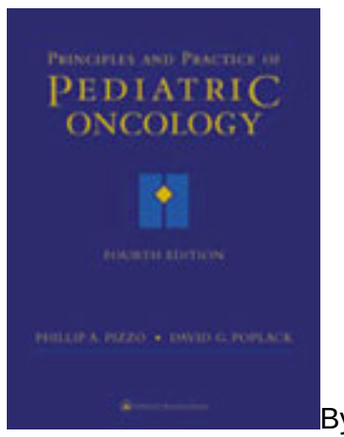
**Principles and Practice of Pediatric Oncology 4th Edition (November 2001):** by Philip A. Pizzo, David G. Poplack (Editor) By Lippincott Williams & Wilkins Publishers



By OkDoKeY

# Principles & Practice of Pediatric Oncology

## CONTENTS

## SECTION V: SUPPORTIVE CARE OF CHILDREN WITH CANCER

## SECTION VI: OTHER ISSUES ARISING AT DIAGNOSIS, DURING TREATMENT, AND AFTER CESSATION OF THERAPY

***Edited by***

## PHILIP A. PIZZO, M.D.

*Since 2001:*
*The Carl and Elizabeth Naumann Professor of Pediatrics*
*and of Microbiology and Immunology*
*Dean*
*Stanford University School of Medicine*
*Stanford, California*
*From 1996–2001:*
*Thomas Morgan Rotch Professor and Chairman*
*Department of Pediatrics*
*Harvard Medical School*
*Boston, Massachusetts*
*Physician-in-Chief and Chairman, Department of Medicine*
*Children's Hospital Boston*
*Boston, Massachusetts*

## DAVID G. POPLACK, M.D.

*Elise C. Young Professor of Pediatric Oncology*
*Chief, Hematology-Oncology Section*
*Department of Pediatrics*
*Baylor College of Medicine*
*Houston, Texas*
*Director, Texas Children's Cancer Center*
*Texas Children's Hospital*
*Houston, Texas*

# CONTRIBUTING AUTHORS

**Orly Eshach Adiv, M.D.** Instructor of Pediatrics, Pediatric Gastroenterology and Nutrition Unit, Technion-Israel Institute of Technology, Bruce Rappaport Faculty of Medicine, Rambam Medical Center, Haifa, Israel

**Bharat R. Agarwal, M.D., D.C.H., D.N.B.** Consultant and Pediatric Hematologist-Oncologist, Institute of Child Health and Research Centre, B. J. Wadia Hospital for Children, Parul, Mumbai, India

**Sarah W. Alexander, M.D.** Instructor, Harvard Medical School, Department of Pediatric Hematology/Oncology, Dana-Farber Cancer Institute, Children's Hospital Boston, Boston, Massachusetts

**Arnold J. Altman, M.D.** Hartford Whalers' Professor of Childhood Cancer, Department of Pediatrics, University of Conneticut School of Medicine, Farmington, Connecticut; Head, Division of Hematology/Oncology, Connecticut Children's Medical Center, Hartford, Connecticut

**Victor M. Aquino, M.D.** Assistant Professor of Pediatrics, University of Texas Southwestern Medical Center at Dallas Southwestern Medical School, Dallas, Texas

**Susan G. Arbuck, M.D.** Head, Developmental Chemotherapy Section, Investigational Drug Branch, National Cancer Institute, National Institutes of Health, Rockville, Maryland

**Robert J. Arceci, M.D., Ph.D.** Director and King Fahd Professor of Pediatric Oncology, Johns Hopkins Oncology Center, Baltimore, Maryland

**Frank M. Balis, M.D.** Professor of Oncology and Pediatrics, Johns Hopkins University School of Medicine, Baltimore, Maryland; Head, Pharmacology and Experimental Therapeutics Section, Pediatric Oncology Branch, National Cancer Institute, Bethesda, Maryland

**Ronald D. Barr, M.B., Ch.B., M.D., F.R.C.P. (Glasg.), F.R.C.P. (Lond.), F.R.C.P.(C.), F.A.C.P., F.R.C.Path.** Professor of Pediatrics, Pathology and Medicine, McMaster University Medical Sciences Graduate Programme, Hamilton, Ontario, Canada; Chief of Service, Department of Hematology-Oncology, Children's Hospital, Hamilton Health Sciences Corporation, Hamilton, Ontario, Canada

**Lori J. Bechard, M.Ed., R.D., C.N.S.D.** Clinical Dietitian Specialist, Department of Gastroenterology/Nutrition, Dana-Farber Cancer Institute, Children's Hospital Boston, Boston, Massachusetts

**Charles B. Berde, M.D., Ph.D.** Professor of Anaesthesia (Pediatrics), Harvard Medical School, Children's Hospital Boston, Boston, Massachusetts

**Stacey L. Berg, M.D.** Associate Professor of Pediatrics, Hematology-Oncology Section, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**Mark L. Bernstein, M.D.** Ste. Justine Hospital, Montreal, Quebec, Canada

**Amy Louise Billett, M.D.** Assistant Professor of Pediatrics, Harvard Medical School, Boston, Massachusetts: Director, Inpatient Oncology Service, Children's Hospital Boston, Boston, Massachusetts; Associate Director, Jimmy Fund Clinic, Dana-Farber Cancer Institute, Boston, Massachusetts

**Susan M. Blaney, M.D.** Associate Professor of Pediatrics, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**Julie Blatt, M.D.** Professor of Pediatrics, Division of Pediatric Hematology-Oncology, University of North Carolina at Chapel Hill School of Medicine, Chapel Hill, North Carolina

**Archie Bleyer, M.D.** Professor and Mosbacher Chair of Pediatrics, University of Texas M.D. Anderson Cancer Center, Houston, Texas

**Melissa L. Bondy, Ph.D.** Associate Professor of Epidemiology, University of Texas M. D. Anderson Cancer Center, Houston, Texas; Director, Childhood Cancer Epidemiology and Prevention Center, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, University of Texas M. D. Anderson Cancer Center, Houston, Texas

**Richard M. Braverman, M.D.** Assistant Professor of Radiology, Baylor College of Medicine, Houston, Texas; Edward B. Singleton Department of Diagnostic Imaging, Texas Children's Hospital, Houston, Texas

**Malcolm K. Brenner, M.D., Ph.D.** Professor of Medicine and Pediatrics, Center for Cell and Gene Therapy, Baylor College of Medicine, Houston, Texas

**Norman E. Breslow, Ph.D.** Professor of Biostatistics, University of Washington School of Public Health and Community Medicine, Seattle, Washington

**Garrett M. Brodeur, M.D.** Professor of Pediatrics, Department of Pediatrics/Oncology, University of Pennsylvania School of Medicine, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

**George R. Buchanan, M.D.** Professor of Pediatrics, University of Texas Southwestern Medical Center at Dallas Southwestern Medical School, Dallas, Texas

**Jeffrey P. Burns, M.D., M.P.H.** Assistant Professor of Anaesthesia, Harvard Medical School, Children's Hospital Boston, Boston, Massachusetts

**Robert P. Castleberry, M.D.** Professor of Pediatrics, University of Alabama at Birmingham School of Medicine, Children's Hospital. Birmingham, Alabama

**Stephen J. Chanock, M.D.** Senior Investigator, Pediatric Oncology Branch, National Cancer Institute, Bethesda, Maryland

**Nai-Kong V. Cheung, M.D., Ph.D.** Member and Attending Physician, Department of Pediatrics, Memorial Sloan-Kettering Cancer Center, New York, New York

**Patricia Chévez-Barrios, M.D.** Assistant Professor, Departments of Pathology and Ophthalmology, Baylor College of Medicine, Houston, Texas

**Murali M. Chintagumpala, M.D.** Assistant Professor of Pediatrics, Hematology-Oncology Section, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**George P. Chrousos, M.D.** Chief, Pediatric and Reproductive Endocrinology Branch, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland

**John J. Collins, M.B.B.S., Ph.D., F.R.A.C.P.** Head, Pain and Palliative Care Service, The Children's Hospital at Westmead, Sydney, Australia

**Max J. Coppes, M.D., Ph.D.** Professor of Oncology and Pediatrics, Southern Alberta Children's Cancer Program, Alberta Children's Hospital, Calgary, Alberta,

Canada

**William M. Crist, M.D.** Dean, School of Medicine Health Science Center, University of Missouri–Columbia School of Medicine, Columbia, Missouri

**Barbara Cushing, M.D.** Professor of Pediatrics, Wayne State University School of Medicine, Children's Hospital of Michigan, Detroit, Michigan

**Janet Dancey, M.D.** Senior Investigator, Investigational Drug Branch, National Cancer Institute, National Institutes of Health, Rockville, Maryland

**Thomas Davis, M.D.** Director, Clinical Development, Medarax, Annandale, New Jersey

**Sarah S. Donaldson, M.D.** Professor of Radiation Oncology, Stanford University School of Medicine, Stanford, California

**ZoAnn E. Dreyer, M.D.** Assistant Professor of Pediatrics, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**Christopher Duggan, M.D., M.P.H.** Assistant Professor of Pediatrics, Harvard Medical School, Division of Gastroenterology and Nutrition, Children's Hospital Boston, Boston, Massachusetts

**Susan S. Ellenberg, Ph.D.** Director, Office of Biostatistics and Epidemiology, Center for Biologics Evaluation and Research, U.S. Food and Drug Administration, Rockville, Maryland

**Ezekiel J. Emanuel, M.D., Ph.D.** Chair, Department of Clinical Bioethics, Warren G. Magnuson Clinical Center, National Institutes of Health, Bethesda, Maryland

**Daniel Fiduccia, B.A.*** Medical Care Ombudsman Program, Medical Care Management Corporation, Bethesda, Maryland

**Milton J. Finegold, M.D.** Professor of Pathology and Pediatrics, Department of Pathology, Baylor College of Medicine, Texas Children's Hospital, Houston, Texas

**Paul Graham Fisher, M.D.** Assistant Professor of Neurology and Pediatrics, Stanford University School of Medicine, Palo Alto, California

**Alison G. Freifeld, M.D.** Associate Professor of Medicine, University of Nebraska College of Medicine, Omaha, Nebraska

**Mark C. Gebbardt, M.D.** Frederick W. and Jane M. Ilfeld Associate Professor of Orthopaedic Surgery, Harvard Medical School, Children's Hospital Boston, Massachusetts General Hospital, Boston, Massachusetts

**Jill P. Ginsberg, M.D.** Assistant Professor of Pediatrics, Division of Oncology, University of Pennsylvania School of Medicine, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

**Todd R. Golub, M.D.** Assistant Professor of Pediatrics, Harvard Medical School, Department of Pediatric Oncology, Dana-Farber Cancer Institute, Boston, Massachusetts; Director, Cancer Genomics, Whitehead Institute/Massachusetts Institute of Technology Center for Genome Research, Cambridge, Massachusetts

**Daniel M. Green, M.D.** Professor of Pediatrics, Roswell Park Cancer Institute, Buffalo, New York

**Holcombe E. Grier, M.D.** Associate Professor of Pediatrics, Harvard Medical School, Boston, Massachusetts; Clinical Director of Pediatric Oncology, Dana-Farber Cancer Institute, Children's Hospital Boston, Boston, Massachusetts

**Louise Grochow, M.D.** Chief, Investigational Drug Branch, National Cancer Institute, National Institutes of Health, Rockville, Maryland

**Paul E. Grundy, M.D., F.R.C.P.(C.)** Associate Professor of Pediatrics and Oncology, Department of Pediatrics, University of Alberta Faculty of Medicine and Dentistry, Edmonton, Alberta, Canada

**Eva C. Guinan, M.D.** Associate Professor of Pediatrics, Harvard Medical School, Department of Pediatric Oncology, Dana-Farber Cancer Institute, Children's Hospital Boston, Boston, Massachusetts

**James G. Gurney, Ph.D.** Assistant Professor of Pediatrics, Division of Pediatric Epidemiology and Clinical Research, University of Minnesota Medical School, Minneapolis, Minnesota

**Lee J. Helman, M.D.** Chief, Pediatric Oncology Branch, National Cancer Institute, Bethesda, Maryland

**Stephen P. Hersh, M.D., F.A.P.A.** Clinical Professor of Psychiatry and Pediatrics, Departments of Psychiatry, Behavioral Sciences, and Pediatrics, George Washington University School of Medicine and Health Sciences, Washington, District of Columbia

**Peter B. Hesseling, M.M.E.D.(P.A.E.D.), M.D.** Chairman, Department of Paediatrics and Child Health, University of Stellenbosch, Tygerberg Children's Hospital, Tygerberg, Republic of South Africa

**M. John Hicks, M.D., D.D.S., M.S., Ph.D.** Associate Professor, Department of Pathology, Baylor College of Medicine, Texas Children's Hospital, Houston, Texas

**Marilyn J. Hockenberry, Ph.D., R.N-C.S., P.N.P., F.A.A.N.** Professor of Pediatrics, Hematology-Oncology Section, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**John S. Holcenberg, M.D.** Clinical Professor of Pediatrics, Department of Pediatric Hematology/Oncology, Children's Hospital and Regional Medical Center, Seattle, Washington

**Marc E. Horowitz, M.D.** Professor of Pediatrics, Hematology-Oncology Section, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**Melissa M. Hudson, M.D.** Associate Professor, Department of Hematology-Oncology, St. Jude Children's Research Hospital, Memphis, Tennessee

**Jill V. Hunter, M.B.B.S., M.R.C.P.(U.K.), F.R.C.R.** Associate Professor of Radiology, Department of Diagnostic Imaging, Baylor College of Medicine, Texas Children's Hospital, Houston, Texas

**Mary Y. Hurwitz, Ph.D.** Assistant Professor, Department of Pediatrics, Hematology-Oncology Section, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**Richard L. Hurwitz, M.D.** Associate Professor, Department of Pediatrics, Hematology-Oncology Section, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**S. Percy Ivy, M.D.** Associate Professor of Medicine, Department of Hematology/Oncology, Children's National Medical Center, George Washington University School of Medicine and Health Sciences, Washington, District of Columbia; Senior Clinical Investigator, Investigational Drug Branch, National Cancer Institute, Rockville,

Maryland

**Elaine S. Jaffe, M.D.** Chief, Hematopathology Section, Laboratory of Pathology, Center for Cancer Research, National Cancer Institute, Bethesda, Maryland

**Tom Jaksic, M.D., Ph.D.** Associate Professor of Surgery, Harvard Medical School, Children's Hospital Boston, Boston, Massachusetts

**F. Leonard Johnson, M.D.** The Robert C. Neerhout Professor of Pediatrics, Oregon Health Sciences University School of Medicine, Portland, Oregon

**Mark E. Johnson, M.D.** Assistant Professor of Orthopedic Surgery, Baylor College of Medicine, Houston, Texas

**Michael B. Kastan, M.D., Ph.D.** Chairman, Department of Hematology-Oncology, St. Jude Children's Research Hospital, Memphis, Tennessee

**Kathi J. Kemper, M.D., M.P.H.** Associate Professor of Pediatrics, Harvard Medical School, Department of Medicine, Children's Hospital Boston, Boston, Massachusetts

**Ilan R. Kirsch, M.D.** Chief, Genetics Branch, Center for Cancer Research, National Cancer Institute, Bethesda, Maryland

**Nancy E. Kline, Ph.D., R.N., C.P.N.P.** Assistant Professor, Department of Pediatrics, Baylor College of Medicine, Houston, Texas

**Alfred G. Knudson, M.D., Ph.D.** Senior Member, Institute for Cancer Research, Fox Chase Cancer Center, Philadelphia, Pennsylvania

**Christian A. Koch, M.D., F.A.C.E., C.N.S.** Attending Physician and Clinical Investigator, Pediatric and Reproductive Endocrinology Branch, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland

**Hanne M. Kooy, Ph.D.** Associate Professor, Department of Radiation Oncology, Harvard Medical School, Massachusetts General Hospital, Boston, Massachusetts

**Robert A. Krance, M.D.** Professor of Pediatrics and Medicine, Baylor College of Medicine, Houston, Texas; Director, Pediatric Stem Cell Transplantation, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**Vikas Kundra, M.D., Ph.D.** Assistant Professor, Department of Radiology, University of Texas M.D. Anderson Cancer Center, Houston, Texas

**Stephan Ladisch, M.D.** Professor of Pediatrics, George Washington University School of Medicine and Health Sciences, Children's Research Institute, Washington, District of Columbia

**Beverly J. Lange, M.D.** Professor of Pediatrics, Department of Oncology, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

**Leslie E. Lehmann, M.D.** Instructor in Medicine, Department of Pediatric Hematology/Oncology, Dana-Farber Cancer Institute, Children's Hospital Boston, Boston, Massachusetts

**Laurie D. Leigh, M.A.** Division of Behavioral Medicine, St. Jude Children's Research Hospital, Memphis, Tennessee

**Michael P. Link, M.D.** Professor of Pediatrics and Chief, Division of Hematology, Oncology, and Bone Marrow Transplantation, Stanford University School of Medicine, Lucile Salter Packard Children's Hospital, Palo Alto, California

**A. Thomas Look, M.D.** Professor of Pediatrics, Harvard Medical School, Boston, Massachusetts; Vice Chair for Research, Department of Pediatric Oncology, Dana-Farber Cancer Institute, Boston, Massachusetts

**Tracy G. Lugo, Ph.D.** Program Director, Division of Cancer Treatment and Diagnosis, National Cancer Institute, National Institutes of Health, Rockville, Maryland

**Crystal L. Mackall, M.D.** Senior Clinical Investigator, Pediatric Oncology Branch, National Cancer Institute, Bethesda, Maryland

**Roger M. Macklis, M.D.** Professor and Chair, Department of Radiation Oncology, The Cleveland Clinic Foundation, Cleveland, Ohio

**Ian T. Magrath, D.Sc.(Med.), F.R.C.P., F.R.C.Path.** Professor of Pediatrics, Uniformed Services University of the Health Sciences, F. Edward Hébert School of Medicine, Bethesda, Maryland; President and Director, International Network for Cancer Treatment and Research, Institute Pasteur, Brussels, Belgium

**David Malkin, M.D., F.R.C.P.C., F.A.A.P.** Associate Professor of Medicine, Department of Pediatrics, Division of Oncology, University of Toronto Faculty of Medicine, Hospital for Sick Children, Toronto, Ontario, Canada

**Judith F. Margolin, M.D.** Assistant Professor of Pediatrics, Hematology-Oncology Section, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**Neyssa M. Marina, M.D.** Professor of Pediatrics, Division of Hematology-Oncology, Stanford University School of Medicine, Lucile Salter Packard Children's Hospital, Palo Alto, California

**John M. Maris, M.D.** Assistant Professor of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

**Giuseppe Masera, M.D.** Professor and Chair, Department of Pediatrics, University of Milano-Bicocca, Monza, Italy; Hospital S. Gerardo, Monza, Italy

**Mary S. McCabe, R.N., M.A.** Director, Office of Education and Special Initiatives, National Cancer Institute, Bethesda, Maryland

**Mary A. McMahon, M.D.** Assistant Professor of Clinical Physical Medicine and Rehabilitation and Clinical Pediatrics, Departments of Physical Medicine and Rehabilitation and Pediatrics, University of Cincinnati College of Medicine, Children's Hospital Medical Center, Cincinnati, Ohio

**Thomas E. Merchant, D.O., Ph.D.** Department of Radiation Oncology, St. Jude Children's Research Hospital, Memphis, Tennessee

**Paul A. Meyers, M.D**. Member, Department of Pediatrics, Memorial Hospital, Memorial Sloan-Kettering Cancer Center, New York, New York

**Linda J. Michaud, M.D.** Associate Professor of Clinical Physical Medicine and Rehabilitation and Clinical Pediatrics, Departments of Physical Medicine and Rehabilitation and Pediatrics, University of Cincinnati College of Medicine, Children's Hospital Medical Center, Cincinnati, Ohio

**Mark Allen Miles, Ph.D.** Assistant Member, Division of Behavioral Medicine, St. Jude Children's Research Hospital, Memphis, Tennessee

**James S. Miser, M.D.** Professor of Pediatrics, Department of Pediatric Hematology/Oncology, City of Hope National Medical Center, Duarte, California

**Grace P. Monaco, J.D.** Director, Medical Care Ombudsman Program, Medical Care Management Corporation, Bethesda, Maryland; Senior Advisor, Childhood

Cancer Ombudsman Program, Childhood Brain Tumor Foundation, Heathsville, Virginia

**Sean E. Morgan, L.M.S.W.** Clinical Social Worker, Cancer Center and Hematology Service, Texas Children's Hospital, Houston, Texas

**Brigitta U. Mueller, M.D.** Associate Professor of Pediatrics, Hematology-Oncology Section, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**Anthony Murgo, M.D.** Senior Investigator, Investigational Drug Branch, National Cancer Institute, National Institutes of Health, Rockville, Maryland

**Karel Pacak, M.D., Ph.D., D.Sc.** Chief, Unit on Clinical Neuroendocrinology, Pediatric and Reproductive Endocrinology Branch, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland

**Alberto S. Pappo, M.D.** Associate Member, Department of Hematology-Oncology, St. Jude Children's Research Hospital, Memphis, Tennessee

**Bruce R. Parker, M.D.** Professor of Radiology and Pediatrics, Department of Diagnostic Imaging, Baylor College of Medicine, Texas Children's Hospital, Houston, Texas

**Susan K. Parsons, M.D., M.R.P.** Assistant Professor of Pediatrics, Department of Pediatric Oncology, Dana-Farber Cancer Institute, Children's Hospital Boston, Boston, Massachusetts

**Elizabeth J. Perlman, M.D.** Associate Professor of Pathology, Oncology, and Pediatrics, Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, Maryland

**Philip A. Pizzo, M.D.** Since 2001: The Carl and Elizabeth Naumann Professor of Pediatrics and of Microbiology and Immunology and Dean, Stanford University School of Medicine, Stanford, California. From 1996–2001: Thomas Morgan Rotch Professor and Chairman, Department of Pediatrics, Harvard Medical School, Boston, Masschusetts; Physician-in-Chief and Chairman, Department of Medicine, Children's Hospital Boston, Boston, Massachusetts

**Sharon E. Plon, M.D., Ph.D., F.A.C.M.G.** Assistant Professor, Departments of Pediatrics and Molecular and Human Genetics, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**James Pluda, M.D.** Senior Investigator, Investigational Drug Branch, National Cancer Institute, National Institutes of Health, Rockville, Maryland

**Ian F. Pollack, M.D.** Walter Dandy Professor of Neurosurgery, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania; Co-Director, UPCI Brian Tumor Center, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania

**Brad H. Pollock, M.P.H., Ph.D.** Professor, Department of Pediatrics, University of Texas Health Science Center at San Antonio, San Antonio, Texas; Director, Center for Epidemiology and Biostatistics, University of Texas Health Science Center at San Antonio, San Antonio, Texas

**Scott L. Pomeroy, M.D., Ph.D.** Associate Professor of Neurology, Harvard Medical School, Children's Hospital Boston, Boston, Massachusetts

**David G. Poplack, M.D.** Elise C. Young Professor of Pediatric Oncology and Chief, Hematology-Oncology Section, Department of Pediatrics, Baylor College of Medicine, Houston, Texas; Director, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**Charles B. Pratt, M.D.** Professor of Pediatrics, University of Tennessee, Memphis, College of Medicine, Memphis, Tennessee; Member, Department of Hematology-Oncology, St. Jude Children's Research Hospital, Memphis, Tennessee

**Bhaskar N. Rao, M.D., F.A.C.S., F.I.C.S.** Associate Professor of Surgery, University of Tennessee, Memphis, College of Medicine, Memphis, Tennessee; Member, St. Jude Children's Research Hospital, Memphis, Tennessee

**Gregory H. Reaman, M.D.** Professor of Pediatrics, George Washington University School of Medicine and Health Sciences, Washington, District of Columbia; Chairman, Division of Hematology/Oncology, Children's National Medical Center, Washington, District of Columbia

**Susan R. Rheingold, M.D.** Assistant Professor, Department of Pediatrics, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

**Raul C. Ribeiro, M.D.** Associate Professor, Department of Pediatrics, University of Tennessee, Memphis, College of Medicine, Memphis, Tennessee; Associate Member, Division of Hematology-Oncology, St. Jude Children's Research Hospital, Memphis, Tennessee; Director, International Outreach Program, St. Jude Children's Research Hospital, Memphis, Tennessee

**Stephanie R. Ried, M.D., M.A.** Medical Director, Pediatric Rehabilitation, Driscoll Children's Hospital, Corpus Christi, Texas

**Lynn A. Gloeckler Ries, M.S.** Health Statistician, Division of Cancer Control and Population Sciences, National Cancer Institute, Bethesda, Maryland

**Michael L. Ritchey, M.D.** Professor of Surgery and Pediatrics, C. R. Bard and Edward McGuire Distinguished Chair and Director, Division of Urology, University of Texas-Houston Medical School, Houston, Texas

**Zora R. Rogers, M.D.** Associate Professor of Pediatrics, University of Texas Southwestern Medical Center at Dallas Southwestern Medical School, Dallas, Texas

**Cliona M. Rooney, Ph.D.** Associate Professor, Department of Pediatrics, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**Lucy B. Rorke, M.D.** Clinical Professor of Pathology, Neurology, and Pediatrics, Department of Pathology, University of Pennsylvania School of Medicine, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

**Robert C. Shamberger, M.D.** Professor of Surgery, Harvard Medical School, Department of Pediatric Surgery, Children's Hospital Boston, Boston, Massachusetts

**Carol L. Shields, M.D.** Associate Professor, Department of Ocular Oncology, Jefferson Medical College of Thomas Jefferson University, Philadelphia, Pennsylvania; Attending Surgeon, Oncology Service, Wills Eye Hospital, Philadelphia, Pennsylvania

**Jerry A. Shields, M.D.** Professor of Ophthalmology, Jefferson Medical College of Thomas Jefferson University, Philadelphia, Pennsylvania; Director Oncology Service, Wills Eye Hospital, Philadelphia, Pennsylvania

**Susan B. Shurin, M.D.** Professor of Pediatrics, Department of Pediatric Hematology/Oncology, Rainbow Babies and Children's Hospital, Cleveland, Ohio

**Mary O. Douglas Singer, M.Ed., A.B.D.** Department of Education, University of New Hampshire, Durham, New Hampshire

**Franklin O. Smith, M.D.** Marjory J. Johnson Professor of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, Ohio; Director, Division of Hematology/Oncology, Children's Hospital Medical Center, Cincinnati, Ohio

**Gilbert P. Smith, J.D.** Senior Manager, Health Management Services Division, MAXIMUS, Inc., Reston, Virginia

**Malcolm A. Smith, M.D., Ph.D.** Head, Pediatric Section, Clinical Investigations Branch, Cancer Therapy Evaluation Program, National Cancer Institute, Bethesda, Maryland

**Paul M. Sondel, M.D., Ph.D.** Rusch Professor, Departments of Pediatrics, Human Oncology, and Genetics, University of Wisconsin Medical School, Madison, Wisconsin

**Poul H. B. Sorensen, M.D., Ph.D., F.R.C.P.C.** Associate Professor, Departments of Pathology and Pediatrics, Division of Hematology/Oncology, University of British Columbia Faculty of Medicine, Children's and Women's Hospital, Vancouver, British Columbia, Canada

**Charles Philip Steuber, M.D.** Professor of Pediatrics, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**Howard Streicher, M.D.** Senior Investigator, Investigational Drug Branch, National Cancer Institute, National Institutes of Health, Rockville, Maryland

**Douglas R. Strother, M.D.** Associate Professor, Department of Pediatrics, Hematology-Oncology Section, Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**Nancy J. Tarbell, M.D.** Professor of Radiation Oncology, Harvard Medical School, Massachusetts General Hospital, Boston, Massachusetts

**Carol J. Thiele, Ph.D.** Head, Cell and Molecular Biology Section, Pediatric Oncology Branch, National Cancer Institute, Bethesda, Maryland

**Gail E. Tomlinson, M.D., Ph.D.** Associate Professor of Pediatrics, University of Texas Southwestern Medical Center at Dallas Southwestern Medical School, Dallas, Texas

**Timothy J. Triche, M.D., Ph.D.** Professor of Pathology and Pediatrics, Department of Pathology and Laboratory Medicine, University of Southern California, Children's Hospital Los Angeles, Los Angeles, California

**Robert D. Troug, M.D., M.A.** Professor of Anaesthesia and Medical Ethics, Department of Anaesthesia and Social Medicine, Harvard Medical School, Boston, Massachusetts

**Richard S. Ungerleider, M.D.** Senior Vice President, Clinical Research Affairs, Theradex Systems, Inc., Princeton, New Jersey

**Teresa J. Vietti, M.D.** Professor Emeritus of Pediatrics, Mallinckrodt Department of Pediatrics, Washington University School of Medicine, St. Louis Children's Hospital, St. Louis, Missouri

**Thomas J. Walsh, M.D.** Senior Investigator and Chief, Immunocompromised Host Section, Pediatric Oncology Branch, National Cancer Institute, Bethesda, Maryland

**Susan L. Weiner, Ph.D.** President, The Children's Cause, Inc., Silver Spring, Maryland

**Leonard H. Wexler, M.D.** Associate Professor of Pediatrics, Memorial Sloan-Kettering Cancer Center, New York, New York

**Lori S. Wiener, Ph.D., D.C.S.W.** Coordinator, Pediatric Support and Research Program, HIV/AIDS Malignancy Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland

**Kristi M. Wilson-Lewis, M.S.S.W.** Baylor College of Medicine, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

**Joanne Wolfe, M.D., M.P.H.** Instructor of Pediatrics, Harvard Medical School, Department of Pediatric Oncology, Dana-Farber Cancer Institute, Boston, Massachusetts

**Shiao Y. Woo, M.B.B.S., F.R.C.P., F.A.C.R.** Professor of Radiation Oncology, Departments of Radiology and Radiation Oncology, Baylor College of Medicine, Methodist Hospital, Houston, Texas

**William G. Woods, M.D.** Professor of Pediatrics and Director and Chief Medical Officer, Emory University School of Medicine, Children's Healthcare of Atlanta, Atlanta, Georgia

**Wendy Liane Wornham, M.D.** Instructor of Pediatrics, Harvard Medical School, Children's Hospital Boston, Boston, Massachusetts

**John Wright, M.D., Ph.D.** Senior Investigator, Investigational Drug Branch, National Cancer Institute, National Institutes of Health, Rockville, Maryland

**Moritz M. Ziegler, M.A. (Hon.), M.D.** Professor of Surgery, Harvard Medical School, Children's Hospital Boston, Boston, Massachusetts

**James A. Zwiebel, M.D.** Head, Biologics Evaluation Section, Investigational Drug Branch, Cancer Therapy Evaluation Program, Division of Cancer Treatment and Diagnosis, National Cancer Institute, Rockville, Maryland

# PREFACE

The publication of the fourth edition of *Principle and Practice of Pediatric Oncology* is occurring at one of the most exciting times in medical history. With the recent completion of the human genome project and the impressive advances in molecular and cellular biology, medical scientists now have at hand extraordinary information and technologies that promise to revolutionize our understanding of human diseases and dramatically improve our ability to diagnose, treat, and prevent them. Although its ultimate benefits are impossible to accurately predict, there is little doubt that the field of genomics holds extraordinary promise for the study of childhood malignancies.

In 1989, when the first edition of *Principles and Practice of Pediatric Oncology* was published, remarkable improvements in the treatment of childhood cancer had already occurred, but the ability to identify genes associated with specific malignancies was nascent. Now, advanced genomic technologies make it likely that, within the next 5 to 10 years, we will identify those genes unique to pediatric malignancies that are responsible for their development, progression, metastases, and resistance to therapy. Equally important, the comprehensive application of functional genomics, proteomics, and molecular pharmacology is likely to lead to the identification of more specific, molecularly targeted therapeutic approaches. In addition, application of these technologies to areas such as molecular epidemiology eventually may make prevention of pediatric cancer a reality. These technologic advances pose a significant challenge to the modern day pediatric oncologist who, in addition to possessing a vast knowledge of traditional clinical pediatric oncology, must have a thorough understanding of the “new biology” and its relevance to pediatric malignancies and their treatment.

To help meet these challenges, the fourth edition of *Principles and Practice of Pediatric Oncology* offers expanded discussions of the molecular biology and genetics of pediatric cancers. Where possible, emphasis has been placed on those recent findings that may provide the basis for the development of innovative therapeutic strategies in the future.

At the same time, the fourth edition of *Principles and Practice of Pediatric Oncology* continues to offer the equally important comprehensive reviews of the diagnosis and treatment of pediatric malignancies. In addition, the fourth edition provides in-depth discussion of the fundamental principles of clinical management and supportive care. The critical importance of offering strong psychosocial support for patient and family is stressed, as is the necessity of embracing a multidisciplinary approach to care for these patients. As with past editions, this new edition offers guidance on how physicians should collaborate with members of the multidisciplinary team to ensure that each child has the best options for living and, when cure is not possible, that death occurs with as much dignity as possible for both the child and family.

We have attempted to produce a book that is an essential resource to all those involved in the care of children with cancer. We are indebted to our many colleagues, each an expert in his or her field, who, by serving as authors, have contributed their knowledge to this endeavor. We are grateful for their time, energy, and wisdom. We also would like to thank Sharon Olsen, who served as our editorial assistant, and Mariann Waldbillig for their extraordinary hard work and loyalty to this project. Their contributions are invaluable. We want to thank Jonathan W. Pine, Jr., Acquisitions Editor, and Tanya Lazar, Developmental Editor, from Lippincott Williams & Wilkins and Sophia Elaine Battaglia, Production Editor, from Silverchair Science + Communications for their guidance and assistance in the preparation of this edition. Through each of the past editions to the current edition, our commitment to the contiguity and excellence of *Principles and Practice of Pediatric Oncology* has been consistent and unwavering for our authors, readers, and the children and families we serve.

*Philip A. Pizzo, M.D.*
*David G. Poplack, M.D.*

## COLOR FIGURE SECTION

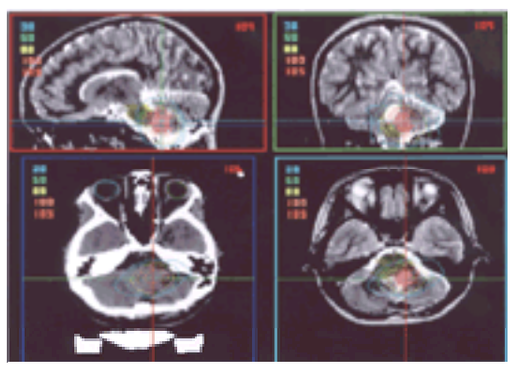

**FIGURE 13-2.** The patient is a 12-year-old girl with a low-grade astrocytoma. The dose distribution is shown superimposed on the sagittal, coronal, and transverse magnetic resonance (MR) sections through the center of the radiation field (radiation isocenter). The corresponding transverse computed tomography (CT) slice is also shown (*lower left*) in contrast to the soft tissue contrast of MR (*lower right*). Radiation treatment planning relies on both CT and MR modalities. The CT is required to accurately calculate the radiation inside the patient, whereas the MR in this case is required to reconstruct the target volume and the nearby brainstem. Dose lines are shown in percent of dose prescription of 50.4 Gy delivered in 25 fractions of 1.8 Gy. (See black and white Figure 13-2.).

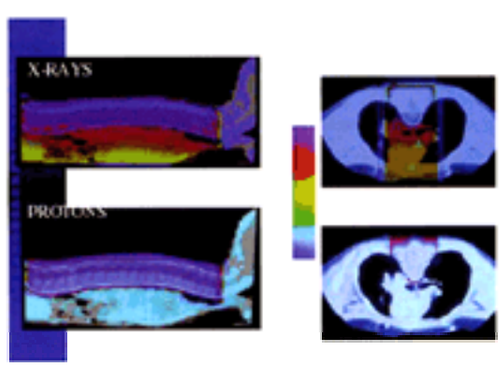

**FIGURE 13-10.** Shown here is the radiation dose in a 43-month-old child with medulloblastoma. The top figures demonstrate the dose from conventional x-rays given to the spine. Because x-rays deposit their energy over a greater distance, 60% of the dose exits to the stomach and intestine. The bottom figures are for protons showing no exit dose to the gastrointestinal tract, lung, or heart. (See black and white Figure 13-10.).

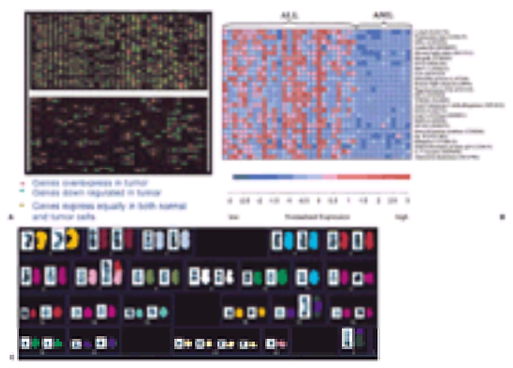

**FIGURE 19-6.** Application of new techniques for the molecular and cytogenetic characterization of acute lymphoblastic leukemia (ALL) blasts. **A:** Complementary DNA/messenger RNA (cDNA/mRNA) microarray. There are several current versions of this technology, including spotted cDNA arrays and oligonucleotide arrays. This example is of a cDNA array undergoing competitive hybridization from two sources of fluorescent-labeled RNA. The relative expression of each of 6,000 genes is measured by quantifying the amount of light emitted at the designated wavelengths at each spot on the array. **B:** Clustering of expression data on 11,000 genes (on an Affymetrix oligonucleotide array) from 38 cases of leukemia, showing that it is possible to use this technology to see differences as well as similarities among disease cases. (From Golub TR, Slonim DK, Tamayo P, et al. Molecular classification of cancer: class discovery and class prediction by gene expression monitoring. Science 1999;286:531–537, with permission.) **C:** Spectral karyotyping (SKY) on leukemic ALL blast cells. This case is remarkable for aneusomy (abnormal number) of chromosomes 21 and 22 as well as several complex marker chromosomes [45, der(X)t(X;17)(p21;q24), –Y, der(7)t(5;7)(a12;p22), and ider(17)(q10)t(X;17)(?q11)]. AML, acute myelogenous leukemia; IL-7, interleukin-7. (SKY results courtesy of X.Y. Lu, C.P. Harris, C.C. Lau, and P.H. Rao, *personal communication*, 2001.) (See black and white Figure 19-6.).

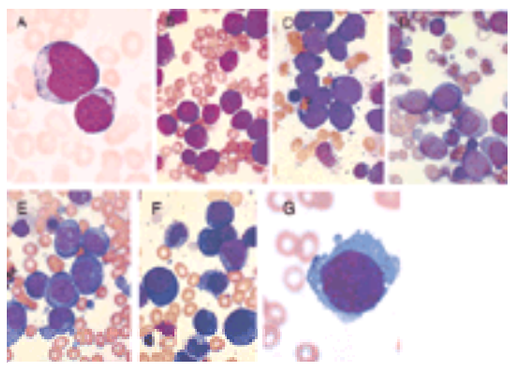

**FIGURE 20-2.** Morphologic French-American-British subtypes of acute myelogenous leukemia: **(A)** M1, **(B)** M2, **(C)** M3, **(D)** M4, **(E)** M5, **(F)** M6, **(G)** M7. May-Grunwald staining was used in all frames. (See black and white Figure 20-2.).

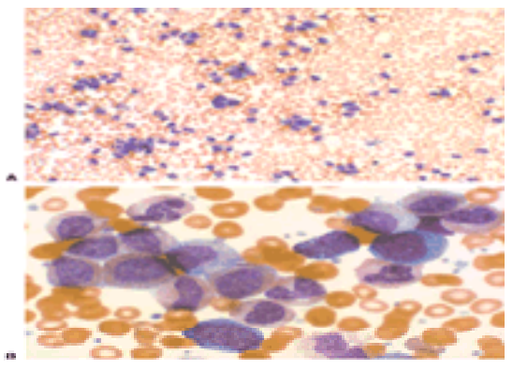

**FIGURE 21-6.** Peripheral blood smear of chronic-phase chronic myelocytic leukemia. **A:** Low-power magnification showing marked leukocytosis. **B:** High-power magnification showing the entire range of myeloid cells from myeloblast to mature polymorphonuclear leukocytes. # CHILDHOOD CANCER: INCIDENCE, SURVIVAL, AND MORTALITY

MALCOLM A. SMITH
LYNN A. GLOECKLER RIES

## INTRODUCTION

Cancer among children is relatively uncommon, with approximately 1 in 7,000 children 0 to 14 years of age being newly diagnosed with cancer each year in the United States. Despite the rarity of childhood cancer, there were approximately 12,400 children and adolescents younger than 20 years of age diagnosed with cancer in 1998 in the United States (8,700 cases among children 0 to 14 years of age and 3,700 cases among 15- to 19-year-olds). [1] The likelihood of a young person reaching adulthood and being diagnosed with cancer during childhood is 1 in 300 for males and 1 in 333 for females. [1] Childhood cancer remains the leading cause of disease-related mortality among children 1 to 14 years of age (Fig. 1-1A), and there are 1,500 to 1,600 cancer-related deaths annually in the United States among children younger than 15 years of age. The relative contribution of cancer to overall mortality for 15- to 19-year-olds is less than that for younger children (Fig. 1-1B), although approximately 700 deaths from cancer occur annually in this age group.

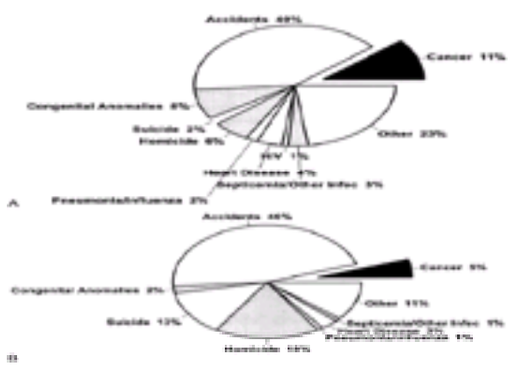

**FIGURE 1-1.** Leading causes of death in children in the United States, 1997. Causes of death among **(A)** children 1 to 14 years and **(B)** adolescents 15 to 19 years of age. (Death data are from the National Center for Health Statistics public-use file.)

The purpose of this chapter is to describe the incidence, survival, and mortality rates for the various types of cancer that arise in children, and to describe how these rates vary by age, race and ethnicity, and gender. Changes in incidence, survival, and mortality over time are also described. The reader is referred to the technical appendix for definitions of the epidemiologic terms used in this chapter. The population-based data for invasive cancer incidence and survival, unless otherwise indicated, are from the Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute (NCI). The SEER data for this chapter are based on 24,254 cases of childhood cancer diagnosed among residents of nine SEER areas that represent approximately 10% of the U.S. population. The mortality data cover all cancer deaths among children in the United States, as provided by the National Center for Health Statistics. The classification scheme used in this chapter is the International Classification of Childhood Cancer, which allocates tumors into 12 major diagnostic groups that reflect the most prevalent tumors in the pediatric population. [2]

## OVERALL CANCER FREQUENCY AND INCIDENCE BY TYPE OF CANCER FOR CHILDREN AND ADOLESCENTS

Figure 1-2 compares the distribution by percentages of the cancers that occurred among 0- to 14-year-olds and 15- to 19-year-olds for the years 1990 to 1997, whereas Table 1-1 provides the annual incidence of the major types of cancer in these two age groups. For children 0 to 14 years, acute lymphoblastic leukemia (ALL) was the most common cancer, accounting for 23.5% of all cancer diagnoses. Acute myeloid leukemia (AML) was the next most common type of leukemia in this age group, occurring at a rate one-fifth that for ALL. Central nervous system (CNS) tumors accounted for 22.1% of cancer diagnoses, and together with ALL and AML made up one-half of cancer diagnoses among children younger than 15 years of age. The most common non-CNS solid tumor in the 0- to 14-year age group was neuroblastoma (7.9%), followed by Wilms' tumor (6.0%) and non-Hodgkin's lymphoma (NHL) (5.7%). Other diagnoses that individually represented 2% to 4% of cancer diagnoses in this age group included Hodgkin's disease, rhabdomyosarcoma, non-rhabdomyosarcoma soft tissue sarcomas, germ cell tumors, retinoblastoma, and osteosarcoma.

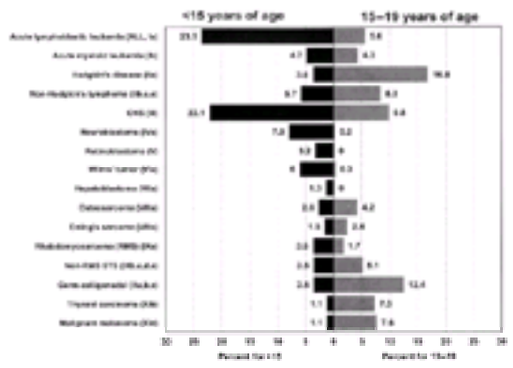

**FIGURE 1-2.** Distribution of specific cancer diagnoses for children (0 to 14 years) and adolescents (15 to 19 years), 1990 to 1997. Percent distribution by International Classification of Childhood Cancer diagnostic groups and subgroups for <15 years and 15 to 19 years of age (all races and both sexes). CNS, central nervous system; RMS, rhabdomyosarcoma; STS, soft tissue sarcoma. (Incidence data are from the Surveillance, Epidemiology, and End Results program, National Cancer Institute.)

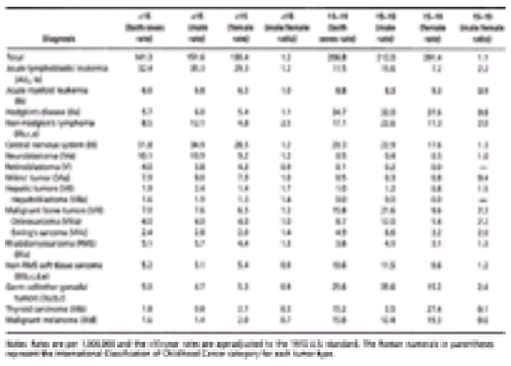

**TABLE 1-1. INCIDENCE OF DIFFERENT CANCERS BY GENDER FOR THE 0- TO 14-YEAR-OLD AND 15- TO 19-YEAR-OLD POPULATIONS (1990–1997)**

A different distribution of cancer diagnoses was observed for 15- to 19-year olds ( Fig. 1-2). Hodgkin's disease (16.8%) and germ cell tumors (12.4%) were the most frequently diagnosed cancers among 15- to 19-year-olds. The percentages of cases represented by NHL (8.3%), melanoma (7.6%), thyroid cancer (7.3%), non-rhabdomyosarcoma soft tissue sarcoma (5.1%), osteosarcoma (4.2%), and Ewing's sarcoma (2.4%) were also higher for 15- to 19-year-olds compared to 0- to 14-year-olds. Although CNS tumors were the third most common tumor type, representing 9.8% of diagnoses (Fig. 1-2), their incidence was lower for 15- to 19-year-olds compared to 0- to 14-year-olds (Table 1-1). ALL accounted for a much lower proportion of cases among 15- to 19-year-olds (5.6%) compared to children 0 to 14 years, and occurred only slightly more frequently than AML (4.3% of cases) in this age group. The percentages for rhabdomyosarcoma and non-rhabdomyosarcoma soft tissue sarcoma were nearly equal for 0- to 14-year-olds, but the percentage for non-rhabdomyosarcoma soft tissue sarcoma was three times higher than that for rhabdomyosarcoma for 15- to 19-year-olds ( Fig. 1-2). Some cancers of young children (e.g., neuroblastoma, retinoblastoma, hepatoblastoma, and Wilms' tumor) occurred at very low rates among 15- to 19-year-olds ( Table 1-1).

### Variation in Childhood Cancer Incidence by Gender

Table 1-1 shows the incidence of cancer by gender for the overall childhood and adolescent population. For both 0- to 14-year-olds and 15- to 19-year-olds, a male predominance was most apparent for NHL, with males having incidence rates more than twice those of females. For children 0 to 14 years of age, other cancer diagnoses that showed a 1.2-fold or higher male predominance were ALL, CNS tumors, neuroblastoma, hepatoblastoma, Ewing's sarcoma, and rhabdomyosarcoma. For 15- to 19-year-olds, the patterns of incidence by gender were generally similar to those observed in younger children, but with the following exceptions:

1. Hodgkin's disease among younger children occurred at a higher incidence among males, whereas among adolescents Hodgkin's disease occurred at a higher incidence among females.
2. For germ cell tumors, females had higher rates among younger children, and males had higher rates among adolescents.
3. Osteosarcoma, which occurred at similar rates in males and females in the 0- to 14-year-old population, occurred at 2.2-fold higher rates in males among 15- to 19-year-olds. Similarly, the male predominance for Ewing's sarcoma was more pronounced in the 15- to 19-year-old group (2.0-fold higher) than in younger children (1.4-fold higher).
4. Thyroid cancer, which was primarily diagnosed among 15- to 19-year-olds, occurred at nearly eight-fold higher rates in females than in males.

### Variation in Childhood Cancer Incidence by Race and Ethnicity

For many adult cancers, black Americans have higher incidence rates than white Americans. For children 0 to 19 years of age, however, the incidence of cancer among white children was approximately 30% higher than that for black children for the years 1990 to 1997 ( Table 1-2; Fig. 1-3). The largest difference in absolute incidence between white children and black children was for ALL (27.8 versus 15.2 per million). This difference was primarily due to the approximately 2.4-fold higher incidence rate for ALL among 0- to 4-year-old white children compared to 0- to 4-year-old black children. [3] The higher rates for leukemia were limited to ALL, as white children and black children had identical rates for AML ( Table 1-2). The incidence of Ewing's sarcoma in white children was nine times higher than that for black children. For melanoma, white children had incidence rates more than 30 times higher than black children ( Table 1-2). White males had much higher rates for testicular germ cell tumors than black males (9.1 versus 1.2 per million), although black females had similar rates of ovarian germ cell tumors as white females (5.6 versus 4.5 per million). [4]

| Cancer type | White | Black | Ratio |
|---|---|---|---|
| Total | 155.9 | 120.8 | 1.3 |
| Acute lymphoblastic leukemia (ALL, Ia) | 27.8 | 15.2 | 1.8 |
| Acute myeloid leukemia (Ib) | 6.1 | 6.1 | 1.0 |
| Hodgkin's disease (IIa) | 15.5 | 9.7 | 1.6 |
| Non-Hodgkin's lymphoma (IIb,c,e) | 10.5 | 7.3 | 1.5 |
| CNS (III) | 27.6 | 22.7 | 1.2 |
| Neuroblastoma (IVa) | 8.0 | 6.7 | 1.2 |
| Retinoblastoma (V) | 2.7 | 3.1 | 0.9 |
| Wilms' tumor (VIa) | 6.2 | 7.1 | 0.9 |
| Hepatoblastoma (VIb) | 1.0 | 0.9 | 1.2 |
| Osteosarcoma (VIIa) | 4.4 | 5.6 | 0.8 |
| Ewing's sarcoma (VIIc) | 3.6 | 0.4 | 9.0 |
| Rhabdomyosarcoma (IXa) | 4.5 | 5.0 | 0.9 |
| Non-rhabdomyosarcoma STS (IXb,c,d,e) | 6.1 | 7.6 | 0.8 |
| Germ cell (Xa,b,c) | 9.3 | 6.1 | 1.5 |
| Thyroid carcinoma (XIIa) | 5.3 | 2.2 | 2.4 |
| Malignant melanoma (XIII) | 5.3 | 0.2 | 35.2 |

CNS, central nervous system tumors; STS, soft tissue sarcoma.
Note: Rates are per 1,000,000 and are age-adjusted to the 1970 U.S. standard. The Roman numerals in parentheses represent the International Classification of Childhood Cancer category for each tumor type.

**TABLE 1-2. INCIDENCE OF DIFFERENT CANCERS FOR WHITE CHILDREN AND BLACK CHILDREN, 0 TO 19 YEARS OLD (1990–1997)**

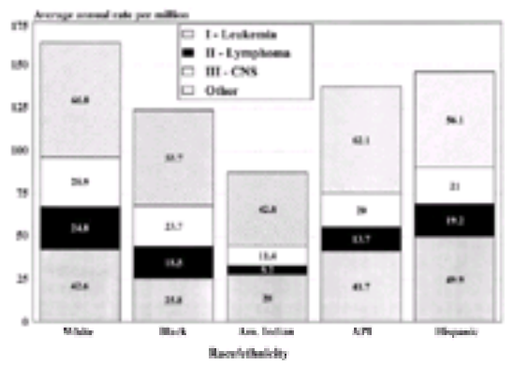

**FIGURE 1-3.** Age-adjusted incidence rates for childhood cancer by race and ethnicity, 1990 to 1997. Data are for International Classification of Childhood Cancer diagnostic groups (age 0 to 19 years and both sexes). Am. Indian, American Indian or Native American; API, Asian/Pacific Islander; CNS, central nervous system; Hispanic, Hispanic of any race and overlaps other categories. (Incidence data are from the Surveillance, Epidemiology, and End Results program, National Cancer Institute, and are adjusted to the 1970 U.S. standard population.)

In contrast to black children, Hispanic children had higher rates of leukemia than white children (49.9 per million versus 42.6 per million) ( Fig. 1-3). However, overall cancer incidence for Hispanic children was lower than that for white children because of lower rates for CNS tumors, lymphomas, and other tumors. The incidence of leukemia was similar for Asian/Pacific Islander children and white children, but Asian/Pacific Islander children had lower rates for CNS tumors and lymphomas.

Overall cancer incidence for American Indian children was much lower than for any other group.

