psychogenic) vomiting*, the onset of nausea and vomiting before the administration of chemotherapy, is difficult to treat because it is a conditioned response and may be related to anxiety.[196,197] Despite major improvements in the management of acute and delayed symptoms, more than one-half of pediatric patients experience anticipatory symptoms.[196,198] Patient factors that increase the probability of severe clinical symptoms in adults include a prior chemotherapeutic experience, a predisposition to nausea and vomiting (e.g., motion sickness), anxiety, and being female.[199] A multivariate analysis found that prechemotherapy nausea, low social functioning, and female gender were extremely predictive of an increased incidence of symptoms.[200] Better control of acute nausea and vomiting is associated with a lower incidence of delayed nausea and vomiting.[201,202] Of note, pediatric studies addressing risk factors are very limited. One pediatric study does suggest that girls have more symptoms than boys and children younger than 6 years may demonstrate fewer symptoms.[203]

## Principles of Therapy

The origin of vomiting must be identified before any therapy is initiated. In addition to chemotherapy, other causes of vomiting common to pediatric cancer patients include stretching of the capsule of an organ, vestibular reflexes (motion sickness), inflammation of the gastrointestinal tract (gastritis, gastroenteritis), gastrointestinal obstruction, increased intracranial pressure, narcotic administration, and ileus. The latter may be induced by chemotherapeutic agents that affect the peripheral nervous system (e.g., vincristine), by narcotics, or by direct gastrointestinal tract damage from disease or treatment. The etiology of vomiting may change with the patient's condition. For example, the same chemotherapy that directly caused acute and delayed symptoms may then cause gastrointestinal inflammation, leading to continued vomiting. Although treatment-induced symptoms generally are predictable, unusual severity, timing, or duration should prompt development of a differential diagnosis, not just a reflexive modification of the antiemetic regimen. Such symptoms could be the manifestation of a completely different process, such as intestinal obstruction or increased intracranial pressure.

To prevent treatment-induced nausea and vomiting, the receptors for the emetic stimulus must be blocked before the stimulus occurs and the blockade must be continued as long as symptoms are likely to occur. If the emetic stimuli are noniatrogenic (e.g., infection or metabolic derangement), therapy cannot be initiated before symptoms become established. Because nausea and vomiting in patients receiving chemotherapy or radiotherapy are predictable, a planned approach to prophylactic antiemetic therapy is indicated. Scheduled doses must be administered in a timely fashion, regardless of whether symptoms appear. The duration of follow-up therapy is determined by both the patient's previous patterns of nausea and vomiting and the expected duration of emetic activity of the stimulus. Intravenous therapy was once the standard of care for all patients. Newly available oral agents offer good bioavailability and marked efficacy in adults but have not been studied in children.[204,205,206,207 and 208]

Knowledge of the emetogenic potential and patterns of vomiting associated with the various chemotherapeutic agents helps to predict the severity and duration of the anticipated symptoms. Table 43-5 lists some of the antineoplastic agents most commonly used in children, categorized by the severity of symptoms. Data addressing potential differences in emetogenicity between adults and children are sparse. Some agents characterized as most emetogenic in adults have been reported as mildly emetogenic in children.[209,210 and 211] Triple intrathecal therapy with methotrexate, cytarabine, and hydrocortisone has been shown to be moderately emetogenic in children, but the effect of each drug alone has not been addressed.[212] The variability in acute and delayed emetogenic potential of these agents is great. The agents at the lower end of the scale may induce moderate nausea accompanied by no vomiting or mild vomiting, whereas those at the upper end may produce debilitating nausea accompanied by severe vomiting. The severity and duration of vomiting also differ among patients. Some patients may experience 20 retching or vomiting episodes each day for 5 days, whereas others may have 50 episodes over a span of a few hours. The time of onset also varies. Acute symptoms may appear immediately (methchlorethamine) or 6 to 12 hours after administration (cyclophosphamide or actinomycin-D). Delayed symptoms do not appear until at least 24 hours after administration. When these agents are used in combination, antiemetic prophylaxis should be based on the most emetic component of the regimen. When combinations of moderately emetogenic agents are used, prophylaxis for severely emetogenic treatment should be considered. The severity of nausea and vomiting usually is increased with increasing dose and decreased with increasing infusion time.[209] Increasing use of multiday chemotherapeutic regimens, recognition of delayed vomiting, and availability of effective antiemetics with few side effects have led to longer administration of antiemetics. Nausea and vomiting associated with radiotherapy are less well understood. Abdominal radiation almost always causes nausea and vomiting, whereas the occurrence and severity of nausea and vomiting from cranial radiation are more variable.