### International Variation in Childhood Cancer Incidence

Figure 1-4 shows the incidence of childhood cancer in selected countries from North America, Europe, Asia, and Australia. [5] Comparisons between countries must be made with caution because of variation in the completeness of cancer registration, as both underdiagnosis and underregistration can lead to inaccurately low estimates of incidence.[5] Given this caveat, cancer incidence was remarkably uniform in many of the countries of Western Europe, North America, Japan, and Australia, with annual incidence for most countries or regions being within 10% to 15% of the incidence observed for white children in the United States. Within these countries, the greatest source of variation was for ALL and for CNS tumors. For ALL, rates for countries shown in Figure 1-4 ranged from 28.4 and 32.8 per million for Japan (Osaka) and the United Kingdom, respectively, to 42.8 and 46.3 per million for Denmark and Costa Rica, respectively. For children living in developing countries, the incidence of childhood ALL appears to be lower than that observed in developed nations. [6,7] The peak in ALL incidence at 2 to 3 years of age observed for children in developed nations (Fig. 1-5B) is absent or greatly diminished for children living in developing nations. [6] For CNS tumors, rates were lower in the United Kingdom and Japan (27 per million for each) and highest in Sweden (41 per million). Differential diagnosis and registration of benign brain tumors and low-grade gliomas may account for a substantial portion of the difference for CNS tumors.

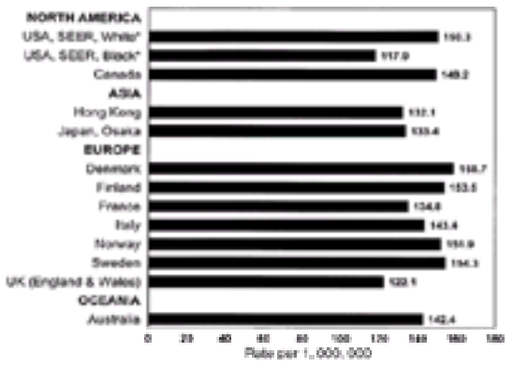

**FIGURE 1-4.** Age-adjusted cancer incidence for children (0 to 14 years). International comparisons. The years included in determining incidence varied for different countries, but generally involved a time period from the early 1980s through the early 1990s. Rates are age-adjusted to the World Standard Population. SEER, Surveillance, Epidemiology, and End Results program. (From Parkin DM, Kramarova E, Draper GJ, et al. International incidence of childhood cancer. Lyon, France: IARC Scientific Publications, 1999.)

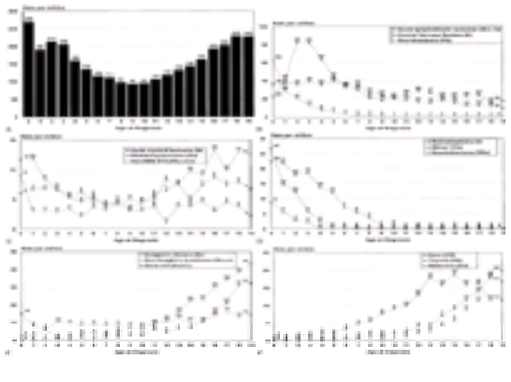

**FIGURE 1-5.** Age-specific incidence rates for childhood cancer by International Classification of Childhood Cancer group (all races and both sexes). Incidence data are from the Surveillance, Epidemiology, and End Results program, National Cancer Institute, and are for the years 1976 to 1984 and 1986 to 1994, unless otherwise indicated. **A:** All cancers (1986 to 1994). **B:** Acute lymphoblastic leukemia (1986 to 1994), brain/central nervous system tumors (1986 to 1994), and neuroblastoma. **C:** Acute myeloid leukemia and non-rhabdomyosarcoma soft tissue sarcomas (non-RMS). **D:** Wilms' tumor, hepatoblastoma, and retinoblastoma. **E:** Hodgkin's disease, non-Hodgkin's lymphoma, and germ cell tumors. **F:** Thyroid carcinoma, melanoma, and bone tumors.

The most dramatic variation in childhood cancer incidence is for those tumors with a clear association to infectious agents. Burkitt's lymphoma, for which one subtype is associated with Epstein-Barr virus infection,[8] represented only a small percentage of cancers diagnosed in most countries, but accounted for more than one-third of childhood cancers registered in some regions of Africa.[5] Similarly, Kaposi's sarcoma was extremely rare in children in most countries where human immunodeficiency virus infection in children is rare,[9] but in some countries of central Africa where human immunodeficiency virus infection is endemic, Kaposi's sarcoma accounted for as much as 15% to 35% of reported cancer cases.[10] Other cancers associated with infectious agents [e.g., hepatocellular carcinoma (hepatitis B virus) and cervical cancer (human papillomavirus)] predominantly manifest in adults, and rates of these infection-related cancers are generally low in children. However, universal hepatitis B vaccination programs reduced the incidence of hepatocellular carcinoma in older children living in a region in which hepatitis B was hyperendemic. [11]

Adrenocortical carcinoma is a rare childhood cancer with an annual incidence of 0.2 per million for U.S. children. [5] In southern Brazil, the annual incidence of adrenocortical carcinoma is approximately 10-fold higher, with rates of 2.8 per million reported by the Goiania Cancer Registry. A very high percentage of children with adrenocortical carcinoma in Brazil have p53 germline mutations, [12] illustrating that differences in childhood cancer incidence between populations may be caused by differences in the concentration of genetically susceptible persons. [13]

### Incidence by Single Year of Age

Childhood cancer incidence is greatest in the first year of life, with a second peak at 2 to 3 years of age, followed by declining rates until age 9 and then steadily increasing rates through adolescence (Fig. 1-5A). Each cancer type has its own distinctive age-distribution pattern.

- ALL incidence peaks at 2 to 3 years of age (Fig. 1-5B).
- In contrast, AML incidence is highest in the first 2 years of life (Fig. 1-5C), with a trough in incidence between age 5 to 9 years, followed by higher rates in adolescence.
- One set of cancers occurs primarily in children younger than 5 years of age. This group includes neuroblastoma, retinoblastoma, Wilms' tumor, and hepatoblastoma (Fig. 1-5B and Fig. 1-5D).
- The incidence of rhabdomyosarcoma is somewhat higher among young children than other age groups (Fig. 1-5C).
- The non-rhabdomyosarcoma soft tissue sarcomas show a peak in incidence in the first year of life (due in large measure to infantile fibrosarcoma), [14] followed by much lower rates until approximately 8 years of age, when rates begin to increase and surpass those for rhabdomyosarcoma (Fig. 1-5C).
- The germ cell tumors also show two peaks in incidence, with the first occurring in infancy and with the second occurring in late adolescence (Fig. 1-5E). The types of germ cell tumors that arise in young children are now known to be biologically distinctive from those that develop in older adolescents. [15]
- A third group of tumors is uncommon among young children and has highest incidence in the 15- to 19-year-age group. This group includes Hodgkin's disease (Fig. 1-5E) and the bone tumors, thyroid cancer, and melanoma (Fig. 1-5F).

### Time Trends for Childhood Cancer Incidence

The incidence of cancer for children 0 to 14 years of age increased by 11.5% between 1975 to 1979 and 1995 to 1997 (125.7 to 140.2 per million) (Table 1-3). Assuming a constant rate of increase in incidence, the estimated annual percentage change (EAPC) in cancer incidence for 1975 to 1997 was 0.7%, but there was

substantial year-to-year variation in rates ( Fig. 1-6A). For example, the incidence varied from 132 per million in 1988 to 148 per million a year later and back down to 134 per million in 1992. The increase in incidence for children 0 to 14 years of age between 1975 and 1997 appears to have primarily occurred before 1985, with incidence for 1995 to 1997 being essentially the same as that for 1985 to 1989, and with the EAPC for 1985 to 1997 being 0.0%.

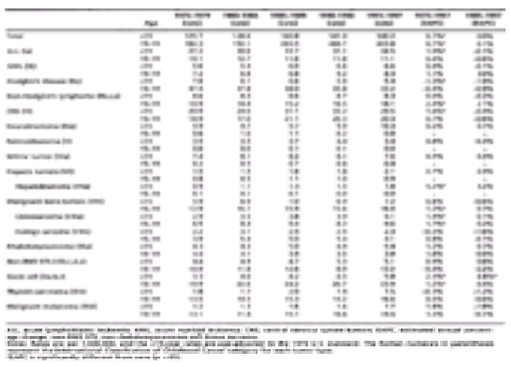

**TABLE 1-3. INCIDENCE OF CHILDHOOD AND ADOLESCENT CANCERS BY 5-YEAR TIME PERIODS AND TRENDS IN INCIDENCE (1975–1997 AND 1985–1997)**

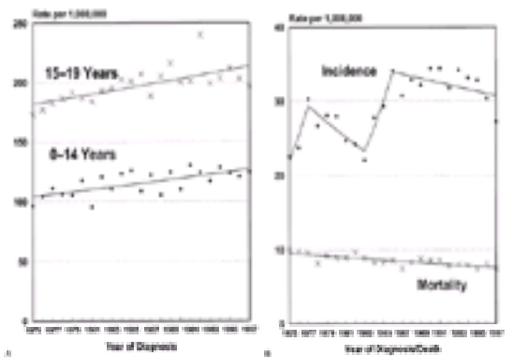

**FIGURE 1-6.** Trends in childhood cancer incidence over time. **A:** Surveillance, Epidemiology, and End Results (SEER) program incidence for all childhood cancers, age 0 to 14 years and age 15 to 19 years (all races and both sexes) for 1975 to 1997. **B:** SEER incidence and U.S. mortality for brain and central nervous system tumors, age 0 to 14 years (both sexes and all races), 1975 to 1997. Rates are age-adjusted to the 1970 U.S. standard million population. Regression lines are calculated using the Joinpoint Regression Program. (Incidence data are from the SEER program, National Cancer Institute. Mortality data are from National Center for Health Statistics.)

The increase in cancer incidence from 1975 to 1979 and 1995 to 1997 for children 0 to 14 years of age resulted primarily from increases in the incidence of CNS tumors and from increases in the incidence of ALL. The increase in childhood CNS tumor incidence did not occur at a steady rate, but instead abrupt increases in incidence occurred in the late 1970s and the mid-1980s, followed by stable or declining rates ( Fig. 1-6B). The increases occurred during periods in which advances in diagnostic imaging for CNS tumors were becoming widely disseminated (computed tomographic imaging in the mid- to late 1970s and magnetic resonance imaging in the mid-1980s).[16,17] The incidence for childhood CNS tumors has not increased since the widespread availability of magnetic resonance imaging in the mid-1980s (EAPC = –0.4% for 1985 to 1997).[18] The periods of abrupt changes in incidence were not associated with changes in CNS tumor mortality rates, which slowly decreased throughout the entire period from 1975 to 1997 ( Fig. 1-6B). The timing of the increases in childhood CNS tumor incidence and the lack of corresponding increases in mortality rate suggest that improvements in diagnosis or reporting, or both, of childhood CNS tumors may account for much of the increase.

Childhood ALL incidence increased from 27.2 per million in 1975 to 1979 to 34.5 per million in 1995 to 1997, but most of the increase occurred between 1975 and 1984. From 1985 to 1997, incidence for ALL was essentially stable (EAPC = –0.1%), although there were unexplained wide variations in year-to-year incidence, with a low of 29 per million in 1994 and a high of 38 per million in 1989. For most of the remaining cancers, incidence remained relatively constant from 1975 to 1997 for children younger than 15 years ( Table 1-3), with only the expected year-to-year variation related to the relatively small numbers of cases of these tumor types diagnosed annually. Statistically significant increases in incidence were observed for hepatoblastoma, osteosarcoma, and germ cell tumors, whereas a significant decrease in incidence was observed for Hodgkin's disease.

For the 15- to 19-year-old population, the annual incidence of cancer increased from 182.3 per million for 1975 to 1979 to 203.8 per million for 1995 to 1997. This represented a significant increase in incidence for the period 1975 to 1997 (EAPC = 0.7%), although there was substantial year-to-year variation in rates ( Fig. 1-6A). Incidence for 1995 to 1997 was essentially identical to that for 1985 to 1989, and the EAPC for 1985 to 1997 was 0.1%. NHL was the largest contributor to the increase in incidence for 15- to 19-year-olds, with incidence rising from 10.9 per million in 1975 to 1979 to 18.1 per million in 1995 to 1997 ( Table 1-3). This increase in NHL incidence for 15- to 19-year-olds, which was not observed for 0- to 14-year-olds, is similar to the increase in NHL incidence that occurred during the same period for adults.[19,20] Significant increases in incidence were also observed for osteosarcoma and for germ cell tumors ( Table 1-3).

## SURVIVAL AND MORTALITY RATES FOR CHILDREN WITH CANCER

Survival rates for children 0 to 14 years of age have improved dramatically since the 1960s when the overall 5-year survival rate after a cancer diagnosis was estimated as 28%.[21] Improvements in survival rates have continued into the 1990s in the United States ( Fig. 1-7), with 3-year survival rates exceeding 80% and 5-year survival rates exceeding 75% for children and adolescents diagnosed during this period ( Fig. 1-7).

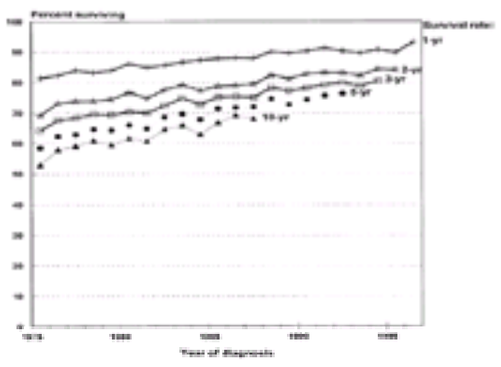

**FIGURE 1-7.** Trends in relative survival rates for all childhood cancers, age 0 to 19 years (all races and both sexes) for Surveillance, Epidemiology and End Results (SEER) program regions (nine areas), 1975 to 1996. (Data are from the SEER program, National Cancer Institute.)

The increase in survival for children younger than 15 years of age was most dramatic for ALL, a virtually incurable disease in the early 1960s and for which 5-year survival rates exceeded 80% in 1989 to 1996 (Fig. 1-8A). Survival rates for childhood NHL increased to nearly 80% in 1989 to 1996, up from 20% to 25% in the early

1960s (Fig. 1-8B), and survival rates for Wilms' tumor increased from 33% to 92% during the same period ( Fig. 1-8B). Five-year survival rates at or above 90% have also been achieved for Hodgkin's disease, retinoblastoma, thyroid cancer, and melanoma ( Fig. 1-9). Five-year survival rates for bone tumors (Fig. 1-8B) and for CNS tumors (Fig. 1-8A) increased to 68% and 65% by 1989 to 1996, respectively, whereas 5-year survival rates for AML remained below 50% ( Fig. 1-8A).

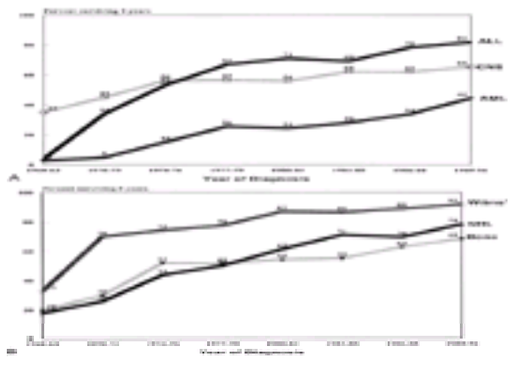

**FIGURE 1-8.** Five-year relative survival rates for specific cancers of children (0 to 14 years) in 1960 to 1996. Data for 1960 to 1963 and for 1970 to 1973 are from the End Results Group at the National Cancer Institute (NCI) and are for white children [21]; 1974 to 1996 data are from the Surveillance, Epidemiology, and End Results (SEER) program regions (nine areas). **A:** ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CNS, central nervous system. **B:** Bone tumors; NHL, non-Hodgkin's lymphoma; and Wilms' tumor.

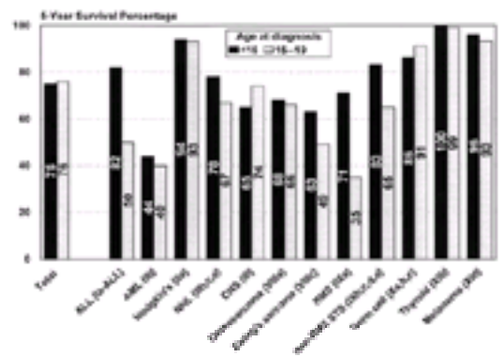

**FIGURE 1-9.** Survival for 0- to 14-year-olds and for 15- to 19-year-olds in Surveillance, Epidemiology, and End Results (SEER) program regions (nine areas), 1989 to 1996. Rates are for all races and both sexes. ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CNS, central nervous system; NHL, non-Hodgkin's lymphoma; non-RMS, non-rhabdomyosarcoma; RMS, rhabdomyosarcoma. (Data are from the SEER program, National Cancer Institute.)

Survival rates for 15- to 19-year-olds were similar to those for younger children for most cancer types, including brain tumors, NHL, osteosarcoma, Hodgkin's disease, Ewing's sarcoma, AML, and germ cell tumors (Fig. 1-9). Survival rates for 15- to 19-year-olds with ALL were lower than those for younger children, which could be due in part to a higher proportion of cases with unfavorable biology among 15- to 19-year-olds. A similar explanation may explain the lower survival rates for 15- to 19-year-olds with rhabdomyosarcoma and non-rhabdomyosarcoma soft tissue sarcoma, and the higher survival rates for 15- to 19-year-olds with CNS tumors. Survival rates above 90% were observed for four of the most common cancers among 15- to 19-year-olds: Hodgkin's disease, germ cell tumors, thyroid cancer, and melanoma.

Cancer mortality rates have decreased for children since the 1950s as a result of improvements in treatment and the resulting increased survival rates. In the 1950s, childhood cancer mortality rates were stable at approximately 80 per million ( Fig. 1-10A). The cancer mortality rate for 0- to 19-year-olds began declining in the 1960s and by the late 1990s had decreased to less than 30 per million. Declines in mortality for the leukemias began in the early 1960s, with rates decreasing from 30 to 35 per million to less than 10 per million by the late 1990s ( Fig. 1-10A). For NHL, declining mortality began in the late 1960s, with rates decreasing from 6 to 7 per million to less than 2 per million by the 1990s (Fig. 1-10B). Mortality from kidney tumors (primarily Wilms' tumor) decreased by 80% over a similar time period from approximately 4 per million to less than 1 per million. Mortality rates also declined for Hodgkin's disease (not shown), with rates decreasing from approximately 3 per million in the 1950s and early 1960s to approximately 0.4 per million in the mid-1990s. The brain cancer mortality rate was approximately 10 per million in 1970 and had decreased to approximately 7 per million by 1997 (Fig. 1-10B).

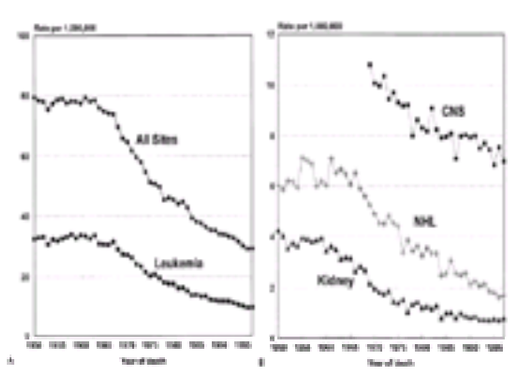

**FIGURE 1-10.** Mortality rate for children and adolescents 0 to 19 years in the United States, 1950 to 1997. **A:** Mortality rates for all cancers and for leukemia. **B:** Mortality rates for non-Hodgkin's lymphoma (NHL), brain/other nervous system (ONS) tumors, and Wilms' tumor. Death data are from the National Center for Health Statistics public-use file. Death rates for brain/ONS tumors are restricted to the years 1969 to 1997 because the coding of brain/ONS tumors in the International Classification of Diseases (ICD), Seventh Revision is not compatible with ICD-8 and -9 (used from 1969 forward). CNS, central nervous system.

Figure 1-11 shows the distribution of causes of cancer death for 0- to 19-year-olds in 1997. Approximately one-third of cancer-related deaths were caused by leukemias, with ALL accounting for an estimated 50% to 60% of deaths, AML for 30% to 40% of deaths, and CML for approximately 5% of deaths. CNS tumors were the second leading cause of cancer mortality among children and adolescents, accounting for 24% of cancer-related deaths. The other primary causes of cancer-related mortality were neuroblastoma (classified under endocrine tumors), bone tumors, soft tissue sarcomas, and NHL.

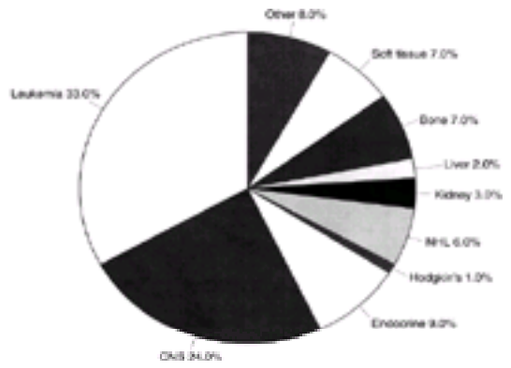

**FIGURE 1-11.** Percent distribution by cause of cancer death in children and adolescents 0 to 19 years. Death data are from the National Center for Health Statistics public-use file. The endocrine category primarily represents neuroblastoma. CNS, central nervous system; NHL, non-Hodgkin's lymphoma.

## SUMMARY

The cancers of children represent a diverse group of diagnoses that have distinctive age-incidence patterns. Even within a single diagnosis, the biologic characteristics of tumor cells may vary between younger and older children. Interpreting changes over time in incidence, survival, and mortality rates for childhood cancers requires consideration of the distinctive age-incidence profiles of the cancers that arise in children.

The incidence of cancer among children 0 to 14 years and among 15- to 19-year-olds increased on average by less than 1% per year between 1975 and 1997. Since the mid-1980s, overall cancer incidence has been essentially stable for both age groups. The increase in incidence for 0- to 14-year-olds was primarily due to increases in incidence for CNS tumors and leukemias (primarily ALL), with increases also observed for osteosarcoma, germ cell tumors, and hepatoblastoma. For 15- to 19-year-olds, increasing incidence was observed for NHL, osteosarcoma, and germ cell tumors. Rates for Hodgkin's disease decreased in both age groups.

Childhood cancer mortality rates decreased dramatically between 1960 and 1997, with decreases in mortality observed for all cancer types. These decreases are a tribute to the clinical investigators who for decades have diligently collaborated to conduct clinical trials that have identified improved treatments for children with cancer. In spite of these remarkable advances, for approximately 25% of children and adolescents diagnosed with cancer, current treatments are not sufficiently effective to allow cure, and more than 2,000 children and adolescents still die of cancer each year in the United States. Identifying curative treatments for these children will require deeper understandings of the mechanisms responsible for survival and growth of specific pediatric cancers and will require new treatment approaches based on these understandings. Given the relative rarity of specific childhood cancers, continued national and international cooperation will be essential for identifying superior treatments that build on an ever-increasing understanding of the biology of childhood cancers.

## TECHNICAL APPENDIX

**Age-adjusted rate** An age-adjusted rate is a weighted average of the age-specific cancer incidence (or mortality) rates, where the weights are the proportions of persons in the corresponding age groups of a standard population. The potential confounding effect of age is reduced when comparing age-adjusted rates computed using the same standard population. Because rates of childhood cancer vary widely by 5-year age group, age-adjustment was used for any age group representing more than one 5-year grouping. Age-adjustment was performed by 5-year age group and weighted by the 1970 U.S. standard million population except for the comparison of international rates, which was age-adjusted to the world standard.

**Age-specific rates** Age-specific rates are usually presented as a rate per million for childhood cancer. The numerator of the rate is the number of cancer cases found in a particular 5-year age group in a defined population divided by the number of individuals in the same 5-year age group in that population. In this publication, there are some rates by single year of age for time periods around the census. Population estimates by single year of age, race, sex, and geographic region are not generally available for intercensal years.

**Estimated annual percentage change (EAPC)** The EAPC was calculated by fitting a regression line to the natural logarithm of the rates (r) using calendar year as a regressor variable (i.e., $y = mx + b$ where $y = \text{Ln } r$ and $x$ = calendar year). The $EAPC = 100*(e^{m} - 1)$. Testing the hypothesis that the EAPC is equal to zero is equivalent to testing the hypothesis that the slope of the line in the above equation is equal to zero. The latter hypothesis is tested using the t distribution of $m/SE_m$ with the number of degrees of freedom equal to the number of calendar years minus two. The standard error of m (i.e., $SE_m$) is obtained from the fit of the regression.[22] This calculation assumes that the rates increased/decreased at a constant rate over the entire calendar year interval. The validity of this assumption has not been assessed. In those few instances where at least one of the rates was equal to zero, the linear regression was not calculated.

**Follow-up** SEER areas attempt to follow-up all cases until death. Although the overall proportion of cancer patients of all ages who are lost to follow-up is only approximately 5%, for pediatric cases (age 0 to 19) it is much larger—approximately 14%. Because survival rates are relatively high, follow-up can be difficult, especially as the child gets older. When children leave their parents' home, they change addresses and, especially for females, they may change last names.

**ICCC classification** At the time the World Health Organization's International Agency for Research on Cancer published their first monograph on Childhood Cancer in 1988, Dr. R. Marsden published an annex giving a classification scheme for childhood cancer that consisted of 12 groups based chiefly on histologic type. [23] The classification by Marsden has been modified and is now called the *International Classification of Childhood Cancers*.[2]

**Incidence rate** The cancer incidence rate is the number of new cancers of a specific site/type occurring in a specified population during a year, expressed as the number of cancers per 1 million people. It should be noted that the numerator of the rate can include multiple primary cancers occurring in one individual. This rate can be computed for each type of cancer as well as for all cancers combined. Except for 5-year age-specific rates, all incidence rates are age-adjusted to the 1970 U.S. standard million population. Rates are for invasive cancer only, unless otherwise specified.

**Mortality data** The mortality data are from public use files provided by the National Center for Health Statistics and cover all deaths in the United States. All mortality rates were based on the underlying cause of death. The rates presented for 1975 to 1978 were coded to the *International Classification of Diseases (ICD), Eighth Revision* and for 1979 to 1995 to the *ICD-9*.[24] Certain groups can be identified as specific entities on death certificates: leukemias, bone cancers, brain and other CNS tumors, Hodgkin's disease, and NHL. However, mortality of all specific groups of the ICCC pediatric classification are not available from U.S. mortality files due to the fact that the codes used for coding death certificates do not include such morphologic types as neuroblastoma, retinoblastoma, germ cell tumors, and Wilms' tumor. For neuroblastoma, to make the data comparable over time, deaths coded to sympathetic nervous system in the *ICD-8* were combined with adrenal in the *ICD-9* and are included in the endocrine tumor category.

**Mortality rate** The cancer mortality rate is the number of deaths with cancer given as the underlying cause of death occurring in a specified population during a year, expressed as the number of deaths due to cancer per 1 million people. This rate can be computed for each type of cancer as well as for all cancers combined. Except for age-specific rates, all mortality rates are age-adjusted to the 1970 U.S. standard million population.

**Population data** Population estimates are obtained each year from the U.S. Bureau of the Census (BOC) at the county level by 5-year age group (0 to 4, 5 to 9, etc., to 85 and older), sex, and race (including white and black). SEER makes county estimates for each state available on the SEER Home Page (http://www.seer.cancer.gov/) for race (whites, blacks, non-white), 5-year age group, sex, and year of diagnosis (each year from 1973 forward). Additional estimates can be obtained from the U.S. Census Bureau Home Page. BOC population estimates for Hawaii were altered according to independent estimates developed from sample survey data collected by the Health Surveillance Program (HSP) of the Hawaii Department of Health. For Hawaii, the all races and black populations are the same as those sent by the BOC. Proportions of the population by different racial groups from the HSP were used to generate estimates for whites, and so forth. Because the HSP survey was for all of Hawaii and not by county, population estimates were not broken down by county. The white population estimates for Hawaii provided by the BOC are generally larger than those generated by the HSP. Because whites in Hawaii account for less than 2% of the total white population represented by the SEER reporting areas, white incidence rates for the entire SEER program are not noticeably affected. Procedures for calculating rates by race for

Hawaii are currently under review.

**Primary site/histology coding** Originally, data for site and histologic type were coded by the *ICD for Oncology* (*ICD-O*), but in 1990, *ICD-O* was revised and republished as the *ICD-O, Second Edition* (*ICD-O-2*).[25] SEER areas began using *ICD-O-2* for cases diagnosed in 1992 and machines converted all previous data to *ICD-O-2*. Most data for NHL can be classified by the Working Formulation based on a conversion from *ICD-O-2*.

**Relative survival rate** The relative survival rate is calculated using a procedure described by Ederer, Axtell, and Cutler whereby the observed survival rate is adjusted for expected mortality.[26] The relative survival rate represents the likelihood that a patient will not die from causes associated specifically with their cancer at some specified time after diagnosis. It is always larger than the observed survival rate for the same group of patients.

**SEER program** This program started in 1973, as an outgrowth of the NCI's Third National Cancer Survey and the End Results program. NCI contracts out with various medically oriented non-profit organizations, local city or state health departments, or universities for collection of these data. Contracts for collecting this data are with the entire states of Connecticut, Iowa, New Mexico, Utah, and Hawaii and with the metropolitan areas of Los Angeles, California; Detroit, Michigan; San Francisco-Oakland and San Jose-Monterey, California; Seattle-Puget Sound, Washington; and Atlanta, Georgia. These organizations collect data on all cancers except basal and squamous cell skin cancers and *in situ* of the cervix uteri. Although data are collected on all people having cancer, the material for this chapter used children from birth through age 19 years. To calculate long-term trends, only nine SEER areas (which together represent approximately 10% of the U.S. population) were used for this chapter: San Francisco-Oakland, California; Seattle-Puget Sound, Washington; Atlanta, Georgia; Detroit, Michigan; Hawaii; Connecticut; Utah; Iowa; and New Mexico. Only residents of the areas designated are included so that the base populations can be properly determined.

# EPIDEMIOLOGIC RESEARCH METHODS AND CHILDHOOD CANCER

JAMES G. GURNEY
MELISSA L. BONDY

## INTRODUCTION

This chapter provides an overview of epidemiologic methods, including study designs, potential biases, and statistical measures of effect, with examples from the literature to illustrate the concepts. Information in this chapter should help clinicians better understand the approaches used in epidemiologic research on the causes and consequences of childhood cancer, and to interpret and communicate research findings to their patients.

## CENTRAL CONCEPTS OF EPIDEMIOLOGY

Epidemiology, a scientific methodology for conducting health-related research, can be defined as the comparative study of the distribution and determinants of disease and other health-related conditions within defined human populations. Identifying, describing, and interpreting patterns of cancer occurrence (distribution), and studying factors that may cause or contribute to the occurrence, prevention, control, and outcome of cancer (determinants), encompass these two activities. [1,2] Historically, epidemiology strove to identify and control sources of infectious diseases and outbreaks, but the focus in modern times, especially in industrialized countries, now includes chronic diseases such as cancer. Epidemiologic studies in the 1950s on smoking and lung cancer were instrumental in developing the study designs and statistical methodologies used today in childhood cancer research.

Epidemiology incorporates aspects of research from biologic, clinical, social, and statistical sciences. Two central concepts of epidemiology are

1. *Disease is not randomly distributed.* Measurable factors influence the patterns and causes of disease within a defined population.
2. *Disease causation is multifactorial.* Few individual agents are necessary or sufficient to cause disease. Disease results from a multitude of endogenous and exogenous factors. Identifying and measuring the relative contribution and interaction of these factors is the principal role of analytic epidemiology.

## SURVEILLANCE AND DESCRIPTIVE STUDIES

Public health surveillance involves the systematic collection, analysis, and interpretation of outcome-specific health data, and timely dissemination to prevent and control disease or injury. Surveillance systems are thus essential to plan, implement, and evaluate public health practice. [3] Surveillance systems provide data on disease incidence and mortality on a population basis for policy makers and researchers. In the United States, an exceptionally high quality cancer surveillance system, begun in 1973, is funded and coordinated by the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program through contract with five state and six large metropolitan cancer registries ( http://www-seer.ims.nci.nih.gov/). The SEER registry collects cancer incidence information on approximately 14% of the U.S. population and currently includes more than 30,000 cases of malignant neoplasms among children age 19 years and younger. These data serve as the primary source of our understanding of the distribution of and trends in childhood cancer in the United States. The impact of SEER data can be seen in the national debate that followed a report of upward trends in childhood cancer incidence rates, including an average increase for brain cancer of approximately 2% per year.[4] Many papers have since been published to discuss whether changing environmental exposures or changes in diagnostic practices and morphologic coding occasioned the increase. Although some disagree, evidence supports the growing consensus that diagnostic technological advances and revisions in histopathologic categorization of brain tumors explain the higher rates. [5]

Because SEER ascertains and describes virtually every new case of cancer in its reporting area, the population-based nature of the data offers information on the entire disease spectrum, and is thus more representative than individual hospital data, which is limited by referral patterns, specialized patient populations, or small case sizes. For epidemiologists, an additional benefit of population-based registries is that, unlike clinical data, researchers can clearly delineate the populations that gave rise to the cases and use them for calculating reliable incidence rates.

SEER information, too, enables descriptive evaluation, otherwise unachievable, of rare childhood malignancies and of cancer patterns in demographic subgroups. Descriptive analyses from cross-sectional (prevalence) or ecologic (correlational) studies allow investigators to develop hypotheses on the patterns and causes of cancer, permitting assessment by analytic approaches.[1,2] Importantly, the individual cancer registries may, under carefully controlled conditions, allow researchers to contact persons in the database to invite them to participate in analytic studies of cancer etiology. The rarity of any specific type of childhood cancer, however, makes it very difficult to recruit enough cases for statistically meaningful studies, even with statewide population-based registries. This problem of conducting good epidemiologic research on rare events has prompted the newly merged Children's Oncology Group to discuss with the National Cancer Institute the development of a nationwide, population-based childhood cancer registry. Such a national registry would even more effectively arm research efforts into the causes and consequences of childhood cancer.

## ANALYTIC STUDY DESIGNS

Some epidemiologic studies, such as randomized intervention trials and randomized controlled clinical trials, follow the principles of scientific experimentation in which a treatment or intervention of interest and the control condition are randomly assigned. [6] The childhood cancer clinical trials compare one treatment regimen to another, such as the recent study of intensive chemotherapy with or without autologous bone marrow transplantation for high-risk neuroblastoma. This national study from the Children's Cancer Group showed a survival benefit from adjuvant 13-*cis*-retinoic acid among patients without disease progression in both primary treatment arms.[7] Despite some beliefs to the contrary, well-designed and well-conducted non-experimental (observational) studies also can provide accurate estimates of treatment effects.[6,8,9]

Non-experimental analytic studies assess the causal influence of potential risk factors unable to be evaluated experimentally because the experiment would be unethical or impractical. An obviously unethical experiment would, for example, randomize pregnant mothers to ingesting different kinds and amounts of organophosphate pesticides to measure subsequent incidence rates of non-Hodgkin's lymphoma in their offspring. It would be impractical, even if ethical, to randomly allocate newly pregnant mothers to receive high daily doses of vitamins C and E to weigh their efficacy in preventing childhood brain cancer. To provide an accurate and reliable conclusion, the trial would require thousands, if not hundreds of thousands, of preconceptual mothers and their children to be followed for many years. Thus, epidemiologists must use several non-experimental, or observational, study designs to identify causal risk factors and quantify the contribution the risk factors

have on disease incidence on populations with “naturally” occurring exposures varied enough to be useful in comparisons. An example is an international childhood brain cancer study that found evidence to suggest a protective effect of vitamin supplementation during pregnancy. [10] Cohort studies and case-control studies are two analytic observational approaches commonly used by epidemiologists.

### Cohort Studies

Cohort studies evaluate subjects initially free of a specific disease of interest and whose exposure status can be classified. Subjects are followed for a defined time period to ascertain endpoints, such as new events in or death from disease. The disease rate in the exposed group is then compared statistically to the rate in the unexposed group. A prospective cohort study resembles a clinical trial, but subjects are not randomly allocated to an exposure arm. Rather, as mentioned previously, exposure (or lack of exposure) occurs “naturally” and the investigator uses variations in natural exposure levels to evaluate differences in the risk of subsequent disease occurrence during some follow-up period.

Cohort studies permit efficient study of relatively common diseases with a reasonably short latency period from exposure to disease onset. Cohort studies are usually impractical for rare diseases, such as childhood cancer, as statistically meaningful results could be achieved only by assembling and following for a very long time a huge number of at-risk subjects. One notable exception, however, was a cohort of 15,895 Japanese children who were in Hiroshima or Nagasaki at the time of the atomic bombing during World War II, were younger than age 10 years during the bombings, and who survived to at least October 1, 1950 (survived 5 years or longer). As part of a study on the health effects of the atomic bombing victims using a detailed and complicated exposure reconstruction procedure, [11] each child's radiation dose was estimated. With follow-up to 1985, children with a dose of greater than 1 Gy had a cumulative cancer death rate of approximately 26 per 1,000, compared with 6.5 per 1,000 among those with a dose of 0.1 Gy or less.[12] The ratio of these rates, 4.0, is a type of relative risk (described below) and a measure of how strong is the association between ionizing radiation exposure and death from cancer. The study, that is, found a four-fold higher cumulative cancer death rate for those children exposed to higher compared with lower levels of ionizing radiation.

Cohort studies can involve active follow-up of subjects in real time (prospective) like clinical trials, or can be retrospective. Retrospective cohort studies use historical records to identify the study population and to reconstruct their exposure and subsequent disease experience. An example was an evaluation comparing three large birth cohorts to determine if contamination of the Salk poliovirus vaccine with simian virus 40 (SV-40) resulted in an excess of cancer incidence among those exposed. One birth cohort was (inadvertently) exposed to the contaminated vaccine during infancy (born 1956 to 1962), one was exposed later in childhood (born 1947 to 1952), and one was unexposed to SV-40 (born 1964 to 1969). Using cancer registries and mortality records, age-specific cancer incidence rates were calculated for each study group. No meaningful differences in cancer rates overall, or for any specific type of malignancy, were found among the three cohorts. [13]

The current Childhood Cancer Survivors Study includes both retrospective and prospective components. This cohort study identified and recruited more than 14,000 childhood cancer survivors (or their parents for those deceased) from a consortium of 25 medical centers. Eligible subjects survived at least 5 years after diagnosis between 1970 and 1986. To evaluate medical late effects and psychosocial outcomes as a function of treatment, researchers are assembling information from treatment records, telephone interviews, follow-up questionnaires, and buccal cells (for DNA analysis). This study addresses the important question of the long-term consequences of childhood cancer and its treatment among survivors. [14]

### Case-Control Studies

For rare occurrences, such as childhood cancer, case-control studies provide a strategy more efficient than cohort studies to evaluate potential causal associations. A childhood cancer case-control study identifies and recruits children (or their parents) who are diagnosed within a defined population and time period. A similar group of children without the disease, but from the same defined population (in time, location, and eligibility criteria) that gave rise to the cases, are recruited to serve as controls. The investigator, as completely and accurately as possible, uses self-report, health records, and biologic specimens to reconstruct the cases' pre-diagnosis exposure experience. Similarly, a “reference” date substituting for a diagnosis date is assigned to each control child, whose exposure experience before that date is reconstructed. The exposure frequency among the case group is then compared statistically to the exposure frequency among the control group. The resultant statistic, known as an *odds ratio* (OR), is analogous to a relative risk and is a measure of the strength of the association between the exposure and the disease.

Examples include a case-control study in the Seattle area that explored the risk of childhood brain cancer from residential sources of extremely low-frequency electromagnetic fields (EMFs), including nearby power lines, among 120 children diagnosed with brain cancer and 240 control children. [15] The study included personal interviews and mail-in questionnaires from parents, and construction of scaled maps of power distribution systems for coding of EMF exposure. The odds of a case having been exposed to high current power lines was nearly identical to the control children (OR = 0.9) (i.e., the study observed no association between high EMF exposure and childhood brain cancer). Protective associations were found for breast-feeding in two case-control studies of childhood acute leukemia conducted through the Children's Cancer Group. Relying primarily on telephone interviews with mothers for information, investigators compared the breast-feeding frequency of 1,744 children with acute lymphoid leukemia (ALL) to 1,879 control children, and 456 children with acute myeloid leukemia (AML) to 539 control children. Breast-feeding was found associated with a reduced risk for ALL (OR = 0.80) and AML (OR = 0.77) and longer duration of breast-feeding strengthened the apparent protective effect.[16]

### Cluster Investigations

It is not uncommon for clinicians to encounter parental concern about multiple cancer occurrences in their child's community. The implication, of course, is that a shared environmental exposure is responsible for the cluster of cancer cases. Cluster investigations use standard epidemiologic study designs, primarily case-control studies, to ascertain whether an unusual number of cancer cases occurred in a specific area (spatial cluster) or time (temporal cluster) or both (space-time cluster).[17,18] The latter, for instance, would be an excess of childhood leukemia in a neighborhood or school over a specific time period. Public health agencies have the responsibility to investigate cancer clusters and communicate findings to the public. [17] Clinicians are well advised to refer cluster inquiries to local health departments or the Centers for Disease Control and Prevention (http://www.cdc.gov/ or http://www.atsdr.cdc.gov/). Such investigations, however, rarely produce evidence that a true childhood cancer cluster exists. [19]

## MOLECULAR EPIDEMIOLOGY

Classical or traditional epidemiology, as discussed above, permits epidemiologists to evaluate risks and causal roles of environmental factors in cancer. Molecular epidemiology, a hybrid of epidemiology and molecular genetics, enables researchers to assess biologic characteristics that may influence cancer susceptibility. The concept that risk of cancer from a given exposure differs between subgroups of a population is known in the epidemiologic vernacular as *effect modification*; biostatisticians often refer to this heterogeneity of effect as *interaction*. With the advent of polymerase chain reaction and other advanced laboratory methods, epidemiologists can incorporate molecular markers into their studies to identify specific suspect endogenous or exogenous host factors at the biochemical or molecular level.[20] Such studies aim to determine the roles, including interactions, of environmental and genetic factors in the initiation and progression of the carcinogenic process. The approach of incorporating genetic markers in epidemiologic studies of childhood cancer etiology shows promise for reducing cancer risk and providing strategies for prevention. Molecular epidemiology is certainly accompanied by challenges, however, such as ensuring the appropriate interpretation of molecular testing and resolving associated ethical, legal, and social concerns.

From molecular epidemiology has come the identification of biomarkers that may provide information on the extent of exposure to carcinogens. Perera and Weinstein[21] delineated four categories of biomarkers that help predict risk: internal dose, biologically effective dose, response, and susceptibility. Biomarkers represent a valuable research tool for detecting early changes caused by exposures, and they identify individuals with particularly high risk of cancer development. Describing and determining the occurrence of suitably selected biomarkers has led to tremendous progress in research on the mechanisms of cancer initiation and promotion, and has begun to make possible the assessment of cancer risk in healthy individuals. The knowledge that gene defects (gene mutations and changes in their expression) underlie carcinogenesis has resulted in focused efforts to detect such aberrant genes and their associated proteins.

The addition of molecular parameters to population-based studies should help identify genes and pathways involved in cancer development due to environmental exposures and to identify susceptible or resistant subpopulations. In turn, information about molecular mechanisms of carcinogenesis should improve risk assessment. Although studies of childhood cancer are currently limited to only a few candidate genes, the exponential growth of scientific technology and information promises future expansion of knowledge about the identity of potential genes and cancer pathways.

The crux of childhood cancer studies of etiology, in addition to identifying causal factors, is determining the critical period of exposure and disease susceptibility.

Exposures *in utero* and during the early years of life can disproportionately increase risk of cancer later in life. [22,23] Laboratory and epidemiologic evidence suggests that differential exposure response or physiologic immaturity raises the risk for infants and children far above that of adults experiencing the same environmental insults. The underlying mechanisms combine to proportionately increase exposure to toxicants and lessen the ability of the child in early stages of development to detoxify or repair damage. The cancer can be initiated *in utero,* with subsequent genetic mutational events and clonal progression occurring later. Adolescence and young adulthood are also sensitive times because of such proliferative surges as hormone outflow and rapid bone growth.

Current studies of molecular epidemiology are based on an understanding of the complex, multistage process of carcinogenesis and heterogeneous responses to carcinogenic exposures. Quantitative methods to measure human exposures to carcinogens improve continuously and have been successfully applied in a number of epidemiologic studies. Genetic predispositions to cancer, both inherited and acquired, have been, and continue to be, identified. The combined approach of correlating genetic polymorphisms with other cancer risk factors is showing considerable promise. For instance, glutathione S-transferases (GST) enzyme activity is involved in the detoxification of carcinogens such as epoxides and alkylating agents. GST genes are polymorphic, and lack of enzymatic activity potentially increases cancer risk. GST null genotype was hypothesized to increase risk of childhood AML and myelodysplasia (AML/MDS) in a recent case-control study of 292 children with AML/MDS. The frequency of GSTM1 null was significantly increased in AML/MDS cases compared with controls (OR = 2.0), whereas the frequency of GSTT1 null genotype in AML/MDS cases was not statistically different from controls. [24] This type of study illustrates the hope that, in the future, molecular epidemiologists will be able to develop an individual's risk profile, including assessment of multiple biomarkers. The field has the near-term potential to have a significant impact on regulatory quantitative risk assessments, which may aid in the determination of allowable exposures. Molecular epidemiologic data may also aid in the identification of individuals who will most benefit from cancer prevention strategies.

Investigators who conduct molecular epidemiology studies use traditional designs, including case-control and cohort studies, with inclusion of one or more genetic markers to determine exposure associations with disease outcome. Scientists agree that chronic diseases, including cancer, likely result from gene-environment interactions. In fact, some researchers have said that “genetics is the loaded gun, and the environment pulls the trigger.” Many are concerned about the question of “nature versus nurture,” and how to evaluate the contribution of each component. A recent large study of twins, although statistically limited, concluded that environment plays a substantial role in causing sporadic cancers, but still requires genetic potential for cancer to occur. [25]

Methodologic challenges of epidemiologic studies (as described below), such as accurate measurement of disease and exposure, appropriate selection of study samples, reducing potential confounding, and optimizing precision of effect measures, also apply to studies in the rapidly growing and promising field of molecular epidemiology. A serious concern lies with assuring an adequate sample size for study. Often, the prevalence of a genetic polymorphism or other biomarker is either quite low or quite high. Hence, the number of cases required to detect an association tends to be very large. Because childhood cancers are rare, it is often necessary to combine data from several studies to obtain adequate statistical power to draw meaningful conclusions. All of these issues speak to the need for investigators to exercise caution when interpreting their study data and the implications of their results. [26]

## BIAS AND CAUSAL INFERENCE

All human studies are susceptible to bias of varying degrees (i.e., producing inaccurate measures of the effect of a treatment or exposure on disease). An important goal of any study is to make every effort feasible to minimize the effect of bias.

Three general types of bias can occur:

1. *Selection bias*, when subjects who are sampled, recruited, enrolled, and complete the study are unrepresentative, in that they inaccurately reflect the exposure-disease relation in the target population
2. *Information (misclassification) bias*, when information collected on exposure, treatment, disease, or other study factors is inaccurate or incomplete
3. *Confounding bias*, when an extraneous factor distorts (increases or decreases) the true magnitude of the exposure-disease association

### Confounding

Randomization in clinical trials, if enough people are in the study, greatly reduces the probability that an extraneous factor will cause bias in the results because such “nuisance” factors should be randomly and evenly distributed among treatment groups. Absent randomization, however, confounding is a threat to validity in observational studies. Confounding requires a variable to be associated with, or a marker for, the disease of interest and for it to occur at a differing frequency between the exposure (or treatment) groups. When these two conditions hold, the extraneous factor may bias the exposure-disease association. Few exogenous risk factors, however, have been identified in the etiology of childhood cancer, and those few represent fairly weak associations. Thus, confounding bias has not been shown empirically to be of major concern in epidemiologic research of childhood cancer, although this possibility cannot be ruled out. Partly because of the implausibility of a biologic connection between EMF and cancer, for instance, some scientists hypothesized that the associations found between power lines and childhood leukemia and brain cancer in early EMF studies [27,28] were due to confounding by unidentified etiologic agents. [29] A recent methodologic study that carefully examined that possibility found little support for the theory. [30]

Statistical methods to control (adjust for, or correct) confounding, such as pooled stratified analysis or multivariate regression analysis, are at hand, but effective only if data on the potentially confounding variables are collected and accurate. Thus, for statistical analysis, observational studies often collect data on many factors not directly related to the cause-effect relation being investigated. Design strategies can also minimize or eliminate confounding. A study of asbestos exposure and lung cancer, for example, could avoid confounding from smoking status by recruiting only non-smokers.

### Information Bias

The most important threat to the validity of epidemiologic research of childhood cancer is inaccurate or incomplete information on study participants' exposure relevant to etiology. It is usually impossible, especially in retrospective studies, to directly measure exposure dose and duration during a time thought biologically relevant to cancer initiation or progression. As such, indirect or surrogate measures of exposure are used in lieu of direct measures. Indirect exposure tools include, for instance, self-reported recall of diet, smoking, and alcohol consumption during pregnancy; 24-hour food intake diaries; parental occupational job titles; recall of household pesticide use or inventory of household pesticide products; power line configurations, personal dosimeters or 24-hour measurements of EMF levels in the child's bedroom; pharmacy records among those in self-contained health maintenance organization plans; census tract information; urinary cotinine levels for smoking intake; and medical records.

These proxy measures may usefully approximate real exposure, but provide only imprecise information on dose, duration, and exposure time period. When exposure measures are equally inaccurate between study groups (non-differential error), as is often the situation, the cause-effect relation may be attenuated or completely obscured. Non-differential misclassification of exposure has no doubt been one reason why few environmental agents are known risks for childhood cancer occurrence.

Differential information bias occurs when accuracy and completeness of exposure information differs between comparison groups. Recall bias in case-control studies, for example, can occur if mothers of children with brain cancer (cases) are more motivated than mothers of healthy children (controls) to recall accurately their history of using household pesticides. This may happen because case mothers want to discover the cause of their children's disease. The control mothers may have hazier memories, and their incomplete or inaccurate recall can lead to underestimates of exposure frequency in the control group, and thus cause exaggeration of the strength of the association between disease and exposure. From a practical standpoint, however, recall bias may be more theoretical than factual. [31] One method sometimes advocated to minimize recall bias is to choose a control group of children with a chronic disease, rather than disease-free. Control mothers might then have equal incentive to recall exposure accurately and completely. Using this approach, one must be sure that the control group's disease is not causally related to the exposure under evaluation, or the resultant risk estimate will be biased as to whether the exposure is causally related to the childhood cancer in question.

### Selection Bias

Because all human studies include some element of sampling from larger (target) populations and require recruitment from the sample identified, selection bias is a potential source of error. Selection bias may occur when exposure or disease frequency among those in the study is unrepresentative of the target population. Case-control studies are susceptible because it is difficult to identify and recruit controls who provide an accurate accounting of baseline exposure frequency in the population that gave rise to the cases. For instance, selection bias is suspected in the apparent association of some childhood cancer–EMF studies. [30,32] If low-income

persons are proportionately less likely to participate as controls than higher-income persons, and low-income persons live in areas with proportionately more high current power lines, baseline exposure (high EMF) will be underestimated. Unlike controls, if case participation is independent of power line status, the odds of exposure among cases will appear higher than that of controls, resulting in a positive association when none really exists. Cohort studies and randomized trials, on the other hand, are susceptible to selection bias from attrition. If participants lost to the study during the follow-up period represent a different outcome experience than those who remain in the study to completion, the final results may be biased. For this reason, great effort must be expended in prospective studies to assure the most complete follow-up possible of study subjects.

### Causal Inference

Epidemiologic studies strive to provide the most accurate and precise risk estimate of an exposure-disease association. Concerns about potential bias of effect measures, however, contribute to the critical approach using inference and judgment to evaluate exposure-disease causal relations. Criteria commonly used to evaluate study results and to help guide judgments on the likelihood that an association indeed is causal and not merely statistical, include

1. *Strength of the exposure-disease association*. Large relative risks are less likely than small relative risks to result from chance or uncontrolled confounding (although this does not preclude other sources of error).
2. *Temporal relation between exposure and disease onset*. Studies are stronger when they can establish that the exposure appropriately preceded the biologic onset of disease.
3. *Biologic coherence*. When a plausible biologic mechanism or when experimental evidence from animal studies, or both, supports the hypothesized relation, there is greater confidence in the observed relation.
4. *Dose response gradient*. If exposure intensity or duration is associated with increased disease frequency when it is hypothesized that such a dose gradient should exist, the results appear more coherent and believable.
5. *Consistency* of results within and across studies. If multiple sources of the same exposure type show similar effects, or if multiple studies using different target populations and study designs show consistent results, or both, there is greater evidence to favor a true relation.

These concepts, which are widely applied, were originally derived from two papers by Sir Austin Bradford Hill and recently reprinted in a monograph on philosophy and epidemiologic reasoning in causal inference. [33]

## STATISTICAL MEASURES IN EPIDEMIOLOGY

Epidemiologic analyses generally focus on estimating effect measures, the strength (magnitude) of an exposure-disease association, rather than statistical hypothesis testing using a *p* value.[2] *p* Values provide a measure of probability for observing the study results, or results more extreme than those observed, if indeed there is no true association. No direct information from *p* values is given, however, on the strength, direction, or precision of an effect measure. Nor do *p* values supply information on the extent to which an association (or lack of an association) can be explained by confounding or other bias.

Effect measures for dichotomous outcomes, such as disease occurrence versus no disease, are often estimated using one of several ratio measures of relative risk.[2,34] In a cohort study, in which disease rates can be directly calculated, the ratio of the incidence rate of leukemia among those exposed to an agent can be compared with the rate of leukemia among those not so exposed. The ratio is 1:1 if the rates are the same in the two comparison groups, a relative risk of 1.0, suggesting no association between exposure and disease. If the exposed group has a higher rate than the unexposed group, the ratio will be larger than 1, suggesting an excess risk due to exposure. If the rate is lower in the exposed compared with the unexposed groups, the ratio will be less than 1, suggesting a protective effect from exposure. The further the effect measure is away from the “null” value of 1.0 in either direction, the stronger the association. Notice that a relative risk of 2.0 (double the risk compared with the reference group) is equivalent in strength to a relative risk of 0.5 (one-half the risk of the reference group). Rates of disease cannot be calculated directly in case-control studies. Alternatively, exposure frequencies are compared between diseased groups and non-diseased groups. The resultant OR is an effect measure on a ratio scale and, as mentioned previously, functionally equivalent to a relative risk. Other types of ratio-based relative risks are rate ratios, hazard ratios, standardized mortality ratios, standardized incidence ratios, and proportional mortality ratios. Confidence intervals are used to measure the precision of an effect measure. Like *p* values, confidence intervals are functions of the variability of the data and the size of the sample. Roughly speaking, a confidence interval provides a likely range in which the true effect measure lies within some level of confidence (often calculated as 95% confidence intervals).

Relative risks are important to help judge whether an association is causal and to estimate the degree to which risk of disease is increased (or decreased) by exposure. Relative risks, however, do not measure the “absolute” risk from exposure. In other words, a relative risk does not measure the number of excess cancers that are likely caused by an exposure. Attributable risk measures provide estimates of the actual rate (or number, or percentage) of cases “due to” exposure, assuming there is a causal relation.[34] Thus, attributable risks indicate the proportion of the disease preventable, if the exposure were removed from the population at risk. Assume for the sake of argument, for example, that living within 50 ft of a high-current power line increases a child's risk of ALL by a factor of 2. The annual rate of ALL in the United States is approximately 34 per million children younger than age 15 years. [35] If 10% of children in the United States lived near high-current power lines, the percentage of childhood ALL cases that could be attributed to the power lines would be 9%. This attributable risk of 9% (sometimes called an *etiologic fraction*) translates to an excess of three ALL cases per million children per year, which is the leukemia rate that hypothetically would be prevented if all children lived away from high-current power lines. Even very large relative risks may explain little of the total disease incidence within a population. Children with Down syndrome have an estimated 20-fold excess risk of ALL,[36] but because the prevalence of Down syndrome is only approximately 1.3 per 1,000 live births, the percentage of ALL in children that can be attributed to Down syndrome is only approximately 2.5%.

## RISK FACTORS FOR CHILDHOOD CANCER OCCURRENCE

Environmental risk factors for adult cancer generally involve long latency periods from exposure commencement to clinical onset of disease. Cigarette smoking illustrates this point: Smoking usually starts during adolescence, but associated malignancies do not become apparent until many decades after smoking is initiated. The genetic processes that go awry and lead to childhood cancer are likely different from that of adult malignancies; at the least, the carcinogenic process in children is much shorter in time. Infancy, when embryonal neoplasms such as neuroblastoma predominate, is the age when cancer incidence rates are highest during childhood.[37] It is reasonable to surmise, therefore, that many childhood cancers result from aberrations in early developmental processes.

To our dismay from a prevention standpoint, the current evidence to support a major etiologic role for environmental or other exogenous factors in childhood cancer is minimal. A comprehensive review of epidemiologic studies of childhood cancer is available elsewhere [31] and will not be reproduced here. The major types of childhood cancer and the few risk factors that are reasonably well documented are shown in Table 2-1. Many other factors are suspected to increase or decrease risk, but are not well established. Even the known risk factors shown in the table explain only a small proportion of childhood cancer cases.

**TABLE 2-1. KNOWN RISK FACTORS FOR SELECTED CHILDHOOD CANCERS**

## SUMMARY

Although knowledge about childhood cancer continues to increase, there is much work to be accomplished before reliable preventative measures can be recommended. In this brief overview, we have discussed the essentials of epidemiologic research approaches in childhood cancer, the role epidemiology plays in understanding the public health impact of childhood cancer, and the ongoing efforts to improve knowledge on the causes of these diseases and the consequences to the children who experience them.

# CHILDHOOD CANCER AND HEREDITY

SHARON E. PLON
DAVID MALKIN

## INTRODUCTION

A question often arises in the minds of parents when their child is newly diagnosed with cancer: “Did this happen because of something I did or passed on to my child?” or “What are the chances that my other children will develop cancer?” In this chapter, we outline the scientific and clinical evidence that is available to answer these questions with regard to genetic susceptibility. Overall, the percentage of childhood cancers that are caused by a clearly inherited predisposition is low. That percentage varies with individual tumor types and is a composite of several different genetic factors. Over the last 10 years, the genes that are mutated in many of these syndromes have been identified, providing the opportunity for genetic testing. After reviewing these syndromes, we also discuss the special issues to be considered in genetic testing for the pediatric oncology patient.

## INHERITED PREDISPOSITION TO PEDIATRIC CANCERS

Overwhelming evidence demonstrates that cancer is the result of multiple mutations in the DNA of the tumor cell. Many of these somatic alterations are discussed in Chapter 4 and in the disease-specific chapters. In contrast to the predominance of somatic mutations, the proportion of pediatric cancers that have a clearly hereditary component is small. *Hereditary* in this case implies a genetic alteration that has been passed on to the child from a parent or that was a new constitutional mutation that occurred in the oocyte or sperm before fertilization. A child therefore can have a hereditary predisposition to cancer with a negative family history because of a constitutional chromosome disorder such as Down syndrome (DS) or a de novo mutation in a cancer predisposing gene such as *Rb*.

Estimates of the hereditary predisposition for an individual cancer are based on epidemiologic studies of the number of familial cases, studies of associated syndromes, and molecular studies if the particular gene involved in a tumor type is known. The percentage of cases due to hereditary factors varies widely among tumor types, as illustrated in Table 3-1, with adrenocortical carcinoma, optic glioma, and retinoblastoma (RB) having the highest inherited fractions and many other tumor types falling in the range of 1% to 10%.[1] For example, a survey of 900 leukemia patients from Australia revealed that 72 had a single first-degree relative with leukemia (twice that expected).[2] However, only a single proband had multiple affected relatives, suggesting that single-gene inheritance that predisposes the carrier to a high risk for leukemia is rare.[3] A study using an alternative approach examined 16,564 cases of childhood cancer[1] and found that 2.6% of children with leukemia had an associated genetic condition, including DS and neurofibromatosis (NF).

| Tumor type | Hereditary component (%)[a] |
|---|---|
| Adrenocortical carcinoma[117,118] | 50–80 |
| Optic gliomas[43] | 45 |
| Retinoblastoma[188] | 40 |
| Pheochromocytoma[267] | 25 |
| Wilms' tumor[31,43] | 3–5 |
| Central nervous system neoplasms[1,345,346] | <1–3[b] |
| Leukemia[1,2] | 2.5–5.0 |

[a]These percentages are approximations from large population studies and may include familial cases and associated syndromes such as Down syndrome.
[b]Studies of pediatric brain tumors vary considerably in detection of a hereditary fraction.

**TABLE 3-1. HEREDITARY COMPONENT OF SEVERAL PEDIATRIC MALIGNANCIES**

Geneticists categorize disorders by the mechanism of inheritance: constitutional chromosomal abnormality; mendelian autosomal dominant, recessive, or X-linked patterns; and nonmendelian inheritance. The latter category includes inherited disorders that are caused by mutations in multiple genes or mitochondrial DNA or caused by mutations affecting imprinted genes. For any tumor type, the overall inherited fraction is the sum of several different genetic mechanisms. For example, an increased risk of Wilms' tumor (WT) is associated with multiple genetic syndromes ( Table 3-2), including a chromosomal deletion syndrome, an autosomal dominant disorder, and a syndrome resulting from disruption of imprinting.

| Disorders predisposing to Wilms' tumor | Mechanism of inheritance |
|---|---|
| WAGR | Interstitial deletion of chromosome 11p13, including *WT1* gene |
| Denys-Drash syndrome | Autosomal dominant—missense mutation in *WT1* |
| Autosomal dominant Wilms' tumor | Autosomal dominant—genes unknown |
| Hemihypertrophy and Beckwith-Wiedemann syndrome | Maternal deletion, uniparental disomy, or disordered imprinting of 11p15 |

WAGR, syndrome including Wilms' tumor, aniridia, genital abnormalities, and mental retardation.

**TABLE 3-2. MULTIPLE GENETIC MECHANISMS THAT INCREASE THE RISK OF DEVELOPING WILMS' TUMOR**

In the following sections, we describe the major types of hereditary disorders. In addition to defined genetic disorders, there may be rare families that show clustering of a particular tumor type. Presumably, these families represent mutations in genes that predispose the members to specific cancers. For example, neuroblastoma has been reported to cluster in very rare families,[4] and current research is focused on identifying the gene mutated in these families that predispose them to this specific cancer.

## CONSTITUTIONAL CHROMOSOMAL ABNORMALITIES

Children with constitutional chromosomal abnormalities present with defined clinical phenotypes that can include dysmorphic features, congenital abnormalities, growth failure, and developmental delay. Most result from errors that occurred during oogenesis or spermatogenesis, with both parents having a normal karyotype. Rarely, these disorders can result when a parent is a carrier for a balanced translocation. Constitutional chromosomal abnormalities are the result of an abnormal number (i.e., aneuploidy) or structural rearrangements of the normal 46 chromosomes (i.e., 22 pairs of autosomes and the sex chromosome pair). Because of the diagnosis in childhood of these syndromes by clinical phenotype and karyotype analysis, an increased association of these disorders with malignancy was recognized early.

### Down Syndrome

One of the most striking predispositions to cancer caused by a constitutional chromosome abnormality is the increased risk of leukemia in children who have trisomy 21.[5,6] An analysis of the Danish population results in an estimated cumulative risk for developing leukemia of 2.1% by 5 years and 2.7% by 30 years. [7] Other studies yield a slightly lower risk of leukemia of 1% by age 10.[6] This represents at least a 20-fold increase compared with the risk for the general population. Trisomy 21 is also a common finding in the karyotype of leukemia cells from patients without DS.[8,9] Thus, presence of an extra chromosome 21 appears to be leukemogenic and may be acquired in the germline or somatically. The specific locus on chromosome 21 responsible for this increased risk of leukemia is unknown. The recent publication of the complete sequence of human chromosome 21 should facilitate this area of research. [10]

In children with DS, the ratio of lymphoid to myeloid leukemia is shifted to 60% lymphoid and 40% myeloid from the ratio in the general population of 80% lymphoid and 20% myeloid.[7] This shift is principally due to the increased incidence of myeloid leukemias in children younger than 2 years of age. An analysis of data from several large Pediatric Oncology Group protocols compared the phenotype at presentation and result of therapy for acute lymphoblastic leukemia in children with and without DS.[11] Overall, the children with DS presented with more favorable leukemic subtypes, as measured by a decrease in the chromosomal translocations that are associated with a poor prognosis. For example, there were no children with the t(9;22), t(1;19), or t(4;11) translocation in the DS group, compared with an expected frequency of 10% to 13% in the non-DS (NDS) population. However, the DS children experienced more toxic effects from the chemotherapy, and their overall outcome therefore was not better than the NDS patients. Analysis of children in the United Kingdom with DS and leukemia treated between 1980 and 1994 also found a decreased survival (57% versus 75% 5-year disease-free survival) for the children with DS. [12]

Most striking is the distribution of types of leukemia among the DS children who develop acute myeloid leukemia (AML). [6] Approximately 30% of DS children with AML develop acute megakaryocytic leukemia (AMKL or M7). This results in an almost 400-fold excess of this particular malignancy in the DS children compared with NDS children. Biologically, children with DS and AMKL also show a different phenotype. In one analysis of 116 children with AMKL, 16 of the NDS children had the characteristic t(1;22)(p13;q13) translocation, compared with none of the DS children. [9] NDS children tended to present in early infancy and to have significant hepatomegaly, but the DS children, on average, presented at 23 months, and a high proportion had myelofibrosis.

Another unusual phenotype of children with DS is the development in infancy of a transient myeloid proliferative syndrome that can appear similar to leukemia but that is self-limited.[13,14] However, 25% of DS children with this syndrome eventually develop frank AML. Children who are mosaic for trisomy 21 in their blood and bone marrow have also developed transient myeloproliferative disorder and subsequent leukemia. [15,16] Similarly, children with DS have a higher rate of myelodysplasic syndromes, which are characterized by thrombocytopenia, abnormal megakaryocytopoiesis, and an abnormal karyotype, most commonly trisomy 8.[5] DS children with transient myeloproliferative disorder, myelodysplasic syndrome, and AMKL also all appear to have a propensity for complete remission. [5] The molecular bases for these differences remain to be determined and may provide insights into the genes responsible for spontaneous remission.

Despite the well-documented increase in the risk of leukemia in children with DS, a study based on exhaustive analysis of the Danish population found no increased risk of solid tumors in children or adults with DS. In particular, cases of breast cancer were significantly less than expected in DS adults compared with an age-matched population.[7]

### Sex Chromosome Abnormalities

Sex chromosome abnormalities comprise a large group of disorders that result from numeric and structural problems with the X and Y chromosomes. The overall incidence of sex chromosome abnormalities is high, with Klinefelter syndrome and Turner syndrome each affecting approximately 1 in 2,000 individuals. The diagnosis of these disorders, unlike DS, is often not made until late adolescence or young adulthood, when problems with the transition through puberty and fertility become apparent. However, children with these disorders are at increased risk for certain malignancies during childhood, arguing for earlier diagnosis.

#### *Y Chromosome*

Any phenotypic female with part or all of a Y chromosome is at risk for development of gonadoblastoma in her streak gonads. [17] The risk can be as high as 25% for individuals in the late second or third decade. Children with this problem include girls with androgen resistance syndromes (i.e., testicular feminization) who have a normal 46XY karyotype, children with gonadal dysgenesis, and girls with Turner syndrome and a mosaic 45X,46XY karyotype. Mosaicism results from an individual with several different populations of cells presumably due to a 46XY zygote losing a Y chromosome in an early mitosis. Approximately 25% of girls with Turner syndrome have some evidence for mosaicism.[18] The *TSPY* gene on the Y chromosome has been implicated as the gene responsible for gonadoblastoma in these conditions (reviewed by Lau[19]).

Phenotypic girls with a Y chromosome component should have prophylactic surgery to remove their gonads. In most circumstances, these gonads are nonfunctional, and removal does not affect the girls medically. However, the discovery of a sex chromosome karyotype that is not consistent with their phenotypic sex can be devastating for patients and their parents and should be carefully handled by a medical team familiar with these disorders. [20]

#### *Klinefelter Syndrome*

The clinical phenotype of Klinefelter syndrome (47XXY) is variable and includes tall stature, infertility, decreased secondary sex characteristics, and gynecomastia. Men with Klinefelter syndrome are often not diagnosed until adulthood, making epidemiologic studies of the increased risk of malignancy in childhood difficult. Nonetheless, some studies suggest an increased risk of dysgerminomas[21] and extra-gonadal germ cell tumors.[22] Men with Klinefelter syndrome have an increased risk of breast cancer[23] that does not appear to correlate with gynecomastia.[24,25] There is controversial evidence for an increased risk of leukemia in men with Klinefelter syndrome, and one large cytogenetic study of men with leukemia demonstrated no increased incidence of 47XXY. [26]

## STRUCTURAL CHROMOSOMAL ABNORMALITIES

### Detection and Impact

As cytogenetic techniques were improved in the 1960s and 1970s, it became clear that many of the complex dysmorphic syndromes were the result of large deletions that could be detected cytogenetically. During the 1980s to 1990s, the development of specific molecular probes and techniques to assay deletions by Southern blot analysis and fluorescent *in situ* hybridization (FISH) permitted further progress in mapping and identifying the underlying cause of these syndromes. Interstitial deletions can result in the loss of several contiguous genes, and the varied phenotype of a particular disorder may result from the loss of these often unrelated neighboring genes. The size of the deletion impacts how many of these genes are lost and how many features of a syndrome the child may manifest. Chromosomal deletions may be de novo events or inherited from either parent. Although these disorders are the results of deletions, the syndromes overlap with autosomal dominant disorders that are the result of smaller mutations affecting a single gene. For example, RB, which can be inherited as an autosomal dominant disorder due

to point mutations in the *Rb* gene, is also associated with a cytogenetically visible deletion in a small percentage of cases. [27] The cytogenetically visible deletions have led to early localization and cloning of these genes in several cases.

### Wilms' Tumor, Aniridia, Genital Abnormalities, and Mental Retardation

The WAGR syndrome is named for the components of the disorder: Wilms tumor, niridia, genital abnormalities, and mental retardation. Riccardi [28] and Francke[29] demonstrated that several children with AGR also had WT, and three of these children had cytogenetically detectable deletions at 11p13. Surveys of children with WT in the United Kingdom[30] and France[31] revealed that 3% and 1%, respectively, of children with WT had aniridia. The children with both WT and aniridia demonstrated mental retardation and genital abnormalities, including hypospadias.

Work from the Housman laboratory defined the minimally deleted region in WAGR and specified the areas responsible for WT, aniridia, and mental retardation. [32,33] This work led to the successful cloning of the gene, *WT1*, responsible for the WT phenotype.[34] *WT1* encodes a zinc finger transcription factor (reviewed by Little [35]). All or part of *WT1* is deleted in children with WAGR and WT. [36] In contrast, point mutations in *WT1* are found in children with the Denys-Drash syndrome, a disorder characterized by severe urogenital abnormalities and WT. [36,37] This is an example in which total loss of a gene product through deletion results in a less severe disease than production of a mutant protein due to a missense mutation. The gene responsible for the aniridia phenotype has also been cloned and is deleted in children with WAGR[38] and sporadic aniridia.[39]

Surprisingly, somatic mutations in the *WT1* gene in sporadic WT are found in only 10% of cases. [35] Also, families with a pattern of cancer consistent with autosomal dominant WT do not have mutations in the *WT1* gene.[40] Linkage studies in familial Wilms' kindreds suggest that there may be more then one locus involved. [41] None of these genes has been identified to date.

Any child with aniridia should have cytogenetic studies, including FISH analysis for deletion of the *WT1* gene, and be carefully screened for the development of WT. Screening of children with WAGR or Denys-Drash syndrome is often carried out by abdominal ultrasound examinations every 4 months until the age of 5 years, with decreasing frequency of examinations at later ages.[42] The recommendation for serial ultrasound scans is controversial and is based on small numbers. The National Wilms' Tumor Study found more stage 1 tumors in children who had been screened. [42] However, the Childhood Cancer Research Group in Oxford found that eight children who had their WTs diagnosed by ultrasound screening did not have more favorable outcomes than those in the group that was not screened. [43] Parents should be counseled to bring the child in for evaluation if they suspect any change in abdominal girth or feel a mass, regardless of whether ultrasound screening is performed.[43,44]

A long-term analysis of children with WT and either Denys-Drash or WAGR found a 62% and 38% rate of renal failure 20 years after the diagnosis of WT. [45] Therefore, children with WT and one of these syndromes require long-term follow-up for evidence of declining renal function.

## OVERGROWTH DISORDERS AND IMPRINTING ERRORS

### Beckwith-Weidemann Syndrome

Not surprisingly, there has long been a recognized relation between disorders of increased growth and predisposition to cancer. Two related syndromes in particular, Beckwith-Wiedemann syndrome (BWS) and hemihypertrophy (HH), are linked to a significantly increased risk of developing abdominal tumors, including WT and hepatoblastoma.[31,46] Of 183 children in the BWS Registry, 13 had developed a tumor by age 4. [47] BWS is characterized by excessive intrauterine and postnatal growth, organomegaly, macroglossia, and unusual linear ear creases.[46] The organomegaly can lead to omphalocele and umbilical hernias. HH in a child is defined as asymmetric growth due to overgrowth of one side relative to the other. It can be limited to a limb or the face or include the whole side. HH can be a feature of BWS or an isolated finding. For children with HH, the risk of WT is approximately 3%. [42] Several studies have demonstrated that children with both BWS and HH have a higher risk of WT than children with either condition alone. [48,49] More recently, studies have also demonstrated that nephromegaly is associated with an increased risk of WT in children with BWS.[50]

The genetic basis of BWS and HH is complex (reviewed by Weksberg [51]). Some families have an apparent autosomal dominant pattern that maps to 11p15.[52,53] In these families, BWS is more likely to be inherited from mothers than fathers. [53,54] There are also children with cytogenetically visible rearrangements in the region of 11p15 that are the result of duplications of the paternal chromosome 11p (reviewed by Slavotinek [55]). Moreover, there are children with apparently sporadic BWS. The mechanisms behind these unusual genetics may be clarified by understanding genetic imprinting. *Imprinting* refers to the fact that certain genes are expressed differently, depending on whether they were inherited from the maternal or paternal chromosome (reviewed by Tycko [56]). This form of inheritance was not predicted by Mendel's laws and can result in unusual pedigrees (e.g., unaffected sisters that can pass on a mutation in an imprinted gene to their children, resulting in affected cousins). BWS may result from cytogenetically normal children who inherit two copies of a paternal chromosome 11 and no maternal copy, termed *uniparental disomy*. Children with BWS and HH may show uniparental disomy of chromosome 11.[57]

There has been significant effort made to identify which imprinted gene is disrupted in BWS. Initial studies focused on the insulin-like growth factor-2 gene (*IGF-2*) in 11p15 as causative in BWS (reviewed by Reik[58]). There are now at least three genes that are imprinted in this locus that have been implicated in BWS. [59,60] *IGF-2* is a maternally imprinted gene (expressed from the paternal copy) involved in growth control. Paternally imprinted genes that show loss of imprinting in BWS include a cell-cycle inhibitory gene (*KIP2*),[61] *H19*, and *LIP1*.[62] Rare patients with BWS have been shown to carry a mutation in the *KIP2* gene.[63,64] Studies of mouse models demonstrate that alterations in both *IGF-2* and *KIP2* can contribute to the BWS clinical phenotype. [65]

Overall, given the increased risk of WT in these conditions, screening for WT by regular serial ultrasound examinations is recommended for children with BWS, HH, or both (see the preceding WAGR section for details about screening). Children with BWS screened for WT were much less likely to present with advanced disease then those who were not screened (0 of 12 versus 25 of 59).[66] Screening until age 8 detects the majority of children with BWS who will develop WT.

### Paraganglioma

Paragangliomata represent an unusual constellation of tumors variously termed *glomus tumors*, *chemodectomas*, and *carotid body tumors*. They essentially comprise a family of neoplasms that arise from paraganglia tissues—chemoreceptor organs distributed throughout the body. Approximately 20% of paragangliomas are familial in their presentation, and in an affected individual, they may occur either unilaterally or bilaterally. [67] The mode of inheritance is thought to be autosomal dominant with incomplete penetrance and variable expression, demonstrating both intra- and inter-familial variability. Maternal imprinting has also been suggested by pedigree analysis, although its molecular mechanism is unknown. At least three genes have been linked to hereditary paraganglioma, with the *PGL1* gene on chromosome 11q23 having been recently cloned.[68] *PGL2* is localized to chromosome 11q13, whereas *PGL3* has not yet been localized, nor do these families exhibit a maternal imprinting pattern.[69,70] Like other genes associated with familial predisposition to cancer, *PGL1* behaves as a tumor suppressor at the cellular level (as described below); it encodes a mitochondrial respiratory chain protein termed *cybS* (cytochrome b small subunit), which is thought to play a role in the $O_2$-sensing system of paraganglionic tissue.[68] Its loss may lead to chronic hypoxic stimulation and cellular proliferation. As with the hereditary overgrowth syndromes, BWS, and others, the complex mechanisms behind maternal imprinting and the unusual phenotypic expression patterns indicate the strong need to ensure that complete and accurate multigenerational family pedigrees are obtained on children with cancer to facilitate effective genetic counseling.

## MENDELIAN INHERITANCE OF A PREDISPOSITION TO CANCER

There are many single-gene disorders that result in an increased cancer risk and are inherited in a fashion consistent with single-gene disorders. In the following sections, we discuss a sampling of the disorders that are relevant to pediatric oncology and that have provided insight into cancer genetics.

### Autosomal Dominant Disorders

Autosomal dominant syndromes comprise the majority of families with single-gene disorders that convey an increased risk of cancer. The features of autosomal dominant inheritance are described in Table 3-3. The disorders are transmitted from the father or mother to a son or daughter, in contrast to X-linked disorders. Often,

there is a multigenerational pattern, and similar to other autosomal dominant conditions, there is variable expression of the disorder within a family, with “skipped” generations (at the phenotypic level) because of incomplete penetrance. *Penetrance* is defined as the probability that a person inheriting the mutation will have the disease. This results in individuals with the same genetic mutation who have a variable phenotype.

| |
|---|
| Multiple generations affected with cancer |
| Transmission through mothers and fathers |
| Earlier age of onset of cancer compared with sporadic cases |
| Increased incidence of multiple and bilateral tumors |
| A clustering of increased risk of one or a few tumor types in the family |
| Variable penetrance can lead to carriers not developing cancer |

**TABLE 3-3. FEATURES OF AN AUTOSOMAL DOMINANT CANCER FAMILY SYNDROME**

***Retinoblastoma***

Much of our knowledge of autosomal dominant cancer families was gained from the study of RB. In a series of landmark papers in the early 1970s, Knudson and Strong performed statistical analysis of children with RB and other pediatric malignancies. [71,72,73 and 74] In 1971, Knudson's hypothesis was that bilateral RB represented the familial form, and those patients had already acquired one “hit” or mutation. [71] The best model consistent with his data indicated that the bilateral form required only one additional hit but that the unilateral form required two hits. Given the epidemiologic nature of the study, the physical basis of the second hit was unknown, but the first was presumably a genetic mutation due to its inherited nature. Before this work, in 1968, Nicholls [75] had proposed that the skin lesions in NF type 1 (NF1) represented two mutational events in the same gene, with the first mutation being inherited and the second mutation occurring somatically. RB may be exceptional in requiring so few mutational events for tumors to develop, because many more than two mutations are required for most adult tumors. [76]

The clinical features of syndromes that follow the two-hit hypothesis are shown in Table 3-3. The most striking features are those initially observed by Knudson: Familial forms of RB present earlier and with a greatly increased percentage of bilateral and multiple primary tumors. Importantly, some patients (approximately 15%) with unilateral disease carry a constitutional mutation. An even milder form of retinal tumor, retinoma, that spontaneously regresses can be seen in apparently unaffected adults. Approximately 10% of people with a germline mutation in RB do not develop RB (i.e., incomplete penetrance). [77] The penetrance varies among families, however, with some mutations characterized by a higher likelihood of developing unilateral disease, termed *attenuated RB*. [78,79]

An additional phenotype common to the autosomal dominant conditions has been found for RB families by long-term follow-up of childhood survivors. Individuals carrying germline mutations in the *Rb* gene are also at increased risk for development of other primary tumors. In particular, there is an increased risk of osteosarcoma [74,80,81] and malignant melanoma. [81,82] Overall, there was a 26% mortality by age 40 from secondary neoplasms in children with bilateral RB. This finding was higher for children treated with radiation and substantially lower for unilateral cases. [83]

Based on the visible cytogenetic deletions, the gene mutated in RB was isolated. [84] Molecular studies allowed confirmation of Knudson's two-hit hypothesis. RB requires loss of both copies (i.e., two hits) of the *Rb* gene for a tumor to develop (Fig. 3-1; see Chapter 28). The normal function of the *Rb* gene product is to negatively regulate the cell division cycle. [85,86] The loss of this function, called *tumor suppression*, is consistent with loss of cell cycle control. In the familial form, a mutation in one *Rb* gene is inherited, and therefore all the cells in the body have only one normal allele. If during development that normal copy is mutated or lost, cell cycle control is disrupted and RB can develop. The most common mechanisms by which the second copy is lost are loss of the whole chromosome, large deletions, and gene conversion normally resulting in loss of heterozygosity for markers near the *Rb* locus. In the sporadic form, mutation or loss of both *Rb* genes must occur in the same somatic retinal cell for RB to develop.

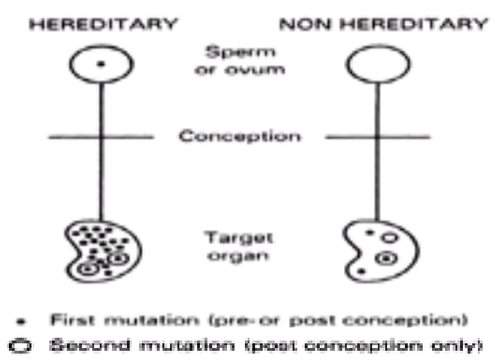

**FIGURE 3-1.** Knudson's two-mutation hypothesis. In all tumors, the same cell must undergo at least two mutations to become malignant, and the second mutation always occurs after conception. In sporadic, nonhereditary tumors (*right*), the first hit also occurs after conception. In hereditary tumors (*left*), the first mutation is in a germ cell, such that all body cells in the offspring have the first mutation. (From Miller RW. Genetics and familial predisposition. In: Calabresi P, Shein PS, Rosenberg SA, eds. Medical oncology: basic principles and clinical management of cancer. New York: Macmillan, 1985:130.)

Although all bilateral patients have been documented to carry constitutional mutations in the *Rb* gene, 80% have no family history of RB. This is due to the majority being the result of a de novo mutation in the *Rb* gene. In Table 3-4, the risk of having a second child with RB for parents of a child newly diagnosed with either unilateral or bilateral RB is given. [77] Surprisingly, for parents of a child with bilateral RB who have normal eye examinations, they retain a 6% risk to have a second affected child. This is because the de novo mutation may occur during the father's germline development and result in a variable percentage of the sperm carrying the mutation (germline mosaicism). A recent analysis of normal parents of 156 children with bilateral RB documented mutations in the father's germline in at least 10% of cases. Therefore, if genetic testing is not pursued, all siblings of children with bilateral RB should have ophthalmic surveillance beginning at birth.

| Clinical scenario | Recurrence risk (%) |
|---|---|
| Offspring of bilateral cases | 45 |
| Offspring of unilateral cases | 7.5 |
| Sibling of bilateral cases (parents unaffected) | 6 |
| Sibling of unilateral cases (parents unaffected) | 1 |
| Sibling of bilateral or unilateral cases (if either parent is affected) | 45 |

**TABLE 3-4. EMPIRICAL RECURRENCE RISKS IN FAMILIES WITH RETINOBLASTOMA**

The discovery of the *Rb* gene[84] has allowed for molecular diagnostics to be offered to families.[87] Several different approaches are used to identify mutations.[88] Standard karyotype analysis coupled to FISH studies using RB probes may reveal deletions of the entire gene, but in fewer than 5% of germline mutation patients.[27] The presence of smaller deletions in a small number of cases also are detected by Southern blot analysis. The remaining mutations that are scattered throughout the gene can only be found by detailed sequence analysis, which, although commercially available, is expensive and labor-intensive.[89] The majority of these mutations results in a truncated protein or disrupt specific functional domains of the Rb protein.[88]

Because a patient with a negative family history and unilateral disease, has only a 15% a priori chance of having a germline mutation, discerning the difference between a pathologic missense mutation or benign change is difficult. For this reason, many molecular diagnostic laboratories first identify mutations in the *Rb* gene in a tumor specimen (for unilateral cases) and then determine if the mutation can be identified in constitutional DNA from the blood.[90] Testing of bilateral RB patients is done directly from a blood sample.

There are several clinical situations in which molecular diagnostic testing is useful. Unaffected parents of a child with bilateral disease often are concerned about their risk for having additional children with RB. The physician first looks for the mutation in the affected child and then studies both parents to ascertain whether they carry the mutation. If a parent is positive, he or she has close to a 45% recurrence risk. As mentioned, even if both parents are negative, they retain a 6% risk of having an affected child due to mosaicism. Siblings of the proband can be tested at birth, and only those positive siblings need surveillance for RB. The adult survivors of childhood RB can also use DNA testing for prenatal diagnosis or immediate postnatal diagnosis of their own children. Current recommendations for ophthalmic surveillance include examination in the first few days of life and then serial examinations every 4 months until 2 years of age (see Chapter 28). In contrast, if DNA diagnostics demonstrate that the child did not inherit the mutation found in the affected relative, the surveillance and anesthesia required for thorough examinations can be avoided, thereby decreasing costs and potential morbidity.[91] Testing of unilateral patients can be particularly informative for parents. If it can be documented that the child does not carry a constitutional *Rb* mutation then (a) the child is not at substantial risk for secondary malignancies, (b) radiation therapy is associated with less hazard, and (c) the parents and eventually the patient have a negligible recurrence risk of having another child with RB.

***Inherited p53 Mutations, the Li-Fraumeni Syndrome, and Its Variant Phenotypes***

In 1969, an inherited cancer predisposition syndrome was reported by Li and Fraumeni on the basis of characterization of four families in which at least two cases of sarcoma occurred in early life.[92,93] Other cancers noted at an increased frequency in these families included premenopausal breast cancer, leukemia, and other sarcomas. Based on prospective analysis of these and other families, these investigators subsequently defined the “classic” syndrome as a proband with sarcoma diagnosed younger than age 45 years, with a first-degree relative with any cancer younger than 45 years, plus another first or second-degree relative with either any cancer younger than 45 years or a sarcoma at any age.[94,95] In addition to sarcomas and premenopausal breast cancer, an excess of brain tumors, leukemias, and adrenocortical carcinomas were noted.[94] An example of a pedigree from a Li-Fraumeni syndrome (LFS) family is shown in Figure 3-2. As more families have been ascertained, the list of possible or probable component tumors has expanded to include gastric cancer, lymphoma, and possibly early onset lung cancer, choroid plexus carcinoma, and colorectal cancer.[96,97 and 98] Birch and colleagues described several families that did not conform to the criteria of the classic LFS that they termed *LFS-like* (LFS-L).[98] The LFS-L families were defined on the basis of a proband with any childhood cancer or sarcoma, brain tumor, or adrenocortical carcinoma diagnosed younger than 45 years of age with one first- or second-degree relative with a typical LFS cancer diagnosed at any age, plus a first- or second-degree relative in the same parental lineage with any cancer diagnosed younger than the age of 60 years. In addition to the wide spectrum of tumor types observed in LFS, Hisada and colleagues showed that gene carriers are at significant risk of developing multiple synchronous or metachronous non-therapy induced neoplasms.[99] In particular, the overall relative risk of occurrence of a second cancer was 5.3 (95% confidence interval = 2.8 to 7.8), with a cumulative probability of second cancer occurrence of 57%.

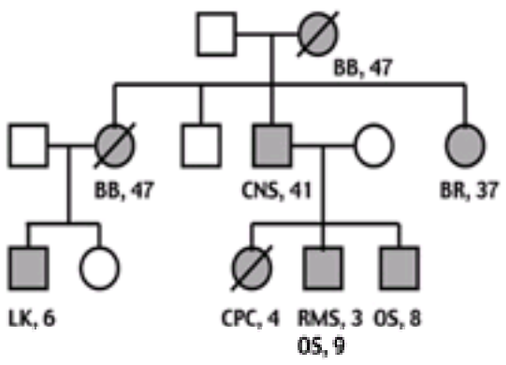

**FIGURE 3-2.** Pedigree of a family with Li-Fraumeni syndrome. Filled circles and squares represent affected members; circles with slashes represent deceased family members. Numbers represent age at diagnosis. BB, bilateral breast cancer; BR, unilateral breast cancer; CNS, brain tumor; CPC, choroid plexus carcinoma; LK, leukemia; OS, osteosarcoma; RMS, rhabdomyosarcoma.

Given the high mortality rate for affected members of LFS families, it was not possible to obtain DNA from extended pedigrees to carry out linkage analysis. In 1990, Malkin and colleagues took a candidate gene approach to determine the underlying genetic lesion in LFS.[100] Based on earlier observations that somatic mutations of the *p53* tumor suppressor gene were observed in more than 50% of sporadic human cancers,[101] and that p53 transgenic mice carrying mutant *p53* alleles developed a wide spectrum of malignancies,[102] these investigators elected to examine this gene in constitutional DNA of LFS kindreds. Heterozygous point mutations were initially detected in five of five families, however, numerous subsequent studies by these and other investigators have shown that only 60% to 80% of “classic” LFS families harbor detectable germline *p53* mutations,[103,104,105,106 and 107] whereas the majority of LFS-L families do not have detectable *p53* mutations in the coding regions of the gene.[107,108] Although a number of possible explanations, including mutations in promoter regions, have been proposed to explain the lack of *p53* alterations in all “classic” LFS families and a high proportion of LFS-L kindreds, none have been clearly documented experimentally.[109] Although it was originally observed that mutations in LFS occurred in a tight cluster within exon 7,[100,103] subsequent studies have confirmed that, in fact, mutations occur throughout the gene, though are primarily confined to highly conserved regions.

Several groups have examined the role of other tumor suppressor genes in these LFS, LFS-L families and individuals with the occurrence of multiple tumors. To date, these studies have been non-informative for germline alterations of *PTEN*, *p16INK4a*, and *p19Arl*. Other genes encoding proteins involved in p53-mediated cellular growth regulatory pathways, either effectors, targets, or binding partners of p53, have also been studied, but no germline alterations detected. Recently, an intriguing observation of heterozygous germline mutations in the checkpoint kinase *hCHK2* in one LFS family and one LFS-L family suggests an alternative mechanism for functional p53 inactivation in LFS.[110] This gene is the human homolog of the yeast *cds1* and *RAD53* G2 checkpoint kinases that are involved in preventing cellular entry into mitosis in response to DNA damage. Studies of murine embryonic stem cells deleted for *Chk2* confirm that the Chk2 kinase and p53 act together in the DNA damage response pathway, providing a molecular rationale for mutations in both genes being responsible for LFS.[111]

*p53*-Deficient mice were generated by Donehower and colleagues in 1992, and subsequently by other groups.[112,113 and 114] These mice have a striking propensity to develop a wide spectrum of cancer at extremely early age (younger than 9 months), with a relative prevalence of lymphomas. Interestingly, *p53*-heterozygous mice, harboring one wild-type and one mutant allele, also have a high incidence of cancer, although the tumors develop at a much slower rate.[115] Furthermore, in a pattern similar to the human LFS, these mice have a higher incidence of sarcoma development. Multiple primary tumors occur as well, again mimicking the human LFS phenotype. Although *p53* behaves as a classic tumor suppressor gene, less than 50% of tumors from *p53*-heterozygous mice and LFS patients have evidence of loss of heterozygosity.[115,116] It remains unclear in these patients how the retained wild-type p53 allele is functionally inactivated en route to malignant transformation of the

cell.

A number of studies have analyzed groups of patients with tumors characteristic of LFS, yet lacking characteristic family histories of cancer, for germline *p53* mutations. Such mutations have been identified in approximately 50% to 80% of children with adrenocortical carcinoma, [117,118] 10% of children with osteosarcoma,[119] and 10% of children with rhabdomyosarcoma.[120,121] The age of onset of tumors in the latter group of patients is strikingly lower (average age approximately 22 months) than in rhabdomyosarcoma patients with intact constitutional *p53*.[120] These observations suggest a possible difference in the biologic nature of malignant transformation of cells in which *p53* is altered as an early in contrast to a late event. One-third of children with sarcomas plus either multiple primary tumors or a family history of cancer have germline *p53* mutations. However, although breast cancer is a principal component of LFS, only 1% to 2% of women with familial, early-onset, or bilateral breast cancer harbor germline *p53* mutations.[122,123]

Presymptomatic molecular testing for germline *p53* mutations in members of Li-Fraumeni kindreds has been met with significant controversy. Because of the variable expressivity, the diverse tumor spectrum, and lack of clear clinical surveillance, preventive, or treatment recommendations, it is unclear how to manage the detection of a *p53* mutant carrier. Furthermore, the concept of predictive genetic testing of a child for a disease that may (or may not) occur in young adulthood poses significant challenges to the perception of the ethics of disclosure of genetic test results, in which the potential beneficiary of these results may wish to uphold the right to “not know.” In an attempt to address these issues, guidelines for testing have been established by both the American Society of Human Genetics and the American Society of Clinical Oncology. [124,125] These guidelines form a useful foundation on which to build practical testing parameters as better-defined genotype:phenotype correlations are generated.

After the publication of the statements of the American Society of Human Genetics and the American Society of Clinical Oncology, the Ethical, Legal, and Social Implications program sponsored by the National Center for Human Genome Research has created an extensive curriculum in Cancer Genetics and Cancer Predisposition Testing that discusses not only the principles of cancer genetics, but relates these to pediatric cancer syndromes as well as to cancer risk assessment, predictive testing, and Ethical, Legal, and Social Implications program concerns. The American Society of Clinical Oncology is making these curricula available to clinical oncologists. The recommendations outlined in these diverse “guidelines” can be applied to a number of cancer-predisposing gene testing programs. Although the interpretation of who should be tested remains a somewhat controversial point, certain common recommendations exist, including: the necessity that cancer risk counseling be part of the mission of clinical oncologists, the need for informed consent, formats for regulation of genetic testing, and continued efforts to address research issues. Specific concerns related to predictive genetic testing for children at risk continue to be raised, particularly when clinical screening protocols of those found to be mutation-positive are not defined.

### *Multiple Endocrine Neoplasia: Inheritance of a Mutation in an Oncogene*

The multiple endocrine neoplasia (MEN) disorders represent at least three different diseases, which are all autosomal dominant cancer family syndromes that affect different endocrine organs. MEN type 1 (MEN1) is characterized by parathyroid, pancreatic islet cell, and pituitary gland involvement (reviewed by Pang and Thakker[126]). Parathyroid involvement is found most frequently, and individuals from MEN1 families can also have their disease complicated by Zollinger-Ellison syndrome. The gene for MEN1 was mapped to human chromosome 11[127] and the gene, *MEN1,* identified.[128] By age 15 years, 28% of mutation carriers have either biochemical or clinical evidence for disease. [129]

Both MEN2A and MEN2B syndromes present in the pediatric period. MEN2A is associated with medullary thyroid carcinoma (MTC), parathyroid adenomas, and pheochromocytomas. MEN2B is a related disorder, but with the onset of tumors in infancy, ganglioneuromas of the gastrointestinal tract, and skeletal abnormalities. Additional families appear to show autosomal dominant MTC without the other features of MEN2A. Because of the life-threatening potential of MTC, treatment for MEN2 is prophylactic thyroidectomy in childhood.[130]

Before identification of the genes responsible for MEN2A and MEN2B, complex biochemical screening regimens were developed to detect patients requiring surgery early in the disease. These screening tests were based on assays of increases in the release of calcitonin in response to a pentagastrin challenge (discussed by Ponder[131]). With the discovery of the molecular basis of MEN2A and MEN2B, these biochemical assays have been replaced by genetic testing.

The gene for MEN2A was initially mapped to a small region on human chromosome 10q11.2.[132,133] The proto-oncogene *RET*, a receptor tyrosine kinase gene, mapped in this region and was known to be translocated in thyroid papillary carcinoma. [134] Analysis of constitutional DNA from multiple MEN2A families revealed a set of highly consistent mutations in the *RET* gene.[135,136] The MEN2A mutations appeared to replace one of four cysteines with another amino acid in the extracellular domain of the protein encoded by exons 10 and 11. Families that have isolated MTC or those with the full MEN2A syndrome share the same mutations. However, there is a correlation between disease phenotype and the specific mutation (e.g., a mutation in cysteine 634 results in a high risk of pheochromocytomas). [137] Studies of individuals from multiple MEN2B patients demonstrated two specific missense mutations in the highly conserved tyrosine kinase domain of the *RET* gene[138,139,140 and 141] in more than 95% of MEN2B patients. Screening of sporadic MTC tumors have revealed a wider range of somatic mutations in the *RET* gene than those seen in the inherited cases.[142]

These findings have both scientific and clinical importance. The pattern of mutation seen in MEN2 families is not consistent with the two-hit hypothesis (reviewed by Mulligan and Ponder[142]). These specific missense mutations are not inactivating, and there is no evidence that the remaining wild-type *RET* allele is lost. Further evidence was gained by demonstrating that transfection of a *RET* allele mutated at a cysteine residue results in transformation of NIH3T3 cells. [143] Thus, current information suggests that MEN2A and MEN2B confer predisposition to cancer due to inheritance of a mutation that activates the *RET* oncogene. Conversely, in an unexpected development, inheritance of an inactivating mutation of the *RET* oncogene appears to be responsible for a small percentage of aganglionic megacolon or Hirschsprung's disease (reviewed by Martucciello[144]).

Clinically, the screening and treatment of MEN2A and MEN2B families have been significantly improved by these genetic discoveries. In comparison of DNA-based screening with calcitonin assays[145,146] there is greatly increased sensitivity and specificity in DNA testing, particularly for young children. The test need only be performed once, and it decreases the cost and morbidity associated with annual pentagastrin stimulation testing. All patients at risk for MEN2 should have molecular analysis of their *RET* gene performed. When possible, an affected member of the family can be screened first to determine the specific mutation in the family, and then at-risk individuals are screened for that particular mutation. If no affected members are available, however, the mutations are specific enough to allow direct screening of at-risk individuals with high sensitivity (particularly for MEN2B). All individuals with MTC (either sporadic or familial) should have DNA analysis performed to ascertain whether they carry a constitutional mutation in *RET* and to determine the need for screening in other family members. All children who are found to be mutation positive need prophylactic thyroidectomy by age 5 years for MEN2A and by age 1 for MEN2B. [147,148] In addition, they require lifelong surveillance for development of pheochromocytoma and parathyroid disease.

### *Atypical Teratoid and Malignant Rhabdoid Tumors and the Rhabdoid Predisposition Syndrome*

Rhabdoid tumor of the kidney is a rare, aggressive childhood cancer. [149,150] Although the infant kidney is the most common site for rhabdoid tumors, they occasionally are observed in other sites and in older children and even adults. The tumor is histologically defined by large cells of unknown origin that may resemble benign or malignant skeletal muscle cells. Some 10% to 15% of rhabdoid tumors of the kidney in infants are associated with separate primary tumors of the central nervous system.[149,150] These histologically resemble primitive neuroectodermal tumors (including medulloblastoma or pineoblastoma) or rhabdoid tumors. Because of its potential to differentiate into heterologous elements at the cellular level, this tumor type has been termed *atypical teratoid/rhabdoid tumor* (ATRT).[151]

Cytogenetic analyses of ATRTs of the central nervous system (CNS) and malignant rhabdoid tumors (MRTs) of the kidney revealed abnormalities of chromosome 22, in particular, loss of one entire copy of the chromosome or deletion or translocation involving 22q11.2. [152,153,154 and 155] In 1998, the *hSNF5/INI1* gene was isolated from chromosome band 22q11.2, and several rhabdoid tumor cell lines have been shown to harbor truncating mutations of this gene. [156] *hSNF5/INI1* encodes a protein that is part of a multi-protein complex involved in chromatin remodeling, an essential process for regulation of gene expression. Beigel and colleagues have reported *hSNF5/INI1* mutations in virtually all MRT/ATRTs examined.[157] In this study, they also reported that approximately 20% of children with apparently sporadic tumors harbored germline mutations of the gene, suggesting a potential hereditary component to the etiology of the disease. Subsequent studies by Delattre and co-workers confirmed this finding and also noted the complete loss-of-function of *hSNF5/INI1* in the tumors arising in the context of a constitutional mutation. [158] These studies suggest that this gene fulfills the features consistent with a tumor suppressor gene, namely biallelic, somatic loss-of-function mutations in sporadic tumors and constitutional alterations associated with somatic loss of the wild-type allele in tumors resulting in a dominantly inherited cancer predisposition syndrome. The proposed condition, termed *rhabdoid predisposition syndrome* may include a spectrum of tumors, including renal and extrarenal MRT, choroid plexus carcinoma,

central peripheral neuroectodermal tumor (PNET), and medulloblastoma.[158] The penetrance of this syndrome is very high at a very young age, and in most cases represents a de novo mutation in the proband with unaffected siblings or parents. Only one family to date has been reported in which the healthy mother of an infant with ATRT carries a heterozygous *hSNF5/INI1* mutation.[159] The high penetrance together with the highly fatal outcome in affected family members probably accounts for the rarity of families with multiple affected generations and the lack of recognition of this cancer frequently being due to constitutional mutation.

***Familial Leukemia: The One-Hit Model***

Acute leukemias are the most frequent malignancy of childhood. However, knowledge about genetic predisposition to leukemia is very limited compared to many less common malignancies. Some well-described autosomal dominant syndromes, including LFS and NF, demonstrate an increased risk of leukemia as one of many features as described elsewhere in this chapter. However, families that demonstrate a specific predisposition to leukemia are extremely rare (reviewed by Horwitz [3]).

Over the last 5 years, progress has been made in mapping loci responsible for these rare families, and the first specific gene has been cloned. Linkage analysis of AML families implicated at least two genetic loci responsible for these families at 9p21-22 and 16q22. [160,161] In addition, this analysis demonstrated an unusual feature of the AML families[160] in that the age of diagnosis of leukemia was significantly lower for later generations within a family. This phenomenon is termed *genetic anticipation* and is well-documented in other genetic syndromes (e.g., myotonic dystrophy) due to progressive expansion of a trinucleotide repeat sequence within the disease-causing gene. There are no cancer genetic syndromes for which triplet expansion has been demonstrated. However, other familial cancer syndromes, including neuroblastoma[162] and Hodgkin's disease,[163,164] have also been reported to demonstrate genetic anticipation. In each of these cases, the specific mutations responsible for the familial cancers have not been identified. Thus, the molecular mechanism responsible for anticipation in cancer families is not known.

Familial platelet disorder with predisposition to AML (FPD/AML) is an autosomal dominant syndrome characterized by both neonatal thrombocytopenia and a very high propensity to develop AML. Although these families are rare, the high penetrance of the platelet disorder facilitated linkage analysis that has resulted in localization of the syndrome to chromosome 21q2.[165] In 1999, the laboratory of Gilliland and colleagues reported on the isolation of the gene responsible for this syndrome.[166] Quite unexpectedly, four FPD/AML kindreds were shown to contain constitutional mutations in the *CBFA2/AML1* gene. This gene had been previously well-described to be translocated in a significant percentage of sporadic cases of AML and is considered an oncogene. [167] At first glance, this might appear to be similar to MEN2 in which activating mutations in an oncogene cause a familial syndrome. What is unique in the FPD/AML case is that the mutations reported in the four pedigrees appear to be inactivating. They include nonsense mutations, splice site mutations (resulting in a downstream frameshift), and an intragenic deletion all of which should prevent production of normal CBFA2/AML1 protein. This pattern of mutation is much more consistent with a tumor-suppressor gene. Even more intriguing is early data that the remaining copy of the *CBFA2/AML1* gene is not disrupted in the leukemic cells from these patients. The authors conclude that haploinsufficiency of *CBFA2/AML1* is sufficient to lead to tumorigenesis. Thus, AML in the FPD/AML syndrome may not require a “second hit.” This analysis has also led to a reevaluation of the impact of translocations on *CBFA2/AML1* function that are found in sporadic leukemia. [167]

***Familial Colon Cancer***

Although not generally considered a pediatric disease, children of familial colon cancer kindreds can present with gastrointestinal manifestations, including frank carcinoma in the adolescent period. In addition, there is an increased prevalence of a variety of pediatric malignancies, including hepatoblastoma and brain tumors. The familial colon cancer syndromes are divided into those associated with polyposis (i.e., familial polyposis coli) and hereditary nonpolyposis colon cancer (HNPCC).

**Familial Adenomatous Polyposis**

The classic carpeting of the colon with thousands of polyps in familial adenomatous polyposis (FAP), also known as *adenomatous polyposis coli* (APC), led to early discovery of the inherited nature of this disorder. [168,169] The major features of the syndrome include onset in the second or third decade of extensive polyposis, with a nearly 90% rate of development of malignant colorectal carcinoma in the third decade and beyond (reviewed by Haggitt and Reid [170]). In 1962, Gardner and colleagues[171] noticed extracolonic manifestations in some kindreds with polyposis, including desmoid cysts, cysts of the mandible, and osteomas. Another feature, congenital hypertrophy of the retinal pigment epithelium is a sensitive diagnostic sign for Gardner's syndrome. [172] However, with the discovery of the gene, these “different” disorders were found in some cases to be caused by identical mutations, and the distinction between Gardner's and FAP no longer appears valid.

In addition to the greatly increased risk of colorectal carcinoma, carriers of this disorder have an increased risk of upper gastrointestinal malignancies, thyroid cancer, and pediatric hepatoblastoma. The upper gastrointestinal tumors include duodenal and periampullary adenocarcinomas and can result in increased mortality in patients post-colectomy.[173,174 and 175] Other environmental or hereditary factors may influence the upper gastrointestinal malignancies; Japanese patients with FAP have a very high rate of gastric cancer that is not seen in Western patients. [174,176]

Of particular importance for pediatric oncologists, the lifetime risk of developing hepatoblastoma for children of FAP families is approximately 1 case per 250 persons, compared with 1 per 100,000 in the general population. [177,178 and 179] Although this represents a minority of children with hepatoblastoma, it is important to inquire about a family history of colon cancer and polyposis in a child diagnosed with hepatoblastoma. In addition, approximately 1% of FAP patients develop thyroid cancer, and some authors recommend beginning surveillance for this at age 15 years. [180]

The gene for FAP (called the *APC gene*), was cloned by using positional methods in 1991. [181,182 and 183] Both constitutional mutations are found in FAP kindreds as well as frequent somatic mutations in the *APC* gene in sporadic colon cancers consistent with a tumor suppressor gene that follows two-hit kinetics. [184] Carriers of *APC* mutations are detected by two methods, protein truncation assays and linkage analysis (reviewed by Nagase and Nakamura [185]). First, approximately 70% of APC mutations result in truncated proteins[186] assayed by a method specifically designed to detect shortened proteins. The particular position of the truncation mutation appears to correlate with severity of the phenotype. [187] The assay is first performed on one affected member of the family. If a shortened protein is found, family members at risk can then be studied specifically for that alteration. Alternatively, if the assay fails, linkage analysis of the family as a whole can be performed to determine the likelihood that at-risk individuals inherited the mutant chromosome 5. [174]

Unlike the situation for LFS, there are clear surveillance and prophylactic surgery guidelines for individuals found to be affected with FAP that appear to be lifesaving. Given the early age at which polyposis develops, screening by serial flexible sigmoidoscopy is recommended to begin between the ages of 8 and 10 years for mutation carriers. Prophylactic surgery that includes total colectomy with removal of the rectal mucosa is recommended after extensive polyposis develops or by late adolescence. Modern surgical techniques allow the maintenance of fecal continence in these patients. [175,188] Surgery is required whether or not polyposis develops, because many carriers of the disorder have few polyps but still develop early colorectal cancer. After prophylactic surgery, carriers need screening of their upper gastrointestinal tracts and rectums (if rectal mucosa is left in place) for development of malignancy.