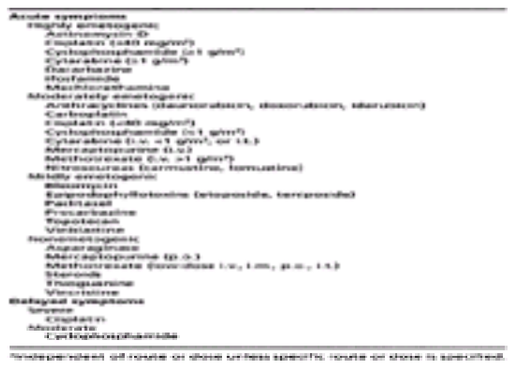

**TABLE 43-5. EMETOGENIC POTENTIAL OF CHEMOTHERAPEUTIC AGENTS**[a]

Additional factors affect the success of the antiemetic regimen chosen. The efficacy of placebo and the negative effects of the vomiting roommate demonstrate the importance of suggestion.[213] Pretreatment anxiety and taste of drugs during injection can also predict symptom development.[214] Hypnosis and supportive counseling can decrease symptoms.[215,216] Removal of known stimuli such as the sight or smell of food also can decrease symptom occurrence. In addition, individual patient preferences regarding oral versus parenteral and soporific versus nonsoporific therapy must be considered. Sleep itself may be used as an antiemetic agent. [217]

### *Pharmacologic Approaches to Control of Acute Symptoms*

Drugs used in the prevention of nausea and vomiting include both true antiemetics and ancillary agents. The latter are not always true antiemetics but are used to potentiate the effects of true antiemetics, to treat anxiety, or to induce sleep. True antiemetics can be classified on the basis of their therapeutic index, which accounts for both efficacy and side effects. Side effects include not only such obvious problems as extrapyramidal symptoms and hallucinations but more subtle symptoms such as dysphoria or soporific effects. Because the vast majority of the antiemetic literature, including most randomized, controlled antiemetic studies, have included only adult patients, we are forced to extrapolate from the adult literature approaches to antiemetic management in children. [210] These studies do not account for potential differences between adults and children as regards antiemetic half-life or side effects or in terms of the emetogenic potential of various drugs.

In pediatric patients, route of administration and available dose forms can greatly affect the efficacy of an agent. Developmental or psychological reasons may prevent administration of oral tablets or capsules in some children. For other children, the only available oral or transdermal dose forms may be inappropriately high. Thus, clinical practice guidelines developed in the adult setting may not be fully applicable to children. [210,218]

Although visual analog scales are used routinely to measure nausea in adults, application of such scales to children is difficult. [219] Interpretation of the pediatric literature is often limited by lack of randomization, heterogeneity of the patient population, and heterogeneity of the emetogenic regimens. Specific dosing parameters are usually unavailable for children because these agents have not received full clinical evaluation in the pediatric population. Table 43-6 outlines various antiemetic agents in the order in which they are discussed. The dosage recommendations presented are the result of our clinical experience and should serve only as a guideline for establishing proper antiemetic regimens.