Substantial research has focused on treating FAP pharmacologically. Sulindac, a nonsteroidal antiinflammatory drug, was found to reduce the number of polyps in patients with FAP.[189,190 and 191] However, the later studies demonstrated that the effect was only partial and that colorectal carcinoma can still develop. The proposed mechanism of action is through induction of apoptosis in the abnormally proliferating colonic epithelial cells. Subsequent studies with the more specific DOC-2 inhibitors have also shown efficacy. [192] Trials to treat mutation-positive children pre-symptomatically are being initiated.

**Familial Juvenile Polyposis**

Familial juvenile polyposis (JP) was originally identified as the finding of isolated or multiple hamartomatous polyps in the rectocolon of young children. These lesions often manifest with abdominal pain and rectal bleeding. [193,194] JP[195] is inherited as an autosomal dominant trait. [196,197] The controversy has centered on whether these lesions carry an increased risk of colorectal carcinoma. [196] In a review of 57 cases, ten patients had malignancies, and several other large pedigrees have shown an increased risk of malignancy,[196,197] with recent studies estimating a 50% lifetime risk of colorectal carcinoma in some affected families. [198] It is unclear if this risk is shared by children having a single, isolated hamartomatous polyp. [199] The genetic basis for JP has been found to be due to mutations in the *SMAD4* gene in a subset of families,[200,201] and genetic testing for this disorder is becoming available. Surveillance recommendations for JP include annual complete blood cell count (to detect anemia due to gastrointestinal blood loss) and semi-annual colonoscopy. Prophylactic colectomy is not recommended because the risk of colorectal cancer is lower than that seen in FAP. Other rare syndromes also associated with intestinal hamartomas include Bannayan-Riley-Ruvalcaba and Cowden syndromes, which are due to mutations in the *PTEN* tumor suppressor gene.[202,203]

### Hereditary Nonpolyposis Colon Cancer

The HNPCC syndromes were originally defined by Lynch, who in following the work of Warthin [204] observed a number of families with an increased risk of colon cancer and absence of polyposis.[205,206] Extracolonic malignancies, including uterine, ovarian, and upper gastrointestinal cancers, are seen in some kindreds. Given the reduced age of onset of cancer, these malignancies can manifest in the second decade of life. [207] In general, screening by colonoscopy is recommended to begin at approximately age 25 years, with continuing screening biannually. [208] For families with particularly early onset, Lynch recommends screening beginning 5 years before the earliest known onset of cancer in the family.[207] A recent analysis of 25 children presenting with colorectal carcinoma younger than age 18 years demonstrated a pattern of colon and uterine cancer in relatives suggestive of HNPCC. [209] Molecular studies have not yet been performed on that cohort to confirm the presence of mutations in genes implicated in HNPCC.

During the search for the genes mutated in HNPCC kindreds, an unusual DNA pattern, termed *microsatellite instability*, was identified.[210,211] The localization of the gene and the finding of microsatellite instability led to the rapid cloning of the first gene, *hMSH2*, mutated in some HNPCC families.[212,213] *hMSH2* is the human homolog of a microbial mismatch repair gene *MUTS*. Subsequent analysis has shown that mutations in three mismatch repair genes, *hMSH2*, *pML1*, and *MSH6*, are responsible for the majority of HNPCC families (reviewed by Bocker[214]). Absence of normal mismatch repair function in colonic epithelial cells leads to microsatellite instability. Although 10% to 20% of sporadic tumors in adults demonstrate microsatellite instability, [215] microsatellite instability is rarely found in pediatric malignancies with the exception of secondary malignancies[216] and brain tumors associated with Turcot syndrome.

### Turcot Syndrome: Association of Brain Tumors with Colon Cancer

Turcot and others first reported an unusual finding of multiple pediatric brain tumors in families that also had an increased risk of polyposis and colon cancer (i.e., Turcot syndrome).[217] Analysis of subsequent families revealed that some had an increased risk of gliomas and other families had an increased risk of ependymoma. The history of polyposis and colon cancer was also variable. Some families with Turcot syndrome were shown to have truncation mutations in the *APC* gene.[218] In a study of 14 families, Hamilton and co-workers[219] found that families with Turcot syndrome have mutations in *APC* (ten families) or HNPCC loci. The type of brain tumor correlated with the mutation; in the families with *APC*-related mutations, there were more medulloblastomas, with a relative risk of developing medulloblastoma 92 times (95% confidence interval = 29 to 269) that of the general population. Three families with glioblastoma multiforme had microsatellite instability in their tumor specimens, as did the original family studied by Turcot. Two of these families had detectable mutations in the mismatch repair genes *hMLH1* and *hPMS2*. Thus, the clinical phenotype of these disorders should be enlarged to include pediatric brain tumors, and careful attention should be paid to a history of colon cancer in relatives of pediatric brain tumor patients. Some authors suggest that there may be a third form of Turcot syndrome due to a recessive condition with brain tumors and polyps coexisting in affected children. Molecular evidence for a recessive form has now been found in one family in whom the children are compound heterozygotes for mutations in the *PMS2* mismatch repair gene.[220]

### *Phakomatoses*

The final group of autosomal dominant disorders that is reviewed are the phakomatoses. The word *phacomatosis* refers to multiple phacomas (Greek for tumor of the lens) and mato (Greek for spot or spotty), which refers to the patchy nature of these disorders. Although these disorders share many features of the other autosomal dominant disorders, their frequency in the pediatric population and their pleomorphic symptoms deserve additional comment.

### Neurofibromatosis Type 1

NF1 is one of the most common genetic disorders in the general population (reviewed by Gutmann and Collins [221]). Approximately 1 in 2,500 people is affected by this disorder. Table 3-5 lists the diagnostic criteria for NF1 that were formulated at a National Institutes of Health conference in 1988 and recently updated. [222] Many of the criteria, including café-au-lait spots, axillary freckling, and neurofibromas, are detectable by general physical examination. Lisch nodules, which are normally detected by slit-lamp examination, are a pathognomonic feature of NF1. They are particularly useful in diagnosing older children and adults, because the prevalence of Lisch nodules is estimated to be greater than 80% for adults older than 20 years with NF1. [223] Lisch nodules do not have any impact on vision and often are not commented on in routine ophthalmologic examination.

| |
|---|
| The diagnosis is confirmed if the patient has two or more of the following features: |
| Six or more café-au-lait spots |
| 1.5 cm or larger in postpubertal individuals |
| 0.5 cm or larger in prepubertal individuals |
| Two or more neurofibromas of any type |
| or |
| One or more plexiform neurofibromas |
| Freckling of armpits or groin |
| Optic glioma (tumor of the optic pathway) |
| Two or more Lisch nodules (benign iris hamartomas) |
| A distinctive bony lesion |
| Dysplasia of the sphenoid bone |
| Dysplasia or thinning of long bone cortex |
| First-degree relative with NF1 |

From Gutmann DH, Aylsworth A, Carey JC, et al. The diagnostic evaluation and multidisciplinary management of neurofibromatosis 1 and neurofibromatosis 2. JAMA 1997;278:51–57, with permission.

**TABLE 3-5. DIAGNOSTIC CRITERIA FOR NEUROFIBROMATOSIS TYPE 1 (NF1)**

The hallmark of NF1 is the development of benign tumors, including peripheral neurofibromas, plexiform neurofibromas, gliomas of the optic tract, other low-grade gliomas, and pheochromocytomas. The peripheral neurofibromas often do not begin to develop until adolescence and rarely cause significant cosmetic problems until adulthood.[224,225] In contrast, plexiform neurofibromas are believed to be congenital in nature and can develop within the first few years of life. [226] Plexiform neurofibromas develop most commonly in the craniofacies, paraspinous region, mediastinum, and retroperitoneum. [225,227] They are deep masses that can be covered by hyperpigmented skin. They can be invasive and can cause significant disability, depending on the structures they invade. There is little malignant potential, but an area of a plexiform neurofibroma that becomes painful or begins to grow rapidly should be investigated. There is no satisfactory treatment for these tumors; partial resection is used if they become too disabling or invade the spinal tract. Clinical studies to determine the efficacy of farnesyl transferase inhibitors have been proposed.[228]

A second benign growth that is common in early childhood is the development of gliomas, especially involving the optic tract. A large percentage (30% to 70%) of children with a new finding of optic glioma have NF1.[229,230] Conversely, approximately 15% of children with NF1 have some optic tract involvement when assayed by magnetic resonance imaging (MRI) or computed tomography scanning.[231] Approximately one-third of these children have lesions that grow large enough to interfere with vision. In general, clinically significant growth occurs in the first 6 years of life. Because of the difficulty in detecting visual changes in young children, MRI of the brain and optic pathway is often performed for a young child with NF1. However, performing scans in asymptomatic children is controversial, as has been discussed by several authors.[222,231,232] If by age 6 a child does not show any sign of optic pathway involvement, the prognosis for lack of eye involvement is excellent. [233] Treatment of optic tract gliomas that are enlarging include irradiation, chemotherapy (carboplatin based), and surgery. [230,232,234] Although treatment guidelines are controversial, several of these large series that demonstrate the optic gliomas associated with NF1 have a more favorable course over long-term follow-up.

Gliomas can also develop in other parts of the central nervous system. These range from very low-grade to high-grade malignant tumors. Indications for imaging include seizures and development of neurologic deficits. In several small studies, the presence of an optic glioma in childhood may predispose the person to the development of other gliomas,[235,236] a finding that will have to be validated by larger studies.

Because NF1 is a common disease, cases of NF1 and malignancy are likely to happen coincidentally. The clearest associations between NF1 and pediatric malignancies is the increased risk of optic gliomas and malignant peripheral nerve sheath tumors (PNST). [237,238] and [239] The increased risk also includes other

sarcomas, presumably representing malignant transformation of the benign lesions seen in most NF1 patients. A large population study from Japan of 26,084 children younger than 15 years revealed a six- to eight-fold increased incidence of cancer in NF1 patients. [237] In particular, gliomas, PNST (i.e., malignant schwannomas), rhabdomyosarcomas, and myelogenous leukemia were all significantly increased compared with the non-NF1 Japanese population. Fifty percent of the patients with malignant PNST had NF1, a percentage similar to that found in a large Dutch study. [239] The Japanese study also highlighted the fact that many physicians were unaware of the diagnosis of NF1 in these patients and that the reporting of NF1 in pediatric cancer patients increased significantly when physicians were specifically asked to identify whether the patient had NF1.

Children with NF1 have an increased risk of several myelogenous disorders, including AML, [240] myelodysplasia, and myeloproliferative syndromes. [241],[242] and [243] Children with NF1 have a higher proportion of myelogenous leukemia than lymphoid leukemia (20:9) compared with the 1:4 ratio expected for the general population. [240] Moreover, bone marrow from children with NF1 and malignant myeloid disorders shows a loss of the normal *NF1* gene in the malignant cells. [244] This finding was unexpected, because the hematopoietic system does not derive from neural crest tissue. However, studies in mouse models of NF1 demonstrate that neurofibromin regulates proliferation of hematopoietic precursors. [245] Thus, *NF1* appears to be a tumor suppressor gene with regard to malignant myeloid disease.

The gene *NF1*, found at 17q11.2, was cloned in 1990 based on positional methods. [246],[247] and [248] The *NF1* gene is quite large and encodes a protein, neurofibronin, which is homologous to the GTPase-activating protein called GAP. This relationship suggests that the NF1 protein normally inhibits the activity of the Ras protein (an oncogene). NF1 follows the two-hit hypothesis in that tumors associated with NF1, such as pheochromocytomas, [238] show a loss of the remaining normal copy of the *NF1* gene. Evidence suggests that the benign neurofibromas also demonstrate mutation or loss of the normal copy. [249] Discovery of the loss of the second *NF1* gene in these lesions completed an almost 30-year cycle from when Nicholls [75] first presented his hypothesis of two genetic events occurring in the same gene, one inherited and one somatic, in the development of NF1.

Although the gene for NF1 has been identified for several years, translation of this knowledge into practical molecular testing has been difficult. Because of the high de novo mutation rate in NF1, most individuals have different mutations, called *private mutations*, scattered throughout a large gene. Early DNA diagnostic testing relied on linkage analysis for markers near 17q11 in those families with enough affected individuals. [250] A priori, this testing could not be used on the 50% of affected individuals who represent de novo mutations or on individuals from small families with few living affected family members. Molecular testing based on the same *in vitro* transcription-translation process as described for FAP is available to identify mutations that result in a truncated neurofibronin protein. [186] Between 60% and 70% of individuals with NF1 may have detectable mutations by this method. More comprehensive sequence-based methods are not yet clinically available. Although most individuals have their NF1 condition diagnosed based on the clinical features described in Table 3-5, molecular testing can be useful in some clinical situations. The first is affected adults requesting prenatal diagnosis (although this currently requires linkage analysis). The second is parents of affected children who appear to have new mutations. In that case, molecular testing is done on the child, and if a mutation is identified, the parents are tested to confirm that they do not carry the mutation. However, negative skin and eye examinations would have already made the likelihood fairly low. A third clinical scenario relevant to pediatricians is a child with a negative family history and multiple café-au-lait spots. This is a common reason for referral to genetics or NF clinics. Children are often examined on an annual basis, but the diagnosis remains uncertain until the child develops another sign of NF1. For these children, a positive molecular diagnostic study would provide strong confirmation of the diagnosis and highlight the surveillance required. One series of 42 young children originally evaluated for café-au-lait spots found that 24 were eventually given the clinical diagnosis of NF1. [251]

### Neurofibromatosis Type 2

NF2 represents a distinct and much rarer disorder than NF1. Because most of the manifestations of NF2 occur in adulthood, they are not discussed in detail here. NF2 is characterized by café-au-lait spots, bilateral vestibular schwannomas, central neurofibromas, and meningiomas (reviewed by Gutmann [222]). The disease has a high degree of morbidity and is difficult to treat because of the multiple tumors that develop. The gene that is mutated in NF2 is found on chromosome 22 and was cloned by positional methods in 1993 (reviewed by Kinzler and Vogelstein [252]). The *NF2* gene encodes a protein, called *merlin* or *schwannomin*, that is homologous to the band 4.1 protein and appears to play a role in cytoskeletal architecture. This represents an unusual function of a tumor suppressor gene and highlights the many aspects of cellular physiology that are involved in tumor development. Children from families with NF2 can be screened by MRI to look for evidence of acoustic nerve tumors. Consideration for teaching of sign language while hearing is intact may aid in communication if deafness develops.

### Tuberous Sclerosis

Tuberous sclerosis (TS) is another phakomatosis disorder that is characterized by pleomorphic features, including benign and neoplastic growths. The classic triad of seizures, mental retardation, and facial angiofibromas (previously called *acne sebaceum*) occur in fewer than 50% of patients with TS. [253] The diagnosis of TS is made clinically and is based on specific criteria. [253] There is a wide range of phenotypes between and within families, [254] with some adults with TS having very high degrees of intelligence. Two-thirds of cases are due to de novo mutations and thus do not have a family history of the disease. Part of the explanation for the heterogeneity may result from the fact that TS is a genetically heterogeneous disorder, with families showing linkage to at least two genes. [255] A locus on chromosome 9q34, named *TSC1*, is implicated in some TS families. The gene mutated on chromosome 9, *TSC1*, was identified in 1997. The function of the protein encoded by *TSC1,* hamartin, is not known. A second gene on chromosome 16p13.3, called *TSC2*, was cloned previously [256] and encodes a protein, tuberin, which has Rag1-Gap activity. [257] Hamartin and tuberin can physically interact. Thus, the protein products of genes mutated in both NF1 and TS participate in the regulation of Ras or Ras-related GTPase-activating protein activity and provides a molecular explanation for the similarities between the two syndromes. A comprehensive analysis of mutations in *TSC1* and *TSC2* in 150 TS patients was recently published. [258] In total, 120 mutations were found, 22 in *TSC1* and 98 in *TSC2.* The majority of *TSC1* mutations were truncating, whereas for *TSC2* there were both missense mutations in the conserved domains and truncating mutations. Clinically, the degree of mental disability was greater for patients with *TSC2* mutations (67% versus 31%).

TS is characterized by the growth of normally benign tumors in several different organs. Loss of heterozygosity for TSC1 and TSC2 has been shown in these tumors, suggesting both have tumor suppressor gene function. [259],[260] Cardiac rhabdomyomas normally develop *in utero* and are often detected during prenatal ultrasound. They typically regress postnatally. [261] The morbidity and mortality associated with these tumors reflect the potential for flow abnormalities in the heart if these tumors grow large enough. In one study, 50% of children with cardiac rhabdomyomas developed clinical criteria for TS during childhood. [262]

Later in childhood and early adulthood, individuals with TS are at risk for the development of retinal hamartomas and giant cell astrocytomas. [253] During adulthood, there is often the slow growth of renal angiomyolipomas. In the British study of childhood cancer, [1] TS was found to be significantly overrepresented in this population. The increase in cancers appears to be due to an increased risk of brain tumors and rhabdomyosarcomas. There are no specific screening guidelines for detection of tumors in TS other than renal ultrasounds periodically in adulthood to screen for renal involvement.

### von Hippel-Lindau Disease

Unlike TS, the hallmark of von Hippel-Lindau (VHL) disease is development of multiple benign and highly malignant tumors. In contrast to the other phakomatoses, this disorder is not accompanied by specific dermatologic or developmental abnormalities. Diagnosis occurs during adolescence or early adulthood, when tumors become clinically apparent. VHL is characterized by four common tumor types: multiple cerebellar hemangioblastomas, retinal angiomas, renal cell carcinoma, and pheochromocytomas. [263],[264] The affected members of these families also have increased rates of pancreatic carcinoma and epididymal cysts. The two leading causes of mortality are the cerebellar lesions and renal cell carcinoma. [264]

The cerebellar and retinal lesions typically develop during the second and third decade of life, although they can occur in the first decade. Presentation is related to the location and mass effect of the tumor. [264],[265] MRI of both the brain and spinal cord can reveal the presence of isolated or multiple lesions with signal intensities characteristic of a hemangioblastoma. Any person with a central nervous system hemangioblastoma should undergo complete evaluation for other VHL-related tumors. Multiple cerebellar hemangioblastomas or a first-degree relative with VHL and an isolated lesion is sufficient for the diagnosis of VHL.

Treatment options include surgery and irradiation. Retinal angiomas can often be asymptomatic and diagnosed on yearly eye examinations. If sufficient in size, they can manifest with new vision defects. Treatment of the retinal lesions can yield excellent long-term results. [264]

Renal cysts accompanied by renal cell carcinoma are one of the hallmarks of the VHL syndrome. The tumors often develop in the third or fourth decade, but the risk of renal cell carcinoma is lifelong. It is necessary to balance curative intent, tumor removal, maintenance of renal function, potential for transplantation, and the

knowledge that the patient is likely to develop other tumors when creating a treatment plan. [266]

Pheochromocytoma as part of VHL can be singular or multiple and may be benign or malignant. One study of a series of individuals with sporadic pheochromocytoma found 23% with evidence for VHL or MEN2A syndrome.[267] Although this high rate of genetic predisposition was not found in other studies, [268] all patients with pheochromocytoma should have a careful family history taken and screening for signs of involvement of other organs consistent with either VHL or MEN2. In VHL, the pheochromocytomas most commonly present in the second decade but have been reported in young children.

Given the predilection in VHL to develop a specific group of tumors, several comprehensive screening protocols have been developed. Table 3-6 outlines the protocol recommended by the large VHL research program at the National Institutes of Health.[263] The important features are annual surveillance examinations for renal masses, pheochromocytoma, and retinal angiomas, with biannual examination for cerebellar lesions. Screening for pheochromocytoma is improved by use of plasma metanephrines[269] as opposed to urine catecholamines. Outcome studies are needed to document decreased morbidity, mortality, and expense for individuals with VHL who are properly screened with the current technology.

| Test | Schedule |
|---|---|
| Urinary catecholamines or plasma metanephrines | From age 2; every 1–2 yr |
| Ophthalmoscopy | From infancy; yearly |
| Enhanced MRI of the brain and spine | From age 11; every 2 yr |
| Abdominal ultrasound | From age 11; yearly until age 20 or during pregnancy |
| Abdominal CT or MRI | From age 20; yearly or every other year |

CT, computed tomography; MRI, magnetic resonance imaging.

Plasma normetanephrine and metanephrine for detecting pheochromocytoma in von Hippel-Lindau disease and multiple endocrine neoplasia type 2. N Engl J Med 1999;340:1872–1875.

**TABLE 3-6. RECOMMENDED SURVEILLANCE REGIMENS FOR VON HIPPEL-LINDAU DISEASE**

The *VHL* gene was cloned in 1994 using positional methods. [270] The original localization of *VHL* to chromosome 3 was based on the finding of frequent loss of heterozygosity for markers on 3q of patients with sporadic renal cell carcinoma. [271] VHL families with pheochromocytoma (referred to as *type 2*), tend to have clustering of missense mutations in specific codons. [272] DNA diagnostic assays have been optimized such that more than 95% of patients with VHL have a detectable mutation in the *VHL* gene.[273] This allows early identification of relatives who have not inherited the mutation and do not require a surveillance protocol and those who have inherited the mutation and need full screening for development of malignancy.

Initial analysis of the *VHL* gene revealed little homology to other known proteins. Subsequently, significant progress has been made in defining the functions of the VHL protein[274] including repression of hypoxia-induced genes (e.g., *VEGF*) at normal oxygen tension. The loss of VHL function results in overexpression of genes required for angiogenesis under normal oxygen conditions. VHL protein also has ubiquitin protein ligase activity when bound to the elongin and cullin complex. [275] Currently, experimental therapeutics are being developed to inhibit these activities.

### Nevus Basal Cell Carcinoma Syndrome or Gorlin-Goltz Syndrome

Gorlin and Goltz described a number of individuals who had multiple nevoid basal cell epitheliomas, odontogenic jaw cysts, and bifid ribs, with the syndrome being inherited in an autosomal dominant fashion.[276] Sometimes referred to as the *fifth phakomatoses*,[277] Gorlin-Goltz syndrome is currently named *nevus basal cell carcinoma syndrome* (NBCCS) due to the predominant finding of multiple basal cell carcinomas. Herzberg described these findings in concert with medulloblastoma.[277] The full syndrome includes the above features and characteristic palmar and plantar pits; mild facial dysmorphisms, including frontal and biparietal bossing; calcification of the falx cerebri; and short fourth metacarpal bones (reviewed by Gorlin [278,279]). Careful clinical examination and x-rays of ribs, skull, and spine is often sufficient to make the diagnosis. In young children with medulloblastoma, examination of the parents may aid in identifying NBCCS in the family. Basal cell carcinomas develop around the time of puberty and can eventually number in the hundreds. There are differences in the number of basal cell nevus syndromes in different racial groups, with significantly fewer found in individuals of African-American descent. [280] It is estimated that 29% of individuals with a basal cell carcinoma younger than age 18 years has NBCCS syndrome.

Meduloblastoma is a significant feature of NBCCS.[281] Analysis of 105 patients with NBCCS evaluated at the National Institutes of Health found four children with the diagnosis of medulloblastoma diagnosed at a mean age of 2.3 years.[280] Conversely, it is estimated that approximately 10% of patients with medulloblastoma diagnosed at age 2 years or younger have NBCCS.[282] Because of the high frequency of medulloblastoma, children with NBCCS are recommended to have biannual neurologic examinations and annual MRI examinations up to age 7 for early detection of medulloblastoma. [280]

In children receiving radiation therapy, the skin within the field can become severely affected with hundreds of nevi with a latency of approximately 5 years. [280] There have also been reports of secondary meningiomas and ependymomas in the radiation field of children with NBCCS. [280,283] Thus, use of radiation therapy for treatment of tumors in NBCCS syndrome should be limited.

The gene for NBCCS syndrome was first localized by linkage analysis and subsequently cloned. [284,285] The gene responsible for NBCCS, *PTCH,* is a homolog of the *Drosophila melanogaster* segment polarity gene Patched. Mutations in *PTCH* are found in the majority of NBCCS families and in a large percentage of sporadic basal cell carcinomas, making it one of the most frequently mutated genes in human cancers.[286] Mouse models heterozygous for *ptc* mutations also develop medulloblastoma.[287] In contrast, analysis of sporadic medulloblastomas have identified *PTCH* mutations in only approximately 10% of cases.[288] Much research is now focused on whether somatic mutations in other human genes in the *PTCH* pathway are prevalent in sporadic medulloblastoma.[289] One recent study from the Mayo clinic did not find mutations in other *PTCH* pathway genes (including *SHH, SMO*, and others) in a series of 24 sporadic medulloblastomas.[290]

### Autosomal Recessive Disorders

Autosomal recessive genetic disorders that predispose to cancer have distinct characteristics when compared with the autosomal dominant disorders. Autosomal recessive disorders are much rarer in the general population. Specific ethnic or geographic groups may have an increased risk of autosomal recessive disorders because of a founder effect or increased prevalence of consanguinity. Given the requirement for two mutant alleles, these disorders normally occur in sibships and are not evident in multiple generations. Within a sibship, there is only a one in four chance that a sibling will have the disorder. For this reason, single affected individuals from a small family may appear to be a sporadic case.

Generally, the range of expressivity in an autosomal recessive disease is more limited and the symptoms often more severe than in autosomal dominant disorders. However, exceptions include the wide range of presentations of Fanconi's pancytopenia. [291] Most of these disorders manifest in childhood, presumably because of the severe nature of the genetic defect. Many of the autosomal recessive cancer syndromes are caused by mutations in genes that encode DNA repair enzymes or DNA damage checkpoint genes, and they are often referred to as *chromosome breakage syndromes*. These deficiencies result in increased sensitivity to spontaneous and exogenous DNA damage and increased risk of specific cancer types. Significant progress has been made in the last 10 years identifying the genes mutated in these disorders.

#### *Xeroderma Pigmentosum, Cockayne Syndrome, and Trichothiodystrophy*

Xeroderma pigmentosum (XP) represents the classic DNA repair defect syndrome. The clinical features of this disorder have been extensively reviewed by Kraemer and colleagues.[292,293] Patients present with cutaneous sensitivity, as revealed by photosensitivity, telangiectasias, and freckling in the first few years of life. Ocular abnormalities are common and are found in ultraviolet light-exposed areas of the cornea, lids, and conjunctivae, including corneal clouding and ocular malignancies.

There is a several thousand–fold increased risk of basal and squamous cell skin carcinomas, which begin developing at approximately 8 years of age ( Fig. 3-3), compared with at approximately the age of 50 for the general U.S. population. There is also a significant increase in melanoma (approximately 5% lifetime risk) in the XP group. The pattern of these skin cancers shows an increased prevalence in sun-exposed areas compared with non-XP skin cancer patients, particularly on the neck, face, and tip of the tongue. A significant but smaller increase in the risk of internal malignancies has also been observed for XP patients. [292]

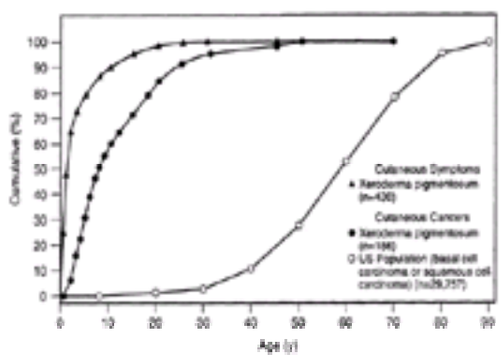

**FIGURE 3-3.** Age of onset of xeroderma pigmentosum symptoms. The ages at onset of cutaneous symptoms (generally sun sensitivity or pigmentation) was reported for 430 patients. The age at diagnosis of the first skin cancer was reported for 186 patients and is compared with distribution for 29,757 patients with basal cell carcinoma and squamous cell carcinoma in the U.S. general population. (From Kraemer KH, Myung L, Scotto J. Xeroderma pigmentosum. Arch Dermol 1987;123:241, with permission.)

Some XP patients have neurologic abnormalities. One group, first reported by DeSanctis and Cacchione, has XP-like dermatologic features and progressive neurologic degeneration beginning at approximately the age of 2 years and accompanied by immature sexual development. [294] These patients tend to cluster in complementation group A. Overall, Kraemer[293] found that 18% of reported XP patients had neurologic abnormalities, some of which resemble the DeSanctis-Cacchione syndrome, and others that have a later onset of neurologic difficulties and that cluster in complementation group D.

Two other disorders can manifest with findings of XP. Trichothiodystrophy is a rare disorder that shares an increased risk of skin cancer and repair defects and the findings of brittle hair and ichthyosis. The XP/trichothiodystrophy patients fall in the XP complementation group D. [295] Cockayne syndrome shares some of the ultraviolet hypersensitivity of XP but is also characterized by neurologic deficits, including developmental delay and decreased skin cancer risk. There are at least three complementation groups for Cockayne syndrome.[296]

At a cellular level, the ultraviolet sensitivity [297] in XP patients was found to result from defects in excision repair.[298] This form of repair is essential for repair of the thymine dimers and other structures that result from ultraviolet damage.

XP is a group of disorders caused by mutations in at least seven different genes. [295] The determination that multiple genes caused the same clinical disorder was based on complementation assays in which fibroblasts from different patients are fused together and the heterokaryon cell is then assayed for complementation of the repair defect (reviewed in Bootsma and Hoeijmakers[299]).

The specific biochemical defects in cells from patients with either XP or Cockayne syndrome has led to successful isolation of almost all of the genes responsible for this defect (reviewed by Cleaver[300]). Most commonly, complementation cloning was performed based on adding either normal genomic DNA, complementary DNAs, or protein extracts to a mutant cell line and screening for the rare clone that has regained normal excision repair. Using a variety of these different but related techniques, the genes for complementation groups XPA-XPG have been found. Analysis of these gene products demonstrate that many of them are related to previously identified DNA repair genes in other eukaryotes, including yeast, mouse and Chinese hamster cells. [301]

Research on Cockayne syndrome has led to a greater understanding of the repair process and its interaction with transcription. Fibroblasts from Cockayne patients appear to have normal levels of general DNA repair.[302] In a normal cell, DNA damage in actively transcribed genes is preferentially repaired before DNA from inactive parts of the genome, a process termed *transcription coupled repair*. Cells from Cockayne patients are deficient in transcription coupled repair due to a mutation in the *ERCC2* DNA helicase, which is also a component of active transcription complex TFIIH.[303] The overlap between transcription and repair functions may explain the more extended phenotype of Cockayne patients, including neurologic dysfunction (reviewed by Cleaver and Hultner [304]). Also the fact that overall repair rates are normal in Cockayne cells may explain the lack of cancer predisposition.

A third group of patients who clinically demonstrate ultraviolet sensitivity but have normal nucleotide excision repair *in vitro* are termed *XP*$^{v}$. This disorder is due to mutation of a specialized DNA polymerase, polymerase eta, which places two adenine residues opposite a thymine dimer photoproduct, thus restoring the normal base sequence.[305,306]

***Helicase Disorders: Bloom, Werner, and Rothmund-Thomson Syndrome***

Three autosomal recessive disorders, although distinct, share some clinical features, including a predisposition to malignancy ( Table 3-7). Children with Bloom syndrome are very small at birth and remain small,[307] have a photosensitive rash, immunodeficiency, and a very high predisposition to develop a wide variety of malignancies, including leukemia/lymphomas and solid tumors.[308] This disorder is more common in children of Ashkenazi descent. Cells from these patients exhibit increased recombination manifested as increased sister chromatid exchange. Werner syndrome is characterized by premature aging (including early-onset atherosclerosis, diabetes, and cataracts beginning in the second decade) with increased incidence of soft tissue sarcomas. [309] The premature aging is manifested at a cellular level as early senescence in fibroblasts from these patients. The third disorder in this group, Rothmund-Thomson syndrome (RTS), is characterized by a very distinct rash termed *poikiloderma* that begins in infancy; skeletal dysplasias, including radial ray abnormalities; and cataracts. Children with RTS have a distinct predisposition to the development of osteosarcoma and, less frequently, skin cancers. [310] No specific cellular defect has been consistently reported in this condition.

| Disease | Clinical features | Cancer predisposition | Gene/ chromosome location |
|---|---|---|---|
| Bloom | Small stature, photosensitive rash, immunodeficiency | Multiple tumor types, including leukemia/lymphoma and solid tumors | *BLM* 15q26.1 |
| Werner | Premature aging, cataracts, diabetes, atherosclerosis | Soft tissue sarcoma and skin cancers | *WRN* 8p11 |
| Rothmund-Thomson | Poikiloderma rash, radial ray defects, cataracts | Osteosarcoma and skin cancers | *RECQL4*? 8q24.3 |

[a]Although *BLM* and *WRN* are the genes mutated in the majority of Bloom and Werner syndrome patients, respectively, to date, only a few patients with Rothmund-Thomson syndrome have been documented to have mutations in *RECQL4*.

**TABLE 3-7. FEATURES OF THE CHROMOSOME INSTABILITY SYNDROMES DUE TO MUTATIONS IN GENES ENCODING RECQ HELICASES**

All three disorders have been shown to be the result of mutations in RecQ helicase genes: the *BLM* gene in Bloom syndrome,[311] *WRN* gene in Werner syndrome,[312] and *RECQL4* in a subset of patients with RTS.[313] The RecQ helicases were first identified in *Escherichia coli.* The most extensive studies have been of

*Saccharomyces cerevisiae* strains mutant for the *SGS1* RECQ helicase gene. These strains show genomic instability, including a hyperrecombination phenotype that may explain the chromosomal instability seen in the human disorders.[314]

***Ataxia-Telangiectasia***

Ataxia-telangiectasia (AT) is a disorder that has fascinated physicians and researchers since its initial description (reviewed by Gatti and colleagues [315]). Children with AT develop ataxia during early years of childhood, with truncal ataxia appearing before appendicular and eventually requiring a wheelchair for mobility. [316] Choreoathetosis and ocular motor apraxia are also common neurologic findings. Intelligence does not appear to be affected. The oculocutaneous telangiectasias normally begin with the conjunctivae and develop between the ages of 3 and 5 years. Useful biochemical markers for diagnosis include elevated alpha-fetoprotein and carcinoembryonic antigen in children with AT.[317]

There is a very high rate of malignancy, particularly the development of leukemias [318,319] and lymphomas, in AT children. Although less emphasized, these AT homozygotes are at increased risk of many different types of solid tumors, including primary central nervous system tumors (reviewed by Hecht and Hecht [319]). Individuals with AT have immunodeficiency characterized by diminished immunoglobulin G2 and immunoglobulin A levels and increased risk of sinopulmonary infections.[315] The major causes of mortality of those with this syndrome are sinopulmonary infection (especially after significant neurologic degeneration) and malignancy (reviewed by Gatti[315]).

In addition to the risk of cancer in the AT homozygous children, heterozygotes carrying one AT mutation appear to have an increased risk of cancer. Swift and colleagues carried out several studies of AT heterozygotes and demonstrated increased cancer risk, particularly for breast cancer, in AT heterozygotes compared with the general population.[320,321] Although the degree of increased breast cancer risk continues to be controversial (despite a large number of studies) [322] mothers of children with AT should be advised of at least a moderate increased risk of breast cancer.

The many cellular defects in AT cells have been intensively studied and are not reviewed here in detail. Fibroblasts and lymphocytes from AT patients have increased sensitivity to DNA-damaging agents, particularly ionizing radiation. [323,324] and [325] In general, this defect results from the loss of checkpoint control, the cell cycle arrest in G1 and G2 that normally accompanies DNA damage.[326]

The gene mutated in AT (called *ATM*) was sought for more than 10 years by complementation studies and positional cloning. The positional studies, which involved several international consortia, centered on using genetic linkage and physical mapping to identify the *ATM* gene. AT was localized to chromosome 11q22-q23 in 1988 by Gatti and colleagues.[327] In 1995, the group led by Yossi Shiloh identified a complementary DNA from this region that was mutated in multiple AT patients. [328] Subsequent studies have revealed that the mutations are spread throughout the gene and primarily result in a truncated or disrupted ATM protein.

The *ATM* gene encodes a protein with homology to the *MEC1/ESR1* gene of budding yeast and the *Rad3* gene of fission yeast. Mutations in these genes result in a defect in checkpoint control in the S and G2 phases of the cell cycle, with remarkable similarity to the defect seen in AT cells (reviewed by Elledge [329]). Subsequent analysis has found that after DNA damage, the ATM protein signals through the p53 and BRCA1 tumor suppressor gene products. [330] The finding of ATM in the same molecular pathway as other genes clearly implicated in breast cancer susceptibility further substantiates the epidemiologic data with regard to breast cancer predisposition in heterozygotes. Although specific screening or surveillance for cancers is not currently recommended for children with AT, the diagnosis of AT has a major impact on treatment decisions for a child who develops a malignancy. Due to the defective DNA damage checkpoint mechanisms, children with AT have increased sensitivity to chemotherapy and radiation treatments. Specific treatment regimens have been developed for these children. [331] Specialized clinical centers that are familiar with recommended regimens for these unique children are available through the support of the A-T Children's Project ( http://www.atcp.org/).

## ISSUES IN GENETIC TESTING FOR THE PEDIATRIC ONCOLOGY PATIENT

Several studies have suggested that 4% to 10% of childhood cancers result from inherited genetic mutations, making it essential for pediatricians and pediatric oncologists to recognize clinical criteria suggestive of familial cancer syndromes. [332,333] As we have discussed in this chapter, specific features in the clinical history are essential for the accurate definition of a familial cancer syndrome. Most of these features rely on an accurate and detailed family history, including all cancers and their age of diagnosis. This is because many cancer predisposition syndromes lack an associated recognized phenotype to identify at-risk individuals. For example, although HH and other features of BWS raise the clinician's alertness to embryonal cancer risk, no known physical features are associated with LFS. As oncologists have become more effective at identifying cancer families, and as novel genes functionally linked to cancer phenotypes are identified and clinical testing made available, it is important to continue to recognize that children are part of a network of family members who may be indirectly affected by testing.

In the practice of pediatrics, DNA-based tests for a large number of non-cancer conditions, including cystic fibrosis, muscular dystrophy, and hemophilia, have been developed and are currently in use. It has been recommended that as children grow and acquire cognitive and moral skills, they should be permitted to participate in decisions concerning testing.[334] For genetic testing for conditions associated with childhood-onset cancers, it is generally accepted that cancer predisposition testing is most helpful for highly penetrant diseases in which individuals at risk for cancer can be identified and followed closely for the development of highly specific tumors (e.g., VHL, FAP, and the multiple endocrine neoplasias). [335] For each of these, clear guidelines for clinical surveillance or prophylactic medical interventions in childhood have been established for mutation carriers as discussed in this chapter.

However, for a variety of other cancer-predisposition disorders, the clinical management of carriers is less well-defined. Such diseases include LFS. Although predisposition testing may identify asymptomatic carriers, and allow institution of preventive or surveillance programs where available, such testing is associated with the following caveats that must be taken into consideration: (a) the genetic heterogeneity of cancer predisposition, (b) the technical difficulty inherent to gene testing and to test interpretation, and (c) the psychosocial impact of testing. Both variable degrees of penetrance and expressivity for many conditions, including LFS, suggest that other genetic events play an important role in defining the particular cancer phenotype of individual members of families. This variability makes predictions of clinical disease and specific susceptible target organs difficult and complicates the design of adequate screening programs.

The technical aspects involved in predisposition gene testing and interpretation are complex. Many tests are only available through research settings where results are made less immediately available, and confirmation of results is less well controlled than in clinically certified laboratories. Databases are now available to facilitate identification of laboratories performing specific genetic tests (e.g., http://www.genetests.org/). Furthermore, such testing, particularly of novel genes, tends to be expensive, and extra effort by the physician often needs to made to obtain insurance coverage of testing. Given the complexity, genetic testing should only be undertaken by a physician or genetic counselor fully capable of interpreting these results. As demonstrated for FAP a significant percentage of physicians ordering a genetic test incorrectly interpreted a negative result in an affected proband. [336]

Genetic testing for any disease, which should now include cancer, has been demonstrated to have profound psychological and emotional impact on patients, and may be further complicated by relationships with parents and other family members.[337] Issues of the “vulnerable child syndrome” in affected carriers and “survivor guilt” in unaffected, non-carrier siblings raise complex psychosocial concerns that may be beyond the general purview of the pediatric oncologist. Furthermore, lessons from studies in adults have demonstrated that although patients learning of their increased risk of disease do well overall they may experience feelings of shock, depression, grief, altered self-esteem, or even guilt. Limited studies in children, parents, and families have yet to clarify the impact of predictive testing for cancer in children.

Based on many of the preceding arguments, a number of recommendations established in 1992 for LFS[338] are still applicable to genetic testing in family cancer syndromes that include children. The quality of information provision on cancer genetics is directly related to the knowledge of professionals and their ability to communicate this to a patient and family regardless of their specialty.[339] This requirement exists in the face of a relative lack of in-depth education in genetics in medical schools and post-graduate education, that then places pediatricians and pediatric oncologists in a difficult position of integrating rapidly evolving technologies with patient care and unfamiliar and complex genetic testing issues.[340] This unfamiliarity extends to more recent issues with respect to physicians' duty to warn “third parties” (i.e., members of extended families who may be at risk of avoidable harm from a genetically transmissible condition), and its legal ramifications. [341] Therefore, for pediatric oncologists without additional training, it is reasonable and preferable to identify appropriate patients and families for referral to a geneticist or genetic counselor with training in cancer genetics. Recently, the multi-disciplinary approach taken by several groups [342] involving pediatric oncologists, clinical geneticists, genetic counselors, psychologists, and ethicists in establishing cancer genetics clinics and programs whose primary focus is to serve children with cancer and their families provides an intriguing and novel mechanism to optimize care of these families and advance the understanding of the role of genetics in the etiology of

childhood cancer.

# MOLECULAR BASIS OF CHILDHOOD CANCER

A. THOMAS LOOK
ILAN R. KIRSCH

## INTRODUCTION

The genetic information found in a cancer cell is not the same as that in its nonmalignant counterpart. This realization, and the generation of the data that support it, constitute one of the successes of the molecular approach to cancer biology. This knowledge represents the resolution of a search begun more than a century ago to define and identify something unique to a tumor cell that could distinguish it from the surrounding normal cells in which it arose. The search has been arduous and frustrating, but now we know that cancer cells are different. They carry within their DNA point mutations, viral insertions, or gene amplifications, deletions, or gene rearrangements, each of which can alter the context and process of normal cellular growth and development. Depending on the genetic locus involved and on the mechanism of its disruption, some of these changes may make small or incremental contributions to malignant transformation. Other changes may be cataclysmic in their unraveling of an ordered and regulated growth process. The identification and characterization of the involved genes and of the mechanisms by which they can be altered provide basic insights into the process of carcinogenesis and offer the hope of specific therapies if the alteration or its effect can be stymied or reversed. At the most fundamental level, cancer is a malevolent example of genomic instability, an inherent property of the evolutionary process and normal human development.

The results of genomic instability are not abstract or intangible. They can be readily characterized by current methods of DNA analysis. In every case, they result in a change in a chromosome. Some changes can only be appreciated by analysis of the fine structure of the chromosome, such as by comparing a nucleotide sequence one base at a time with the corresponding sequence from a nonmalignant cell. The point mutations revealed can terminate protein translation, alter protein function, or change the regulatory target sequences that control gene expression. Other changes cause chromosomal alterations that generate morphologically distinct structures that can be appreciated by refined cytogenetic analysis. These aberrations create new genetic contexts within the genome, leading to the formation of novel proteins or to the dysregulation of genes displaced by the aberrant event.

Although the genome in each person is inherently unstable, that instability can be increased or decreased through inheritance and exposure to destabilizing factors in the environment. Certain inherited syndromes are characterized by a marked increase in the tendency for chromosomes to break and rejoin or by a marked predisposition to develop point mutations. Invariably, these syndromes are associated with marked increases in cancer incidence. Even in the absence of a frank cancer-predisposing syndrome, humans have inherited a panoply of genes that govern the ability to cause, recognize, or repair mismatched or altered nucleotides and chromosome breaks. Similarly, each person carries genes whose products can detoxify mutagens or increase their mutagenic potential. Interactions with the environment—locations of homes, types of occupations, medicines taken, and food eaten—affect the stability of the genome and the likelihood of acquiring a gene mutation that can move a cell along a pathway toward malignant transformation.

With this perspective in mind, we can begin to consider the specific nature of the genetic alterations that are the basis of cancer. To begin this discussion, we review events that result in a fundamental alteration of the normal linear organization of genetic material, gross chromosomal aberrations, a particularly dramatic and instructive form of genomic instability. These aberrations result in a change in the “neighborhood” in which particular genes are located as opposed to changes restricted to the gene's primary structure. For most of the past 30 years, delineation of these chromosomal aberrations has focused on changes that could be observed in metaphase chromosome preparations analyzed by light microscopy. Advances in cytogenetic and molecular biologic technologies have vastly improved our ability to detect and resolve the precise consequences of chromosomal aberrations.

## GENERAL NATURE OF CANCER-ASSOCIATED CHROMOSOMAL ABERRATIONS

Figure 4-1 shows the general classes of chromosomal alterations that have been associated with malignant transformation. The occurrence of these defects or changes is not restricted to malignant cells. Gaps, breaks, monosomies, trisomies, deletions, and translocations occur in nontransformed cells and can be observed as incidental findings during karyotypic analysis of normal individuals. Their frequency is a function of the age of the individual, the individual's exposure to DNA-interactive agents, the cell type being studied, and whether the cell is being studied directly or after *in vitro* cell culture.

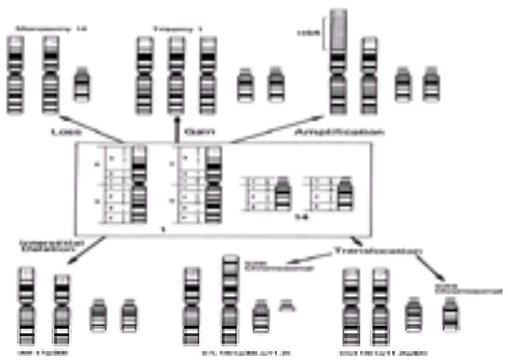

**FIGURE 4-1.** The spectrum of morphologically apparent gross chromosomal aberrations, with chromosomes 1 and 14 as examples.

The frequency of any incidental abnormality in a routine karyotypic analysis of a normal population of cells hovers at approximately 1%. [1,2,3,4] and [5] These karyotypically abnormal cells that are observed incidentally do not appear to be clonally proliferative (by definition, they are unique in a given analysis) and therefore are assumed not to confer any selective advantage on the cell in which they occur. Whether they are completely random or have some cell-type specificity is not entirely clear. Certainly, a fraction of the recurring chromosomal translocations and inversions in normal individuals are cell-type specific. A background level of chromosomal instability exists. Rarely, a chromosomal aberration occurs that provides a growth or selective advantage to the affected cell and dysregulates the growth of the cell and starts it down a pathway of malignant transformation. Individual aberrations do not appear to exert their dysregulating effect uniformly, but they seem to have variable effects depending on the cell type in which they occur. A gene product must already be part of a growth-affecting pathway of a particular cell or be able to insinuate itself into that pathway for its dysregulation to have an impact. This lesson is one derived from cancers associated with constitutional and acquired karyotypic defects.

## CONSTITUTIONAL CHROMOSOMAL ABERRATIONS

When chromosomal deletions, translocations, amplifications, point mutations, or nondisjunction events occur in a gamete, the abnormality exists in the germline, and the entire organism that develops after conception bears the alteration in each and every cell. A variation on this theme can occur when the alteration or nondisjunction event occurs in a somatic cell early in its lineage development, leading to mosaicism for the entire organism or for particular cell types. The frequency of generation of chromosomal abnormalities is high enough that everyone harbors chromosomally abnormal cells, and everyone is mosaic. Usually, mosaics are appreciated only when the aberration occurs and expands early in development, and only those abnormalities that occur during the initial formation of cell lineages or in the germline are considered to represent constitutional abnormalities.

Constitutional deletions or monosomies can predispose an individual to the development of cancer. That the cancers are cell-type specific underscores the fact that one is often dealing with a gene function that only makes a contribution to growth or development within a particular milieu or physiologic context. The classic examples of this phenomenon taken from the pediatric oncology literature are the chromosomal abnormalities associated with the hereditary forms of retinoblastoma and Wilms' tumor (nephroblastoma). The consequences of the disruption of the *RB* gene in retinoblastoma and of *WT1* and other genes in Wilms' tumor are discussed in a later section of this chapter, but the fundamental observations are presented here.

Hereditary and sporadic occurrences of retinoblastoma[6] have been distinguished on the basis of clinical and epidemiologic presentations. The hereditary form (i.e., familial or de novo germline mutation) is estimated to comprise approximately 40% of affected individuals. In this form, the age of onset is earlier and the frequency of bilateral tumors is increased. There is often a positive family history for this cancer. These observations led Knudson [7] to propose a “two-hit” mechanism of carcinogenesis in which the first genetic defect, already present in the germline, must be complemented by an additional spontaneous mutation before a tumor can arise. In the sporadic form, cellular transformation occurs only when two spontaneous mutations take place in the same cell. [7] Support for this concept came from karyotypic analysis of patients with a particular syndrome associated with retinoblastoma. These individuals carried a constitutional deletion of part of the long arm of one allele of chromosome 13.[8,9] This finding not only fit conceptually with the Knudson model but also pointed directly to the chromosomal region in which the crucial gene was likely to be found.

The involvement and often deletion of one of the two alleles from this region of chromosome 13 in patients with retinoblastoma was proven by molecular analysis of restriction endonuclease fragment length polymorphisms. The somatic, unaffected tissue of a particular patient with retinoblastoma was studied with a series of DNA probes from the 13q14 region that show a polymorphic heterozygous pattern (with each allele on the two chromosomes 13 contributing its own distinctive pattern) on Southern blot analysis (Fig. 4-2). The tumor tissue was likewise analyzed, and the contribution of one of the two alleles was found to be missing. There had been a “reduction to homozygosity,” consistent with an acquired monosomy in the tumor tissue.[10] These kinds of analyses continued to focus attention on a particular chromosomal region and led to the successful cloning of the first tumor suppressor gene, *RB*.[11]

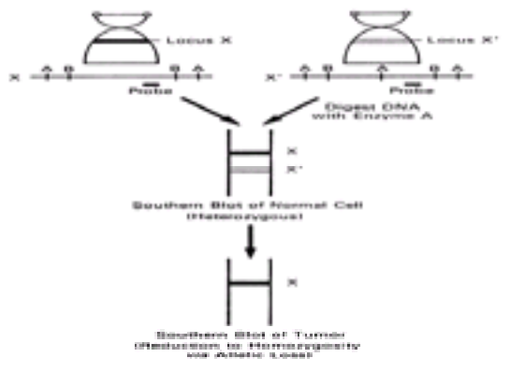

**FIGURE 4-2.** Polymorphic variation and reduction to homozygosity. A locus “X” is polymorphic for a DNA sequence, which is the target site for cutting of the restriction endonuclease “A.” The individual in this example carries one copy of each of two polymorphic variants. After digestion of the individual's genomic DNA, size fractionation through a gel matrix, denaturation, and transfer and fixation to a solid matrix (i.e., Southern blotting procedure), the “blot” is hybridized to a labeled probe that is homologous to a part of the locus. In normal cells, DNA fragments corresponding to both alleles (and therefore polymorphic variants) are seen. In the DNA derived from the tumor of this individual, only one of the two DNA fragments is observed. The other allelic variant has been lost. This loss can occur by simple deletion of the locus or chromosome carrying the other allele, by loss of one and reduplication of the other locus, by point mutation of the polymorphic site, or by gene conversion. In any case, there has been a reduction to homozygosity of the DNA for this particular locus ( *locus X*).