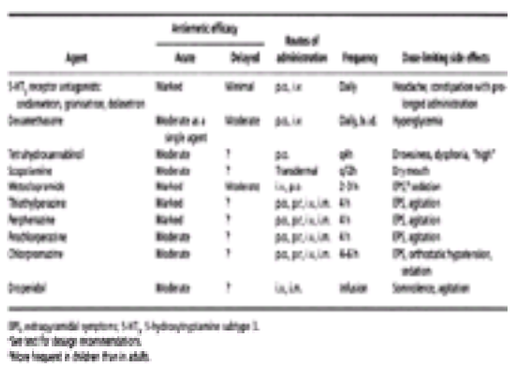

**TABLE 43-6. ANTIEMETIC AGENTS**[a]

### *5-HT$_3$ Receptor Antagonists*

The 5-HT$_3$ receptor antagonists are potent antiemetics with a wide therapeutic margin. Their development in the 1980s and widespread use in the 1990s has revolutionized the prevention of nausea and vomiting in cancer patients. Prior to the availability of these agents, the efficacy of the most widely used antiemetics, metoclopramide and the phenothiazines, was severely limited by their extrapyramidal side effects. Initial research on the different 5-HT $_3$ receptor antagonists focused on each individual agent to determine appropriate dosing, efficacy as compared to metoclopramide and phenothiazines, and optimal use of concomitant agents. More recent research has shown a threshold effect but no dose response, relative equivalence of oral and parenteral routes, and remarkable therapeutic and toxic equivalence between the different 5-HT$_3$ receptor antagonists.[206,208,210] Their role in the control of delayed symptoms is unclear at best.[220,221,222,223,224,225] and [226] Because these agents are costly, development of clinical practice guidelines is encouraged to ensure their appropriate use. [227]

Ondansetron was the first 5-HT$_3$ receptor antagonist commercially available in the United States. For control of acute symptoms in adults, ondansetron is highly effective[171,228,229,230,231] and [232] and superior to metoclopramide.[233,234,235,236,237] and [238] Its efficacy is enhanced by the addition of dexamethasone.[239] The majority of the early studies in adults used a three-dose intravenous regimen of 0.15 mg per kg per dose or 8 mg per dose, with or without subsequent oral maintenance. Subsequent adult studies have shown that single-dose regimens of 16 to 32 mg are at least as effective as divided dose regimens and benefit from the addition of dexamethasone.[224,240,241] Oral regimens offer good bioavailability and have been shown to be effective for moderately and highly emetogenic chemotherapy but have not been studied as extensively as intravenous therapy. [204,242,243] Toxicityin most studies has been minimal and consists primarily of headache (10% to 15%), transient elevation of hepatic transaminases (6% to 8%), and constipation (5%).

Nonrandomized pediatric studies have shown ondansetron to be effective in children receiving a variety of chemotherapeutic agents and radiation.[211,212,244,245,246,247,248,249,250] and [251] Randomized pediatric studies with ondansetron have shown better efficacy compared to metoclopramide, that doses greater than 5 mg per m$^2$ do not add to efficacy, and that the addition of dexamethasone improves efficacy.[252,253,254] and [255] Some pediatric studies show a lower incidence of headache (<5%) and constipation (<1%) than in adults.[247,255,256] Although pharmacokinetic studies in adults have shown trends to correlations between antiemetic efficacy and the area under the curve, the clinical impact of the shorter half-life of ondansetron in children as compared to adults is unknown. [251,257,258]

Few data regarding ondansetron dosing in children are available. Most published studies have used divided-dose regimens with three daily doses of 0.15 mg per kg per dose or 5 mg per m$^2$ per dose. Oral ondansetron twice daily has been given after the initial intravenous drug in many studies. A two-dose regimen of 0.15 mg per kg has been effective in mildly and moderately emetogenic chemotherapy.[211] When ondansetron first became available in the United States, our clinical practice was to administer 0.15 mg per kg per dose before and 8 and 16 hours after chemotherapy. For convenience and cost savings, we have extrapolated from adult data to arrive at our usual ondansetron dose of 0.45 mg per kg per day given intravenously as a single dose.

Granisetron, the next 5-HT$_3$ receptor antagonist to become commercially available in the United States, usually is administered as a single intravenous or oral dose

prior to the administration of emetogenic chemotherapy. Conflicting data appeared in earlier studies regarding the optimal dose, schedule, and route of administration.[195,259,260] Current adult consensus guidelines and recent studies use a dose of 2 mg by mouth daily. For the control of acute symptoms, the combination of dexamethasone and granisetron is more effective than granisetron alone.[223,261] Limited pediatric granisetron data are consistent with adult data in terms of efficacy.[163,262,263,264,265 and 266] The appropriate pediatric dosage of granisetron is unclear at present. Despite the manufacturer's recommended dose of 10 mcg per kg, at least one study has shown lack of efficacy at that dose.[267] Data regarding the relative efficacy of 20 mcg per kg and 40 mcg per kg are conflicting.[203,268] Data regarding the use of oral granisetron in children are not found in the literature.

Dolasetron, the 5-$HT_3$ receptor antagonist most recently available in the United States, is usually administered as a single intravenous or oral dose of 100 mg or 1.8 mg per kg.[269,270,271 and 272] Pediatric studies with small numbers of patients suggested the possibility of increased efficacy with a single dose of 1.8 mg per kg given either intravenously or orally.[273,274] This same group found a shorter half-life for the active metabolite of dolasetron in younger children but studied an insufficient number of patients to determine the clinical significance of this finding.

Tropisetron, a 5-$HT_3$ receptor antagonist that is not currently available in the United States, is characterized by excellent oral absorption, a high area under the curve after a single dose, and few side effects.[275] Dose-finding studies suggest that a single daily dose of 5 mg is adequate in adults.[276] Efficacy as a single agent is good[277,278] and, as is true for all 5-$HT_3$ receptor antagonists, its efficacy is increased with the addition of dexamethasone.[278,279 and 280] Doses of 0.20 mg per kg, 5 mg per $m^2$, and 2 to 5 mg per day have been shown to be effective and well tolerated in children receiving various chemotherapeutic regimens.[281,282 and 283]

On the basis of the published literature, finding an efficacy or toxicity rationale to support the use of one 5-$HT_3$ receptor antagonist as opposed to another is difficult.[210] In general, all the 5-$HT_3$ receptor antagonists share a number of characteristics, including a wide therapeutic margin, a threshold effect with little or no dose response, minimal toxicity, and high cost.[195,206,208,271,284,285 and 286] Although the pediatric literature is very limited, major differences from the adult literature have not been identified. Of note, remarkably few data about the use of 5-$HT_3$ receptor antagonists in infants have been published.[287] The choice of agent to use for antiemetic prophylaxis in adults can be driven by such factors as cost and convenience. The relevance of these factors in children, however, may be limited, owing to such considerations as limited dose sizes and potential difficulty with compliance with oral regimens. Some studies have demonstrated decreased efficacy for tropisetron or dolasetron as compared to ondansetron and granisetron, but final conclusions about differences cannot be determined.[225,288,289 and 290] One randomized, double-blind pediatric study found no differences between ondansetron and granisetron in the bone marrow transplant setting.[163]