The fact that familial retinoblastoma exists at all is, to some extent, the result of a medical success. A highly penetrant familial childhood cancer syndrome could not have existed during previous generations of human development. Such affected individuals would have died from their malignancies and never reached reproductive age. Only when individuals harboring *RB* mutations in the germline had their retinal tumors treated effectively so that they reached reproductive age and passed the mutation on to their offspring did the entity of familial retinoblastoma become manifest. Essentially, all patients who present with bilateral or trilateral (i.e., affecting the pineal body) disease carry a germline mutation of the *RB* gene, but this mutation may have been inherited from a parent or generated de novo in the patient. An exception to this scenario has been appreciated with the recognition of families that present with the phenotype of partially penetrant retinoblastoma. In these families, familial predisposition is clearly evident by pedigree analysis, but tumors may not always be present or, if present, may be predominantly unifocal in obligate carriers. In many of these families, the *RB* alteration has been demonstrated to be caused by mutation that leads to an unstable temperature-sensitive protein. These selected amino acid changes cause fluctuation in the ability of *RB* to interact with its relevant binding partners. [12]

Another example of a constitutional chromosomal aberration providing insight into a disease entity followed from an analysis of the presentation and family history of

patients with Wilms' tumor. A rare syndrome of Wilms' tumor consisting of aniridia, genitourinary defects, and mental retardation (WAGR) was found to be correlated with a constitutional deletion of chromosome band 11p13,[13] and a Wilms' tumor susceptibility gene, *WT1*, has been cloned from this region.[14,15] It encodes a DNA-binding transcription factor whose expression in fetal kidney and embryonic structures suggests its involvement in genitourinary development.[16,17] Patients with another rare syndrome associated with a chromosomal abnormality distinct from the WAGR syndrome also show an increased susceptibility to the development of Wilms' tumor. These individuals with the Beckwith-Wiedemann syndrome (i.e., macroglossia, somatic gigantism, visceromegaly, hypoglycemia, and abdominal wall defects), often have constitutional duplications of the 11p15 region, and their Wilms' tumors manifest a reduction to homozygosity of marker DNA segments in this region, although not in 11p13.[18] There is evidence that genomic imprinting occurs within this region (see the section Genomic Imprinting), and thus differential loss of a duplication of the active allele may contribute to tumorigenesis.[17] Candidate loci for this event include IGFII, H19, and p57 $^{KIP2}$. Other chromosomal regions implicated in Wilms' tumor include 16q, 1p, 7p, and the p53 gene on 17p. Thus, there appears to be more than one Wilms' tumor predisposition gene.

**Genomic Imprinting**

Part of the complexity of the etiology of neoplasms such as Wilms' tumor may be derived from a de facto inactivation of one of the two alleles of certain genes in the absence of a structural deletion or alteration of the locus. The inactivation is imposed because of the origin of the gamete from which it was derived. For example, there can be a cellular “memory” about whether a particular chromosome was derived from the egg or sperm, and the two chromosomes, or at least certain genes that reside on them, may be activated or suppressed differentially. It represents a constitutional difference in the expressability of the two genes derived from homologous chromosomes in the individual. There may be nothing wrong with the structure of a gene itself, but it may not be expressed in a particular individual because it resides on the maternally or paternally derived chromosome. That the gene itself is completely functional can be demonstrated by following its movement into the opposite type of gamete. For example, a gene not expressed on the paternally derived chromosome but transcribed normally when passed through the female germline has the opportunity to be transferred to the next generation through the female ovum, and because the gene is then maternally derived, it is functional in the offspring ( Fig. 4-3).

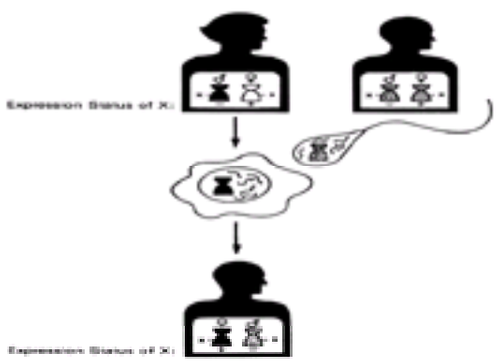

**FIGURE 4-3.** Genomic imprinting. The activity of a gene can be a function of which parent donates (i.e., imprints) it. In this example, a woman carries a particular gene “X,” one copy of which comes from her father (*male symbol*) and one from her mother (*female symbol*). The gene from her father is inactive only because it was inherited from her father; nothing is inherently wrong with it. The gene donated by her mother is active. This woman produces an ovum within whose haploid complement of chromosomes is the gene X inherited from her father. The egg is fertilized by a sperm that similarly carries a haploid chromosomal constitution. Together, they generate a diploid human organism. The specific allele that had been inactive in this offspring's mother (because it had come from her father) is active in the offspring because it was derived from his mother.

Genomic imprinting is being invoked to explain a variety of phenomena that appear to violate a simple mendelian model of inheritance. One can appreciate how this effect can complicate cancer genetics, because a particular predisposition to develop a specific kind of cancer (e.g., Wilms' tumor) may not always show linkage with a particular aberrant gene (e.g., one on chromosome 11p13 or 11p15) but rather may be related to whether the otherwise normal gene was derived from the patient's mother or father. This kind of situation does seem to be relevant to Wilms' tumor,[19,20,21] and[22] osteosarcoma,[23] and embryonal rhabdomyosarcoma. In one study, normal and tumor tissue from six patients with embryonal rhabdomyosarcoma and normal tissue from their parents were analyzed with DNA marker probes from chromosome 11. A reduction to homozygosity was seen in each tumor; invariably, it was the paternally derived chromosome 11 that had been retained in the tumor tissue.[24] These data led the investigators of this study to propose a modification of the Knudson model of tumorigenesis. They suggested that aberrations of cancer-related genes because of their imprint can lead to a constitutional lack of expression from one allele, thereby contributing to an inherited predisposition to certain types of cancer. In Beckwith-Wiedemann syndrome, also an example of the impact of genomic imprinting, there is a correlation between the presence of two paternal copies of the 11p15.5 region and the development of this disorder.[25] Although not completely understood, the mechanism by which a gene is imprinted seems to reside in complex coordination of *cis*-regulatory elements and differential methylation.[25,26,27,28,29] and[30]

**Trisomy**

The monosomic form of chromosomal aneuploidy was discussed previously in the context of a two-hit model of carcinogenesis, which involves a genetic or epigenetic knockout of a functional growth-affecting gene. Conceptually, the impact of that kind of monosomy may be easier to envision than the impact of trisomy resulting in the addition of one extra copy of a particular gene or genes. Trisomies in the germline result in dramatic phenotypic variance from normal growth and development and are for the most part incompatible with life, an intolerance that is much more acute in mammals than in other genera.[31,32] Only trisomies of chromosomes 13, 18, and 21 occur with any frequency in the germline of viable human beings, and each is associated with a defined syndrome.[33]

It is possible that an unbalanced number of chromosomes by itself causes a problem for the cell during normal cell division, but this seems unlikely given the vigorous growth of aneuploid cell lines *in vitro*. It would seem more likely that the presence of an extra chromosome poses a basic developmental problem due to a 50% increase (for autosomes) in the dosage of a particular gene or genes. In many instances, there can be a wide tolerance by the organism for twofold variation in the dosage of particular genes, as in the many recessive syndromes in which obligate heterozygotes are phenotypically normal. The impact of trisomies underscores the fine tuning and dose dependency of certain growth and developmental pathways in higher organisms.

The classic constitutional aneuploidy that demonstrates predisposition to certain kinds of cancer is trisomy 21, also called *Down syndrome*.[34,35] and[36] An immediate question is whether the increased risk of leukemia in Down syndrome is directly related to a gene or genes on chromosome 21 or is an indirect effect of some other aspect of the Down phenotype. It would appear that the former may be the case. In trisomy 21 mosaics, it is the trisomic cell that is at risk for leukemic transformation, and acquired trisomy 21 is a relatively frequent chromosomal abnormality found in acute lymphocytic or nonlymphocytic leukemias.[37,38,39] and[40] Acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML) can occur in patients with Down syndrome[41]; acute megakaryoblastic leukemia may be the most common leukemia seen in these patients.[42,43]

A different but probably related hematopoietic disorder, transient leukemoid reaction (TLR), is also associated with Down syndrome, or trisomy 21 mosaicism, although it is not restricted to this population.[44,45,46] and[47] TLR classically manifests in newborns or early infancy as a myeloproliferative disorder that can include hepatosplenomegaly, leukocytosis, and circulating myeloblasts; the morphologic picture is consistent with congenital leukemia except that spontaneous remission occurs. This condition is not unequivocally benign, however; 20% to 30% of Down syndrome patients with TLR develop overt megakaryoblastic leukemia at 1 to 3 years of age.[48]

With the development of extensive high-resolution genomic maps that unite cytogenetic landmarks with the rough draft of the human sequence,[49,50] there is no dearth of potential growth-affecting genes at almost any chromosomal location, including those on chromosome 21. A critical region and candidate Down syndrome genes have been identified on chromosome 21.[51,52] Genes relevant to chromatin structure, lymphocyte adhesion, interferon action, DNA transcription, and signal transduction reside on chromosome 21, but none has been implicated in the constitutional phenotype or leukemogenic risk of patients with Down syndrome.[53] Through the use of restriction fragment length polymorphism analysis, it is similarly possible to determine the origin of the extra chromosome 21 in Down syndrome. A DNA polymorphism present on a maternal chromosome 21 is present in two copies in the affected offspring. In trisomy 21, this analysis has demonstrated that the

extra chromosome 21 is of maternal origin in approximately 95% of cases.[54] Scattered reports based on small numbers of patients seem to suggest that, among individuals with TLR or leukemia, there is an increased paternal contribution of the extra chromosome 21. If this observation is confirmed in additional studies, it will suggest that more complex genetic and epigenetic factors may influence the risk of leukemia or TLR among patients with trisomy 21. [55]

### Sex Chromosome Abnormalities and Neoplasia

The clearest example of a sex chromosome abnormality associated with neoplasia is Klinefelter's syndrome. The classic sex chromosome constitution of these individuals is 47,XXY. The presence of the Y chromosome confers phenotypic maleness on these individuals, but they may also have atrophy and dysgenesis of the seminiferous tubules and palpable breast tissue. [56] An association exists between Klinefelter's syndrome and breast carcinoma,[57,58] with a 20-fold increased risk of developing this tumor compared with that in the normal male population. Individuals with Klinefelter's syndrome also have an increased incidence of germ cell tumors.[59]

Gonadoblastoma and dysgerminoma can be associated with Turner's syndrome, although not in cases with the classic 45,XO karyotype. Those with karyotypic variants in which a part or all of the Y chromosome is present are the population at particular risk for these tumors. [56] The increased risk of tumorigenesis in those with Klinefelter's syndrome or in a subset of individuals with Turner's syndrome may result in part from inappropriate hormonal stimulation, from germ cell developmental defects, or perhaps from a combination of the two. The answer will come with better molecular definition of the character and interaction of the sex-determining genes on the X and Y chromosomes, gene dosage effects, and the targets of action of these genes.

## SOMATICALLY ACQUIRED CHROMOSOMAL ABERRATIONS

For the past 30 years, cytogeneticists have been describing an increasing number of specific chromosomal abnormalities, each associated with particular cell types or histologically distinct malignancies. These abnormalities differ from those discussed in the previous section in that they are confined to the malignant clone and not found in the normal tissues from the same individuals. There is a continuum from a constitutional chromosomal abnormality present in every cell in the patient's body, to constitutional mosaicism in which an abnormality may be present in a large proportion of the patient's cells or tissues, and to those abnormalities found only in a particular tissue or cell type. The main distinguishing features are the stages of development in which they occur and whether they are capable of being transmitted vertically from generation to generation. The kinds of constitutional abnormalities discussed in the previous section occur in every cell (more or less) but are only phenotypically significant in a subset of cell types. For example, patients with constitutional abnormalities of chromosome band 13q14 show a predisposition to the development of retinoblastoma and osteosarcoma, although not rhabdomyosarcoma. Cell-type–specific or cancer-specific abnormalities are often more directly correlated with a phenotypic effect. When found, they seem to be of significance to that cell lineage; they are seldom observed in cells in which their expression has no importance. This raises the issue of whether there is something about the state of a particular cell type in terms of chromatin accessibility, nuclear matrix proteins, or transcriptional regulation that predisposes the cell to the development and selection of a particular chromosomal aberration.

The association of a particular chromosomal abnormality with a specific type of malignancy began in 1960 with the identification of the Philadelphia chromosome in the malignant cells of patients with chronic myelogenous leukemia.[60] This chapter focuses on the chromosomal aberrations that have been associated with malignancies that particularly affect the pediatric population, although there is overlap with malignancies that also affect adults, and the lessons derived from cytogenetic analyses of one population are relevant to the other. However, the distinctiveness of many of the chromosomal aberrations reiterates the fact that childhood cancers often differ from cancers in older individuals because of the progenitor cells involved and the mechanisms of malignant transformation.

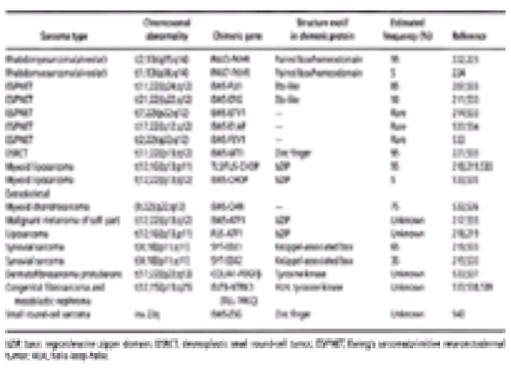
## PROTO-ONCOGENE CONVERSION

The cancers of childhood are ultimately the products of somatically acquired genetic abnormalities that modify protein function. The classes of proteins affected by these changes include growth factors and their receptors, kinase inhibitors, signal transducers, and transcription factors, which may act dominantly as cellular oncoproteins or recessively through loss of function, as in the case of tumor suppressors. Studies of the structure and properties of dominantly acting oncoproteins have contributed importantly to our understanding of the molecular events that initiate and sustain the neoplastic state. The general paradigm emerging from this work is that certain types of molecular lesions activate or repress key regulatory genes whose abnormal expression may be tumorigenic in specific hematopoietic and mesenchymal progenitors. Most candidate oncoproteins are poorly characterized with regard to their mode of action; however, their remarkable similarity to proteins involved in the earliest stages of invertebrate development suggests important roles in the integration of pathways regulating the growth, differentiation, and survival of normal and neoplastic cells.[61]

### Activation of Transcriptional Control Genes by Chromosomal Rearrangement

Disruption of transcriptional control genes is a common mechanism by which chromosomal rearrangements contribute to the genesis of acute leukemias and sarcomas (Table 4-1 and Table 4-2). Such genes are preferred targets because their transcription factor products bind to regulatory elements in DNA, such as promoters and enhancers, where they stimulate or sometimes inhibit gene transcription and the expression of messenger RNA. More than 80% of these proteins can be classified on the basis of recurring structural motifs within their DNA- and protein-binding domains, designated as basic region/helix-loop-helix (bHLH), basic region/leucine zipper (bZIP), zinc finger, and homeodomain (helix-turn-helix; Fig. 4-4); other motifs with similar functional significance are termed *A-T hook, Ets-like*, *runt homology*, and *cysteine-rich (LIM)*.[61,62] and [63] The modular organization of transcription factors provides an ideal framework for their multiple functions, particularly binding to DNA in heterodimeric complexes.[64] It also explains why disruption and rearrangement of transcriptional control genes by chromosomal translocations can produce functional hybrid proteins rather than inert peptides.

### TABLE 4-1. ALTERED TRANSCRIPTIONAL CONTROL GENES THAT CONTRIBUTE TO THE ACUTE LEUKEMIAS



| Sarcoma type | Chromosomal abnormality | Chimeric gene | Structure motif in chimeric protein | Estimated frequency (%) | Reference |

### TABLE 4-2. CHIMERIC TRANSCRIPTIONAL CONTROL GENES IN THE CHILDHOOD SARCOMAS

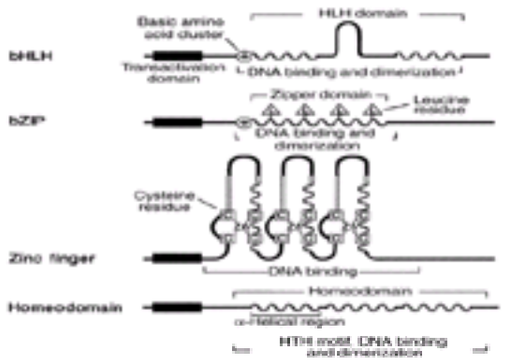

**FIGURE 4-4.** Structural motifs characterizing the major oncogenic transcription factors in childhood cancer. Each defining structure—basic region/helix-loop-helix (bHLH), basic region/leucine zipper (bZIP), zinc finger, and homeodomain—functions in DNA binding, protein dimerization, or both. +, positive charge; C, cysteine; HTH, helix-turn-helix; L, leucine; Zn, zinc. (Adapted from Papavassiliou AG. Molecular medicine: transcription factors. N Engl J Med 1995;332:45.)

In an effort to develop a unifying hypothesis that would account for the tumorigenicity of altered transcription factors, Rabbitts [62] emphasized similarities between these oncogenic proteins and the products of so-called master genes, which specify lineage-specific patterns of gene expression during embryologic development. Most intriguing are the similarities between the conserved regions of mammalian transcription factors and those of developmental proteins regulating *Drosophila* embryogenesis (Table 4-3).[65,66 and 67] Current observations suggest that aberrant transcription factors may act positively to up-regulate critical target genes or negatively to interfere with normal regulatory cascades that coordinate the expression of proteins required to complete cell differentiation. [61,68]

| Human protein | DNA-binding domain | *Drosophila* protein |
|---|---|---|
| HLF | Basic region/leucine zipper | Giant |

**TABLE 4-3. EXAMPLES OF STRUCTURAL MOTIFS SHARED BY ONCOGENIC TRANSCRIPTION FACTORS AND PROTEINS REGULATING MORPHOGENESIS IN *DROSOPHILA* EMBRYOS**

Chromosomal translocations modify transcription factors in one of two ways. Most often, the DNA-binding, dimerization, and *trans*-effector regions of discrete proto-oncogenes are "stitched together" to produce a chimeric transcription factor with altered function. A second consequence is the dysregulated expression of intact transcription factor coding sequences caused by their relocation to sites near the promoter/enhancer elements of T-cell receptor (TCR) or immunoglobulin genes. The transcription factors involved in leukemia and sarcoma pathogenesis have unique transforming properties that are specific for the different types of progenitors within these two developmental pathways (illustrated for the leukemias in Fig. 4-5).

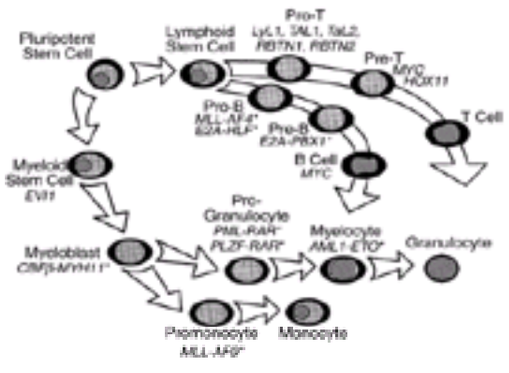

**FIGURE 4-5.** Hematopoietic cells transformed by dysregulated transcription factor genes. A recurring theme in research on oncogenic transcription factors is their specificity for early stages of the myeloid and B- or T-lymphoid cell lineages. The pattern of activation shown here supports the concept that such genes contribute to malignancy by specifically disrupting normal programs of cell differentiation. Hyphenated genes ( *asterisk*) are created by translocation-mediated fusion events. (From Look AT. Oncogenic roles of "master" transcription factors in human leukemias and sarcomas: a developmental model. In: Vande Woude G., ed. Advances in cancer research. San Diego: Academic Press, 1995:25–55, with permission.)

### *TEL-AML1 Fusion Gene in Early B-Lineage Acute Lymphoblastic Leukemia*

Although the most common cytogenetic abnormality found in children with ALL is the t(12;21)(p13;q22), this translocation is missed by conventional cytogenetic analysis because the rearranged chromosomal fragments closely resemble the morphology of the involved chromosomes. When analyzed by molecular approaches (fluorescent *in situ* hybridization, Southern blotting, or reverse transcriptase-polymerase chain reaction), the t(12;21) is found in approximately one-fourth of pediatric B-cell ALL cases,[69,70] and approximately 3% to 4% of adult ALL cases.[70] This rearrangement results in the fusion of the oligomerization domain of *TEL (ETV6)* on chromosome 12 to the entire coding region of *AML1 (CBFA2)* on chromosome 21 (Table 4-1).[71] Both of these genes are also involved in different translocations in both lymphoid and myeloid malignancies. TEL contains a dimerization motif conserved in the ETS family of proteins and has been identified in fusion with many different partners, such as *TEL-PDGFRb* in chronic myelomonocytic leukemia; *TEL-MN1*, *TEL-ABL*, and *TEL-EVI1* in AML; and *TEL-JAK2* in ALL.[71] *AML1 (CBF2A)* on chromosome 21 encodes a protein that closely resembles the *Drosophila* runt protein[72] and also is involved in the pathogenesis of AML through its fusion with the *ETO* gene in AML cases with the t(8;21).[73]

The loss of the normal *TEL* allele is frequently observed in t(12;21) $^{+}$ ALL, suggesting that TEL-AML1 (ETV6-CBFA2) requires a second genetic lesion and that TEL loss of function may contribute to leukemic transformation.[74] The vast majority of ALL cases with *TEL-AML1* (*ETV6-CBFA2)* rearrangement belongs to a favorable age group (age 1 to 9 years), with 70% to 80% diagnosed in patients aged 3 to 6 years. [75] Immunologically, the presence of this translocation is associated with a CD10 $^{+}$ early B-cell progenitor phenotype, an increased frequency of CD13 and CD33 myeloid-associated antigen expression, [76] KOR-SA3544 negativity, and a pseudodiploid karyotype.[77]

Cases of ALL with the t(12;21) have a good prognosis independent of clinical risk factors, such as age and white blood cell count at presentation. [69,78,79] These patients have a superior clinical outcome, with relapse-free survival rates approaching 90% in studies testing a variety of drug regimens, [69,78,79,80] and [81] especially those based on L-asparaginase and antimetabolites.[78] Some doubt about the prognostic value of the t(12;21) has been raised by analysis of this abnormality in relapsed ALL cases, however, because an unexpected high frequency of the *TEL-AML1* translocation (20% to 24%) has been observed in several series of relapsed lymphoblastic leukemias.[82,83] and [84] Other groups, however, report only a 10% incidence of this fusion in their relapsed cases. [75,85,86] This discrepancy is likely explained by differences in the efficacy of the induction and maintenance regimens used by the study groups. Notably, the best results with *TEL-AML1*$^+$ ALL were obtained in clinical trials of the Dana-Farber Cancer Institute Consortium, which included intensive L-asparaginase treatment.[86] In two other studies, *TEL-AML1* fusion conferred a favorable outcome only in patients who received intensive chemotherapy. [87,88] Additional prospective studies are needed to determine the true prognostic significance of the *TEL-AML1* fusion gene.

### *E2A-PBX1 Fusion Gene in Pre–B-Cell Acute Lymphoblastic Leukemia*

The *E2A* gene, located on chromosome 19, band p13.3, encodes a bHLH transcription factor. Its fusion with the *PBX1* homeobox gene on chromosome 1 as a result of the t(1;19)(q23;p13), which occurs in approximately 5% of childhood ALL cases ( Table 4-1), yields several species of chimeric proteins that differ in their extreme carboxyl ends due to differential messenger RNA splicing. [89,90,91] and [92] E2A-PBX1 hybrids retain the amino-terminal *trans*-activation domain of E2A but not its bHLH region, which is replaced by the homeobox DNA-binding and protein-protein interaction domain of PBX1. Thus, the gene targets of E2A-PBX1 are probably those specified by the homeodomain of PBX1; the homeodomain is an approximately 60–amino-acid motif first identified in *Drosophila* homeotic selector (Hom) proteins that regulate segment identity during embryogenesis.[93]

Evidence suggests that acquisition of the E2A *trans*-activation domain by PBX1 converts the latter into a positive regulator of gene transcription in lymphoid cells, which normally do not express this protein. [94,95] and [96] However, the E2A-PBX1 hybrid may not regulate transcription of downstream target genes by itself; it may function through a heterocomplex with specific homeobox proteins, analogous to the regulatory complex formed by the extradenticle protein with a subset of Hom proteins in *Drosophila*.[93,94,97,98] and [99]

Reports of E2A-PBX1 involvement in human disease have been restricted to ALLs with a pre–B-cell phenotype. However, Kamps and Baltimore [100] induced AML in lethally irradiated mice repopulated with bone marrow stem cells that had been infected with recombinant retroviruses containing *E2A-PBX1* fusion genes. Further oncogenic versatility is suggested by the induction of thymic lymphomas in transgenic mice harboring *E2A-PBX1* genes in the germline.[101] In these animals, lymphopenia involving T and B cells preceded malignant transformation, suggesting that E2A-PBX1 proteins can induce apoptosis in murine lymphocyte precursors. The failure to induce pre–B-cell leukemias in these experimental systems may reflect a heightened sensitivity of the murine lymphoid compartment to E2A-PBX1–induced programmed cell death.

Occasionally, the t(1;19) occurs in less mature (pro-B) rather than the usual pre-B (cytoplasmic µ heavy chain–positive) lymphoblasts, raising questions about its molecular repercussions in leukemias with an atypical phenotype. Privitera and co-workers [102] analyzed 17 cases of t(1;19)-positive ALL using reverse transcriptase polymerase chain reaction to amplify junctional sequences from leukemic cell RNA. Characteristic E2A-PBX1 chimeric transcripts were identified in 10 of the 11 pre-B cases but in none of the six with a pro-B phenotype, all of which lacked evidence of E2A-PBX1 fusion at the genomic level or by analysis of protein expression. These findings suggest that the genes affected by a t(1;19) in B-lymphoid progenitors depend on the cells' developmental status.

### *E2A-HLF Fusion Gene in Pro–B-Cell Acute Lymphoblastic Leukemia*

*E2A* gene elements are also involved in fusion events instigated by the t(17;19)(q22;p13) translocation, which juxtaposes the amino-terminal sequences of E2A (including the *trans*-activation domain) with the DNA-binding and protein dimerization region of the protein encoded by the hepatic leukemia factor gene ( *HLF*; Fig. 4-6). Assigned to a specific subfamily of the bZIP superfamily of transcription factors, [103,104] the HLF product is normally expressed predominantly in the liver, brain, and kidney but not in lymphoid cells. It bears significant homology to both DBP, [105] an albumin gene promoter D box binding protein, and thyrotroph embryonic factor, which *trans*-activates thyroid-stimulating hormone b expression during anterior pituitary development. [106] Leukemias that express E2A-HLF share a number of clinical and biologic features: disease onset in early adolescence, pro-B immunophenotype, hypercalcemia, and disseminated intravascular coagulation. Although relatively rare, the E2A-HLF–associated leukemias have a poor prognosis, even when treated with intensive, multi-agent chemotherapy.

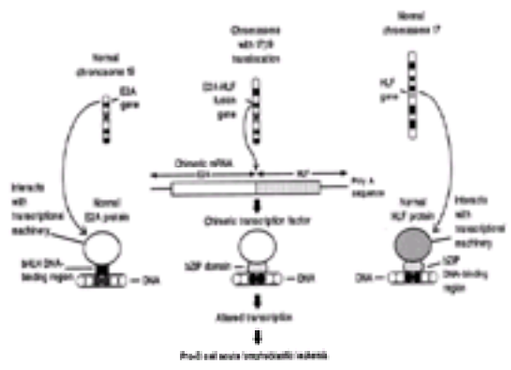

**FIGURE 4-6.** Schematic diagram of the E2A-HLF chimeric transcription factor formed in pro-B lymphoblasts by action of the 17;19 chromosomal translocation. As shown, the fusion event combines the *trans*-activation domain of the E2A protein with the basic region/leucine zipper (bZIP) DNA-binding and dimerization domain of HLF, a member of the bZIP family that normally regulates gene expression in hepatic, brain, and renal (but not lymphoid) cells. Evidence suggests that the hybrid protein binds to DNA sequences normally recognized by HLF, or perhaps a close homologue, to disrupt regulation of vital developmental programs in pro-B cells. bHLH, basic region/helix-loop-helix; mRNA, messenger RNA. (Adapted from Look AT. Oncogenic roles of “master” transcription factors in human leukemias and sarcomas: a developmental model. In: Vande Woude G, ed. Advances in cancer research. San Diego: Academic Press, 1995:25–55.)

Studies have identified a 10–base-pair DNA consensus sequence, characterized by a dyad-symmetric motif, that mediates the specific binding of both HLF and E2A-HLF proteins.[107] and [108] The chimera appears to bind DNA preferentially as a homodimer in leukemic cells, [107] suggesting that its regulatory activities may not depend on cross-dimerization with other bZIP proteins. The tumorigenicity of E2A-HLF has been demonstrated in NIH-3T3 cells and requires the *trans*-activation domain of E2A and the leucine zipper dimerization domain of HLF. [109]

Taken together, these findings suggest that the E2A-HLF fusion protein binds as a homodimer to its consensus sequence in the promoter or enhancer regions of downstream target genes, where it aberrantly regulates transcriptional programs controlling the growth, differentiation, or survival of early B-cell progenitors. Research to identify the targets of E2A-HLF binding has yielded provocative clues. In the BAF3 line of interleukin 3–dependent murine pro-B cells, overexpression of the fusion protein prolonged cell survival after withdrawal of interleukin 3, suggesting a primary effect on genes responsible for the prevention of cell lineage-specific apoptosis.[110]

### *MLL Fusion Genes in Leukemias with 11q23 Rearrangements*

An extraordinarily diverse group of chromosomal translocations and deletions affect the q23 band of chromosome 11, accounting for as many as 10% of all acute leukemias in children and adults[111] and as many as 85% of secondary leukemias in patients treated with topisomerase II inhibitors. [112,113] Of the more than 20 different chromosomal loci that have been identified as fusion partners in 11q23 translocations, [114] the most common resides on chromosome 4q21 (Fig. 4-7). This site has been implicated in approximately 4% of cases of childhood ALL overall and one-third of such cases in infants. [115]

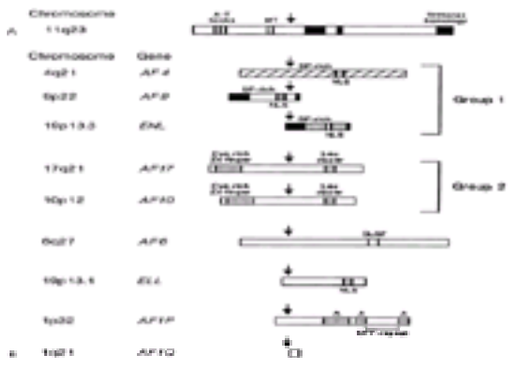

**FIGURE 4-7.** The *MLL* gene and some of its fusion partners. Clearly one of the most versatile proto-oncogenes in the acute leukemias, *MLL* can combine with at least 20 different partner genes to give rise to transformed myeloid or lymphoid progenitors. **A:** The major structural features of *MLL*, including the A-T hook and mammalian DNA methyltransferase (MT) regions, which uniformly are retained in fusion products, as indicated by the characterized breakpoint ( *arrow*). **B:** Nine of the genes known to participate in fusion events with *MLL*. Group 1 genes are rich in serine and proline (SP) and contain nuclear localization signals (NLS), and those in group 2 are notable for a cysteine-rich zinc finger (Zn-finger) domain and a leucine-zipper motif. The *AF6* gene contains a novel glycine-leucine-phenylalanine (GLGF) domain, and *AF1P* is distinguished by three acidic (*A*) regions, together with an amino acid repeat motif consisting of aspartic acid–proline-phenylalanine (DPF). Regions on the right of the breakpoints (*arrows*) are retained in the fusion product. (Adapted from Downing JR, Look AT. *MLL* fusion genes in the 11q23 acute leukemias. In: Freireich EJ, Kantarjian H, eds. Leukemia: advances in research and treatment. Boston: Kluwer Academic Publishers, 1995:73–92.)

Leukemic blasts carrying the t(4;11)(q21;q23) tend to have a pro-B phenotype, with expression of HLA-DR antigens and rearranged immunoglobulin heavy-chain genes.[116,117,118 and 119] Clinical correlates of this rearrangement include leukocyte counts more than 100 × $10^9$/L and an adverse prognosis, even with use of intensive combination chemotherapy.[120,121 and 122]

Unlike most other chromosomal lesions in childhood ALL, translocations affecting the 11q23 region can also be found in the myeloid leukemias, suggesting transformation of a pluripotential stem cell. A striking example is the t(9;11)(p22;q23), which occurs with high frequency in acute monocytic leukemia, [123] as well as in mixed-lineage leukemias and myeloid leukemias arising after treatment for ALL. [124] Moreover, leukemic lymphoblasts with 11q23 abnormalities can be induced to express monocytic features *in vitro*, strengthening the notion that such lesions arise in uncommitted stem cells or affect genes that control lineage commitment. [118,119]

Remarkably, the many breakpoints that can occur at the 11q23 locus affect the same gene, regardless of the phenotype of the altered cell. The *MLL* gene, also called *HRX, ALL1*, and *Htrx1*, becomes disrupted within a small region situated midway through the gene's coding region, [125,126,127,128,129 and 130] resulting in loss of two zinc finger regions and retention of an A-T hook domain and a region homologous to mammalian DNA methyltransferase (MT; Fig. 4-7). This consistent pattern of alteration suggests a common mechanism of tumorigenicity. The A-T hooks, which may bind to DNA in the minor groove, could allow interactions with potential target gene promoters and access to other transcription factors, and the MT domain could affect transcription by modifying the methylation status of bound DNA.

Although targets of MLL action have not been identified, it may be important that the normal protein is the mammalian counterpart of trithorax, a putative *Drosophila* transcription factor known to regulate the actions of a wide spectrum of homeotic genes in the bithorax complex of the fly, and it is absolutely required throughout embryogenesis for differentiation of the head, thorax, and abdomen. [126,127,128 and 129,131] The identity of the fusion partner in 11q23 translocations appears to be of secondary importance to retention of the A-T hook and MT domains of the MLL protein, although it may influence the lineage predilection of the leukemia. MLL certainly qualifies as the most promiscuous of all transcription factor proto-oncogenes in acute leukemia, as 23 different partner genes have now been cloned that form fusion proteins with MLL (Table 4-4). Appropriate model systems are needed to explore the mechanistic implications of fusion proteins juxtaposing the same domains of MLL with a variety of partners.

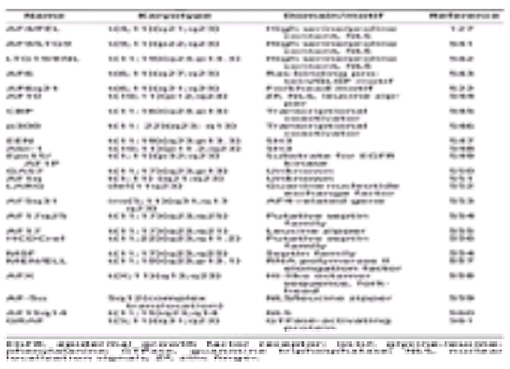

**TABLE 4-4. PARTNER GENES INVOLVED IN MLL REARRANGEMENTS**

The *MLL* gene may participate in leukemogenesis more often than is indicated by studies of 11q23 cytogenetic changes. Schichman and co-workers [132,133] found tandem duplication of an internal portion of the *MLL* gene in the absence of 11q23 translocations, a process that links the intact gene to a duplication of its amino-terminal region. All duplications have contained the A-T hook and DNA MT motifs, reinforcing the presumed critical importance of these regions in leukemia induction.

### *Oncogenic Fusion Genes in Acute Myeloid Leukemia*

The same general mechanisms responsible for proto-oncogene activation in ALL have been identified in AML. A prime example of a chimeric transcription factor in this disease is the AML1-ETO protein resulting from the t(8;21) translocation. [134,135 and 136] The most frequent cytogenetic abnormality in the myeloid leukemias, t(8;21), primarily affects myeloblasts with evidence of granulocytic differentiation [i.e., M2 designation in the French-American-British (FAB) classification scheme]. The sequence-specific DNA-binding and protein-protein interaction properties of the fusion protein are provided by a large domain in the *AML1* gene[137] showing 68% homology with the *Drosophila* pair-rule segmentation gene, runt, whose product helps to determine the structures derived from each segment of the developing embryo.

AML1 forms complexes with members of the CBF protein family, which lack DNA-binding domains.[138,139] One such protein, CBFb, is involved in another major chromosomal rearrangement in AML, the inversion 16, found in association with myelomonocytic differentiation and increased bone marrow eosinophils (i.e., M4-Eo designation in the FAB system). This rearrangement joins the amino-terminal sequences of the *CBFb* gene to the carboxyl terminus of the heavy-chain gene of smooth muscle myosin (*MYH11*), resulting in the formation of a CBFb-MYH11 fusion protein.[140] Both AML1 and CBFb appear to be normally expressed in early myeloid cells, suggesting that the oncogenicity of the respective fusion proteins stems from disruption of a transcriptional regulatory complex specific for myeloid developmental processes.[141]

The combinatorial versatility of the *AML1* locus can be seen from its fusion with sequences from the *EVI1* gene in t(3;21)-positive chronic myeloid leukemia (CML) in blast crisis[142] or the *EAP* gene (coding for Epstein-Barr virus RNA-associated protein) in myelodysplastic syndrome. [143] Inclusion of the runt-homologous DNA binding/dimerization domain of AML1 and the zinc finger DNA-binding domains of EVI1 in the AML1-EVI1 chimeric protein affords numerous opportunities for aberrant regulation of target genes. The AML1-EAP protein contains carboxyl-terminal EAP sequences fused out of frame to AML1 sequences, resulting in a truncated AML1 protein that may dominantly interfere with normal AML1 function during myelopoiesis, as has been postulated for the AML1-ETO chimera. [134]

Leukemia specialists have long envisioned treatments based on a molecular understanding of the proteins that generate and maintain the neoplastic state. Major progress toward this goal has been achieved in acute promyelocytic leukemia (APML) with the t(15;17)(q21;q11-q22), in which the critical ligand- and DNA-binding sequences of the retinoic acid receptor a (*RAR*a) gene on chromosome 17 are fused to sequences of the *PML* gene on chromosome 15.[144,145,146,147 and 148] In its unaltered form, the RARa protein binds first to the retinoic acid ligand and then to DNA through its zinc finger region. PML proteins, which also possess zinc finger motifs, are normally located in novel macromolecular nuclear organelles, called *PML oncogenic domains* (PODs), which include at least three other proteins.[149,150 and 151] The PML-RARa fusion proteins disrupt these subnuclear structures, causing normal PML, RXR, and other nuclear proteins to disperse in an abnormal microparticulate pattern.[149,150 and 151] They also interfere with normal myeloid cell development, possibly through adverse effects on the assembly of PODs that contain PML, leading to arrest of differentiation in the promyelocytic stage.

These fundamental observations provide a rationale for use of all-*trans*-retinoic acid to treat patients with APML.[152,153,154,155 and 156] In pharmacologic doses, the compound binds to the RARa fusion partner, followed by reorganization of PML and its associated proteins into normal-appearing nuclear PODs ( Fig. 4-8). Subsequently, the leukemic cells develop into mature myelocytes with limited life spans. Retinoid treatment of APML does not result in permanent remissions, however. Resistance to the hormone generally develops within 3 to 4 months, limiting the agent's therapeutic role in the remission-induction period and to combination therapy with standard cytotoxic drugs.[136,137,155,156] Nonetheless, the results justify continued efforts to devise therapies directed to the oncogenic proteins that drive neoplastic proliferations in the childhood cancers.

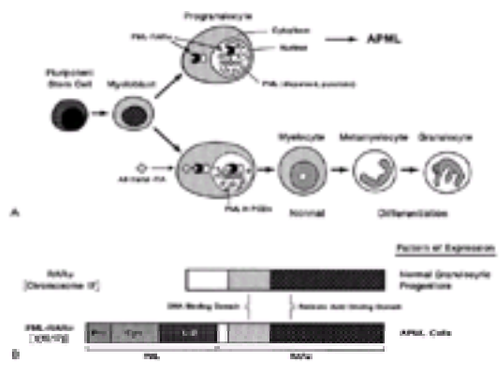

**FIGURE 4-8.** Possible mechanism of action of all-*trans*-retinoic acid in acute promyelocytic leukemia (APML) expressing the PML protein fused to the retinoic acid receptor a protein (PML-RARa). Therapeutic rationales based on knowledge of chimeric transcription factors are rare. In the example shown in **A**, expression of PML-RARa in progranulocytes as a result of the t(15;17) causes dispersion of novel macromolecular nuclear organelles called *PML oncogenic domains* (PODs), leading to the development of APML. Treatment with all-*trans*-retinoic acid (RA) supplies a ligand that binds to the RARa fusion partner, followed by reorganization of PML and its associated proteins in PODs. Subsequently, the leukemic progranulocytes show normal patterns of differentiation. (Adapted from Look AT. Pathobiology of the acute lymphoid leukemia cell. In: Hoffman R, ed. Hematology. 2nd ed. New York: Churchill Livingstone, 1995:1046–1066.) **B:** RARa structural domains retained in the chimeric protein. Pro, proline; Cys, cysteine; L-Z, leucine zipper.

### *MYC Activation in B-Cell Acute Lymphoblastic Leukemia*

ALL often arises from translocations that affect the immunoglobulin and TCR genes of lymphoid progenitors, which must undergo diverse clonal rearrangements to permit development of the specialized populations of T and B cells needed to support a competent immune system. Even though the transformed cells display abnormal growth patterns, they tend to retain the characteristics of normal T and B lymphoblasts. Only rarely does one encounter aberrant gene expression indicating involvement of lymphoid and myeloid cells (i.e., mixed-lineage leukemias). Consequently, the immunophenotypes of developing lymphoid cells correlate remarkably well with particular chromosomal translocations and the transcription factor genes they affect ( Table 4-1). In B-cell acute leukemia (also Burkitt's lymphoma), the predominant (8;14)(q24;q32) translocation moves one allele of MYC, a prototypic bHLH/leucine ipper transcription factor gene on chromosome 8, into the heavy-chain immunoglobulin locus on chromosome 14q32, adjacent to the coding sequences of the immunoglobulin constant region.[157,158 and 159] This juxtaposing of MYC transcriptional promoter sequences with strong immunoglobulin enhancer elements leads to overexpression or inappropriate expression of the MYC protein.

Although the t(8;14) accounts for most B-cell ALL cases with rearranged *MYC* loci, two of its variants are also capable of activating this proto-oncogene. In cells with the t(2;8) or the t(8;22), the *MYC* gene remains on chromosome 8, and portions of the k or l light chain genes on chromosome 2 or 22, respectively, are translocated to a site downstream of the *MYC* locus (reviewed elsewhere[160]). These rearrangements lead to aberrant MYC expression.[161,162,163,164,165 and 166]

How does the MYC oncoprotein transform cells? The favored model posits a transcriptional network involving a minimum of three other factors, each having bHLH and bZIP domains (Fig. 4-9). MYC is able to heterodimerize with the MAX protein,[167,168] which binds to DNA, to itself (i.e., MAX:MAX homodimers), and to other proteins, including MAD and Mxi-1.[169,170] Because only MYC:MAX heterodimers are transcriptionally active, and MYC and MAD have equal affinities for the MAX protein,[171,172] an increase in MYC expression resulting from gene rearrangement could disrupt the MAX heterodimer equilibrium in lymphoid progenitors, leading to inappropriate transcription of downstream targets and ultimately to malignant transformation.[173] Experimental support for this hypothesis comes from the induction of B-cell neoplasms in transgenic mice carrying the MYC oncogene driven by an immunoglobulin gene enhancer.[174,175] An activated MYC gene also induces tumorigenic conversion when it is introduced *in vitro* into B lymphoblasts infected with human Epstein-Barr virus.[176]

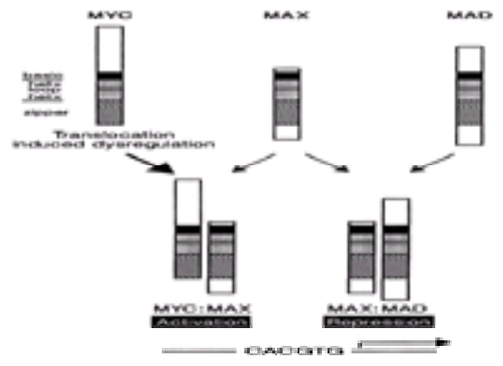

**FIGURE 4-9.** Model for the oncogenicity of the MYC protein activated by the t(8;14) in B-cell acute lymphoblastic leukemia (ALL). Normally, MYC participates in a transcriptional network involving at least two other proteins—MAX and MAD—in which it heterodimerizes with MAX, which can also bind to DNA, to itself, and to MAD. Overexpression of MYC in B-cell ALL is thought to shift the equilibrium between transcriptionally repressive MAX:MAD and activating MYC:MAX heterodimers to the latter complex, leading to aberrant transcription of downstream targets and ultimately to malignant transformation. Conserved DNA-binding and protein dimerization domains are indicated by different patterns of shading. (Adapted from Dowing JR, Look AT. MLL fusion genes in the 11q23 acute leukemias. In: Freireich EJ, Kantarjian H, eds. Leukemia: advances in research and treatment. Boston: Kluwer Academic Publishers, 1995:73–92.)

### *bHLH, LIM, and HOX11 Genes in T-Cell Acute Lymphoblastic Leukemia*

Transcription factor genes are the preferred targets of chromosomal translocations in the acute T-cell leukemias. Notable examples include the bHLH genes *MYC*,[177,178 and 179] *TAL1/SCL*,[180,181 and 182] and *LYL1*,[183] which are essential for the development of other lineages such as erythroid cells (TAL1/SCL), but with the

exception of MYC, they are not expressed in normal T-lymphoid cells. When rearranged near enhancers within the TCR-b–chain locus on chromosome 7, band q34, or the a/d chain locus on chromosome 14, band q11, these regulatory genes become active, and their protein products bind inappropriately to the promoter or enhancer elements of upstream targets.

A useful model of aberrant transcription factor expression in T-cell ALL is provided by *TAL1* activation due to the t(1;14) or to intragenic deletion of the upstream side of the gene, changes that characterize as many as one-fourth of all cases of childhood T-cell leukemias. [184] Because the TAL1 protein dimerizes with the E2A protein to form DNA-binding complexes,[185] its ectopic expression in T cells would be expected to activate specific sets of target genes that are normally quiescent in T-cell progenitors.

Other types of regulatory genes can be rearranged near TCR loci, including those encoding the "LIM domain only" (LMO) proteins, LMO1/RBTN1/TTG1 and LMO1/RBTN2/TTG2, within the cysteine-rich LIM family. [186,187,188 and 189] Although present in high concentrations in the central nervous system, [187] the LMO proteins are only minimally expressed or absent altogether in T cells and their progenitors. Both LMO1 and LMO2 possess zinc finger–like structures in their LIM domains [190] but lack the homeobox DNA-binding domains common to other transcription factors in this family, suggesting that the LIM domain functions in protein-protein rather than protein-DNA interactions. Conceivably, it could even mediate the action of other transcription factors, as indicated by the ability of LMO2 to bind to the bHLH protein TAL1 *in vitro*.[191,192] Moreover, LMO1 induces thymic lymphomas in transgenic mice whose thymocytes bear the *LMO1* gene under the control of a proximal Lck promoter.[193] In this context, inappropriate expression of a LIM family protein appears to have selectively transformed a rare subset of $CD8^{+}$, $CD4^{-}$, and $CD3^{-}$ thymocytes. Whatever the tumorigenic mechanism, ectopic expression of LMO1 or LMO2 because of t(11;14)(p15;q11) or t(11;14)(p13;q11) could be expected to affect similar T-cell developmental pathways.

*HOX11* completes the list of developmental genes that are inappropriately placed under the control of TCR loci. Located on chromosome 10, band q24, [194,195,196 and 197] this gene encodes a homeodomain transcription factor that can bind DNA and transactivate specific target genes. [198] It is most closely related to *Hlx*, a murine homeobox gene expressed in specific hematopoietic cell lineages and during mouse embryogenesis, [199] and it is distantly related to the *antennapedia* homeobox genes of *Drosophila*, which regulate segment-specific gene expression along the anteroposterior axis of the fly embryo. [93] A specific homeotic role of *HOX11* in mammalian development was demonstrated by homozygous disruption of this gene, which blocked the formation of the spleen in otherwise normal mice. [200] In the mouse, Hox11 is normally expressed in specific regions of the branchial arches and ectoderm of the pharyngeal pouches of the developing hindbrain, as well as from a single site corresponding to the splanchnic mesoderm beginning on embryonic day 11.5. [200] Because the nervous system develops normally in these mice, the roles of Hox11 proteins in branchial arch and hindbrain structures appear to be compensated for by other transcription factors expressed by the cells; however, the role of Hox11 in cellular organization at the site of splenic development is absolutely essential for the genesis of this organ. Lymphoid and other types of hematopoietic cells, normally lacking expression of Hox11 proteins, were not affected by loss-of-function mutations in this gene, except for the presence of asplenia-related Howell-Jolly bodies in circulating erythrocytes. Activation of *HOX11* by chromosomal translocations, either the t(10;14)(q24;q11) or the t(7;10)(q35;q24), in developing T cells must therefore interfere with normal regulatory cascades to promote malignant transformation.

### *EVI1 Activation in Acute Myeloid Leukemia*

In some cases of AML with high platelet counts, the inv(3)(q21;q26.2) or the t(3;3)(q21;q26.2) moves promoter/enhancer sequences from one site on chromosome 3 into the *EVI1* locus on the same chromosome,[201] leading to increased gene expression. The same effect is produced in murine myeloid leukemias by insertional mutagenesis.[202] The EVI1 protein binds to promoter/enhancer sequences containing the GATA sequence motif, and its tumorigenicity may come from interference with regulatory signals normally mediated by the GATA family of hematopoietic transcriptional regulators. [203,204,205 and 206] The tissue distribution of EVI1 in oocytes and kidney cells and its dominant interfering effect on normal myelopoiesis suggest an important developmental role in regulatory pathways of proliferation or differentiation.

### *EWS, FUS, and PAX Gene Fusions in Childhood Sarcomas*

Progress in understanding the genetic changes that affect solid tumors has been conspicuously slower than for the acute leukemias, primarily because of the difficulty in obtaining satisfactory karyotypes and in growing solid tumor cells *in vitro*. Nonetheless, chimeric transcription factors arising from chromosomal translocations have been identified in a large number of soft tissue sarcomas (Table 4-2).

The first translocation to be characterized at the molecular level in sarcomas was the t(11;22), which is virtually pathognomonic of Ewing's sarcoma (EWS) or its close relative, primitive neuroectodermal tumor. The fusion gene created by this rearrangement, *EWS-FLI1*,[207] encodes a hybrid protein containing amino-terminal sequences of EWS linked to the Ets-like DNA-binding domain of FLI1 (named for Friend leukemia integration site 1). [208] Using *in vitro* transformation assays, May and colleagues[209] established that malignant conversion of cells by this protein requires both EWS sequences and the FLI1 DNA-binding domain, suggesting that the chimeric protein acts by disrupting transcriptional regulatory pathways.

Variant translocations fuse identical EWS sequences to the DNA-binding domains of two related Ets family members, ERG [210,211,212 and 213] and ETV1 (Table 4-2).[214] As is the case for EWS-FLI1, the RNA recognition motif of EWS is absent from these variant proteins, replaced by the DNA-binding domains of the fusion partners. The amino-terminal sequences of EWS are rich in glutamine, serine, and tyrosine, making this domain a potent *trans*-activator of gene expression.[215,216] Hence, fusion proteins containing the EWS *trans*-activation domain and an Ets-like DNA-binding domain could act by dominantly and aberrantly up-regulating the expression of critical target genes.

Fusion of the *EWS* gene to the bZIP domain of *ATF1* in the wake of a t(12;22)(q13;q12) translocation leads to an entirely different tumor: malignant melanoma of the soft parts.[217] In malignant liposarcoma, the t(12;16)(q13;q14) fuses the amino terminus of an EWS-related gene called *FUS* (or *TLS*) to the bZIP domain of *CHOP*, initially characterized as a non–DNA-binding, dominant negative inhibitor of other bZIP proteins of the CAAT box–binding C/EBP family. [218,219] The abundant EWS and FUS/TLS proteins can form ternary complexes with a variety of RNA-binding proteins, such as A1 and C1/C2. [201] In addition, the amino-terminal sequences of FUS and EWS can be interchanged in chimeric constructs without affecting the results of *trans*-activation and transformation assays.[220]

The ubiquitous involvement of EWS and FUS combined with the lineage-specific association of the DNA-binding domains of fusion proteins in the malignant solid tumors suggests that the DNA-binding region specifies the downstream target gene and thus the phenotype of the arrested and transformed malignant mesenchymal progenitor cell. This principle is well illustrated by the Wilms' tumor gene, *WT1*, which gives rise to desmoplastic round cell tumors when it becomes fused to *EWS*.[221] In its normal state, *WT1* is a potent tumor suppressor gene whose homozygous inactivation leads to Wilms' tumor.