**Steroids**

Although their mechanism of action is not understood, steroids have been used as antiemetic agents. Dexamethasone is the most extensively evaluated steroid, with doses ranging from 5 to 48 mg in single and multiple doses.[291,292,293,294 and 295] Recent studies focus on doses of 10 to 20 mg per day, but administration of five daily doses totaling 120 mg per day have been reported.[244] Dexamethasone and metoclopramide have been shown to have similar efficacy in adults receiving moderately and highly emetogenic chemotherapy.[292] For adults receiving moderately emetogenic chemotherapy, ondansetron was somewhat more effective than dexamethasone.[296] Although only moderately effective alone, dexamethasone is highly effective when used to potentiate the efficacy of other antiemetics.[294] The addition of dexamethasone significantly improves emesis control in patients receiving metoclopramide and all the 5-$HT_3$ receptor antagonists.[223,280,297,298,299 and 300] One of the few studies to evaluate the dose-effect of dexamethasone in conjunction with another agent found significant improvements in complete control with dexamethasone doses of at least 10 mg and only slight additional benefit with doses of 20 mg. Several studies have also shown that dexamethasone is effective in the control of delayed vomiting and that its efficacy in this setting is increased when used in combination with metoclopramide but not with 5-$HT_3$ receptor antagonists.[201,221,301] Overall, dexamethasone appears to be a safe, effective adjunct to antiemetic regimens.

The risks and benefits of dexamethasone must be considered carefully in certain clinical and research scenarios. Dexamethasone may adversely affect the efficacy of a biologic response modifier by increasing immunosuppression. Sudden withdrawal of a steroid may exacerbate radiation pneumonitis in patients who have received prior lung irradiation.[302] Dexamethasone may have a direct antitumor effect in lymphoid malignancies and so may affect the interpretation of research studies. No clear dexamethasone dose guidelines are available for children. Our starting dosage is 10 mg/$m^2$ to a maximum dose of 10 mg, given once daily. In the most symptomatic patients, the total daily dosage is doubled, and divided into a twice daily regimen with a maximum of 10 mg given twice daily. Early studies with methylprednisolone have not led to more recent work.[303]

**Phenothiazines**

Prior to the availability of 5-$HT_3$ receptor antagonists, the phenothiazines and metoclopramide were the mainstay of therapy for children. At the usual therapeutic doses, many phenothiazines appear to depress CTZ activity and also may directly depress the vomiting center.[165] Two distinct chemical classes of phenothiazines exist, each with its own therapeutic and toxic characteristics. The aliphatic class, of which chlorpromazine (Thorazine) is the prototype, has limited antiemetic activity and is associated with a high incidence of orthostatic hypotension, sedation, prolongation of the sedative effects of narcotics and barbiturates, and blood dyscrasias. The piperazine class, which includes prochlorperazine (Compazine), thiethylperazine (Torecan), and perphenazine (Trilafon), has pronounced antiemetic activity but is associated with an increased incidence of extrapyramidal effects. Evidence in dogs indicates that the efficacy of perphenazine at nontoxic doses is 24 times greater than that of chlorpromazine and 8 times greater than prochlorperazine in preventing apomorphine-induced emesis.[304] The major disadvantages of these agents—the development of extrapyramidal reactions or agitation—can be decreased by very slow (45 to 60 minutes) intravenous administration with concomitant administration of an antihistamine such as diphenhydramine (Benadryl). Although generally immediate, the side effects can appear as much as 48 hours after drug administration. Thus, repeated dosing of diphenhydramine for an additional 24 hours is recommended for patients who receive prolonged courses of phenothiazines.

The doses and routes of administration vary among the phenothiazines. Thiethylperazine, available for intravenous, intramuscular, oral, and rectal administration, should be given in 10-mg doses every 6 to 8 hours for children aged 12 years or older and in 5-mg doses for younger children. Use of thiethylperazine is not recommended for children younger than 2 years. The recommended loading dose of perphenazine is 2 to 5 mg intravenously over 60 minutes, depending on the age of the child. The loading dose can be followed by either a continuous infusion of 0.25 to 0.5 mg per hour or an oral dose of 2 to 4 mg every 4 hours. Prochlorperazine is considered to be the safest phenothiazine in children younger than 5 years but has only minimal antiemetic efficacy. The development and widespread use of the serotonin receptor antagonists led to the near abandonment of the phenothiazines. More recent studies suggest that phenothiazines can be used in conjunction with the serotonin receptor antagonists to achieve better control of symptoms.[305,306]