In alveolar rhabdomyosarcoma, translocations affecting chromosome 13q14 fuse either the *PAX3* or the *PAX7* gene with a portion of a forkhead domain gene, *FKHR*.[222,223 and 224] In tumor cells with the t(2;13)(q35;q14), the paired box and homeodomain regions of the *PAX3* gene are preserved, but the carboxyl-terminal sequences are replaced by a portion of the forkhead DNA-binding sequences from *FKHR*. A variant translocation, t(1;13)(p36;q14), truncates the *PAX7* gene in a similar fashion,[224] suggesting that a common set of target genes recognized by both of the PAX proteins are involved in the pathogenesis of rhabdomyosarcoma. The complete or partial constitutional loss of function of the *PAX3* gene has been correlated with a distinctive inherited condition, Waardenburg's syndrome 1, characterized by pigmentary disturbances, lateral displacement of the inner canthus of each eye, deafness, and mental retardation. [225] This observation, together with evidence that partial or complete disruption of the murine *PAX3* gene leads to abnormalities of the central nervous system,[225] suggests that *PAX* genes participate in critical developmental processes and that the PAX3 product must be present in high concentrations at precise junctures during development. The *SYT-SSX* gene of synovial sarcoma remains an enigma because neither fusion element shows homology to previously described sequences. [226]

## Tyrosine Kinase Gene Activation

Cellular tyrosine kinase genes can be aberrantly activated through a variety of mechanisms: truncation of the ligand-binding domain of growth factor receptors, loss or replacement of carboxyl-terminal regulatory tyrosine residues, and point mutations. [227] Instances of childhood tumors with an altered tyrosine kinase gene as the underlying molecular abnormality are rare, although the two leading examples represent substantial groups of patients who present difficult problems in clinical management (Table 4-5).

| Leukemia type | Karyotype | Activated genes | Reference |
|---|---|---|---|
| Ph⁻ CML | t(5;10)(q33;q21.2) | TEL-PDGFβR | 562 |
| Ph⁺ CML, ALL | t(9;22) | BCR-ABL | 563 |
| T-ALL | t(9;12)(p24;p13) | JAK2 | 564,565 |
| AML | t(12;15)(p13;q25) | TRKC/NTRK3 | 566 |
| AML-M3/M4Eo | t(1;12)(q25;p13) | ARG/ABL2 | 524,567 |
| Lymphoma | t(5;6)(q35;p21) | FLT4 | 568 |
| T-ALL | t(1;7)(p34;q34) | LCK | 569,570 |
| Anaplastic large cell lymphoma, non-Hodgkin's lymphomas | t(2;5)(p23;q35) | ALK | 260,571 |
| Myeloproliferative disorder, lymphoma, acute myelogenous leukemia | t(8;13)(p12;q12) | FGFR-1 | 572,573 |

ABL, v-abl Abelson murine leukemia viral oncogene homolog 1; ALK, anaplastic lymphoma kinase; ALL, acute lymphocytic leukemia; ARG, ABL-related gene; CML, chronic myelogenous leukemia; FLT4, fms-related tyrosine kinase 4; JAK2, Janus kinase 2; LCK, lymphocyte-specific protein tyrosine kinase; PGFR-1, fibroblast growth factor receptor 1; PDGFβR, platelet-derived growth factor beta receptor; Ph, Philadelphia chromosome; TRKC/NTRK3, neurotrophic tyrosine kinase, receptor type 3.

**TABLE 4-5. TYROSINE KINASE GENES ALTERED BY CHROMOSOMAL TRANSLOCATIONS IN HEMATOLOGIC MALIGNANCIES**

### *BCR-ABL in the Chronic Myeloid and Lymphoid Leukemias*

The Philadelphia chromosome, a product of the t(9;22)(q34;q11) translocation, was originally identified in patients with CML; subsequently, it was found in 3% to 5% of children and 30% to 40% of adults with ALL.[209,210 and 211,228,229] Its breakpoints on the distal tip of the long arm of chromosome 9 are variable in CML, occurring at any point over a distance of more than 100 kb within the *ABL* proto-oncogene, upstream of the tyrosine kinase domain.[230,231 and 232] By contrast, the breakpoints on chromosome 22 are confined to a 5.8-kb region of DNA known as the *major breakpoint cluster region*,[233] which lies within a gene called *BCR*.[233,234] The 9;22 translocation produces a *BCR-ABL* fusion gene consisting of 58 (upstream) sequences from *BCR* and 3' (downstream) sequences from *ABL*.[235,236,237,238 and 239] The 8.5-kb fusion transcript found in CML encodes a 210-kd hybrid protein that is activated as a tyrosine-specific protein kinase, similar to the *v-abl* protein product.[240,241,242 and 243]

Although routine karyotyping does not distinguish between the t(9;22) in CML and ALL, molecular analysis of the *BCR* and *ABL* proto-oncogenes, which are rearranged in both diseases, has revealed potentially important differences.[244,245 and 246] In ALL, the rearrangement produces a 6.5- to 7.0-kb fusion transcript and a 185- to 190-kd hybrid protein. Both are distinct from the products of the rearranged *BCR-ABL* fusion gene in CML. The breakpoints on chromosome 22 in ALL cases are not within the 5.8-kb region of *BCR* that contains the breakpoints in CML. Instead, they lie in a second minor breakpoint cluster region located farther upstream, within the *BCR* gene.[247,248 and 249] The ALL fusion protein includes amino-terminal BCR amino acids but lacks the internal residues found in the CML fusion proteins near the *BCR-ABL* junction.

The amino-terminal sequences of *ABL* are replaced in oncogenic forms of the gene, by the Moloney virus *gag* gene in the case of *v-abl*[250,251 and 252] and by *BCR* sequences in the *BCR-ABL* fusion gene of CML and ALL.[240,241,242 and 243] Both products of the *v-abl* and the *BCR-ABL* fusion genes can transform pre-B cells, but the latter cannot transform fibroblasts unless it is fused to the *gag* gene product.[253] The amino-terminal alterations influence the ability of *ABL* to function as a lineage-specific transforming gene and affect the tyrosine kinase activity of the protein product.

The exceedingly poor prognosis of patients with the Philadelphia chromosome has been attributed to transformation of a primitive hematopoietic stem cell that is inaccessible to most forms of chemotherapy.[121,229,254,255] Long-term responses (i.e., probable cures) have been induced in a subset of childhood BCR-ABL $^{+}$ ALL patients with low presenting white blood cell counts by using extensively reinforced early phase chemotherapy, followed by rotational treatment with pairs of non–cross-resistant drugs.[256] Maintenance therapy with interferon for patients in complete remission after either chemotherapy or autologous stem cell transplantation may contribute to more stable responses.[257] An experimental drug, STI-571, which inhibits the tyrosine kinase activity of ABL and BCR-ABL has shown a strong antileukemic effect in BCR-ABL$^{+}$ malignancies and will broaden the therapeutic options in the management of this disease.[258] For most patients, however, the recommended strategy is allogeneic bone marrow transplantation in first remission. Patients who lack suitable related donors should be considered candidates for alternative intensified therapies, including unrelated-donor allogeneic bone marrow transplantation in first remission, although relapse rates with such treatment are high and the outcome after relapse is extremely poor.[259]

### *NPM-ALK in Large Cell Lymphoma*

The 2;5 translocation in anaplastic large cell non-Hodgkin's lymphoma creates a novel fusion gene in which amino-terminal sequences from the nucleophosmin (*NPM*) nucleolar phosphoprotein gene on chromosome 5q35 are linked to the catalytic domain from a previously unidentified tyrosine kinase gene on chromosome 2p23, called *ALK* for *anaplastic lymphoma kinase* (Fig. 4-10).[260] Expressed in nervous system–derived cells of small intestine, testis, and brain, but not in normal lymphoid cells, ALK shares greatest homology with members of the insulin receptor subfamily of receptor tyrosine kinases. Unscheduled expression of a truncated ALK kinase in activated T lymphocytes probably contributes to malignant transformation leading to anaplastic large cell lymphoma.

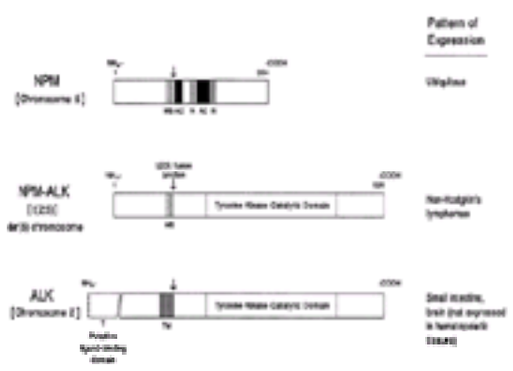

**FIGURE 4-10.** Schematic representation of the NPM and ALK proteins and the fusion resulting from the t(2;5)(p23;q35) in anaplastic large cell non-Hodgkin's lymphoma. Identified in approximately 30% of pediatric large cell lymphomas, the NPM-ALK chimera consists of the N-terminal end of NPM (nucleophosmin) fused in-frame to the intracellular kinase domain of *ALK*, (anaplastic lymphoma kinase). As shown, NPM is a 294–amino acid protein containing a metal-binding domain (MB), acidic amino acid cluster (AC), and two nuclear localization signals (N). The normal transmembrane receptor tyrosine kinase ALK possesses a membrane-spanning region and a kinase domain. The 2;5 translocation results in inappropriate expression of ALK, driven by the strong NPM promoter. Constitutive activation of the protein's kinase activity, potentially through NPM-mediated constitutive dimerization, may contribute to malignant transformation by inappropriately phosphorylating intercellular substrates involved in cell growth or development. [Adapted from Morris SW, Kirstein MN, Valentine MB, et al. Fusion of the tyrosine kinase gene ALK to the nucleolar phosphoprotein gene NPM in human t(2;5)-positive lymphomas. Science 1994;263:281.]

Non-Hodgkin's lymphomas include a diverse group of neoplasms that often present challenging diagnostic problems to the pathologist. In particular, cytogenetic analysis of lymphoma biopsy samples has been difficult in clinical settings, and a significant number of large cell lymphoma cases with the t(2;5) may be overlooked. The ability to reproducibly identify *NPM-ALK* fusion junctions in large cell lymphomas with the t(2;5) using an RNA-based polymerase chain reaction technique should greatly improve early recognition of these tumors.[261]

## Gene Amplification

Gene amplification at the DNA level enables a cell to increase expression of critical genes whose products are ordinarily tightly controlled. The cytogenetic hallmarks

of gene amplification are double-minute chromatin bodies and homogeneously staining regions, which contain the amplified DNA sequences, called *amplicons*.

Several clinically important examples of proto-oncogene amplification can be found among the solid tumors of children and adults. The *MYCN* gene is amplified tenfold to 300-fold in tumor cells from approximately one-third of childhood neuroblastoma cases. Overexpression of the MYCN oncoprotein has been linked to an advanced stage of disease and a poor prognosis.[262,263 and 264] Members of the *MYC* gene family, including *MYC*, *MYCN*, and *MYCL*, are also amplified in DNA extracted from small cell lung cancer lines and show higher levels of amplification when the tumor cells have been exposed to chemotherapy.[265,266] The *HER-2/NEU/ERBB-2* proto-oncogene, a relative of the epidermal growth factor receptor gene, is amplified in approximately one-third of human breast cancers, in which amplified levels of the oncoprotein are associated with poorer disease-free and overall survival rates.[267,268] Extra copies of the *CCND1* (cyclin D1) gene have been reported in breast carcinoma and squamous cell carcinomas of the head and neck,[269,270 and 271] and increased copies of an amplicon on the long arm of chromosome 12, containing the *GLI*, *MDM2*, and *CDK4* genes, have been detected in the sarcomas.[272,273,274 and 275]

Gene amplification has also been reported in isolated cases of human leukemia. For instance, *MYC* was shown to be amplified eightfold to 32-fold in DNA from the HL-60 promyelocytic cell line and in fresh leukemia cells from the same patient.[276,277] The *MYB* gene is amplified in rare cases of AML,[278,279] and the E2F-1 gene is amplified and overexpressed in the HEL human erythroleukemia cell line.[280]

Fluorescence *in situ* hybridization offers a rapid and reliable method for detecting gene amplification in solid tumors.[281,282] Although still in the experimental phase of development, this assay has the potential to improve the staging (hence, prognosis) of several types of tumors, including neuroblastoma and breast carcinoma.[262,263,264,265,266,267 and 268]

### *RAS* and *G-CSF* Gene Activation

Activation of cellular proto-oncogenes by point mutation is difficult to detect because the resulting lesions are not apparent by cytogenetic methods. Through the use of experimental systems, it has been possible to predict the types of genes most likely to be activated by point mutations in human tumors. The *RAS* family comprises the prototypic genes of this class.

Human tumor DNAs were found to contain activated homologues of *HRAS* or *KRAS*[283,284 and 285] after such proto-oncogenes had been identified from comparative studies of viral oncogenes. Gene transfer methods identified an additional *RAS* homologue called *NRAS*[286,287] that had not been previously observed as a component of a transforming retrovirus. These three human genes—*HRAS*, *KRAS*, and *NRAS*—encode 21-kd proteins that are associated with the inner surface of the cytoplasmic membrane[288] and function as intermediates in signal transduction pathways that regulate cell proliferation. The somatic mutations that activate *RAS* proto-oncogenes to transforming status affect the amino acids specified by codons 12, 13, or 61.[289] Mutated *RAS* genes also bind guanine nucleotides, but they have diminished capacity to hydrolyze guanosine triphosphate (GTP) to guanosine diphosphate.[290,291 and 292] The transforming properties of activated RAS proteins may result from their constitutive presence in an activated, GTP-bound form, which continuously activates the RAS signal transduction pathway.

Human *RAS* genes activated by point mutations have shown considerable tumorigenicity in experimental systems, transforming NIH-3T3 murine fibroblasts *in vitro* and primary cultures of embryo fibroblasts.[293,294,295 and 296] Their role in mammalian tumorigenesis is also confirmed by studies of carcinogen-induced animal tumor models.[297,298 and 299]

Among the childhood cancers, activated *NRAS* genes appear to be preferentially involved in the leukemias, having been detected in myeloid cell lines,[300,301] in fresh leukemic cells from patients with acute and CMLs,[302,303 and 304] and in lymphoblastic leukemias with a T-cell immunophenotype.[305] *NRAS* gene mutations involving codon 13 or 61 were found in approximately 20% of AML cases, regardless of the morphologic subtype.[302,306] A mutation of codon 12 of the *KRAS* gene was also observed in 2 of 37 AML cases.[306] In a study of lymphoblasts from children with ALL, cells from 2 of 19 patients showed mutated *NRAS* genes; in both cases, the changes involved codon 12.[307] *RAS* mutations have also been documented in patients with preleukemic syndromes, indicating the potential involvement of these genes in the earliest stages of leukemia development.[308,309]

Point mutations in the gene for the granulocyte colony-stimulating factor receptor in myeloid progenitor cells may also be involved in leukemogenesis. In an analysis of this gene in two cases of myeloid leukemia preceded by severe congenital neutropenia, investigators found a thymine-for-cytosine substitution at the codon for glutamine (i.e., position 718 in one patient and position 731 in the other), leading to truncation of the carboxyl-terminal cytoplasmic region of the receptor.[310] Presumably, activation of the cell cycle and survival-signaling functions of this molecule contributes to the pathogenesis of AML in patients with neutrophil elastase mutations, which disrupt normal myeloid cell differentiation.[311]

## TUMOR SUPPRESSOR GENES

In addition to the proto-oncogene–activating lesions described in the section Proto-Oncogene Conversion, recurring genetic changes in human cells affect a second class of genes, known as *tumor suppressors* or *antioncogenes*, whose products normally provide negative controls of cell proliferation. Loss of function of one or more of these proteins through the deletion or mutational inactivation of their corresponding genes liberates the cell from growth constraints, contributing to malignant transformation. The cumulative effect of genetic lesions that activate proto-oncogenes or inactivate tumor suppressor genes is a breakdown in the balance between cell proliferation and cell loss due to differentiation or apoptosis, resulting in clonal overgrowth within a specific cell lineage. The evidence suggests that the progression of tumors to clinically recognizable forms requires both types of changes.

The first indication that negatively acting proteins contribute to cancer came from research with somatic cell hybrids, showing that tumor cells fused to normal cells no longer exhibited malignant growth properties.[312,313] These observations were supported by the epidemiologic studies of Knudson[7] on the inherited predisposition for retinoblastoma development, characterized by an early age of onset for bilateral tumors compared with a later onset for unilateral tumors. His genetic model of carcinogenesis (Fig. 4-11) specifies two rate-limiting mutations, the first of which can be germline (in bilateral tumors) or somatic (in unilateral tumors), with the second invariably being somatic. Subsequent findings made it clear that both types of inactivating mutations target the alleles of a single susceptibility locus, the *RB* gene, which resides on the long arm of chromosome 13.[10,314]

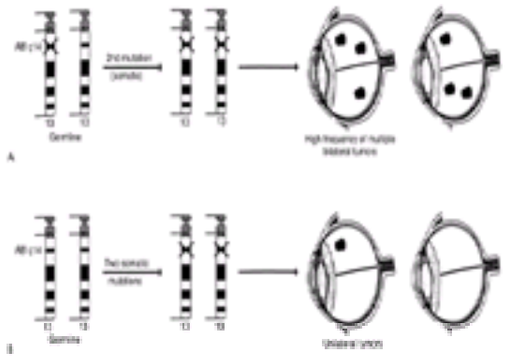

**FIGURE 4-11.** Knudson's hypothesis illustrated by the development of familial **(A)** and sporadic **(B)** retinoblastoma. Children with multiple, bilateral tumors of the eye carry a germline mutation of the *RB* gene that may be inherited or acquired. A somatic mutation affecting the second *RB* allele leads to tumor formation, usually during the first year of life. By contrast, children with single, unilateral tumors developing after infancy lack germline mutations of *RB* but have somatic mutations in both *RB* alleles. The “two-hit” model of carcinogenesis, first proposed by Alfred Knudson, has greatly influenced the direction of cancer research during the past two decades.

Although the list of known and potential tumor suppressors has increased rapidly since the discovery of *RB* (Table 4-4), this gene remains the paradigm for

understanding the dominant mode of inheritance of recessively acting genes that increase susceptibility to cancer. New genes will undoubtedly be added from studies of the hereditary cancer syndromes and from efforts to identify negative regulators of signal transduction pathways. In this chapter, we discuss the *RB*, *p53*, *WT1*, *NF1*, and *NF2* genes and refer briefly to a group of more recently identified suppressors.

### *RB*, the Retinoblastoma Susceptibility Gene

Originally isolated by Friend and co-workers,[11] the *RB* gene was shown to encode a ubiquitously expressed 105- to 110-kd nuclear phosphoprotein, now termed *pRB*.[315,316] The mechanism of pRB tumorigenicity remained elusive until research on the cell cycle revealed the central role of this protein in regulating the progression of cells through the first gap ($G_1$) phase of the cell cycle (as reviewed by Weinberg[317]). As discussed in the section Aberrant Control of the Cell Cycle, pRB serves as a versatile gatekeeper of the cell cycle, transducing physiologic signals that instruct cells to remain in $G_1$ or to move past a defined restriction point and prepare for DNA replication. The transducing function of pRB resides in whether it is phosphorylated by cyclin-kinase complexes. In its unphosphorylated state, pRB binds and represses the function of members of the E2F family of transcription factors, which participate in effector pathways vital to cell division. Phosphorylation results in the uncoupling of pRB and E2F, freeing the latter protein to activate the expression of its downstream target genes.[318]

Any abnormalities that impinge on pRB function could be expected to carry dire consequences, most ominously carcinogenesis. Three classes of viral transforming proteins can deplete cells of pRB by binding to the hypophosphorylated form of the protein.[319,320,321 and 322] The net result is analogous to that produced by inactivation of both *RB* alleles in human retinoblastoma.[320] Most often, the *RB* locus is disrupted by localized deletions of critical gene segments and by point mutations that affect messenger RNA splicing or frameshift mutations leading to truncation of the protein by introducing premature stop codons. Other point mutations give rise to stable proteins with single amino acid substitutions within the binding regions recognized by viral oncoproteins.[323,324 and 325] Such mutants lose the ability to bind cell cycle regulatory proteins, such as E2F, which then can participate without restraint in cell cycle progression (as reviewed by Nevins[318]).

Mutations resulting in homozygous inactivation of the *RB* gene are invariably found in retinoblastoma[316,326,327,328 and 329] but are not restricted to this malignancy. Patients with germline mutations of one *RB* allele characteristically develop bilateral retinoblastoma in the first year of life and are predisposed to develop osteosarcoma and soft tissue sarcomas as well (as reviewed elsewhere[330]), although these tumors occur later in childhood and in adolescence, during the period of maximum growth of these tissues. Somatically acquired *RB* mutations figure prominently in the development of many adult tumors, such as bladder, prostate, breast, cervical, and small cell lung carcinomas,[331,332,333,334,335,336 and 337] even though germline mutations are not predisposing events. Apparently, the inactivation of pRB is an early and essential step in the cascade of genetic changes leading to retinoblastoma and possibly to osteosarcoma; in adult carcinomas, *RB* mutations are not rate limiting but do contribute to tumor progression.

### *p53* Gene

The p53 gene in humans is located on chromosome 17, band p13, and encodes the p53 nuclear protein,[338,339,340 and 341] which is expressed in all cells and tissues of the body. This tumor suppressor has one of the most important etiologic roles in human cancer. It can be inactivated by mutation or lost through chromosomal deletion in a wide variety of human tumors,[342] including carcinomas of the colon,[343,344] lung,[345] breast,[346] esophagus,[347,348] stomach,[349] liver,[350,351] anus,[352] ovary,[353] and prostate.[354] In these neoplasms, *p53* mutations tend to occur as point mutations within the gene's four highly evolutionarily conserved domains, producing a protein that lacks normal regulatory function. Often, the second allele is lost from the malignant clone by deletion, resulting in a reduction to homozygosity for the mutant allele.[342,343] The *p53* gene is also frequently inactivated in childhood tumors such as osteosarcoma,[355,356 and 357] rhabdomyosarcoma,[357,358] brain tumors,[342] CML in blast crisis,[359] Burkitt's lymphoma, and B-cell leukemia, and less frequently inactivated in T-cell– or B-cell–progenitor ALL.[360,361 and 362] Although these tumors can arise from the same types of missense mutations that occur in carcinomas, more often they contain deletions or gross chromosomal rearrangements of both alleles, resulting in total loss of the p53 protein rather than in the production of a faulty protein.

Heritable cancer-associated changes of the *p53* tumor suppressor gene occur in families with Li-Fraumeni syndrome, an autosomal dominant predisposition for the development of rhabdomyosarcoma, other soft tissue and bone sarcomas, premenopausal breast cancer, brain tumors, adrenocortical cell carcinoma, and acute leukemia.[363,364,365 and 366] The Li-Fraumeni syndrome appears to be rare, consistent with its autosomal dominant pattern of inheritance and its high fatality rate.[367] Statistical modeling suggests a 50% probability of invasive cancer by age 30 years in members of Li-Fraumeni families who carry the mutated *p53* gene, compared with a 1% risk by age 30 years in the general population.[367,368] Germinal *p53* mutations could be inherited or could arise as de novo mutations early in embryogenesis or in one of the parent's germ cells.

In contrast to patients with bilateral retinoblastoma, in whom 85% of germline mutations in the *RB* gene appear to arise de novo,[7,11] most germline mutations of the *p53* gene are inherited from an affected parent. This principle became clear from detection of inherited *p53* mutations in children and young adults who developed second malignant neoplasms after successful treatment for the first cancers but who lacked a typical family history of cancer.[342,364] Most inherited mutations of the *p53* tumor suppressor gene produce functionless proteins,[366,369,370 and 371] although splice-site mutations that affect conserved intron-exon boundary sequences of the *p53* gene, resulting in frameshifts and premature termination signals, may account for a significant fraction of the Li-Fraumeni syndrome families in whom no exonic missense mutation has been found.[372,373] These findings suggest the need to examine the entire *p53* gene for splice-site, frameshift, nonsense, and missense mutations in families with multiple cancers of the types found in the Li-Fraumeni syndrome. Because epidemiologic criteria alone are imprecise and can lead to confusion between familial cancer syndromes caused by mutations in tumor suppressor genes other than *p53*,[374,375 and 376] the term p53 *familial cancer syndrome* should be applied to clusters of tumors in families with documented germline *p53* mutations, regardless of the histopathologic findings or pattern of tumor development.[372]

Diagnosis of the *p53* familial cancer syndrome depends on molecular analysis of the entire *p53* coding and splice-site consensus sequences in noncancerous tissue, a technical feat achievable with improved screening methods, such as constant denaturant gel electrophoresis,[377] single-strand conformational polymorphism analysis,[378] functional screens in yeast recombination assays,[379,380] or RNA-DNA heteroduplex digestion.[381] Identification of childhood cancer patients who carry germline mutations of the *p53* gene has had a significant impact on our understanding of the origins of pediatric tumors and will increasingly influence our approach to therapy and genetic counseling of affected persons.[382] The impact of genetic screening will also extend to family members who harbor a mutated allele of the *p53* gene. Knowledge of *p53* gene status could influence reproductive decisions, guide health screening, and lead to studies of prophylactic measures to prevent tumors in affected family members who have not developed malignant disease.

The existence of multiple independent *p53* mutations in both sporadic and familial tumors,[369,383,384] and the variety of familial tumors that can result from a single point mutation[369,384] suggest that the wild-type p53 gene product is critical to normal cellular DNA damage-response pathways and that alterations in *p53* function lead to the transformation of diverse cell types. Available evidence suggests that *p53* functions, at least in part, as a transcription factor[384,385 and 386] and that its conserved domains include an amino-terminal activation domain[387,388] and a central sequence-specific DNA-binding domain.[389,390] Clues to the types of genes targeted by *p53* came from the realization that its levels are increased in response to DNA damage by ultraviolet radiation.[391] The prevailing view is that *p53* functions as a cell cycle checkpoint, blocking cell division in $G_1$ phase to allow repair of damaged DNA or even triggering apoptosis in cells that have defective genomes.[392] In this way, the protein is thought to function almost exclusively as a tumor suppressor, preventing the development of malignant clones from cells with damaged genomes.

This view is borne out by the phenotype of mice that have been rendered p53 deficient by homologous recombination. A total absence of p53 protein expression in the mouse does not produce deleterious effects during embryologic development, but it predisposes these animals to the early development of a variety of neoplasms.[370,393] Thus, the p53 protein is not essential for normal cell division within any lineage during development; rather it acts as a gatekeeper, stopping the cell cycle and repairing or removing cells with damaged genomes that might otherwise evolve into malignant tumors.

### *WT1*, the Wilms' Tumor Gene

The *WT1* gene, located on chromosome 11, band p13, encodes a 50-kd nuclear transcription factor that contains four zinc finger DNA-binding domains (reviewed elsewhere[394,395]). Its identification was the logical end of studies demonstrating large constitutional deletions of the 11p13 region in patients who developed the WAGR syndrome.[13] As predicted by Knudson's hypothesis, tumors from these patients showed mutations of WT1 in the remaining allele, indicating homozygous loss at this locus.[396] Somatic disruption of both WT1 alleles has also been demonstrated in patients with unilateral Wilms' tumors.[397] Overall, 5% to 10% of Wilms' tumors have demonstrable homozygous WT1 mutations,[397,398] although this number may be underestimated, because approximately 20% of such tumors show a loss of

heterozygosity within the region encompassing this gene.[14,15,399]

Unique *WT1* mutations have been demonstrated in individuals with Denys-Drash syndrome, which includes intersexual disorders, nephropathy (e.g., mesangial sclerosis), and Wilms' tumor. These constitutional missense mutations affect single amino acid residues within exon 9 of the gene, which encodes the third zinc finger of the protein.[400,401,402,403 and 404] A defective WT1 protein produced from one allele can apparently interfere with the function of normal WT1 produced from the intact allele, producing developmental anomalies and tumor predisposition. An additional form of the protein resulting from a splicing alteration and lacking exon 2 has been identified in tumor cells but not normal cells, and this combination may represent a distinct mechanism for inactivation of *WT1* in Wilms' tumor.[405]

Expression of the *WT1* gene is restricted during development to mesenchymal tissues, occurring in specific cells of the collecting system within the kidney; non–germ cell components of the gonads, uterus, and spleen; and the mesothelium.[14,16,406] Targeted disruptions of the *wt1* gene in the mouse result in embryonic lethality in the homozygous state, secondary to the failure of kidney and gonad development.[407] The transcriptional properties of the WT1 protein have been analyzed extensively *in vitro*, and it has been shown to be a repressor of several genes encoding proteins important in cell growth control, including insulin-like growth factor II, platelet-derived growth factor, and epidermal growth factor 1.[408,409 and 410] Evidence suggests that the WT1 protein can also activate transcription in certain promoter contexts.[411] The precise mechanism by which WT1 exerts its effects during normal development and prevents tumor formation in the kidney awaits identification of the actual target genes that it regulates *in vivo*.

**Neurofibromatosis Genes, *NF1* and *NF2***

*NF1* is constitutionally mutated in von Recklinghausen's (type 1) neurofibromatosis, an inherited condition characterized by abnormal proliferation of cells of neural crest origin (reviewed elsewhere[412]). In addition to benign neurofibromas, patients with type 1 neurofibromatosis are at increased risk for developing malignant tumors such as pheochromocytomas and malignant schwannomas, which involve loss of the normal *NF1* allele, consistent with the interpretation that *NF1* acts as a tumor suppressor gene in cells of neural crest origin.[413,414 and 415] Another report linked loss of the normal *NF1* allele to malignant myeloid disorders, such as juvenile chronic myelogenous leukemia, which occur with increased frequency in neurofibromatosis patients, suggesting that NF1 may participate in the down-regulation of RAS proteins early in myelopoiesis.[416] Reports have also documented loss of expression and somatic deletion of *NF1* in neuroblastoma and melanoma,[417,418] even though the frequency of these tumors is not increased in neurofibromatosis patients. Thus, NF1 mutations can be an early and predisposing event in the progression of some tumor types but a later and non–rate-limiting step in others.

NF1 is related to GTPase-activating protein, which catalyzes the hydrolysis of the activated GTP-bound form of RAS proteins. Loss of NF1 appears to down-regulate GTPase activity in schwannomas, consistent with a mechanism involving constitutive activation of the RAS pathway, but neuroblastomas and melanomas lacking NF1 have normal GTPase activity, suggesting that loss of NF1 function can contribute to tumorigenesis through a separate and unknown mechanism.[417,418]

The spectrum of malignancies associated with neurofibromatosis type 2 include astrocytomas, meningiomas, and melanomas. The gene associated with this condition, *NF2*, is found on the long arm of chromosome 22 and encodes a protein of the merlin (i.e., moesin, ezrin, radixin-like; also known as *schwannomin*) family believed to be involved in a linkage of the cellular cytoskeleton to the cellular membrane and with cell-cell and cell-extracellular matrix interactions.[419,420 and 421] The mutations in *NF2* result in the formation of a truncated protein. Sporadic meningiomas commonly are associated with mutations of the *NF2* gene, and loss of the chromosome 22 carrying the normal *NF2* gene often accompanies the development of meningiomas.

**Other Known Tumor Suppressors and Newly Identified Candidates**

*RB*, *p53*, *WT1*, *NF1*, and *NF2* are just 5 of the 12 tumor suppressor genes that have been molecularly cloned at the time of writing (Table 4-6). The others—von Hippel-Lindau (*VHL*),[422] adenomatous polyposis coli (*APC*),[423,424] deleted in colorectal cancer (*DCC*),[425] inhibitor of CDK4 ($p16^{INK4A}$, reviewed elsewhere[426,427]), ataxia-telangiectasia mutated (*ATM*),[428] the PITSLRE kinase locus (*CDC2L1*),[429] and breast cancer 1 (*BRCA1*)[430]—were discovered more recently, and less is known about their mechanisms of action. However, some of these proteins have shown a remarkable ability to control signal transduction pathways by forming complexes with other regulators of cell growth and development. For example, the VHL tumor suppressor was found to bind to the heterotrimeric elongin (SIII) complex, thereby inhibiting its capacity to regulate transcriptional elongation of messenger RNA by RNA polymerase II.[431,432,433 and 434]

**TABLE 4-6. MOLECULARLY CLONED TUMOR SUPPRESSOR GENES AND THEIR FUNCTION IN PATHOGENESIS OF NEOPLASMS**

Linkage studies and identification of consistent chromosomal deletions will undoubtedly add new tumor suppressor candidates to the growing list. An especially rich source may be the protein inhibitors of cyclin-dependent kinases (CDKs), which positively regulate the $G_1$ phase of the cell cycle. It is already clear that two specific inhibitors of the cyclin D–associated kinases, $p16^{INK4A}$ and $p15^{INK4B}$, are frequently deleted in a wide variety of leukemias and solid tumors,[427] suggesting that the removal of negative cell cycle controls may be an important step in tumorigenesis.

## ABERRANT CONTROL OF THE CELL CYCLE

Early studies with the light microscope depicted eukaryotic cell division as a mysterious process in which unknown factors held the chromosomes in proper alignment, dictated their duplication, and then signaled for their condensation and segregation. This view has given way to the realization that orderly cell division requires a complex set of molecular controls, coordinated in part by the CDKs.[435,436 and 437] Many of the signals that drive cells from one phase of the cell cycle to another culminate in the phosphorylation of proteins by CDKs, whose active forms are complexes of a catalytic kinase subunit and a regulatory cyclin subunit and often other proteins. Changes in the components of cyclin-kinase complexes determine the proteins that are activated or inactivated by phosphorylation and hence ensure the integrity of the cell cycle. In mammalian cells, the series of kinase and cyclin subunits that are expressed during progression from the first gap phase ($G_1$) to mitosis have been designated CDKs 1 through 8 and cyclins A through H.[435,436 and 437]

Cells must also depend on other kinases, phosphatases, and inhibitors to regulate the CDKs. Perhaps the most intriguing of these factors are the CDK inhibitors (CDKIs)—$p15^{INK4B}$, $p16^{INK4A}$, $p18^{INK4C}$, $p19^{INK4D}$, $p21^{CIP1,WAF1,SDI1,CAP20}$, $p27^{KIP1}$, and $p57^{KIP2}$—which negatively regulate the cell cycle in response to internal and external stimuli.[426] The product of the retinoblastoma tumor suppressor gene, pRB, occupies a central position in the interplay among several of the cyclins, CDKs, and CDKIs (Fig. 4-12).[317] In mammalian cells, this protein undergoes phosphorylation at a point approximately two-thirds of the way through $G_1$ phase, a time coinciding with the cells' advance through a so-called restriction point (R), marked by a transition from mitogen dependence to relative independence from serum factors.[438]

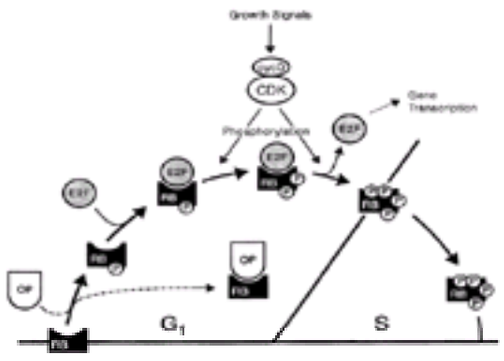

**FIGURE 4-12.** Multifaceted role of the retinoblastoma susceptibility gene product (pRB) in regulation of the $G_1$ to S cell cycle transition. As a nonphosphorylated or hypophosphorylated protein entering $G_1$ phase, pRB binds the E2F transcription factor or a related protein. Because of the action of cyclin D-CDK kinase complexes (cycD-CDK) in response to growth signals originating outside the cell, pRB becomes hyperphosphorylated and releases E2F to activate a group of genes whose products participate in critical downstream effector pathways. Growth inhibitory signals block pRB phosphorylation and thus the passage of cells through $G_1$. Alternatively, some viral oncoproteins (OP) can bind hypophosphorylated pRB, making it unavailable for interaction with E2F ( *dashed line*), so that the cell cycle proceeds without the usual restraints. Mutations in *RB* can likewise prevent pRB-E2F binding, resulting in dysregulated cell proliferation.

Considerable evidence indicates that pRB phosphorylation by CDKs (i.e., CDK4, CDK6, and possibly CDK2), under regulation of the D cyclins, determines whether a cell can successfully breach the R point and be eligible to reach the DNA synthetic (S) phase. Current models uggest that growth signals originating outside the cell stimulate pRB phosphorylation largely through increases in cyclin D levels, leading to activation of CDK4 and CDK6, and perhaps through extended kinase cascades.[426] In its phosphorylated form, pRB uncouples from an E2F family partner, enabling the transcription factor to activate a number of genes (e.g., *MYC*) whose products are important components of downstream effector pathways (reviewed elsewhere[318]). Growth inhibitory signals emanating from outside the cell can block pRB phosphorylation and hence the passage of cells through $G_1$.[317] The retinoblastoma gene product acts as a restriction-point turnstile, transducing physiologic signals into “go–no go” decisions at the critical $G_1$ to S phase transition.

Because cancer cells show many defects in proliferation, one would predict a carcinogenic role for the proteins affecting pRB function. Evidence to support this notion is quite compelling. Mechanisms causing inactivation of pRB include mutations of the *RB* gene that abolish pRB function in retinoblastoma, sarcomas, and other tumors.[335] Other mechanisms operate through increased phosphorylation, rendering pRB inactive, including overexpression of the cyclin D1 gene ( *PRAD1*) as a result of rearrangement with the parathyroid hormone gene locus in benign parathyroid adenomas [439] and cyclin D1 amplification and overexpression in approximately 20% of breast carcinoma cases,[440] 34% to 64% of head and neck squamous cell carcinomas,[441,442] and [443] 30% of esophageal cancers,[444] and 10% of hepatocellular carcinomas.[445,446] Similar increases in pRB phosphorylation may result from amplification of the *CDK4* gene, a common finding in many glioblastomas[447,448] and sarcomas.[272,273,274] and [275]

One of the most striking observations is the frequent deletion of the $p16^{INK4A}$ and $p15^{INK4B}$ CDKI genes from chromosome 9p21 in cases of childhood ALL with either a T or B immunophenotype.[427,449] These tandemly linked *CDKI* genes function as specific inhibitors of cyclin D–associated kinases, suggesting that their elimination within cells could remove negative growth regulatory signals emanating from pRB, resulting in a proliferative advantage and perhaps tumor formation under some conditions. The implications of this discovery are far reaching, in that the 9p21 band, where the $p16^{INK4A}$/$p15^{INK4B}$ locus resides, is a frequent target of homozygous inactivation by deletion and mutation. From the studies reported, $p16^{INK4A}$ appears to be one of the most frequently altered components of the cell cycle machinery in human cancer.[427] It should be stressed that the cancer-related molecular changes described previously ultimately involve pRB inactivation, by which cells are given unrestrained passage into late $G_1$ phase and subsequently are able to progress unimpeded into S phase, the period of DNA replication.

Breakdowns in the p53 checkpoint constitute a second major class of carcinogenic events linked to the cell cycle. [392] If cells become genetically damaged while in $G_2$, M, or early to middle $G_1$, there is an increase in steady state levels of p53, leading to activation of the p21 CDK inhibitor, which blocks the activity of CDK complexes—including those that normally phosphorylate pRB—and prevents DNA replication by binding to PCNA. [450,451,452,453,454] and [455] In this manner, defective cells are “gated” from further progression through the cell cycle while DNA repair enzymes restore the integrity of the genome. This mechanism is fundamental to preventing inadvertent replication of unrepaired DNA sequences that could be passed on to succeeding generations of progeny. When the p53 checkpoint is not available to cells because of inactivating mutations or gene deletions, conditions favor a greatly increased rate of cancer induction. [392]

Whether inappropriately expressed cell cycle control genes serve as true oncogenes is unclear. Their transforming ability in experimental systems has not been impressive, generally requiring additional genetic events to produce frank neoplastic changes. [427] The most appealing hypothesis is that defects in cell cycle control are not in themselves sufficient to cause malignancy. Rather, they give rise to uncontrolled proliferation and genetic instability preceding and predisposing to chromosomal rearrangements, gene amplifications, and aneuploidy—the hallmarks of clinically apparent neoplasia. They may constitute only a single step in the complex series of changes that produce a pediatric cancer.

Molecular lesions in the cell cycle machinery may ultimately afford a new kind of target for chemotherapy. [456,457] For example, much of the success of modern chemotherapy against the childhood leukemias can be attributed to the rapid induction of apoptosis, but in other types of cancer, the cells appear relatively resistant to this effect. Because some of the gene products that control progression from $G_1$ to S phase (e.g., p53) are also involved in apoptosis, [458,459,460] and [461] it may be possible to target this checkpoint so that malignant cells would be directed to apoptosis instead of cycle arrest. Other potential therapeutic targets include proteins involved in the choreographed degradation of cyclin/CDK complexes, which must be removed after they are needed for the cell cycle to continue (reviewed elsewhere[462]). As our knowledge of cell cycle control elements increases, it should be possible to devise therapeutic strategies that take advantage of differences in cycle regulation between normal and malignant cells.

## DEFECTS IN MISMATCH RECOGNITION AND REPAIR

Living organisms have been selected for their ability to replicate their genomes with fidelity but not absolute precision. This property ensures a certain degree of species continuity and stability while allowing the dynamic of genetic change essential to environmental adaptation and consequent evolution. The process of DNA replication, so fundamental to our understanding of biology and inheritance, has been a focus of investigation from the beginning of the modern era of biologic research. The unwinding and copying enzymes that replicate DNA on the basis of complementarity of nucleotides (i.e., guanosine with cytidine and adenosine with thymidine) and hydrogen bond formation form a highly efficient and accurate replicative complex. However, the process of DNA replication is not perfect.

Mistakes in base pairing are occasionally made depending on the organism, the specificity and accuracy of individual DNA polymerases, and the peculiarities of the local environment that may make such mistakes more or less likely. Some stretches of DNA are more likely to accumulate errors than others. In particular, stretches of DNA that consist of tandemly repeated units can present difficulties to precise replication by DNA polymerases. Such mono ($[A]_n$), di ($[CA]_n$), tri ($[CAG]_n$), or tetra ($[CACG]_n$) nucleotide repeats can lead to *strand slippage* during the replication process, in which the two DNA strands come apart and then reanneal with appropriate hydrogen bond formation but out of register by one or more repeat units ( Fig. 4-13). These areas of tandem repeats are also called *microsatellite regions.* Assaying their frequency of gain or loss of one or more repeat units (i.e., their relative instability) has become a means of determining the mismatch repair capability of a particular cell line, tumor, or tissue.

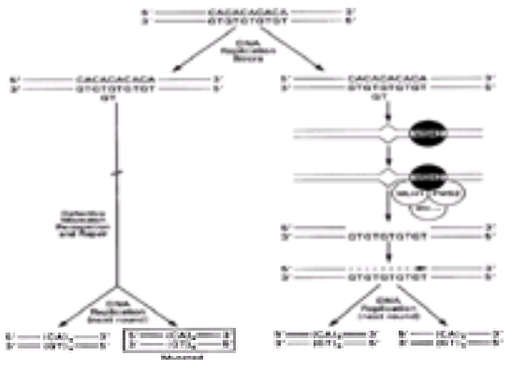

**FIGURE 4-13.** Competent or defective nucleotide mismatch recognition and repair after “strand slippage” during DNA replication. During DNA replication, a looping out of one of the “microsatellite” repeat units occurs on one or another strand. In the example on the right of the figure, this looped-out sequence is recognized as a mismatch. The recently synthesized strand is targeted for excision, partial resynthesis, and ligation by the mismatch repair complex consisting of MSH2, MLH1, PMS2, and other enzymes. The result is the maintenance of sequence fidelity. On the left of the figure, in the absence of a competent mismatch recognition and repair complex, the looped-out nucleotides are not dealt with. At the next round of DNA replication, one of the two daughter cells receives (in this example) an allele for this sequence in which an additional repeat unit has been added to the genomic sequence.

Certain types of cancers show marked defectiveness in their ability to recognize and repair nucleotide mismatches and thereby have marked instability in the microsatellite repeats scattered throughout their genomes, called *replication errors*. For these malignancies, it is believed that the mismatch repair defectiveness is an early step in the process leading to their malignant transformation. [463,464] The consequence of this defect is hypermutability within the cell. Such hypermutability creates a situation in which mutations of growth-affecting genes become much more likely. [465]

Positive selection of the hypermutable, growth-dysregulated clone leads incrementally to malignant transformation. The genes that are responsible for recognition and repair of nucleotide mismatches have been conserved in evolution from bacteria to humans. [466] Of what is likely to be a larger number, six human genes have been identified that play distinct roles in nucleotide mismatch recognition and repair: *MSH2*,[467,468] *MLH1*,[469,470] *PMS1*,[471] *PMS2*,[471] *GTBP* (MSH6),[472,473] and [474] and *MSH3*.[475,476]

**Hereditary Nonpolyposis Colorectal Cancer**

The etiologic impact of defective nucleotide mismatch repair in oncogenesis is most firmly established for a subgroup of colorectal cancers. Within this subgroup is included the hereditary predisposition to colorectal cancer, a condition called *hereditary nonpolyposis colorectal cancer* (HNPCC) or Lynch's syndrome.[477] Polyps are not absent in the families affected by this syndrome, but the clinical manifestations are distinct compared with another and less common form of hereditary predisposition to colon cancer, familial adenomatous polyposis, in which the affected individuals manifest hundreds to thousands of colonic polyps at an early age and, at the molecular level, are found to carry a germline mutation of the *APC* gene.[478]

HNPCC probably accounts for approximately 5% of all colorectal cancer cases. The actual percentage is still controversial, because most estimates are based on family studies or information from referral centers, and definitive population-based studies are still in progress. General criteria for defining HNPCC have been suggested by the International Collaborative Group on Hereditary Non-Polyposis Colorectal Cancer. [479] These include the onset of colorectal cancer in at least three individuals spanning two generations, at least one of whom is a first-degree relative of the other two, with the diagnosis for at least one of the individuals occurring before age 50 years. The stringency of these criteria makes it likely that a number of individuals with an inherited predisposition to colorectal cancer may not be included in this defined set. A higher proportion of HNPCC malignancies occur in the cecum and ascending colon than in other colorectal sites, where tumor development is based on different genetic mutations. The pathology of colorectal cancer in these families is not entirely distinctive but does include an increase in the number of tumors that are poorly differentiated and produce mucin.[477] Such pathologic findings are often seen in children with colorectal cancer as well. Families with HNPCC also show an increased susceptibility to some other kinds of cancer. In particular, there have been associations with endometrial and ovarian malignancies in women and some reports of an increased predisposition to stomach, pancreatic, and genitourinary cancers. [480]

It is unclear what determines the sensitivity or resistance to malignant transformation of particular cell lineages affected by defective mismatch repair. The distinctive pattern of malignancies for which an HNPCC gene carrier is at risk suggests that some kind of environmental or hormonal influence makes certain tissues with defective mismatch repair more susceptible to malignant transformation, or that regions of the genome more susceptible to the effects of a failure in nucleotide mismatch correction are regions that influence cell growth in only a subset of cell lineages.

The propensity to develop nucleotide mismatches during normal cell growth and the conservation of the mismatch repair system throughout evolution suggest that this mechanism is critical to normal development. However, it also seems that a defective mismatch repair system is not incompatible with viability. In general, the nontumor tissue of patients with HNPCC have normal microsatellite stability, suggesting that a single normal allele of the relevant genes is all that is needed for appropriate nucleotide mismatch recognition and repair. In these HNPCC patients, only their tumors, having experienced a loss of the other normal allele, show microsatellite instability. In some individuals, however, mutations in *MLH1* or *PMS2* apparently result in microsatellite instability in all tissues of the body. [481] These persons do not differ appreciably from HNPCC patients whose nontumor tissue appears normal. They do not experience a marked increase in cancer above the already increased predisposition imposed by HNPCC itself, although one could interpret the data as suggesting that the onset of colorectal cancer might be occurring earlier than in other HNPCC kindreds (i.e., an individual had the onset of colorectal cancer at age 12 years and another had two separate colorectal cancers by age 31). The spectrum of malignancies, however, is not significantly expanded.

Murine models have been developed in which *MSH2*, *MLH1*, or *PMS2* was homozygously deleted.[482,483] and [484] Such mice are viable, although in the case of the *PMS2* deletion, the males are infertile, with spermatozoa showing aberrant synapsis during the first meiotic division and in the *MLH1*-deleted mouse both males and females are sterile. In such mice, the spectrum of malignancy does seem to be expanded to include hematopoietic neoplasms, particularly lymphomas.

The spectrum of malignancies influenced by defective nucleotide mismatch recognition and repair has been extended into the pediatric population. In Turcot's syndrome, some of the associated colorectal adenomas and primary central nervous system tumors can manifest microsatellite instability. [485,486] Mutations of *MLH1* or *PMS2* were demonstrated in association with colorectal adenomas and glioblastoma multiforme in 2 of 14 registry-defined Turcot's syndrome families; ten of the families did not show defective mismatch repair but did carry germline mutations of the *APC* gene. The predominant brain tumor in these ten families was medulloblastoma.

**Sporadic Colorectal Cancer**

Defective nucleotide mismatch recognition and repair are etiologic factors in sporadic malignancies. It is estimated that 10% to 20% of the colorectal cancers occurring in individuals without a significant family history demonstrate microsatellite instability, compared with nonmalignant tissue from the same person. In the sporadic colorectal cancers that do show microsatellite instability, it is often impossible to implicate a mutation in *MSH2*, *MLH1*, *PMS1*, *PMS2*, or *GTBP* as the basis for the mismatch repair defect. Approximately one-half of the sporadic mismatch repair–defective colorectal cancers carry biallelic mutations of one of these genes in the tumor cells.

The frequency of colorectal cancers with defective mismatch repair is higher in younger adults with an inherited predisposition to cancer than in older persons. [487,488] The incidence of mismatch repair–defective tumors, believed to arise on the basis of somatic mutation, begins to rise again in the elderly. [489] In the older group, fewer than 10% of the individuals harboring these tumors carry a germline mutation in one of five critical genes, contrasted with 40% to 50% of patients younger than 35 years.[489] This younger population comprises a mixture of individuals from previously unrecognized HNPCC families and others who carry de novo germline mutations. There can be variable penetrance of colorectal cancer in families who carry the same gene mutation, [489] suggesting that other genetic and environmental factors influence whether a mismatch repair mutation progresses to overt cancer.

### Targets of Defective Nucleotide Mismatch Repair

A cell that is defective in the recognition and repair of nucleotide mismatches is not, based only on this defect, a malignant cell. The defect predisposes to the development in certain cell lineages of additional oncogenic mutations, which then combine to malignantly transform the cell, giving rise to a cancer. Oncogenic targets for defective nucleotide mismatch repair, therefore, are of interest for charting the pathway from a normal cell to cancer.

One such target in mismatch repair–defective colorectal cancer may be one of the two polypeptides that serve as the receptor for the growth-controlling factor: transforming growth factor-b (TGF-b). Within the coding region of one of the chains of the TGF-b receptor (TGF-b RII) is a run of ten adenosines. It had previously been demonstrated that certain colorectal adenoma cell lines became resistant to the growth-controlling effect of exogenously administered TGF-b as they progressed to frank malignancy.[490] This finding was extended, and resistance to growth control by TGF-b was found to occur exclusively in the subgroup of colorectal malignancies that were defective in nucleotide mismatch recognition and repair. A closer look at the receptor for TGF-b in these tumors showed that they no longer made functional TGF-b RII polypeptide because of frameshift mutations within the track of ten adenosines found within the coding sequence. [491] The frameshifts involved gain or loss of A residues, consistent with the types of mutations associated with microsatellite instability. At least one possible consequence of mismatch repair defectiveness is the increased propensity to mutate the TGF-b RII molecule, enabling cells to escape from the antiproliferative effects of TGF-b.

## TELOMERASE

Aging is a complex phenomenon. In a textbook on pediatric oncology, it is perhaps puzzling to encounter a discussion that begins with a sentence conveying a common geriatric focus. However, it is worth considering through certain examples that there are common features within the fundamental themes of development, aging, and malignant transformation. Much of what is considered to be aging (and dying) can be related to how the lifestyles, behavior patterns, and genetic predispositions of individuals interact to determine physiologic responses to DNA damage and metabolic and toxic challenges.

Although there has been a marked increase in the average life expectancy of humans in developed countries during the past century, there is no evidence that even the most carefully ingested diet and well-structured exercise program delivered within the most pristine and germ-free environment could result in immortality or even a substantial lengthening of life beyond the 100 to 120 years that appear to be the maximum life expectancy for *Homo sapiens*. One possibility is that even in the most controlled of environments, the accumulation of mutations in critical cells and tissues eventually leads to organ failure and death. Although the effect of accumulated mutations should not be discounted, it is also clear that individuals and their cells are programmed from birth to have a finite lifespan. It is only cancers that have been able to circumvent this program and achieve a kind of immortality.

Cells derived from the explants of tissues from higher organisms grow in culture for a limited time that can be measured in cell *generations*. After a certain number of doublings, often characteristic of the animal from which the cells were derived, the culture goes into a crisis and then dies. An inherent “biologic clock” seems to govern cell senescence. The process of cell death may be a passive process in which the nutrient and metabolic resources of the cell deteriorate or an active process in which, in response to senescent stress, a group of death genes are expressed that lead the cell to commit suicide.

What is the basis of the clock whose ticking proscribes our immortality? One potential mechanism in eukaryotes is directly related to the linear structure of eukaryotic chromosomes; they have ends, called *telomeres*.

### Telomeres

Telomeres have a specific structure characterized by dozens to thousands of simple G-rich repeats (distinct for distinct species; the human telomere repeat is TTAGGG) that run 58 to 38 toward the end of the chromosome and that extend in a single-stranded fashion for at least 12 to 16 nucleotides beyond the complementary strand at the chromosome terminus.[492] DNA ends, in general, are reactive moieties, and telomeres have the potential for being sites of great DNA instability, chromosome-to-chromosome translocation, and occasional loss with cell division. The structure of telomeres, through nucleotide-nucleotide or DNA-protein interactions, seems to stabilize chromosome ends to limit such breakages, fusions, and losses. [493]

### DNA Replication and the End-Replication Problem

There is a particular obstacle to the faithful replication of the ends of chromosomes ( Fig. 4-14A, Fig. 4-14B). DNA polymerases can only add nucleotides onto preexisting nucleotides. Hence, there is a requirement for priming, usually provided by short RNA molecules, in the initiation of DNA synthesis. There is also a directionality to DNA synthesis; one of the two strands of the double helix is synthesized in a 5' to 3' direction, and the other must be synthesized (globally) in a 3' to 5' direction. Because DNA polymerases only add nucleotides in a 5' to 3' direction, replication of the two strands of a double helix must be accomplished in distinct ways. The “leading” strand is replicated continuously in a 5' to 3' direction, providing a directional vector to the replicative fork. The opposing strand is replicated by a succession of priming and 5' to 3' syntheses of short fragments (i.e., Okazaki fragments) that displace the successive primers and are subsequently ligated together (i.e., the lagging strand).