**Metoclopramide**

Metoclopramide (Reglan), a procainamide derivative, has both central and peripheral antiemetic actions: It inhibits chemotherapy-induced vomiting and accelerates gastric emptying. Because of its short half-life, it must be administered frequently.[307,308 and 309] The standard regimen in adults has been 2 mg per kg 30 minutes before chemotherapy and again at 1.5, 3.5, 5.5, and (sometimes) 8.5 hours after chemotherapy. Anecdotal evidence and our experience suggest that a dose of 1 mg per kg intravenously over 60 minutes repeated every 2 to 4 hours for a total of five doses is effective. Children are at higher risk for extrapyramidal symptoms than are adults, and so prophylaxis with diphenhydramine is required.[310] The incidence of akathisia and extrapyramidal reactions increases greatly at doses in excess of 1.5 mg per kg.[310] Note that much lower doses of metoclopramide (e.g., 0.2 mg per kg every 6 hours) are effective for postoperative nausea or for acceleration of gastric emptying.

**Miscellaneous Agents**

Although not a true antiemetic, *lorazepam* has proved particularly useful in combination.[311,312,313 and 314] Lorazepam is useful both for its amnestic and its anxiolytic effects. It produces anterograde amnesia and therefore is useful in allaying anticipatory nausea and vomiting by causing patients to forget their previous experiences with chemotherapy.[315] Lorazepam should always be used in combination with a true antiemetic. The dosage of lorazepam is 0.025 to 0.050 mg per kg intravenously or orally, administered 30 minutes before chemotherapy and repeated every 6 hours as needed.[313,315] To avoid perception disturbances associated with higher doses, it is prudent to start with a lowest appropriate dose and avoid exceeding 1 mg.

*Scopolamine* (hyoscine) is a potent anticholinergic agent available in a transdermal patch for the treatment of motion sickness. It has been reported to be effective as a single agent in preventing emesis due to methotrexate and in combination to prevent cisplatin-induced emesis.[316] Its major side effects are sedation and dry mouth.

The transdermal patch should be applied the evening before or the morning of intended chemotherapy. Because of the fixed dosing, it cannot be used in small children.

The *cannabinoids*, the active ingredients of marijuana, have proven antiemetic properties. Delta-9-tetrahydrocannabinol (THC) has been shown to be more effective than both placebo and prochlorperazine in preventing vomiting in patients receiving antineoplastic drugs. [317,318 and 319] Although the exact mechanism of action is unknown, recent work suggests that THC acts as a ligand for a newly-described class of specific cannabinoid receptors, both in the periphery and in the central nervous system. Many patients report relief of nausea while reporting no sedation. Interest in the cannabinoids has led to the development of synthetic analogs of THC, one of which is commercially available as dronabinol (Marinol). Although cannabinoids are not considered first-line therapy, they have been effective in children, in dosages ranging from 2.5 to 7.5 mg per $m^2$.[320] Side effects range from drowsiness to dysphoria, the most common side effect being the development of a "high."[318]

Although they have no direct antiemetic activity, *barbiturates* such as pentobarbital can be used for their sedative effects when patients experience breakthrough vomiting. Although a theoretical risk of aspiration exists in patients with a depressed level of consciousness, the emetic impulse is such a powerful stimulant that patients usually awaken to vomit and then return to their somnolent state. Given the potential risk, however, this approach is recommended only in a controlled setting when all other therapeutic avenues have been exhausted.

*Droperidol* (Inapsine), a butyrophenone, is a potent inhibitor of the CTZ. In numerous studies, using doses ranging from 0.5 to 2.5 mg as single or multiple doses or by continuous infusion, droperidol has been found to be somewhat effective.[321] Reported toxicities include hypotension, tachycardia, somnolence, agitation, and extrapyramidal effects. Experience with droperidol in young children is very limited. In older children, a loading dose of 2.5 mg intravenously over 60 minutes followed by a continuous infusion of 1 mg per hour is recommended.