**FIGURE 4-14.** DNA replication, the “end-replication” problem, and the action of telomerase. **A:** Schematic of DNA replication. One strand is synthesized continuously in a 5' to 3' direction (i.e., the leading strand), which moves in the direction of the replicating fork. The other strand is synthesized discontinuously (i.e., Okazaki fragments) in a 5' to 3' direction and is subsequently ligated, (i.e., lagging strand). In both strands, synthesis proceeds from RNA primers. At the ends of the chromosome, the lack of additional template makes RNA priming impossible, and the 5' ends of the newly synthesized strands bear deletions compared with their opposing templates. **B:** Successive rounds of DNA replication as diagrammed in **A** result in gradual shortening of the ends of the chromosomes by one or more telomeric repeat units. **C:** Mechanism of telomerase action. The RNA component of the telomerase complex includes a portion (*white letters on black circles*) that is complementary to the nucleotide repeats on the 3' end of the strand that forms the end of the chromosome. The reverse transcriptase activity of the protein component of telomerase adds deoxyribonucleotides (DNA; *black letters on white circles*) to the 3' end of the strand using the telomerase RNA as a template. The 3' end is elongated by additional telomeric repeat units, with the number of additional repeats determined by the number of times the telomerase complex translocates along the end of the chromosome. The opposing strand is then synthesized in a 5' to 3' direction ( *black letters on white diamonds*) by conventional DNA polymerases. The newly synthesized 5' ending strand does not shorten with each round of replication. Compare this result with the result in **A** and **B**.

The 5' ends of both newly synthesized strands cannot be completely replicated without an additional mechanism being invoked ( Fig. 4-14A). The RNA that primes from the extreme 5' end of the strand cannot be displaced by DNA because there is, by definition, no template to allow the DNA polymerase to accomplish that final displacement. Over time, with each successive cycle of replication, the chromosome is shortened by failure to complete replication of the 5' ends of the double helix (Fig. 4-14B).

### Telomere Shortening and Aging

Models based on the mechanism of DNA replication propose that at some point after a certain number of cell divisions a critical shortening of the ends of chromosomes is reached, chromosomal instability ensues, and the cells die. Telomere shortening is proposed as a “cellular clock” and a mediator of senescence.[494,495 and 496] Support for this model, although mostly correlative, is compelling. For example, when fibroblast cultures were established from individuals of widely different ages, the initial telomere length was found to be proportional to the number of generations that the individual cultures could sustain. Moreover, in cells derived from patients with progeria, a syndrome of premature aging, it was found that telomere length was significantly shorter than that in cells from age-matched controls and that the “progeric” cells had less proliferative capacity. [497] When fibroblasts are serially passed in culture, their telomeres become progressively shorter.[498,499]

The production of sperm and ova must be resistant to the end-replication problem and the successive telomere shortening that accompanies cell division. Otherwise, a species would be incapable of perpetuating itself from generation to generation. By starting off with critically shortened chromosome ends, the next generation would be incapable of maintaining the requisite number of cell divisions for growth and development. Germ cells maintain the size of their telomeres through the action of the enzyme telomerase.[500] It is the absence of telomerase activity in most somatic tissues that initiates the clock mechanism described in the previous section.

### Telomerase Activity

An enzyme activity capable of adding telomeric sequences onto single-stranded oligonucleotides already containing telomeric repeats was first demonstrated in cellular extracts derived from the ciliate *Tetrahymena*, an organism with a large number of chromosomes.[501] Subsequently, the terminal transferase activity was shown to require the presence of a particular RNA molecule in the extract [502]; the RNA sequence included a segment that was complementary to approximately 1.5 telomeric DNA repeat sequences.[503] Analyses of telomerase activity in many different organisms, including humans, have demonstrated the essential consistency of these initial findings. Telomerase is a ribonucleoprotein complex in which the RNA component is used for the recognition and as a template for the extension of telomeric repeats. The complex has terminal transferase and reverse transcriptase activities. [500] After additional telomeric repeats have been added to the strand whose 3' end forms the end of the telomere, the opposing strand is thought to be synthesized by the standard 5' to 3' DNA polymerase activity described in the previous section ( Fig. 4-14C). Additional telomere-recognizing DNA-binding proteins probably place a rough upper limit on the number of additional repeats that telomerase can add. [504]

### Telomerase Reactivation, Immortality, and Cancer

The scenario presented in the section Telomere Shortening and Aging for senescence in cell culture after the loss of telomeric repeats is true without exception. When nonmalignant cells are placed in culture, they do divide for a finite time, after which they die. Certain types of cells, however, more often cells of certain species or strains, may survive this growth crisis and emerge as immortal cell lines. Shortening of telomeres has been observed in cultured cells before their growth crisis; however, the cells that emerge from crisis and are capable of continued growth show a stabilization of their telomere length and a reactivation of telomerase activity.[505] When more than 100 immortal cell lines were assayed, most demonstrated telomerase activity. [506,507 and 508] Equally striking was the finding of telomerase activity in more than 84% of frank malignancies, comprising more than a dozen distinct tumor types. [500, 506,507 and 508]

In the presence of p53 heterozygosity, a new tumor spectrum was observed in mice deficient for the essential RNA subunit of telomerase. When these mice were bred for several generations they experienced the expected shortening of their telomeres, but in addition began to develop the kind of epithelial cancers frequently observed in human populations but occurring only rarely in mice. The tumors were notable for cytogenetic evidence of a preceding period of cataclysmic genomic instability associated with telomere-telomere fusion, breakage-fusion-bridge cycles, translocation, duplication, and deletion—the hallmarks of many human epithelial tumors.[509] A testable model has arisen in which this mutation causing cataclysm is resolved by the reactivation of telomerase stabilizing the reconfigured genome and granting the now transformed cell immortality.[510]

In some cases, levels of telomerase activity may correlate with tumor virulence and prognosis. For example, of 100 neuroblastoma cases analyzed, 94 had detectable telomerase activity.[511] The higher the activity, the more additional genetic changes were apparent and the poorer the prognosis. Three of the tumors that lacked telomerase activity were classified as stage IVS, a form characterized by spontaneous regression.

### Telomeres and Telomerase: Implications for Cancer Therapy

The preceding discussion suggests a possible avenue to overcoming the cancerous state. If, for example, the action of the telomerase RNA-protein complex could be inhibited, there might be a critical shortening of telomeres within the malignant cell, leading to chromosomal instability and death. Research directed toward this and related possibilities has been undertaken in academic and commercial laboratories; however, it is too early to know whether this strategy will be successful for any, all, or no malignant diseases.

The available data indicate several obstacles to this strategy. First, not all malignancies may be immortal, and some cancers may be lethal even with a limited lifespan. Second, some tumors may have telomeres of such length that inhibition of telomerase, although effective, would not result in lethal instability within a therapeutic time frame. Third, there may be telomerase-independent ways of elongating the ends of chromosomes.[512] Nonetheless, if blocking, repressing, or inhibiting tumor-reactivated telomerase works for any cancer, a major and insightful therapeutic breakthrough will have been achieved.

## SUMMARY

Childhood cancer is ultimately a disorder of genes, whose identity and function have preoccupied cell biologists for more than 20 years. The genetic portrait of the diverse group of neoplasms we call *pediatric tumors* is being rapidly filled in. We know that aberrant activation of transcription factor or tyrosine kinase genes by translocation-mediated fusions with normally unrelated partners or by rearrangement to sites near immunoglobulin or TCR genes can lead to acute leukemia, lymphoma, and sarcoma.

It is intriguing that most of such genes have close homologues in the genes controlling *Drosophila* morphogenesis, underscoring their faithful conservation in nature and their relevance to programs of early cell differentiation. The inappropriate expression of specific oncogenes in hematopoietic or mesenchymal progenitor cells could be expected to block normal programs of differentiation.

The tumor suppressor genes, best exemplified by *p53* and *RB*, can give rise to pediatric tumors through an entirely different mechanism. Rather than inappropriate activation (i.e., gain of function), these antioncogenes must be deleted or otherwise inactivated (i.e., loss of function) before their carcinogenic effects become apparent. Every human cancer contains mutations of one or more genes from the oncogene and antioncogene categories, implying a multistep process leading to full-blown malignancy.

Newer classes of cancer genes include defects in nucleotide mismatch recognition and repair, which can lead to hypermutability within cells, a condition ideal for productive mutation of growth-affecting genes and mutations resulting in reactivation of the telomerase gene, whose activity can restore telomere length to chromosomes and thereby confer immortality to cells.

The discovery of key molecular events in the pathogenesis of childhood tumors has not translated into major advances in therapy, but evidence from many fronts, including the treatment of APML with all-*trans*-retinoic acid, suggests that cancer will eventually yield to molecular intervention, assuming that we can find and fully characterize the proper targets.

## ACKNOWLEDGMENTS

We thank John Gilbert for editorial assistance and critical comments, Adolfo Ferrando and Tingxi Liu for helpful comments, and Doris Dodson for typing the manuscript.

# BIOLOGY OF CHILDHOOD CANCER

CAROL J. THIELE
MICHAEL B. KASTAN

## INTRODUCTION

Within the processes of normal cellular development and tissue formation and renewal, cells evolve to perform highly specialized functions. These processes are tightly regulated in response to the physiologic needs of the host. The idealized cell ( Fig. 5-1) has several developmental decisions: continued progression through the cell cycle, differentiation to a specialized cell type, or programmed cell death. The probability that a cell embarks on these paths is influenced by its genotype and its environment. Cells have evolved complex signal transduction pathways that enable them to sense and respond to neighboring cells and their extracellular milieu. These signaling paths influence survival/death, growth/growth arrest, differentiation/undifferentiated, motile/non-motile, and angiogenic/anti-angiogenic decisions and, ultimately, cell fate. Components of these pathways include membrane-bound protein receptors, cytoplasmic/nuclear receptors, phospholipid signaling systems, and ion channels and are highly conserved, being found in yeast, flies, worms, and mammals.

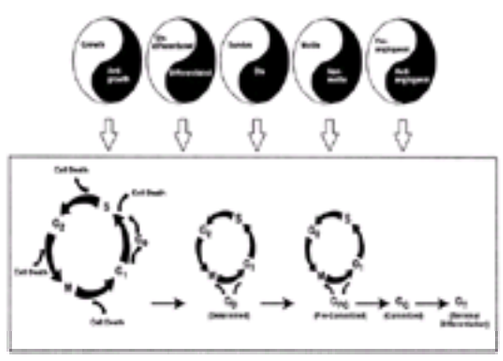

**FIGURE 5-1.** Model of the developmental decisions (proliferation, differentiation, and death) a cell encounters during ontogeny and the potential external influences that shape decisions (growth versus anti-growth; survival versus death; differentiate versus undifferentiate; pro-angiogenic versus anti-angiogenic; motile versus non-motile). Functionally defined stages of cell cycle are S, DNA synthesis; M, mitosis; $G_1$, gap between M and S; and $G_2$, gap between S and M. $G_0$ is the temporary withdrawal from the cell type.

Carcinogenic events can occur at any time during ontogeny or tissue renewal, leading to a tumor composed of cells with distinct developmental characteristics and potentials.[1] *In vitro* carcinogenesis studies in animals indicate that tumorigenesis is a multistep process, functionally defined by initiation, promotion, and progression. [2] Initiation is the alteration of a cell resulting in a heritable change that may affect its fate. Although initiated cells may develop normally, initiated cells may also have alterations in genes that lead to a conditionally lethal state and the induction of cell death or apoptosis. If an initiated cell with a conditionally lethal genetic change acquires a subsequent alteration(s) that suspends or bypasses the lethal state, then the initiated cell may develop into a tumor. Genomic instability, chemicals, growth factors, and hormones produced by the cell or in its environment that alone are not carcinogenic may promote tumorigenesis by suspending a fundamentally lethal condition in an initiated cell. Tumor progression is marked by the ability of a tumor cell to adapt or influence its microenvironment principally by stimulating a vascular supply. The multistep process of tumorigenesis is the result of a series of alterations in genes that function in signal transduction pathways that regulate at least four major parameters of a cell's own fate as well as its interaction with its microenvironment: (a) regulation of cell cycle progression, (b) apoptosis, (c) differentiation, and (d) migration and angiogenesis.[3] Studies indicate tumor cells have different or variable potentials that may include the development of nonmalignant, malignant, and highly malignant or metastatic tumor cells. These potentials reflect the environment in which the tumor cell resides, the acquisition of additional mutations, or a

combination of these factors.[2,3 and 4]

An inherent property of tumor cells is increased genetic instability that may lead to an accumulation of mutations that also influence and alter their biologic properties.[3] In a tumor cell, unlimited proliferation may be favored despite normal cellular and environmental restraints, and characteristics associated with differentiated functions are frequently diminished. This implies that the normal regulatory links between growth control and differentiation have been uncoupled. The ability of chemicals and biologic response modifiers to control cell growth and induce differentiation or cell death in tumor cells suggests that some compounds may bypass altered signal transduction pathways that control these processes.[5,6]

There are two major types of signaling pathways: those whose activities are mediated by membrane-bound receptors and those whose activities are transduced by cytoplasmic or nuclear receptors. The targets of these paths are transcription factors, DNA-binding proteins that regulate the transcription of genes that ultimately control cell function. Members of the membrane-bound signaling pathways include receptors that have an intrinsic kinase activity, such as the epidermal growth factor receptor (EGFR), and receptors that lack an intrinsic kinase activity such as integrins that interact with intracellular kinases (e.g., members of the src family) ( Table 5-1). Another major type of signaling pathway involves cytoplasmic/nuclear receptors, such as hormone, lipid, and vitamin receptors that directly bind DNA sequences in the regions of genes that regulate RNA transcription.

**TABLE 5-1. GROWTH FACTORS AND THEIR RECEPTORS**

The ability of any factor (e.g., polypeptide, vitamin, hormone) to activate a signal transduction pathway is a function of its concentration in the extracellular milieu and the number of receptors expressed by a cell. The intensity of the stimulated signal transduction pathway and its ultimate effects on cell function also depend on the concentration and activation state of the downstream intracellular effectors of the signal transduction pathway. Because the signal transduction pathways of many different receptors use common downstream effectors or intermediates, a cell's response reflects its ability to transmit and integrate a number of different signals that may be incoming at any given time. A cell's response to a factor reflects the convergence of these signals on nuclear transcription factors that specifically activate or repress transcription of genes important in stimulating or inhibiting cell proliferation, cell death, cell differentiation, cell migration, or angiogenesis.

The biochemical paths by which extracellular factors regulate gene transcription and the synthesis of specific proteins that control developmental decisions are complex, as is the role of these proteins in tumorigenesis. They may be directly involved in tumorigenesis, as genetic alterations may occur in proteins within the signal transduction pathway or their target transcription factors, resulting in constitutively active or repressed signal transduction pathways. However, they may also play an indirect role as epigenetic phenomena active in a cell as a part of its normal developmental program that continues to affect the biology of a cell during and after the tumorigenic genotype is established.[7]

A discussion of every growth factor and signal transduction pathway and the intricacies of their interactions is beyond the scope of this chapter. This chapter reviews the current state of knowledge for the major molecular mechanisms regulating cell growth, apoptosis, differentiation, metastasis, and angiogenesis; comments on the involvement of known cancer genes in these processes; and discusses current therapeutic strategies and clinical protocols using drugs and biologics targeted to these pathways.

## GROWTH-REGULATING FACTORS, RECEPTORS, AND SIGNAL TRANSDUCTION PATHWAYS

*Growth factor* is the historical name given to polypeptides, first isolated from the conditioned media of cells grown *in vitro*, that stimulated a cell response such as cell survival or proliferation. One example, transforming growth factor-b (TGF-b), was also called *sarcoma growth factor*, because it stimulated anchorage-independent cell growth, an *in vitro* property of transformed cells.[8] Now, TGF-b is known to inhibit the growth of many cell types.

Many peptides were first identified as hormones [e.g., insulin-like growth factors (IGFs)]. Although the action of these peptides may be endocrine and may occur over great distances, their activities may also be paracrine or local, influencing neighboring cells. Cells may produce factors that are autocrine or autostimulatory. If these factors are secreted, they may be involved in a public autocrine loop, or if the factors are stimulatory even if not secreted, they may be considered as intracrine or stimulating a private autocrine loop. Juxtacrine factors are not secreted but are expressed on the cell surface and influence neighboring cells. Table 5-2 provides a glossary of terms.

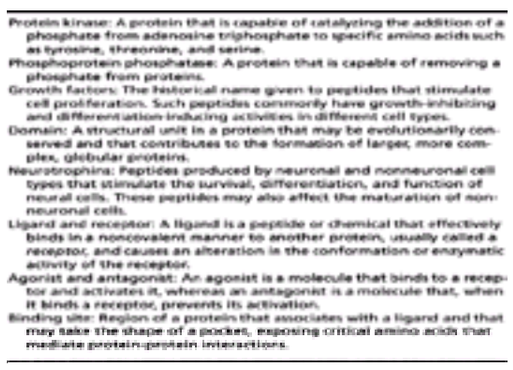

**TABLE 5-2. GLOSSARY**

## TRANSMEMBRANE RECEPTOR PROTEIN KINASES AND THEIR SIGNAL TRANSDUCTION PATHWAYS STRUCTURE

Protein tyrosine (Tyr) kinase receptors consist of a polypeptide chain that may be functionally and structurally separated into distinct domains: the extracellular domain, a transmembrane domain, the juxtamembrane region, the Tyr kinase domain, and the carboxyl-terminal domain (Fig. 5-2).

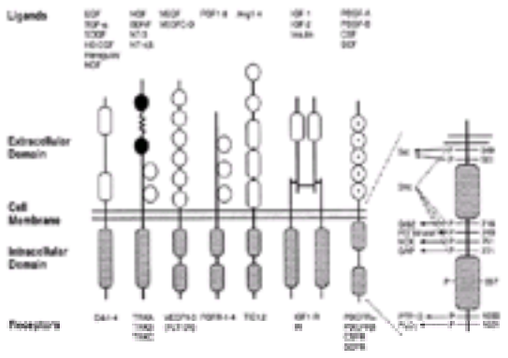

**FIGURE 5-2.** Schematic representation of receptor protein tyrosine kinases. Receptor protein tyrosine kinases contain an extracellular domain that binds ligand, a transmembrane domain that spans the cell membrane (*stippled horizontal line*), and an intracellular domain. The open horizontal bars represent cysteine-rich regions, the open circles to the right of the line are Ig-like loops, and open circles with a dot in the middle are leucine-rich areas. The closed circles separated by a jagged line in the Trk receptor family represent cysteine-rich regions separated by fibronectin type III repeats. The tyrosine kinase domain ( *striped rectangles*) expands to the left of the platelet-derived growth factor (PDGF) receptor to illustrate the known tyrosine amino acids ( *numbered*) that are phosphorylated (P) and known intracellular proteins or protein motifs that bind to specific phosphorylated tyrosines after ligand binding and receptor dimerization. Ang 1-4, angiogenesis stimulating factors; BDNF, brain-derived neurotrophic factor; CSF, colony-stimulating factor; EGF, epidermal growth factor; ErbB1-4, epidermal growth factor receptors; FGF, fibroblast growth factor; GAP, Ras-GTPase-activating protein; HB-EGF, heparin-binding EGF-like growth factor; IGF, insulin-like growth factor; IR, insulin receptor; NDF, neu differentiation factor; NGF, nerve growth factor; NT, neurotrophin; R, receptor; SCF, stem cell factor; SDGF, schwannoma-derived growth factor; TGF, transforming growth factor; Tie 1,2, receptors for Ang; TRK, tropomyosin receptor kinase; VEGF, vascular epithelial growth factor.

The extracellular domain binds ligand. Ligands may be monomers that may bind two receptors simultaneously [e.g., epidermal growth factor (EGF)], disulfide-linked dimers (e.g., platelet-derived growth factor), or noncovalently linked dimers [e.g., stem cell factor (SCF)]. In addition to binding ligand, the extracellular domain is characterized by several motifs, such as cysteine-rich domains, immunoglobulin (Ig)-like loops, leucine-rich motifs, fibronectin-like repeats, and EGF-like repeats, that may be involved in ligand binding, stabilization of the receptor dimer, or non-ligand–mediated receptor-receptor interactions. Ligand-receptor interaction may cause an allosteric change in a receptor or dimerization, or both, or oligomerization of receptors that lead to activation. The transmembrane region anchors the receptor in the lipid bilayer of the cell membrane, and the juxtamembrane region separates the transmembrane domain from the cytoplasmic domains. Upon ligand binding and receptor dimerization, Tyr residues in this region are autophosphorylated and mediate interactions with cytoplasmic binding proteins. [6]

The amino acid sequence of the Tyr kinase domain is the most highly evolutionary conserved domain among different receptors, and single amino acid alterations in the adenosine triphosphate–binding site can lead to a loss of function. The catalytic activity of the Tyr kinase domain involves the ability of the protein to phosphorylate neighboring Tyr residues. Phosphorylation of key residues in the kinase domain can increase its catalytic activity. Protein phosphorylation at Tyr, serine, or threonine amino acid residues by kinases and dephosphorylation by phosphatases represents a major component of the “signal” in signaling pathways. Phosphorylation plays a critical role in biologic processes because it can rapidly alter protein activity or alter protein-protein interactions. [9] Forms of receptors lacking the Tyr kinase domain have been identified in an increasing number of receptors, including receptors for neurotrophins and fibroblast growth factor. Although their precise role is not clear, truncated receptors may have unique signaling pathways, facilitate ligand binding, or act as dominant negative proteins that, by binding a ligand, sequester it from kinase-active receptors. The carboxyl-terminal domain contains several Tyr residues that are phosphorylated by the kinase domain. The ability to make site-directed mutants of various residues in this regions has defined the importance of these residues and delineated their intracellular intermediaries in signaling pathways.

## SIGNAL TRANSDUCTION PATHWAYS

Ligands, which may exist as monomers or dimers or remain cell bound, may interact with receptors and activate several intracellular signal transduction pathways: a mitogen-activated protein kinase (MAPK) pathway,[10] a protein kinase C (PKC) pathway,[11] or the phospholipase C-g (PLC-g) signal transduction pathway. [12] The members of these pathways, their mechanisms of activation, and their interactions are under intense investigation, and, because of their complexity, the models presented here are schematic (Fig. 5-3).

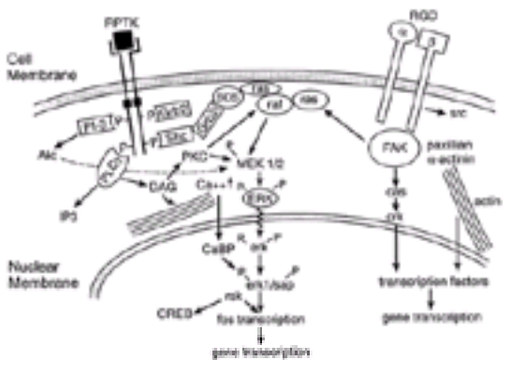

**FIGURE 5-3.** Schematic diagram of common signal transduction pathways used by growth factor receptors and cell adhesion molecules. Growth factors ( *squares*) or RGD-containing proteins (RGD) interact with membrane-bound receptors, facilitating receptor dimerization or oligomerization that initiates the signal transduction cascade. In the case of receptor protein tyrosine kinases (RPTKs), activation involves enhanced activity or intrinsic receptor kinase, and with cell adhesion molecules that lack an intrinsic kinase, activation leads to interaction with intracellular protein kinases that propagate the signal. Solid arrows represent predominant signal transduction pathways activated, and dotted lines indicate ancillary activation pathways. Ca, calcium; CaBP, Ca-binding protein; DAG, diacylglycerol; FAK, focal adhesion kinase; IP3, inositol-3-phosphate; PI-3, phosphotidylinositol-3; PKC, protein kinase C; PLCg, phospholipase C-g.

Ligand-receptor interaction leads to homoreceptor or heteroreceptor dimerization, followed by the reciprocal autophosphorylation of Tyr residues in the cytoplasmic region of one receptor by the kinase domain of the other receptor. [13] Tyr residues within the catalytic domain are phosphorylated (with the exception of the EGFR), and this may enhance receptor kinase activity. Phosphorylation of other Tyrs in the juxtamembrane region and the carboxyl terminus creates docking sites for downstream signal transduction proteins.

The binding of the receptor to downstream partners in the signal transduction pathway and the binding of these intermediaries to each other are mediated by specialized domains within the proteins. [14,15] SH2 and SH3 were originally identified as src homology 2 (SH2) and 3 (SH3) domains. SH2 is a 100 amino acid domain whose tertiary structure forms a binding pocket for a phosphorylated Tyr (PTyr) and the immediate surrounding amino acids found on a receptor. These domains recognize short linear stretches of four to ten amino acids usually surrounding a phosphorylated Ser/Thr or Tyr. SH2, SH3, PTB, WW, FHA, SAM, LiM, PX, EH EVH1, and PDZ are examples of protein-protein interaction domains. [15] These domains mediate alterations in protein conformation that change the catalytic activity of interacting proteins or alter subcellular protein location, concentrating proteins to the cell membrane or cytoskeleton. Differences in the binding affinities of these protein domains to receptors can influence signal transduction. If multiple receptors are activated in a cell at the same time, there may be competition for these proteins, leading to signal “squelching” or signal amplification or to activation of additional pathways, a process called *crosstalk*.

Receptors can directly activate signaling pathways by binding to proteins that have intrinsic kinase activities, such as src or phosphatidylinositol-3 kinase (PI-3 kinase), or that activate second messengers, such as PLC-g. The SH2 domain in PLC-g binds a specific PTy in the receptor, leading to the formation of inositol-1,4,5-triphosphate and diacylglycerol. This leads to a slow release of $Ca^{2+}$, which can bind and alter the activity of a number of $Ca^{2+}$-binding proteins, such as calmodulin and PKC, both ubiquitous modulators of protein kinases and other enzymes. [16,17] Diacylglycerol is also potent activator of PKC. Numerous compounds

identified as tumor promoters are strong activators of PKC.[16] Proteins can also directly interact with lipids via the “pleckstrin” homology domain, which recognizes specific phospholipids and enables membrane associations dependent on lipid second messengers.

The identification of adapter proteins, such as Grb, IRS-1, Shc, Crk, and Nck, that bind specific receptor PTy coupled Tyr kinase signals to the MAPK and ras signaling pathways.[18] Although adapter proteins lack intrinsic kinase activity, they function in many receptor signaling pathways by binding PI-3 kinase and PLC-g. The adapter protein Grb2 binds to the guanine nucleotide exchange factor, Sos, which activates ras-guanine triphosphatase (GTPase) activity. Activated ras stimulates the MAPK pathway by recruiting Raf to the plasma membrane, where it is activated by another, unknown signal from the Tyr kinase. The MAPK pathway may be viewed as a model for a growing number of signal transduction pathways that have as their core three serine-threonine kinases that are sequentially activated; a serine-threonine protein kinase (MAPKKK) that phosphorylates and activates a dual specificity serine-threonine kinase (MAPKK), which phosphorylates and activates another serine-threonine kinase (MAPK).[10] In Figure 5-3, the Raf functions as the MAPKKK, and its activation initiates the signal cascade, phosphorylating and activating Mek, the MAPKK, which is a dual-specificity serine-threonine kinase that phosphorylates and activates extracellular signal-regulated kinases (ERKs), the MAPK.

Activation of transcription factors by extracellular signals can occur at the cell membrane, in the cytoplasm, or in the nucleus, but it is usually accompanied by a nuclear translocation step.[19] Primary substrates for the MAPK (i.e., ERK) are transcription factors such as Elk-1 or Sap-1. Elk and Sap are major regulators of the promoter region of the transcription factor Fos. Transcription factors act as homodimers or heterodimers and frequently as multiprotein complexes that coordinately regulate gene transcription. A number of transcription factors were originally identified as viral oncogenes (e.g., jun, fos, myc, myb, rel, and ets), and synthesis of their normal counterparts is part of the immediate or early response of cells to growth factor stimulation. Ultimately, these transcription factors participate in the regulation of genes controlling progression through the cell cycle, DNA replication, metastasis, angiogenesis, cell differentiation, and cell death.

## EPIDERMAL GROWTH FACTOR FAMILY

### Epidermal Growth Factor and Its Receptor

EGF was initially identified in extracts of murine submaxillary glands as a factor that promoted premature eyelid separation and tooth eruption by enhancing epidermal growth and differentiation.[20,21,22] and [23] Extensive studies documented its ability to stimulate epidermal cell proliferation in cell and organ cultures *in vitro*.[21] The human homologue was first characterized as a factor, urogastrone, that inhibited gastric secretion and stimulated the differentiation of rat and human intestine. Although EGF and urogastrone had seemingly different properties, amino acid analysis revealed that the factors were identical. [24] Mature EGF is composed of 53 amino acids and three internal disulfide bonds. It is derived by proteolytic cleavage from a precursor molecule of 120 amino acids that consists of eight EGF repeats and a hydrophobic carboxyl terminus. The EGF precursor molecule can be found as a glycosylated membrane–bound protein and may function as a juxtacrine growth factor.

The EGF family includes TGF-a, which is normally found in epithelial cells; amphiregulin, which is found in human placenta, ovarian, and breast tissue; neuregulin 1-3, which is detected in mammary tissue and Schwann cells; heparin-binding EGF-like growth factor (HB-EGF); and betacellulin, which is most highly expressed in lung, uterus, and kidney. EGF-induced crosslinking identified a 170-kd receptor that contains two extracellular cysteine-rich domains ( Fig. 5-3). Isolation of the gene encoding the EGF receptor (ErbB-1) and its use in low-stringency screening led to the identification of additional members of this family: ErbB-2, ErbB-3, and ErbB-4. EGF and TGF-a bind primarily to ErbB-1, causing receptor dimerization. Neuregulin 1-3 primarily binds to heterodimers of ErbB-3 and ErbB-4. Betacellulin and HB-EGF primarily bind to ErbB-1 and ErbB-4. ErbB-2 may be considered an orphan receptor as it has no known high-affinity ligand, although it does form heterodimers with ErbB-1, ErbB-3, and ErbB-4. Overexpression of ErbB-2 may lead to receptor dimerization of ErbB-2 in the absence of ligand and constitutive activation of the receptor. The structure of ErbB-3 lacks several highly conserved amino acid residues in its kinase domain, and it is unclear whether the receptor contains an intrinsic kinase activity. ErbB-3 may serve as a substrate for the ErbB-2 kinase activity in the heterodimer and provide docking sites for downstream SH2 domain-containing signal transduction intermediates. Some experiments indicate that a kinase-negative mutant of ErbB-1 is capable of activating the MAP kinase pathway, but is not able to induce phosphorylation of GTPase-activating proteins. [25] Studies in the fruit fly indicate that the principal EGF signaling path is EGFR>Grb2>SOS>RAS>RAF>MEK>MAPK > nucleus.[25] Relevant properties of some members of this family are summarized in Table 5-1.

### Role of Epidermal Growth Factor Family in Cancer

High levels of EGF, TGF-a, and their receptors have been reported in glioblastoma and head, neck, breast, and bladder cancer tumor specimens, and an autocrine mechanism of growth has been observed in several of these tumor cell models.[26] High levels of HER2/neu (ErbB-2) with or without gene amplification are found in ductal carcinoma of the breast squamous cell carcinomas of the lung and most adenocarcinomas of the lung. [27] In breast and lung cancer, high-level expression is associated with shorter overall survival, and in breast cancer, it also correlates with a shorter relapse-free survival and a failure to respond to hormonal therapy. [28] In neuroblastoma (NB), the median survival of patients whose tumors stained with HER2/neu antibodies was 12 months, whereas those whose tumors were negative survived 138 months.[29]

As single agents, several monoclonal antibodies against EGFR produce a tumorstatic response in mice xenograft models, whereas in combination with chemotherapeutics and cytokines such as tumor necrosis factor-a (TNF-a), the response is tumoricidal. Inhibition of the EGF signal transduction path decreases cell proliferation, and, in some cell types, this is accompanied by the induction of apoptosis. Furthermore, some studies indicate that anti-EGFR antibodies decrease pro-angiogenic factors in tumor cells[30] and inhibit metastases.[31] Selected radiolabeled anti-EGFR and anti-HER2/neu antibodies (e.g., MAb4D5) are under clinical evaluation as imaging agents and for their antitumor activity. [30] Trastuzumab (Herceptin) is a humanized monoclonal antibody against the EGFR that has been in clinical trials primarily in patients with ErbB-2 over-expressing breast cancer. A 24% partial and complete remission was seen in patients without prior chemotherapy compared to a 11% to 14% response in patients receiving chemotherapy. Patients receiving Trastuzumab and chemotherapy have a 24% reduction in risk of death as compared to those receiving standard chemotherapy.[32]

## FIBROBLAST GROWTH FACTOR FAMILY

### Fibroblast Growth Factors and Their Receptors

Basic fibroblast growth factor (bFGF) was originally identified in extracts of pituitary cells on the basis of its ability to stimulate fibroblast and chondrocyte cell proliferation.[33] Properties of FGFs are summarized in Table 5-1. The ability of FGFs to bind heparin facilitated their purification and identified other members that were also known as heparin-binding growth factors.[34,35] Because monomeric FGF interacts with the receptor, heparin induces oligomerization of FGF, leading to FGF receptor (FGFR) dimerization and activation.[36]

There are nine members in the FGF family: acidic FGF (aFGF or FGF-1), bFGF (or FGF-2), int-2 (FGF-3), hst/KS3 (FGF-4), FGF-5, FGF-6, keratinocyte growth factor (KGF or FGF-7), androgen-induced growth factor (AIFG or FGF-8), and glia-derived growth factor (GAF or FGF-9). FGFs stimulate the growth of cells of mesenchymal, neuroectodermal, and epidermal origin, and many stimulate angiogenesis. bFGF and aFGF, derived from an acid extract of bovine brain, are single polypeptide chains of 17 kd that share approximately 55% amino acid sequence homology. These peptides bind glycosaminoglycans and are highly concentrated in extracellular matrix. FGF-2 was originally identified as int-2, a common integration site for mouse mammary tumor virus. Normal expression of int-2 is limited to embryonic tissues, but in int-2 transgenic mice, females have mammary gland hyperplasia and males have benign prostate epithelial hyperplasia. [37] FGF-4 was first identified as an oncogene from a human stomach tumor (hst) and a Kaposi's sarcoma (KS3).[38] FGF-5 was identified as a transforming gene caused by the insertion of a retroviral promoter upstream of its own promoter and leading to a constitutive gene transcription. [39] FGF-7 or KGF is unique among the members of this family, because it stimulates keratinocyte cell proliferation but not fibroblast or endothelial cell proliferation. Analysis of the FGF-7 gene placed it in the FGF family; it had 38% amino acid homology with aFGF and bFGF. It is highly expressed by stromal cells and may be an important regulator of epithelial cell proliferation. [40]

There are four major FGF receptors (FGFR-1 through FGFR-4) and a number of receptor isoforms that are generated by differential messenger RNA (mRNA) splicing (Fig. 5-3).[41] Cell- and tissue-specific RNA processing in the regions encoding the three extracellular Ig-like disulfide loops leads to variant FGFRs with differences in receptor binding activity and specificity. FGF stimulation of an FGFR carrying a mutation in Tyr766 fails to bind PLC-g and stimulate hydrolysis of phosphatidylinositol or increase $Ca^{2+}$ mobilization; however, disruption of this signaling pathway does not prevent FGF-induced mitogenesis. [42]

### Role of Fibroblast Growth Factor Family in Cancer

The products of hst/KS and fgf-5 members of the FGF family were identified by their ability to transform NIH-3T3 cells, and int-2 is implicated in mouse mammary tumor virus–induced murine mammary tumors. Overexpression of bFGF is also capable of transforming cells. When an Ig signal sequence was linked to the bFGF, the transforming ability was dramatically increased, suggesting that altering bFGF to a secreted form may be transforming in itself. The products of hst/KS, fgf-5, and int-2 all contain signal sequences and are more likely to be secreted. [42,43 and 44]

The finding of FGFs in normal brain tissue led to analysis of their expression in tumors. FGFs are expressed in human gliomas, astrocytomas, and glioblastoma multiforma.[45,46 and 47] Increased expression of an alternatively spliced variant of FGFR-1 and decreased expression of FGFR-2 is detected in more malignant astrocytomas compared with lower-grade tumors or normal cells.[48] Antisense oligonucleotides to FGF inhibit the growth of transformed astrocytes or glioblastoma cells, indicating an FGF-mediated autocrine growth mechanism and identifying a potential therapeutic target. [49,50]

FGFs may contribute to oncogenesis by their ability to stimulate tumor angiogenesis. Tumor angiogenesis appears to be a key feature in the development of solid tumors. Both aFGF and bFGF are potent stimulators of angiogenesis in various *in vivo* assays.[51,52] *In vitro*, FGFs are capable of acting as mitogens and chemotactic factors for endothelial cells and stimulating protease secretion from these cells, which may also be important in tumor angiogenesis and tumor metastasis. [53] The inhibition of FGF-induced tumor angiogenesis may provide a new target for anticancer therapy.

## INSULIN-LIKE GROWTH FACTOR FAMILY

### Insulin-Like Growth Factors and Their Receptors

IGFs were first identified as serum factors, named *somatomedins*, that interacted with growth hormone to stimulate skeletal tissues. [21,22 and 23,51,54] Somatomedin C is now called *IGF-1*, and multiplication stimulating factor is referred to as *IGF-2*. IGF-1 and IGF-2 are 7.5-kd, single-polypeptide chains, sharing 48% and 50% amino acid homology with insulin, respectively. Both IGFs share 70% amino acid homology and are synthesized as prepropeptides whose carboxyl-terminal amino acids are cleaved to yield a 70 amino acid acidic basic IGF-1 protein and a 67 amino acid basic IGF-2 peptide. [55]

IGF-binding proteins (IGFBPs) are a family of proteins that bind to IGFs with high affinity and specificity and are involved in the vascular transport of IGF. IGFBPs modulate IGF interaction with receptors and regulate IGF growth-promoting activity. At least six distinct proteins (IGFBP-1 through IGFBP-6) have been identified and cloned.[56] IGFBP-4 enhances IGF proteolysis, and IGFBP-5 prevents degradation. IGF-1 and IGF-2 predominantly circulate as a complex with IGFBP-3 and an acid-labile glycoprotein. IGFBP-3 may inhibit or stimulate growth *in vivo* and *in vitro*. However, proteolytic cleavage results in IGFBP fragments with decreased binding affinity for IGFs. This serves to regulate free IGF and IGFBP levels in serum and tissues. IGFBPs may also affect cell function independent of IGFs and IGF receptors.

Three membrane-bound receptors bind IGFs: the insulin receptor (IR), the IGF-1 receptor (IGF-1R), and the IGF-2 receptor (IGF-2R). [57] The IR and IGF-1R are structurally related, membrane-bound Tyr kinase receptors. They have a unique heterotetrameric structure composed of two disulfide bounded alpha chains, containing the ligand-binding domain, that are linked by two disulfide bonds to two transmembrane beta chains that contain the intracellular kinase domain ( Fig. 5-3). The IGF-1R binds IGF-1 with the highest affinity, followed by IGF-2 and insulin. [58] The IGF-2R is a transmembrane protein with a short cytoplasmic region and is homologous to the mannose-6-phosphate receptor. The IGF-2R binds both IGFs, but not insulin. Evidence links IGF-2R to a G-coupled receptor signaling system. [59]

Unlike other Tyr kinase receptors, the IGF-1R exists in the membrane as a heterodimer. Ligand binding is thought to cause a conformational change in the dimeric receptor that initiates signal transduction. [60] Key to IGF-1R signal transduction is the phosphorylation of the IR substrate-1 (IRS-1), which contains more than 50 potential Tyr, threonine, and serine phosphorylation sites that, when phosphorylated, mediate interactions with a number of signaling intermediaries. Phosphorylated IRS-1 binds and activates PI-3 kinase and binds Grb2, linking IGF-1R to the ras-raf signaling pathways. In quiescent fibroblasts, IGFs induce immediate early gene transcription (e.g., fos and myc) in early $G_0/G_1$ and make cells competent to progress through the cell cycle after stimulation with platelet-derived growth factor (PDGF) in late $G_1$.[61] Antibodies to ras but not to other G proteins alter IGF function in late $G_1$ but not in early $G_0/G_1$, indicating that the ras pathway mediates a cell's competence to enter S phase.[62]

IGFs are mitogenic in a variety of physiologic conditions, including compensatory organ hypertrophy, nerve regeneration, and wound repair. [63,64,65 and 66] IGFs act synergistically with other growth factors to stimulate DNA synthesis. [64,67] IGFs induce differentiation in myoblasts, chondroblasts, osteoblasts, and neuroblasts and can rescue c-*myc* overexpressing cells from programmed cell death under certain conditions. [68,69 and 70] IGFs also stimulate cell motility.[71,72] IGF-1 appears to mediate the action of growth hormone on skeletal cartilage formation. Because high levels of IGF-2 have been found in cerebrospinal fluid, there may be a role for it in the central nervous system.[73] IGF-1R knockout mice ($IGFR^{-/-}$) are only 30% the size of their normal litter mates, indicating a role for signals mediated by IGF-1R in embryonal growth.[74] Fibroblasts derived from these $IGFR^{-/-}$ mice grow slower in culture, with all phases of the cell cycle protracted. $IGFR^{-/-}$ fibroblasts are unable to grow in serum-free medium, even if supplemented with other growth factors; however, re-introduction of IGFR into these cells by gene transfections renders them sensitive to growth factor stimulation. The IGFR is necessary for cells to be competent to proliferate. [75]

### Insulin-Like Growth Factors and Cancer

Many human tumors have increased IGF-1 ligand or receptor expression, suggesting an autocrine or paracrine role in their growth or survival. These tumors include breast carcinomas, colon carcinomas, hepatocellular carcinomas, lung carcinomas, liposarcomas, and pancreatic carcinomas. [76,77,78,79,80 and 81] Overexpression of IGF-2 mRNA has also been found in breast and colon carcinomas, leiomyosarcoma, pheochromocytoma, hepatocellular carcinoma, Wilms' tumor, NB, and rhabdomyosarcoma.[82,83,84,85,86 and 87] Prostate-specific antigen (PSA) is an IGFBP-3 protease.[88] IGFBP-3 fails to inhibit IGF-1–stimulated growth of prostatic epithelial cells if cultured in the presence of PSA.[89]

IGF-2 may play a role in several pediatric tumors, including Wilms' tumor, rhabdomyosarcoma, and NB. Wilms' tumors express high levels of IGF-2 mRNA, and a blocking monoclonal antibody to the type I receptor (aIR-3) inhibits the growth of tumor heterografts in nude mice. [90] The Wilms' tumor suppressor gene, WT1, is a DNA-binding, serine- and proline-rich, $Zn^{2+}$-binding transcription factor that recognizes several DNA sequences, one of which is a specific binding site for members of the early growth response family of transcriptional activators. [91] Consistent with its role as a suppressor factor, WT1 represses the activity of the IGF-2 promoter and the IGF-1R promoter.[91,92] WT1 mutation, deletion, or underexpression in Wilms' tumor may result in increased expression of the IGF-2/IGF-1R signal transduction pathway. Rhabdomyosarcoma cell lines secrete IGF-2 and grow in serum-free media. The growth of rhabdomyosarcoma cell lines is inhibited by aIR-3. [72] IGF-2 is uniformly expressed by rhabdomyosarcoma tumors, suggesting an autocrine growth loop in most of these tumors.[93] Normally, the IGF-2 gene is silent or imprinted at the maternal allele. In Wilms' tumor and rhabdomyosarcoma, however, evidence indicates that imprinting has been lost, and this may also contribute to the overexpression of IGF-2 in these tumors.[94,95] Although an autocrine role for IGF-2 has been identified in an NB cell line, subsequent studies in tumor tissue rarely detected IGF-2 expression in tumor cells. In most NB tumors, IGF-2 expression was detected in stromal tissues, suggesting a possible paracrine role for this growth factor in NBs growth or survival.[88,89]

Known oncogenes, such as SV40 large T and activated ras, fail to transform fibroblasts from $IGFR^{-/-}$ animals, indicating that the expression of an oncogenic protein alone is not sufficient to transform cells. Transfection of IGFR into $IGFR^{-/-}$ fibroblasts restores the transforming activity of these oncogenes. The necessity of upstream signals, such as IGFs, to induce tumors indicates that IGFs, perhaps by their overexpression, can act as tumor promoters. The concept of IGF-2 acting as a tumor promoter has also been proposed based on studies of transgenic mice that overexpress IGF-2 at puberty. After a long latency period, these mice have a high incidence of hepatocellular carcinoma, sarcomas, and lymphomas, suggesting a role for IGFs as a tumor progression factor. [96]

## PLATELET-DERIVED GROWTH FACTOR FAMILY

The platelet-derived growth factor (PDGF) family is composed of PDGF-A and PDGF-B, vascular endothelial growth factor (VEGF), vascular permeability factor, colony-stimulating factor-1, and SCF. There is limited sequence homology among these peptide factors, and their assignment in this family is based predominantly on the structure of their receptors. Their receptors contain five Ig-like extracellular domains and an insert in their Tyr kinase domain ( Fig. 5-3).

### Platelet-Derived Growth Factor and Its Receptor

PDGF was originally identified as a mitogen derived from platelets that stimulated cells of mesenchymal origin. It consists of two heat-stable polypeptide chains designated A and B that are found as heterodimers or homodimers.[97,98] The PDGF receptors (PDGFRs) are encoded by two distinct genes, alpha and beta, which can also form homodimeric or heterodimeric receptors.[99,100] Ligand specificity is determined by the type of homodimeric or heterodimeric receptor formed; A chains bind only a-PDGFR, and B chains bind a-PDGFR or b-PDGFR. The response to PDGF depends on the isoform of PDGF and on the number of a-PDGFR and b-PDGFR on the responding cell.[101]

The intracellular portion of the b-PDGFR contains at least nine identified autophosphorylation sites that, when phosphorylated, bind distinct SH2-containing proteins (Fig. 5-4). Differences in signal transduction have been observed between aa-PDGFR and bb-PDGFR homodimers that may be due to the differential ability of the cytoplasmic domains to bind intermediary signaling proteins. PDGF-AB induces ab-PDGFR heterodimers and a stronger mitogenic response than detected in homodimeric receptors. This action is due to a unique autophosphorylation site found in the heterodimeric receptor that may interact with additional signaling intermediaries.[102] PDGFR binds the SH2 domain of a protein Tyr phosphatase protein (SH-PTP2), and this may bind Grb2 and mediate activation of ras. Evidence also links the PDGFR to activation of an Akt serine-threonine kinase.[17]

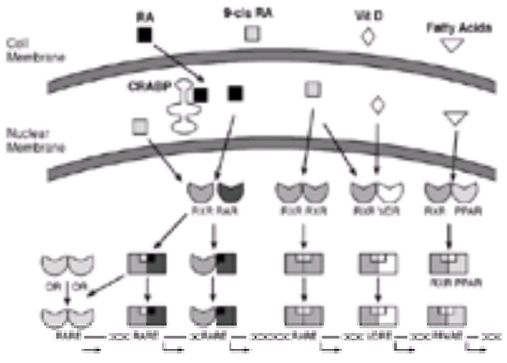

**FIGURE 5-4.** Schematic of cytoplasmic and nuclear receptor regulation of gene transcription. Free hormone or protein-bound hormone (not pictured) transverses the cell membrane, where it interacts with cytoplasmic binding proteins (CRABPs) that may regulate transport or metabolism or nuclear hormone receptors. Retinoic acid receptors (RARs), retinoid X receptors (RXRs), vitamin D receptors (VDRs), thyroid receptors, peroxisome proliferator receptors (PPARs) and orphan receptors (ORs) are depicted by the circular symbols; on dimerization and ligand binding, the receptors are capable of recognizing and complexing with specific response elements (REs) in the promoters of genes. RARE, retinoic acid response element. (Adapted from Pfahl M. Signal transduction by retinoid receptors in skin. Pharmacology 1993;6:8.)

SCF, which is also known as *steel factor*, *Kit ligand*, or *mast cell growth factor*, is a secreted and membrane-bound glycoprotein dimer with a molecular weight of 70,000 to 90,000 that plays a role in hematopoiesis, melanogenesis, and gametogenesis. Its receptor is c-kit, a Tyr kinase. Alterations in SCF, which maps to the murine Sl or steel locus, or c-kit, which maps to W or the white-spotted locus, cause defects in murine coat color. C-kit is the normal homologue of the v-kit oncogene from a feline sarcoma virus, in which the transforming gene contains a deletion in a region that includes the transmembrane domain.[103]

### Platelet-Derived Growth Factor and Cancer

The gene encoding PDGF-B is the human homologue of the simian sarcoma virus oncogene, v-sis.[104,105] This finding was the first clue linking alterations in growth factors to tumor formation. Simian sarcoma virus can infect many cell types but only transforms cells that express PDGFR, suggesting that autocrine stimulation of cell proliferation is associated with transformation. The finding that overexpression of PDGF-B or c-sis also induces cellular transformation [106] led to several studies that identified high levels of PDGF-A chains in a number of human tumors, including osteosarcoma, melanoma, and glioblastoma.[107,108] and [109] In a study of 50 glioblastoma multiforme and anaplastic astrocytoma tumors, 26% of tumors evaluated had amplification of the a-PDGFR or EGFR genes, and an additional 14% had increased protein levels of these genes.[110] A subgroup of chronic myelomonocytic leukemia (CMML) was shown to contain a t(5:12)(q33;p13) involving the fusion of the b-PDGFR Tyr kinase domain to tel, a novel ets-like gene. It remains to be determined what role this chimeric receptor plays in CMML, or if it is involved in the progression of CMML to acute myeloid leukemia (AML).[111] In a subset of ovarian cancers, 10% contain amplification of a downstream effector of PDGF, the Akt serine-threonine kinase.[17]

Autocrine SCF/c-kit signal transduction pathways have been found to regulate the growth of NBs and glioblastomas.[112,113] The c-kit receptor is also highly expressed in some leukemias and may be associated with a myeloid phenotype. In adults with AML, c-kit expression is associated with a poor response to chemotherapy, but in children, expression of c-kit by AML blasts does not predict a poor response to chemotherapy.[114]

## NEUROTROPHINS AND THEIR RECEPTORS

Nerve growth factor (NGF) was first identified as a peptide that stimulated neurite extension in sympathetic ganglion cultures.[115] It is the prototype of the neurotrophin family of peptides that includes brain-derived neurotrophic factor (BDNF), NT-4/5, and NT-3. Neurotrophins encode proteins of 12 to 15 kd and are expressed in a wide variety of neuronal tissues and tissues (e.g., muscles) that require innervation. Neurotrophins stimulate the survival, maturation, and differentiation of discrete but sometimes overlapping populations of neurons and exhibit a developmentally regulated pattern of expression.[116]

The action of neurotrophins is mediated by the trk Tyr kinase receptors. The trk gene was originally isolated as a transforming gene from a human colon carcinoma. It was created by the fusion of the 5' region of the constitutively expressed tropomyosin gene to the Tyr kinase domain of a novel member of the receptor Tyr kinase family; hence, the acronym trk stands for tropomyosin receptor kinase.[117] *In situ* analysis of c-trk indicated that it was highly expressed in neuronal cells, and subsequently trk was identified as the Tyr kinase receptor for NGF. The trk Tyr kinase receptors consist of TrkA, TrkB, and TrkC and alternately spliced variants of TrkB and TrkC that lack the intracellular Tyr kinase domain. Neurotrophins activate Trks through ligand-stimulated receptor Tyr phosphorylation. The p140TrkA binds NGF and, weakly, NT-3. The p145TrkB is activated by BDNF, NT-3, and NT-4/5, and p140TrkC is activated by NT-3. Trk receptors are differentially expressed during development.[118]

Activation of Trk receptors can cause mitogenic signals in fibroblasts [119] or differentiation signals in neural cells.[120] Analysis of signal transduction pathways indicates that the growth-stimulating and differentiating responses induced by activation of Trk receptors involves PI-3 kinase, PLC-g, and ras activation.[121] All neurotrophins also bind to a pan-neurotrophin receptor, NGFR, that is a member of the death receptor family of receptors. Signals mediated by NGFR may be survival or cell death, depending on the cell type and whether Trk receptors are activated.

## TRK RECEPTORS AND CANCER

Oncogenic trk fusion genes are found in high frequency in medullary thyroid cancer but rarely in colon carcinoma, from which it was first derived.[117,122] Relatively high levels of TrkA mRNA and protein expression are detected in NB tumors from patients with a good prognosis, with little expression detected in tumors from patients with a poor prognosis.[123,124,125,126] and [127] Poor-prognosis, advanced-stage tumors primarily express TrkB mRNA and its ligand, BDNF.[128] Differential Trk expression may affect the biology of NB tumor cells with activation of TrkA, leading to growth arrest or apoptosis, whereas activation of TrkB stimulates cell survival, induces neurite extension, and increases cell invasiveness, a characteristic of metastatic cells.[124,129] It is possible that the differences in clinical course of NB patients reflect differences in the basic biology of the cell (i.e., a distinct lineage or maturation state) when tumorigenesis occurred.