Many *antihistamines* have mild antiemetic properties,[322] but no correlation can be drawn between antihistaminic potency and antiemetic activity. Both dimenhydrinate (Dramamine) and diphenhydramine are effective antiemetics for motion sickness and may be used in combination with other antiemetic therapy to potentiate effectiveness or to decrease toxicity.

### *Pharmacologic Approaches to Control of Delayed Symptoms*

The control of delayed symptoms has received far less attention in the literature than the control of acute symptoms. Initial studies demonstrated the marked efficacy of the combination of dexamethasone and metoclopramide after the administration of high-dose cisplatin.[201] Dexamethasone alone is effective for patients receiving moderately emetogenic regimens.[301] A recent study has shown significant efficacy in the control of delayed symptoms with a three-drug combination of granisetron on day 1, dexamethasone on days 1 through 5, and prochlorperazine on days 1 through 3.[323] Another encouraging study piloted the use of delayed symptom treatment beginning at hour 16 after cisplatin infusion.[324] The role of 5-$HT_3$ receptor antagonists in the management of delayed symptoms is less clear. Although several studies have shown a benefit to a 5-$HT_3$ receptor antagonist as compared to placebo, other studies have shown no benefit to a 5-$HT_3$ receptor antagonist as compared to dexamethasone alone or metoclopramide alone.[195,220,221,224] Clear evidence of increased incidence of constipation in patients receiving prolonged courses of 5-$HT_3$ receptor antagonists also exists.[220,221] The 5-$HT_3$ receptor antagonists may have increased utility for patients with poor control of acute symptoms. Until more clear-cut studies are conducted that demonstrate the utility of the 5-$HT_3$ receptor antagonists in the control of delayed symptoms, cost should preclude routine use of these agents. Further studies are needed to determine the role of substance P inhibitors in the control of delayed symptoms.[183,184,186,325]

### Approach to Therapy

Clinical practice guidelines developed in the adult setting have focused on the appropriate use of prophylactic regimens both to improve symptom control and to decrease costs.[210,218,227] As in adults, any such guidelines for children must address the acute and late emetogenicity of the regimen and the efficacy and side effects of the agents available. In addition, however, pediatric guidelines must also consider limited dose forms and how best to extrapolate from the adult literature.[326] Table 43-7 summarizes the clinical practice guideline in use at our institution regarding agents to be used with the first administration of any chemotherapeutic regimen. It is critical to adjust the prophylactic regimen used in subsequent courses to the pattern of symptoms and response to prophylactic and any rescue agents used in the prior course of the same agents. In general, we recommend a 5-$HT_3$ receptor antagonist alone for mildly and moderately emetogenic regimens and in combination with dexamethasone for more emetogenic regimens as initial therapy for all patients. Although there is a lack of published experience with ondansetron in very young children, we and others have used ondansetron in infants. For prevention of delayed emesis, we use dexamethasone with or without metoclopramide (with diphenhydramine to prevent extrapyramidal symptoms). For breakthrough emesis, we recommend the sequential addition of dexamethasone, lorazepam, scopolamine (if weight is more than 40 kg), dronabinol (if older than 6 years) or metoclopramide (with diphenhydramine). Because pentobarbital is not currently available, we no longer use a soporific agent. If more than one or two doses of an agent that can cause extrapyramidal symptoms are administered on one day, we recommend continuing diphenhydramine for an additonal 24 hours. Because anticipatory and psychogenic nausea and vomiting can be a significant problem, the most effective regimen is one that prevents nausea and vomiting in the chemotherapy-naive patient. Success or failure of a particular regimen is ultimately determined by the patient's acceptance of future courses of chemotherapy. Although complete elimination of symptoms may not be possible in all patients, a substantial reduction in both the degree and duration of symptoms can usually be achieved, making the treatment more tolerable.

### Somnolence, Fatigue, and Insomnia

Sleep disorders, daytime sedation, fatigue, and lack of mental clarity are common problems among children undergoing cancer treatment, in the setting of advanced cancer, and in some long-term cancer survivors. Fatigue or lack of energy is extremely common among children with cancer.[13,327,328 and 329] These symptoms can occur during treatment with chemotherapy or radiation, after surgery, in the setting of advanced disease, or even in long-term in disease-free survivors.[320] The causes of fatigue often are multifactorial and may reflect a combination of medical and psychosocial factors.[331,332] Sleep disturbance, depression, and anxiety often are associated with daytime fatigue. Depressed mood and anxiety are common in patients with cancer; in most cases, these subjects had no history of mood disorders prior to the onset of the cancer.

One's approach to the child with fatigue should include identification of remediable medical factors (e.g., anemia, cachexia, endocrine or electrolyte disturbances). When depression or anxiety is present, consideration should be given to psychotherapy and pharmacologic treatment. Fatigue often coexists with sleep disturbance. Lifestyle change, including improved sleep hygiene and avoidance of caffeine in the evening, may be helpful to improve sleep. Low doses of an antidepressant are our preferred pharmacologic treatment of persistent sleep disturbance. Fatigue and somnolence, especially in patients taking opioids, may improve with administration of methylphenidate or other stimulants.[149] Graded aerobic exercise programs have shown promise[333]; they may also improve sleep and ameliorate depressed mood.

### Constipation

Constipation is common among patients with cancer. Often but not exclusively, it is due to opioids. [334] Some studies suggest differences among opioids in the severity of constipation. For example, in some studies, transdermal fentanyl was found to produce less constipation than oral morphine. [335]

Although laxatives often are prescribed, they frequently are ineffective, for several reasons: (a) They often are not administered even when prescribed, (b) they often are administered in fixed doses, even when ineffective, and (c) they often are administered only after constipation is persistent and severe. [336]

### Dyspnea

Dyspnea is a common and distressing symptom in pediatric palliative care. [119] Among adults, it is a common feature of lung and head and neck malignancies. [337] In children, dyspnea is commonly seen with solid tumors metastatic to the lungs and pleural spaces. The causes of dyspnea are multifactorial and may be associated with obstructive, restrictive, or mixed abnormalities on spirometry, as well as hypoxemia or hypercarbia. Dyspnea may also result from extrapulmonary causes, including generalized cachexia and fatigue that affects the respiratory as well as other muscles. [338]

In selected cases, palliative interventions may include palliative chemotherapy or radiotherapy, diuretics, pleurocentesis with or without chest tube drainage, pleurodesis, and supplemental oxygen. Occasional patients with reactive bronchoconstriction respond to bronchodilators.

Opioids often are beneficial in reducing the distress of dyspnea, whether due to increased work of breathing or due to hypoxemia or hypercarbia. In the majority of cases, opioids improve dyspnea without inciting significant respiratory depression. [339] Although dyspnea often is accompanied by anxiety, and benzodiazepines frequently are administered to patients with dyspnea, controlled trials have generally found benzodiazepines ineffective in the treatment of cancer-associated dyspnea. [340]

Some palliative care centers use inhaled morphine specifically for dyspnea, although the evidence regarding whether this agent works by a local versus a systemic mechanism remains controversial. Opioid receptors are present at comparatively high density in many parts of the tracheobronchial tree, particularly at the level of bronchioles and lung parenchyma. [341]

## CONCLUSION

Management of symptoms and suffering is an essential part of the care of children with cancer. Each symptom should not be viewed in isolation but rather in the context of the individual child's overall situation. Despite the limitations and imperfections of available methods of treatment, attentive care and the application of pharmacologic principles should allow physicians to ameliorate their patients' distress in the great majority of circumstances. More prospective research is needed on the clinical pharmacology of medications used for symptom management in children and on outcomes of different treatment approaches.