Trk immunoreactivity is also detected in medulloblastoma, Ewing's sarcoma, peripheral neuroepithelioma, Wilms' tumor, rhabdomyosarcoma, and glioblastoma. [132,133] and [134] An analysis of medulloblastoma tumors indicates that some patients who had a longer disease-free survival interval expressed relatively high levels of TrkC mRNA and its ligand NT-3.[135] CEP-751, which interferes with the Trk signaling, inhibits the growth of NB and medulloblastomas in a pre-clinical mouse model. [136]

## GLIAL-DERIVED NEUROTROPHIC FACTOR/REARRANGED DURING TRANSFECTION TYROSINE KINASE

RET, which stands for rearranged during transfection, was a laboratory artifact in which lymphoma DNA rearranged during a transfection was found to transform NIH 3T3 cells.[137] Sequence analysis indicated that one of the rearranged genes, RET, was a membrane-bound Tyr kinase receptor. Many properties of RET are similar to Trk; both are highly expressed in neural cells and rearrangements of RET and Trk are frequent in papillary thyroid cancer and lead to kinase active receptors. Transfection of RET and Trk into fibroblasts triggers mitogenesis, but transfection into neuronal cells stimulates differentiation. [139] Studies using mutant RET genes in which the kinase is constitutively active have identified Shc, Grb2, and PLC-g as signaling intermediaries. [138]

Glial-derived neurotrophic factor (GDNF) is a RET ligand. [139] GDNF is a member of the TGF-b family of ligands. GDNF binds to GDNFR-a (GDNFR-a1 to 4), which is anchored in the membrane by glycosyl-phosphatidylinositol and is unable to signal on its own. GDNF activation and binding to RET requires GDNFR-a binding. The dependence of the GDNF/RET signal transduction path on the GDNFR-a accessory receptor is similar to the TGF-b signal transduction pathway except that RET is a Tyr kinase receptor. Other ligands utilizing the RET/GDNFR-a signaling path include neuturin, artemin, and persephin. [140]

Eighteen different mutations in five different codons of the RET gene are associated with the inheritance of multiple endocrine neoplasia type 2A (MEN2A), type 2B (MEN2B), and familial medullary thyroid carcinoma.[141,142] These syndromes are inherited endocrinopathies characterized by medullary thyroid carcinoma, and MEN2A and MEN2B may include pheochromocytoma and ganglioneuromas. Mutations in MEN2A occur in the extracellular binding domain, and a large number of mutations in MEN2B occur in the Tyr kinase domain. RET knockout mice have defects in kidney and enteric nervous system, and the pattern of RET expression in the developing mouse is consistent with the clinical manifestations of MEN2A and MEN2B. [143,144]

## TRANSFORMING GROWTH FACTORS AND THEIR RECEPTORS

TGF-b is the prototype of a family that includes activins and inhibins, bone morphogenic proteins, and müllerian-inhibiting substance whose transmembrane receptors contain an intrinsic serine-threonine kinase. [145] These peptides have membrane-bound receptors that are distinct from other growth factor receptors in that they have serine-threonine kinase activity. TGF-b is the prototypic multifunctional peptide growth factor, and TGF-b mediates wound healing, angiogenesis, and inflammation.[145,146] and [147] TGFs also regulate cellular proliferation, stimulating or inhibiting proliferation depending on the cell type. [145,146,147,148,149,150,151] and [152]

At least five separate forms of TGF-b (TGF-b1 through TGF-b5) have been identified. [153,154,155] and [156] TGF-b1 was initially purified from sarcomas and TGF-b2 was purified from various sources, including a human glioblastoma cell line. The multiple forms of TGFs suggest distinct regulatory mechanisms for expression and may allow a cell using this molecule to generate complex and variable signals, depending on the context of its expression. Inhibins and activins decrease follicle-stimulating hormone secretion from the pituitary, müllerian inhibitory substances affect sexual dimorphism, decapentaplegic gene complex functions as a pattern gene in *Drosophila*, and bone morphogenic proteins may represent the mammalian counterpart of decapentaplegic gene complex. TGFs are secreted in an inactive or latent form that cannot bind receptors. [157,158] and [159] Proteolytic cleavage or acid pH releases an active TGF-b dimer from the latent complex. [160]

Ligand binding studies have found that TGF-b binds three receptors: TGF-b-RI, -RII, and -RIII. Genetic studies indicate that TGF-b-RIII is not involved in the transduction of signals that inhibit growth, but it may sequester or clear bioactive TGF-b. [161,162,163,164] and [165] TGF-b-RII has an intrinsic serine-threonine kinase activity and exists as a dimer on the cell surface. In the absence of TGF-b-RII, TGF-b-RI cannot bind ligand. On binding ligand, TGF-b-RII recruits TGF-b-RI into the hetero-oligomeric structure, and the intrinsic kinase activity of TGF-b-RII phosphorylates a serine residue on a domain in TGF-b-RI called the *GS box*, leading to intracellular signal transduction. Because TGF-b-RI only binds ligand in the presence of TGF-b-RII, TGF-b-RI may also be viewed as the first substrate in the ligand-receptor signal transduction pathway. [166,167] and [168]

Smads were first identified in *Drosophila* (Mad = mothers against dpp) and *C. elegans* (SMA-2) and are the intracellular signaling intermediaries of the TGF-b-RI and TGF-b-RII signal transduction path. There are nine Smads that fall into three classes based on sequence similarity and function. Class I Smads (Smad1, 2, 3, and 5) and the class II Smad (Smad 4) are directly phosphorylated by TGF-b-RI. Upon phosphorylation, class I Smads translocate to the nucleus. Class II Smads may associate with Class I Smads to move to the nucleus. In the nucleus, either alone or complexed with other transcription factors, Smads regulate gene expression. Class III Smads (Smad6, 7) may act as negative regulators of the TGF-b signaling path. [168,169] The tumor-suppressing activity of the retinoblastoma protein and the growth-inhibiting activity of TGF-b1 appear to function through a common pathway. [170,171] and [172] Studies indicate that activation of the TGF-b signal transduction stimulates phosphorylation of cell-cycle cyclin-cdk complexes and induces p16, an inhibitor of these complexes. [172] “Crosstalk” among the TGF-b signaling path and other intracellular signaling paths, such as the ras and MAP kinase paths, may modulate functional responses to TGF-b in some cell types.

## TRANSFORMING GROWTH FACTOR b AND CANCER

TGF-b was initially identified by its ability to induce anchorage-independent growth in rodent fibroblast cell lines. In many human tumors, however, it is a failure to respond to the normal growth-inhibiting signal of TGF-b that may be a factor in the loss of growth control. Now there is strong evidence that TGF-b suppresses the growth of normal epithelial and lymphoid cells. [168,169,173,174,175] and [176] Aberrant TGF-b-RII genes have been identified in a large number of gastric carcinomas. [177] Alterations in TGF-b processing or in its signal transduction pathway may also contribute to the tumorigenic phenotype. A human lung carcinoma cell line, A549, only produces a latent, inactive form of TGF-b, but cell growth can be inhibited if treated with active TGF-b. [178] Further evidence supporting a role for TGF-b as a growth suppressor in human tumors comes from studies in which the anti-proliferative effects of antiestrogens on human breast cancer cell lines [179] or retinoids on promyelocytic leukemia cell lines or NB cell lines are associated with increases in TGF-b secretion and frequently with upregulation of its receptors. [180,181]

Ewing's sarcoma and related peripheral neuroectodermal tumors carry recurrent translocations involving the EWS gene on chromosome 11 to a member of the ets transcription factor family, most commonly FLI1 but also ERG, ETV1, E1A-F, or FEV on chromosome 22. Although the normal ets family genes stimulate TGF-b-RII transcription, the EWS–FLI fusion proteins suppress TGF-b-RII expression. Ewing's sarcoma tumors and cell lines express relatively low levels of TGF-b-RII, and reconstitution of the TGF-b–signaling path in Ewing's sarcoma cell lines suppresses tumor cell growth. This indicates that TGF-b-RII is a target of the EWS-ets fusion proteins and may be important in the genesis of Ewing's sarcoma.[182,183] In NB tumors, low levels of TGF-b-RIII have been reported in advance-stage NB tumors.[184] TGF-b is a potent regulator of bone formation, and, in a sampling of osteosarcoma, tumors that expressed high levels of TGF-b3 had a significant decrease in disease-free survival. [185]

Mutations in Smads have been identified in human cancers. The candidate tumor suppressor gene DPC4, which show loss of heterozygosity in almost 50% of pancreatic cancers, was found to encode Smad4.[186] A subset of sporadic colorectal cancers have mutations in Smad2. [187] Thus, loss of the TGF-b signal transduction path may be an important feature in the genesis of many types of human cancers.

## CELL CYCLE

Extracellular growth stimulating and inhibiting signals converge on a set of evolutionarily conserved enzymes that drive cell cycle progression. The cell cycle is functionally divided into four components; the DNA synthesis or S phase in which DNA is replicated, the mitotic or M phase in which duplicated chromosomes segregate and cytokinesis occurs, the first gap or $G_1$ phase between the end of M phase and the beginning of the S phase, and the second gap or $G_2$ phase between the end of DNA replication and the initiation of cytokinesis ( Fig. 5-1). Although the length of the S, $G_2$, and M phases are essentially comparable among cells, the length of $G_1$ is quite variable and accounts for the varying lengths in cell cycle doubling times for different cell types. A cell is said to be in $G_0$ if it is quiescent and withdraws from the cell cycle either permanently, as in the case of differentiated cells, or for an extended period, as in the case of memory B cells.

Two classes of proteins, cyclins and cyclin-dependent kinases (cdks, cdc), form complexes that serve as an engine driving the progression of the cell division cycle via sequential phosphorylation of target proteins. The cyclin-dependent kinase inhibitors (CKIs) regulate the activity of cyclin-dependent kinases and serve essentially

as a braking system for the cell cycle machinery. CKIs include members of the CIP/KIP family (p21, p27) and members of the INK4 family (p15, p16, p18, and p19). Although the steady-state levels of the various cdks and cdc are constant throughout the cell cycle, transcriptional and post-translational mechanisms variably regulate the levels of cyclin proteins at different stages of the cell cycle. Growth factors activate signal transduction paths, initiating a signaling cascade involving the ras and MAP kinase paths that cause increases in early response genes such as myc, fos, and jun that stimulate cyclin D expression. Cyclins D1 to 3 form complexes with cdk4, cdk6 and are active early in $G_1$. Cyclin E forms complexes with cdk2, is active in late $G_1$, and is considered essential for entry into S. Cyclin A expression peaks in S and forms complexes with cdk2, regulating cell cycle progression through S phase; whereas in $G_2$, cyclin A complexes with cdc2. Cyclin B expression peaks in M and forms complexes with cdc2 regulating the complex series of events needed for mitosis. To ensure that cyclins are present at a particular stage of the cell cycle, they are targeted for proteolysis by ubiquitin and the proteosome pathway. [188,189 and 190]

Cells require exposure to growth stimulatory factors only during the first two-thirds of $G_1$ during which time they become competent for DNA synthesis and no longer require growth factors for cell cycle progression. Cells that do not receive sufficient growth factor stimulation during this time, termed the *restriction* (R) *point*, exit from the cell cycle and either return to $G_0$ or commit to a differentiated state. The retinoblastoma protein, pRB, serves as the molecular switch controlling the $G_1$ R point transition.[191] Growth factor stimulation during $G_1$ leads to increases in cyclin D/cdk4 and cyclin D/cdk6 kinase activity followed by increases in cyclin E/cdk2 kinase activity that sequentially phosphorylate and inactivate pRB, thus enabling cell cycle progression. In the unphosphorylated state, pRB is active and binds a series of transcription factors (E2F1 to 5) preventing them from regulating genes needed for DNA synthesis such as thymidine kinase, DNAa polymerase, cyclin A, B, and cdc2. Although active pRB (hypophosphorylated) can bind E2F that is bound to the promoter regions of genes, Rb is thought to prevent gene transcription by recruiting co-repressors that have a histone deacetylase (HDAC) activity that causes a closed chromatin conformation and prevents access of RNA polymerase to the promoter regions of E2F target genes.[192,193]

Growth inhibitory signals, such as serum starvation or TGF-b, negatively regulate the cyclin-dependent kinase activity and impede cell cycle progression. Withdrawal of serum before the R point causes a decrease in cyclin D and an increase in the cdk inhibitor p27, which binds and inhibits cyclin E–dependent kinases causing a $G_1$ arrest. Activation of the TGF-b signal transduction path increases expression of the cdk inhibitor $p15^{INK4B}$. If $p15^{INK4B}$ binds cyclin D/cdk4 and cdk6 kinases and inactivates these kinases, cells arrest at the R point in $G_1$. If a cell has passed the R point, TGF-b cannot inhibit cell cycle progression. The effective concentrations of cdk inhibitors and active cyclin-dependent kinases determine whether a cell becomes competent to transit the $G_1$/S restriction point.

Another mechanism influencing cell cycle progression is control of genomic integrity. Checkpoints during $G_1$ and $G_2$ ensure that damaged cells or improperly replicated cells are either repaired or exit the cell cycle. Damage to the genome leads to the activation of ATM/ATR and DNA PK family of protein kinases that stabilize p53 levels. p53 levels increase and translocate to the nucleus where, as a transcription factor, p53 stimulates transcription of p21, a cdk inhibitor that inhibits cyclin-dependent kinases. p21 acts on both $G_1$ and $G_2$ cyclin-dependent kinases. Cells arrest until damage is repaired, or, if damage is irreparable, cells undergo apoptosis.[191]

**Cell Cycle Machinery and Cancer**

The loss of both alleles of the RB gene defined RB as the prototypic tumor suppressor gene in retinoblastoma. However in other cancers loss of RB function may be through point mutations, in consensus phosphorylation sites, and/or in the “RB pocket,” which binds the E2F transcription factors. In addition to retinoblastoma, osteosarcoma, Burkitt's lymphoma, and glioblastoma also have mutations in RB.[194]

The CDKN2A gene, which is frequently mutated in human cancer, gives rise to $p16^{INK4A}$ as well as $p16b^{ARF}$. Deletions, mutations, and transcriptional silencing are three mechanisms by which tumor cells functionally inactivate CDKN2A. Almost 100% of glioblastomas do not express p16 either through gene deletion or transcriptional silencing, whereas 65% of astrocytomas have mutations of deletions of CDKN2A.[195] In other pediatric solid tumors, reports of p16 loss vary, perhaps owing to the small sample populations analyzed in each study. Thirty-two percent of NB tumors have LOH at 9p involving the CDKN2A locus. Alterations in the p16 path may contribute to the progression of NB, as 72% of NB cell lines fail to express p16, with 40% of these having methylated promoters.[196] In a small analysis, five rhabdomyosarcoma cell lines and 3 of 12 tumors had homozygous deletions of CDKN2A (p16) and CDKN2B (p15) but not CDKN2C (p18).[197] Thirty percent of Ewing's sarcoma tumors and almost 50% of cell lines showed loss of p16 expression.[198] Deletions of the p15, p16 gene are one of the most common alterations in pediatric acute lymphocytic leukemia.[199]

Genetic alterations in CKI $p27^{kip}$ are rare. Low levels of $p27^{kip}$ expression were associated with a poor prognosis and a shorter median survival compared to aggressive colorectal carcinomas[200] and in breast cancer, prostate, non-Hodgkin's lymphoma, and lung cancer.[201] Systematic studies of p27 levels have not been reported for pediatric tumors.

**Therapeutic Strategies Aimed at Growth Factors, the Cell Cycle Machinery, and Their Signal Transduction Pathways**

As the participants in growth stimulatory signal transduction pathways have been defined, strategies to target and block the action of these proteins has led to the development of a new array of anticancer drugs. Similarly, drugs targeted at potentiating growth inhibitory or suppressing pathways have tremendous therapeutic potential (Table 5-3). Interruption of ligand-receptor interaction can be accomplished by ligand antagonists or antibodies against ligands or receptors. Peptide antagonists have been difficult to develop, but naturally occurring binding proteins, such as IBP-3, that binds IGFs can inhibit peptide activity.[56] Suramin is a polysulfonated napthylurea that interferes with the biologic activities of PDGF, FGF, TGFs, EGF, and IGFs.[202,203,204,205 and 206] Suramin is undergoing clinical phase I and phase II evaluations, and antitumor activity has been seen in treating prostate carcinoma, although the mechanism of antitumor activity is unknown. Although suramin has many activities that are unrelated to its ability to block growth factor activity, drugs based on suramin's chemical structure may be designed to specifically block growth factor activity. Pentosan polysulfate is a polyanionic compound that binds heparin-binding growth factors and has been shown to inhibit tumor cell growth *in vitro*.[207] Extensive preclinical studies identified antibodies to the EGFR or IGFR that are active in inhibiting growth of tumor xenografts.[30,90] Antibodies (Trastuzumab) to EGFR are active in breast cancer, especially in combination with chemotherapy.[32] Receptor-specific antibodies conjugated to radioisotopes have been used for imaging and targeted radiotherapy, and antibodies conjugated to recombinant toxins have tumoricidal activity.

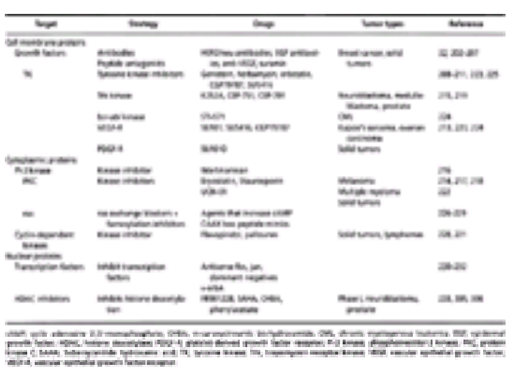

**TABLE 5-3. TARGETING SIGNAL TRANSDUCTION PATHWAYS**

Tyr kinase inhibitors target events at the initiation of signal transduction.[208] Natural products, such as genistein,[209,210 and 211] herbimycin,[212] and bryostatin[213,214] inhibit kinase activity. Genistein inhibits adenosine triphosphate interaction with Tyr kinase domains. Herbimycin A and simple benzoquinones inhibit Src, Bcr-Abl, EGFR, and HER2/neu Tyr kinase activity, presumably by targeting proteins for degradation. Some inhibitors selectively inhibit specific receptors, suggesting selective interference with receptor substrate interactions. For example, a K252A derivative selectively inhibits Trk but not EGFR Tyr kinase activity,[136,215] and wortmannin inhibits PI-3 kinase activity.[216] CGP 53716 inhibits PDGFR autophosphorylation, cellular Tyr, and c- *fos* induction but not similar activities stimulated by EGFR, IGF-1R, or FGFR. This compound also inhibits the growth of v-sis–transformed cells in *in vivo* xenograft models, but not tumors overexpressing EGFR.[217] Bryostatin is a natural product isolated from a marine organism that activates PKC and has broad antitumor activity *in vitro*. A number of these compounds are in phase I testing

(Table 5-3).

Many proteins reside in the cell membrane after posttranslational modifications involving myristoylation (i.e., addition of N-myristyl), palmitylation (i.e., addition of S-palmityl), or prenylation (i.e., addition of geranylgeranyl or farnesyl). [225,226 and 227] An exciting new group of drugs that interfere with protein lipidation have antitumor activity. Prenylation can occur on a protein containing a motif called the *CAAX box*, in which a cysteine is the fourth amino acid from the carboxyl terminus. The ras gene contains a CAAX box and requires farnesylation to function. The finding that oncogenic ras proteins lose their transforming capacity on deletion of the CAAX box led to the development of drugs that could inhibit farnesylation. These drugs mimic the CAAX peptide and, by inhibiting farnesyl transferase, they can inhibit tumor cell growth. The drugs have little activity against normal cell lines *in vitro* but can inhibit tumor growth in animal models.[225,226,227,228 and 229]

The ultimate convergence of signal transduction pathways is to activate transcription factors that regulate gene expression. Antisense nucleotide strategies targeted to promoters or coding regions of transcription factors have been explored primarily in *in vitro* studies.[230] Mutant proteins that interfere with wild-type proteins are called *dominant negative proteins*. One of the first described was v-erb, which produced a mutant thyroid hormone receptor that was capable of blocking the normal thyroid hormone receptor.[231] Dominant negative proteins of known transcription factors can block signal transduction at the level of gene transcription. [232,233]

A direct cdk inhibitor, flavopiridol [220] finished phase I clinical trials in adults with some activity in kidney cancer patients and limited toxicity. Flavopiridol in a phase II trial in patients with metastatic renal carcinoma had a 6% response rate, yet was considered ineffective at the dose and schedule administered. [221] Based on insights from the activity pattern of flavopiridol, the National Cancer Institute drug screen identified paullones, a novel class of small molecule inhibitors of cyclin-dependent kinases.[234] Because cyclin-dependent kinases are key to cell proliferation, the cyclin-cdk or -cdc interaction sites are being analyzed to rationally design drugs that specifically target this site and the protein's kinase activity. [235]

## NUCLEAR HORMONE SIGNAL

### Transduction Pathway

During development, the differentiation and function of many cell types is influenced by hormones, vitamins, and their metabolites and fatty acids. These molecules have nuclear or cytoplasmic receptors, as they do not require surface receptors to transverse the plasma membrane. The nuclear hormone receptors have a modular protein organization: a ligand-binding domain, a DNA-binding region that recognizes target sequences called *hormone-responsive elements*, a receptor dimerization domain, and a transactivation domain termed *AF2* whose protein interactions change upon ligand binding. [236,237] The hormone receptors for retinoic acid, vitamin $D_3$, thyroid hormone, and fatty acids use the retinoid X receptor (RXR) as a heterodimeric partner and bind direct repeat DNA sequences separated by one to five nucleotides (Fig. 5-4 and Fig. 5-5). These receptors bind to DNA in the absence of ligand and may act as repressors of gene transcription. Transcriptional control can act at several levels. Hormone receptors can interact directly with the basal transcriptional apparatus to control the rate of initiation by RNA polymerase II. Another level of regulation occurs through modifying local chromatin structure, thus controlling access of transcription components to the promoter sequence. Recently, a number of transcriptional regulatory molecules called *co-activators* (SRC, ACTR, pCIP, PCAF ) and *co-repressors* (mSin3A, mSin3B, N-CoR) have been found to bind hormone receptors. In the presence of ligand, co-activators bind to the AF2 region of hormone receptors. Co-activators, such as SRC-1 and ACTR, contain an intrinsic histone deacetylation (HAT) activity, whereas other co-activators may bind proteins that contain HAT activity. For some hormone-responsive genes, Creb-binding protein/p300 is recruited to the promoter by binding to the co-activator SRC-1. The ligand-bound nuclear receptor, co-activator, and CPB/p300 complex associate with RNA pol II and with several other accessory factors, to acetylate histones. This leads to a more open chromatin structure which promotes gene transcription (Fig. 5-5A). In the absence of retinoic acid, a co-repressor, N-Cor, binds nuclear hormone receptors, replacing SRC-1 and the associated Creb-binding protein/p300 and RNA polymerase II complex. N-Cor recruits mSin3 and HD1, an HDAC, which leads to deacetylated histones, chromatin condensation, and repression of transcription (Fig. 5-5B). Thus, in the presence of ligand, nuclear receptors switch from binding a protein co-repressor complex containing HDAC activity, which represses gene transcription, to a co-activator protein complex that contains HAT activity and activates transcription. [238]

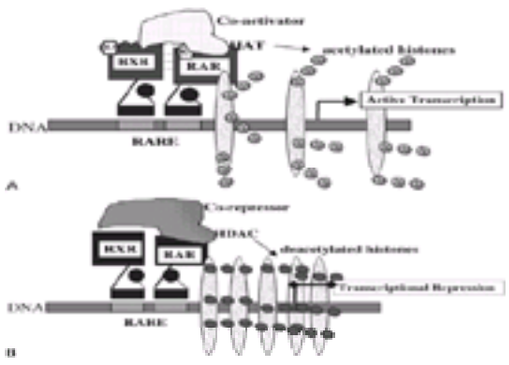

**FIGURE 5-5.** Transcriptional activities of nuclear hormone receptors. **A:** Nuclear hormone receptors upon binding ligand cause an allosteric change in receptor interaction that enables binding of co-activator molecules (such as SRC, ACTR) that may possess an intrinsic histone acetyltransferase activity (HAT) or bind other proteins that contain HAT activity. Acetylated histones lead to an open chromatin conformation that enables access of the basal transcription machinery and RNA polymerase II to the promoter regions. **B:** In the absence of ligand, nuclear receptors are bound by proteins called *co-repressors* (N-CoR, SMRT) that contain an intrinsic histone deacetylase activity (HDAC) or bind other proteins that contain HDAC activity. Deacetylated histones lead to a more closed chromatin conformation and repress transcription. RA, retinoic acid; RAR, retinoic acid receptor; RARE, retinoic acid response element; RXR, retinoid X receptor.

### Retinoids

In the early 1920s, a deficiency in vitamin A, a retinoid derivative, was linked to cancer in rodents. [239] Animals are not capable of de novo synthesis of retinoids, and the primary dietary source is plant carotenoids. Carotenoids in the intestine are converted to retinal and retinol, and retinol is carried through the bloodstream to the liver, where it is stored or distributed by specific binding proteins to various tissues in which it is converted to retinoic acid. [240,241] Intracellular levels of retinoids may be affected by the presence of cytoplasmic retinoid-binding proteins. [242] Vitamin A is necessary for normal epithelial differentiation and limb morphogenesis. [243]

The activities of most retinoids are mediated by nuclear receptors that belong to the steroid hormone receptor superfamily. [244] The DNA sequences of the retinoic acid receptors (RAR)-a, -b, and -g are highly homologous, expressed in a wide variety of tissues, and bind retinoids with various affinities. [245,246 and 247] The RXR class of receptors also contains three subtypes (RXR-a, -b, and -g). The primary RXR ligand is 9- *cis*-retinoic acid.[248] All-*trans*-retinoic acid (ATRA) directly activates RAR and presumably activates RXR through its metabolism to 9-*cis*-retinoic acid.[264] All RAR and RXR subtypes contain multiple isoforms, leading to a great number of combinatorial possibilities by which retinoids may signal, distinguishing them from other hormone or vitamin receptors.

RAR and RXRs bind to DNA sequences called *retinoic acid response elements* that have been found in the promoter regions of the cellular retinoic acid-binding protein II and the RAR-b, laminin B1, and hoxA genes. In some cases, these retinoic acid response elements also contain sequences that are recognized by other transcription factors such as AP-1, a heterodimer of fos, and jun proteins. AP-1 is induced by activation of the PKC signal transduction pathway, growth factors, and the phorbol ester class of tumor promoters.[249] RAR-mediated inhibition of AP-1 activity may be a major mechanism by which retinoids block the action of tumor promoters such as phorbol esters.

### Retinoids and Cancer

The mechanisms by which retinoic acid controls cell growth, suppresses tumorigenicity, and induces differentiation or apoptosis in many tumor types are under investigation.[250] In NB and promyelocytic leukemia cell lines, retinoic acid inhibits growth and induces differentiation ( Fig. 5-6). Among the earliest changes observed in retinoic acid–treated tumor cells is decreased transcription of the oncogenes myc, myb, and cell cycle genes, [251,252 and 253] and induction of TGF-b and its receptors.[180,181] Retinoic acid–inhibition of the growth of the promyelocytic leukemia cell line, HL-60, depends on induction of TGF-b and its receptors and activation of

the TGF-b signal transduction pathway.[180] The differentiation of NB cell lines depends on the ability of retinoic acid to induce the TrkB receptor, and because many NBs constitutively produce the TrkB ligand, BDNF, this leads to the autocrine activation of this signal transduction pathway and neurite extension.[130] Thus, retinoids may exert their effects by activating genes that participate in signal transduction paths involved in the control of cell proliferation and induction of differentiation or apoptosis.

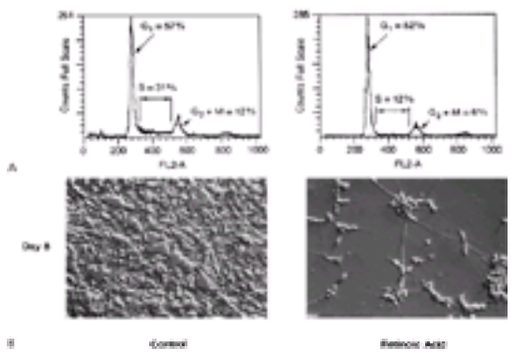

**FIGURE 5-6.** Retinoic acid treatment of a primary culture of cells from neuroblastoma tissue results in a decrease in cell proliferation and induction of morphologic differentiation. **A:** DNA content analysis, using a fluorescence-activated cell scanner of neuroblastoma cells treated with control solvent ( *left panel*) or 5mM RA (*right panel*). A decrease in the percentage of cells in S + $G_2$ + M (18%) is apparent in retinoic acid–treated cells compared with controls (43%). **B:** Dramatic morphologic differentiation induced by retinoic acid in some neuroblastoma cells.

The dermatologic use of retinoids led to studies of epithelial malignancies ( Table 5-4).[254,255] and [256] Isotretinoin (13-*cis*-retinoic acid) was given to patients with advanced squamous cell cancer or preneoplastic lesions, such as keratoacanthomas. Toxic effects included mild joint pain, nausea, headaches, and increases in serum triglycerides. Retinoids are effective in preneoplastic syndromes, such as cervical dysplasia, keratoacanthomas, oral leukoplakia, and papillomas of the bladder.[257,258,259,260,261] and [262] Among patients with xeroderma pigmentosum who developed skin tumors at a high rate, there was a 63% reduction in skin cancers during 13-*cis*-retinoic acid treatment. After cessation of retinoid therapy, the tumor frequency increased 8.5-fold over the previous reduced rate during retinoid therapy. Patients surgically rendered free of head and neck cancer are at high risk for recurrence and developing second tumors. Retinoid therapy reduced the incidence of second primaries (i.e., 12 in controls versus two in isotretinoin-treated patients) but had no effect on primary disease recurrence.[263,264] These studies are consistent with retinoids being effective as chemoprotective agents. A 5-year study of the use of beta-carotene to prevent basal cell and squamous cell cancers of the skin concluded that, in persons with a previous nonmelanoma skin cancer, treatment with beta-carotene does not reduce the occurrence of new skin cancers.[267]

| Tumor | Drug | Toxicity | Parameter | Reference |
|---|---|---|---|---|
| Squamous cell carcinoma | ATRA | Nausea, dry mucous membranes, joint pain, increased triglycerides | 45–83% response | 254, 268, 275 |
| Basal cell carcinoma (xeroderma pigmentosum) | 13-cis-RA | Same as ATRA | 63% reduction in new tumors | 253 |
| Head and neck cancer | 13-cis-RA | Same as ATRA | Prevents second primaries | 252, 254 |
| MDS | 13-cis-RA | Same as ATRA | 25% response | 261 |
| APL | ATRA | Nausea, dry membranes, headache | 67% complete remissions | 267–270, 278 |
| Neuroblastoma | 13-cis-RA | Cheilitis, fissured lips | 22% responses | 279 |
| Cervix | 13-cis-RA + IFN-α | 13-cis-RA toxicities | 50% response | 286 |
| Squamous cell | | Flu-like symptoms, fever, myalgia | 60% response | |
| Neuroblastoma | ATRA + IFN-α | — | Determine activity in selected pediatric solid tumors | 282 |
| Wilms', rhabdomyosarcoma | | | | |
| Neuroblastoma | 13-cis-RA | | Result: increased event-free survival | 283 |
| Solid tumors, breast, colorectal, prostate cancer | Vitamin D | Hypercalcemia | Disease | 295, 296 |
| Liposarcoma, solid tumors | EB1089 | Reduced hypercalcemia | Lipid accumulation in tumor and decrease in cell cycle proliferation | 300, 301 |
| | Troglitazone | — | | |

ATRA, acute promyelocytic leukemia; ATRA, all-trans-retinoic acid; IFN, interferon; MDS, myelodysplastic syndrome; RA, retinoic acid.

**TABLE 5-4. CLINICAL TRIALS USING DIFFERENTIATION AGENTS**

The ability of ATRA and 13-*cis*-retinoic acid to differentiate promyelocytic leukemia cell lines has been studied since 1980. At that time, 13- *cis*-retinoic acid, the only clinically approved retinoid, was beneficial only in isolated cases of patients with acute promyelocytic leukemia (APL).[268,269] A 1988 study reported that ATRA induced complete remissions in 90% of a group of patients with APL,[270] and confirmatory studies also extended this finding to pediatric patients with APL.[271,272] By progressively monitoring bone marrow cells, signs of differentiation were observed in the APL blast cells. APL is highly sensitive to induction chemotherapy with anthracyclines and ATRA. ATRA alone or in combination with chemotherapy improves the disease-free interval compared with chemotherapy alone (complete remission rates range from 72% to 95%) in patients with newly diagnosed APL.[273,274] Retinoid therapy seems to be active in APL patients whose tumor cells contain a t(15:17). The t(15:17) involves the disruption of the RAR-a gene on chromosome 17q21 and the pml (promyelocytic leukemia) zinc-finger transcription factor gene on chromosome 15, leading to a novel chimeric transcription factor, pml-RAR.[275,276] and [277] It is believed that the pharmacologic levels of ATRA relieves the transcriptional repression of the mutant pml-RAR transcription factor by recruiting co-activators with HAT activity to target genes.[278] Retiniod-resistant APL has been found to be sensitive to arsenic trioxide therapy, although the mechanism of arsenic trioxide action is unknown.[279]

In pediatric solid tumors, 13-*cis*-retinoic acid, ATRA, or 9-*cis*-retinoic acid have little activity in phase I trials.[280,281,282] and [283] However, ATRA administered on an intermittent schedule in combination with interferon-a2a has shown limited activity in a Wilms' tumor and NB.[284] For solid tumors, advanced-stage, rapidly progressing disease that has failed conventional therapy may not be the best setting in which to test differentiation agents such as retinoids. To this point, in a randomized trial (CCG-3891) of more than 434 children and adolescents with newly diagnosed Evans stage IV NB, it was shown that patients receiving post-consolidation therapy with high-dose 13-*cis*-retinoic acid achieved 46% 3-year, event-free survival compared to 29% in controls.[285]

## VITAMIN D

### Vitamin D and Its Receptor

Vitamin D is produced in the skin when sunlight or ultraviolet irradiation converts 7-dehydro-cholesterol into a precursor that is transported to the liver by specific binding proteins and processed to the active hormone, 1,25-dihydroxyvitamin D.[286] Vitamin D regulates calcium metabolism and stimulates bone, keratinocyte, and hematopoietic stem cell differentiation. The vitamin D receptors (VDRs) are expressed in a variety of tissues but may be more highly expressed in immature cells such as osteoblasts or crypt cells of the intestinal mucosa.[287,289] A mutation in the DNA-binding domain of VDR occurs in patients with vitamin D–dependent rickets type II, leading to hypocalcemia, rickets, and secondary hyperparathyroidism and elevated levels of vitamin D in plasma. VDR homodimers or heterodimers bind vitamin D response elements, which have been found in the promoters of the osteopontin and osteocalcin genes.[290] Like retinoids, the expression of a number of other genes may be indirectly increased (e.g., calbindins, c-fms, TGF-b, and c- *fos*) or decreased (i.e., c-*myc*, c-myb, colony-stimulating factor, and calcitonin) by vitamin D treatment.

### Vitamin D and Cancer

Vitamin D inhibits the growth and induces differentiation of a number of tumor cell lines *in vitro*. A number of metabolites and synthetic analogs of vitamin D (proposed to be named *deltanoids*) have been developed.[291,292] Clinically useful deltanoids retain their differentiating effects but do not alter $Ca^{2+}$ metabolism. Vitamin D analogs inhibit the growth and induce differentiation of NB,[293] osteosarcoma cell lines,[294] and human breast cancer cell lines. Clinical studies have been limited by hypercalcemia, but stabilization of disease in breast and colorectal cancers has been reported.[295, 296]

## FATTY ACIDS

### Fatty Acids and the Peroxisome Proliferator-Activated Receptors

Peroxisome proliferator-activated receptors (PPARs) are nuclear receptors that bind fatty acids as well as peroxisome proliferators, a group of chemicals that when fed to rodents cause hepatomegaly, peroxisome proliferation, and an increase in the capacity of peroxisomes to metabolize fatty acids. [297,298] PPARs heterodimerize with RXR and, like other nuclear receptors, bind to specific DNA sequences and activate gene transcription upon ligand activation. There are three PPAR receptors. PPARa is predominantly expressed in hepatocytes, cardiomyocytes, enterocytes, and proximal tubule cells of the kidney. Natural ligands are arachidonic acid–derived eicosanoids, and synthetic ligands include fibrates, drugs that are used in the treatment of hypertriglyceridemia. Activation of PPARa regulates oxidation of fatty acids and detoxification of xenobiotic compounds. PPARg is primarily expressed in adipose tissue and the immune system. PPARg activation drives adipogenesis and the expression of genes involved in the uptake, metabolism, and storage of fatty acids, such as lipoprotein lipase, acyl-coenzyme A synthase, and phosphoenol pyruvate carboxykinase. Natural PPARg ligands are arachidonic metabolites derived from the cyclooxygenase path, whereas synthetic ligands include thiazolidinediones (orally active antidiabetics agents) and certain non-steroidal antiinflammatory drugs. PPARd is ubiquitously expressed and may be involved in metabolism of high-density lipoproteins. Eicosanoids, ethylesters of palmitic and oleic acids are natural ligands of PPARd.

### Peroxisome Proliferator-Activated Receptors and Cancer

PPARg can arrest the growth and induce differentiation in adipocytes, fibroblasts, and muscle cells. [299] PPARg ligands, such as troglitazone, have been shown to inhibit growth or induce apoptosis, or both, in liposarcomas and breast and prostate cancer cells. Troglitazone was found to cause differentiation as assessed by a decrease in lipid accumulation, a more normal histology, and a decrease in a marker of proliferation in the liposarcomas patients [300]; PPARg agonists inhibited the growth of both androgen-dependent and -independent prostate cancer cells, causing a decrease in the production of PSA. Preliminary results from a clinical trial in patients with prostate cancer showed stabilization of PSA levels ( Table 5-5).[301]

| Drug | Trial | Mechanism |
|---|---|---|
| TNP-470 | Phase II: advance adult; phase I: solid tumors, lymphoma, acute leukemias | Inhibits endothelial growth |
| Thalidomide | Phase II: head and neck, ovarian, prostate, Kaposi's sarcoma; phase III: lung, prostate | Unknown |
| Squalamine | Phase II: non-small cell, ovarian; Phase I: advanced cancers | Inhibits sodium-hydrogen exchanger; NHE3 |
| Endostatin | Phase I: solid tumors | Inhibition of endothelial cells |
| SU5416 | Phase III: Kaposi's sarcoma, glioma, advance cancer; phase II: metastatic colorectal | Blocks VEGF signaling |
| SU6668 | Phase I: advanced cancer | Blocks VEGF, FGF, and PDGF signaling |
| Anti-VEGF antibody | Phase I: refractory solid tumors; phase II: renal cell cancer | Monoclonal antibody to VEGF |
| Interferon-α | Phase VIII | Inhibition of bFGF and VEGF production |
| EMD121974 | Phase I: patients with advanced/metastatic cancer | Blocks integrin present on cell surface |
| IFA | Phase I in combination with chemotherapy in solid tumors; Phase II: ovarian | Inhibitor of $Ca^{2+}$ flux |
| Marimastat | Phase II: lung, and breast cancer | Synthetic inhibitor of MMPs |
| Neovastat | Phase II: non-small cell lung cancer | Naturally occurring inhibitor of MMP |
| AG3340 | Phase III: non-small cell lung, hormone refractory prostate cancer; phase II: glioblastoma multiforme | Synthetic inhibitor of MMP |

bFGF, basic fibroblast growth factor; FGF, fibroblast growth factor; MMP, matrix metalloproteinase; PDGF, platelet-derived growth factor; VEGF, vascular endothelial growth factor

**TABLE 5-5. ANTI-ANGIOGENIC/METASTASIS THERAPY**

The action of PPARg may be cell type specific or influenced by other cellular alterations, or both. In colon cells, the activation of PPARg has been shown to inhibit growth[302] yet increase polyp formation in an animal model predisposed to colon neoplasia. [303] Furthermore, somatic mutations in PPARg have been detected in 4 of 55 sporadic colon cancers analyzed, and each led to aberrant PPARg function. [304]

## FUTURE THERAPEUTIC DIRECTIONS

The dramatic results achieved with retinoic acid and its associated mild toxicities indicate that differentiation therapy has come of age. With a further understanding of the mechanisms by which these agents work and the nature of the genetic lesions in cancer cells, we should be able to fully integrate differentiation agents into clinical use. Agents that only partially inhibit cell growth may be useful between cycles of chemotherapy if the associated toxicities are minimal and different from those of the cytotoxic drugs. The efficacy of cytotoxic drugs can be enhanced if used in combination with differentiation agents. Agents that induce partial differentiation may be useful if the affected tumor cells express new cell surface proteins that make them more sensitive to innate host defenses or applied immunotherapy. Differentiation agents alone or integrated with biologic response modifiers, chemotherapy, or radiotherapy can significantly amplify the available therapeutic strategies.

The development of nuclear receptor agonists that have better pharmacologic properties than their natural counterparts was the initial step in the development of transcriptionally based therapies. The finding that an inhibitor of histone deacetylation was active in a retinoic acid–resistant APL cell line [278] has led to the development of a number of drugs with similar activities that target transcription at a different level. A group of hybrid polar compounds has been shown to inhibit HDAC. Suberoylanilide hydroxamic acid is capable of significantly suppressing the growth of prostate cancer xenografts in nude mice with little side effects as measured by hematologic anomalies, body weight, and histology[305] and m-caroxycinnamic bis-hydroxamide–induced apoptosis in NB cells.[306]

## ANGIOGENESIS AND METASTASIS

Neovascularization plays a role during initial tumor growth and for the development of metastases. Blood vessels form via two distinct mechanisms: (a) vasculogenesis, which involves the differentiation of endothelial cells from mesodermal precursors., and (b) angiogenesis, which involves the generation of new vessels from preexisting ones. The process of angiogenesis occurs normally in adults during female reproductive cycles; repair, remodeling, or regeneration of tissues; and during wound healing.[307] A number of factors stimulate [e.g., VEGF, angiopoietin-1 (Ang-1), bFGF, PDGF, IGF-1, hepatocyte growth factor, matrix metalloproteinase (MMP), hypoxia-inducing factor, nitric oxide, and Eph ligands] or inhibit [e.g., interferon-a, -b, -g, angiostatin, thrombospondin, tissue inhibitor-2 of MMPs (TIMP-2), heparinases, interleukin-12 (IL-12), endostatin, plasminogen activator inhibitor, and Ang-2] angiogenesis. It is the net tumor cell and micro-environmental balance of these factors that ultimately regulates tumor blood supply. [308,309]

Mechanistically, the angiogenic cascade initiates when the concentration of pro-angiogenic factors in the environment activates receptors [e.g., VEGF interacts with VEGF receptor (VEGFR)] leading to vasodilatation, increases in vascular permeability, and endothelial cell proliferation ( Fig. 5-7). The increase in vascular permeability enables the extravasation of plasma proteins that form a primitive scaffold and degrade basement membrane proteins. Degradation of the basement membrane proteins enables endothelial cells to migrate to the scaffold and become incorporated into the growing vessel sprout. Proteinases of plasminogen activator, MMPs, and heparinases promote angiogenesis by degrading basement membrane proteins, whereas TIMPs interfere with the action of MMPs and plasminogen activator and inhibit angiogenesis. Once a path has been cleared, endothelial cells migrate to the angiogenic stimulus and proliferate, forming the growing vessel sprout.

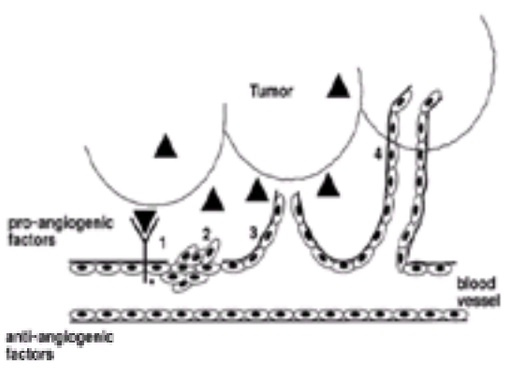

**FIGURE 5-7.** Schematic representation of the critical steps in the angiogenic process. In this model, a pro-angiogenic factor secreted by tumor cells interacts with ligand and activates the receptor tyrosine kinase (1), which leads to vasodilatation, an increase in vascular permeability, and endothelial cell proliferation. This leads to extravasation of proteins that form a primitive scaffold as well as degrade the basement membrane proteins (2). Endothelial cells migrate to the scaffold and form the growing vessel sprout (3), and the elaboration of proteinases enables the endothelial cells to migrate toward the pro-angiogenic stimulus and invade the tumor margins (4).

Metastasis is the process by which a tumor cell leaves its primary environment, enters the circulatory system, survives in the circulation, arrests in the microcirculation of a target organ, extravasates, and begins to grow in a new environment. Both autocrine and paracrine stimuli can provoke the metastatic process. The mechanisms fundamental to the metastatic process are also normal physiologic events that are important during development and tissue renewal. Adhesion, proteolysis, and migration are processes that are used by immune cells during wound healing, neurons during neuritogenesis, neural crest cells during embryogenesis, trophoblasts during endometrial implantation, and, as discussed previously, endothelial cells during angiogenesis. [310]

The first event in the metastatic process is for the tumor cell to lose cell-to-cell adhesive contacts and migrate to a vascular access site. Migration requires cellular motility and the ability to degrade via proteolysis the local stroma and basement membrane proteins. The second key event is vascular access, which requires adhesion to the outside of the vascular basement membrane, local degradation of matrix proteins, and migration through the basement membrane and between endothelial cells to enter the circulation. Once in the circulation, many patterns of dissemination follow circulatory flow, and studies using videomicroscopy have shown that the vast majority of cells arrest in the microcirculation due to capillary restriction. [311] Chemoattractant cytokines may also provide homing signals for metastasizing tumor cells and target tumor cells to various organs. Tumor cells tend to lodge in the first downstream capillary bed and extravasate shortly thereafter. The rate-limiting step in metastasis formation is growth after extravasation. Metastatic tumor cells in their new environment may proliferate and form new tumor foci, remain dormant for extended periods, or die. The processes of cell adhesion, proteolysis, and motility are key to metastatic spread and also play a role in angiogenesis. [310]

Cell adhesion is a process by which cells interact with their environment to facilitate migration or proteolysis and may involve homotypic (e.g., between tumor cells), heterotypic (e.g., between tumor and endothelial cells), and stromal interactions. Adhesion itself consists of attachment, spreading, and, in some cases, detachment. Cell-cell and cell-stromal interactions are mediated by a number of different type of receptors; integrins, laminin receptors, cadherins, cell adhesion molecules, selectins, and CD44. [310]

Proteolysis is the process of degradation of the extracellular matrix proteins of the basement membrane, and it requires the production, release, and activation of a number of different enzymes. Proteolysis is regulated by the presence of proteolytic enzymes as well as by the balance of activators and inhibitors of proteolytic activity. Major proteases and their inhibitors include: (a) plasminogen activators (serine proteases) and SERine protease inhibitors (SERPINS), (b) cathepsins (cysteine proteases) and cathepsin inhibitors, and (c) MMPs (require $Zn^{2+}$ for their activity) and the TIMPs. [310]

Motility is key to the process of metastasis and angiogenesis. Cellular locomotion requires the extension of a pseudopodia or invadapodia, membrane ruffling, attachment to extracellular matrix of the leading edge, and detachment from the extracellular matrix of the trailing edge. The dynamic polymerization and depolymerization of the cytoskeleton and filamentous actin enables the extension of invadapodia. Integrins play a key role in the attachment of invadapodia to the extracellular membrane proteins. Motility can be influenced by the directional movement of a cell toward a concentration gradient of a stimulus (chemotaxis), the random movement of the cell to the stimulus (chemokinesis), or the movement of a cell to an immobilized stimulus (haptotaxis). [310]

Angiogenesis and metastasis are inextricably linked. The following sections delineate some of the proteins that play a role in these processes.

### Vascular Endothelial Growth Factor and Its Receptors

Central to the process of angiogenesis is the family of VEGFs and their Tyr kinase receptors. [312] There are six members of the VEGF family of peptides that are secreted dimeric glycoproteins characterized by eight regularly spaced cysteines that form the cysteine knot; VEGF-B, VEGF-C, VEGF-D, the orf virus VEGF-E, and placenta growth factor (PIGF). VEGF stimulates endothelial cell survival, proliferation, migration, tube formation, and degradation of extracellular membrane proteins in *in vitro* systems while *in vivo* it also regulates vascular permeability. Alternative splicing of VEGF exons leads to $VEGF_{121}$ and $VEGF_{165}$ isoforms, which have different biologic properties. $VEGF_{121}$ does not contain a heparin-binding site and is freely soluble, whereas $VEGF_{165}$ is increasingly more basic and contains a heparin-binding domain that enables it to bind to cell surface heparin sulfate proteoglycans and remain more cell associated.

During development, VEGF is widely expressed and its activity is limited by the spatially restricted endothelial expression of its receptor VEGFR-2. Transcription of VEGF is stimulated by a number of growth factors and cytokines, including PDGF-BB, EGF, TNF, TGFs, and ILs. Tissue oxygen tension tightly regulates VEGF, as hypoxia rapidly and reversibly induces gene expression whereas normoxia decreases VEGF production. In adults, VEGF is expressed in brain, kidney, lung, liver, and spleen. PIGF was derived from placenta and is weakly expressed in lung and thyroid tissues. VEGF-B is most abundant in heart and skeletal muscle; EGF-C is expressed at low levels in the heart, placenta, ovary, small intestine, and the thyroid gland; and VEGF-D is most abundant in lung, heart, and skeletal muscle, the colon, and small intestine. [312]

The VEGFRs, VEGFR-1(Flt-1), VEGFR-2 (KDR/Flk-1), and VEGFR-3 (flt-4), consist of seven Ig-homology domains, a transmembrane sequence, and an intracellular split Tyr kinase domain. The second Ig domain of VEGFR-1 is crucial for VEGF binding, which leads to receptor dimerization and auto- or transphosphorylation. Neuropilin-1, a semaphorin/collapsin receptor involved in axonal guidance, has been identified to bind to some isoforms of VEGF and may enhance VEGFR signaling. In adult tissues, VEGFR-1 is expressed in vascular endothelial cells and binds VEGF, VEGF-B, and PIGF. VEGFR-2 is also expressed on vascular endothelial cells and binds VEGF, VEGF-C, and VEGF-D. VEGFR-3 is mainly expressed on lymphatic endothelium and binds VEGF-C and VEGF-D. [311,312]

### Tie and Eph Receptors

The Tie and Eph receptors are endothelial Tyr kinases that also play a role in the formation and maintenance of the vascular system. There are four known ligands; Ang-1 and Ang-4 bind to Tie-1 whereas there are no known ligands for Tie-2. Ang-2 inhibits Ang-1–dependent signaling. Typically, Tie-1 and -2 are expressed in the vascular endothelium and some hematopoietic progenitor cells. Like VEGFR, inhibition of Tie-2 has also been shown to inhibit angiogenesis and tumor growth. [311,312] and [313]

The Eph receptors are the largest family of Tyr kinase receptors and are thought to play key roles in developmental processes. The ligands of the Eph receptor, are membrane-bound proteins that are divided into two groups; Ephrin-A (EFNA), of which there are currently three identified proteins that are anchored to the membrane by a glycosylphosphatidylinositol link, and ephrin-B (EFNB), of which there are six factors that contain a transmembrane region. Receptors interacting primarily with EFNA are termed *EphA receptors*, whereas those interacting with EFNB are termed *EphB receptors*. Mice lacking EFNB2 and some double mutants lacking the EphB2 and EphB3 receptors die *in utero* due to defects in the vascular system. [314] *In vitro*, EFNB ligands can induce vessel sprouting comparable to Ang-1 and VEGF.

### Cellular Adhesion Receptors

Integrins are a large family of heterodimeric transmembrane cell surface glycoproteins that serve as the major receptors for extracellular matrix proteins and mediate cell adhesion, migration, cytoskeletal structure, angiogenesis, cell survival, proliferation, and differentiation. [315] There are 16 different alpha and eight beta chains that have been identified and a number of variants due to alternate splicing. The alpha-V integrins share a common alpha-V subunit of approximately 150 kd that associates with one of five beta subunits of 115 kd. The alpha-V integrins recognize an RGD amino acid motif that is found on a number of extracellular matrix proteins such as vitronectin, thrombospondin, fibronectin, type IV collagen, laminin, and fibrinogen. Integrin-mediated cell interactions involve interaction with other cell adhesion molecules such as cadherins, intercellular adhesion molecules, and leukocyte-expressed cell adhesion molecules.

Integrins do not possess an intrinsic kinase activity and are linked to the cytoskeleton via a complex of cytoplasmic proteins that includes talin, paxillin, a-actinin, vinculin, and focal adhesion kinase (FAK) ( Fig. 5-1). [316] Paxillin is a multifunctional adaptor protein that can bind intracellular Tyr kinases such as FAK, src, and crk.

The N terminal end of FAK binds to B integrins whereas its C terminal end is involved in focal adhesion targeting and paxillin interactions. The clustering of integrins and adhesion molecules after ligand interaction leads to focal adhesions and activation of FAK and increases in intracellular kinases. Additionally, FAK associates with several different intracellular signaling proteins such as Src-family protein tyrosine kinases, p130Cas, Shc, Grb2, and PI 3-kinase. [317] This enables integrin signaling to activate the ERK and MAP kinase paths as well as the G protein–dependent paths. [318]

Cellular adhesion molecules (CAMs) are transmembrane glycoproteins that are part of the Ig superfamily. These receptors do not possess intrinsic kinase activity, and associated kinase activity has not been reported to date. CAMs have been identified based on their tissue of origin; neural cell adhesion molecules, carcinoembryonic antigen, liver, vascular endothelial, and intercellular adhesion molecules. These molecules are important in mediating homotypic cellular interactions during development and, in the case of neural cell adhesion molecules, are important in neurite extension.

CD44 is a cell surface glycoprotein that also facilitates cell-cell and cell-substrate interactions. CD44 has a role in binding extracellular matrix hyaluronic acid, fibronectin, and collagens, and has a role in the catabolism and production of hyaluronan. [319,320]

Cadherins are transmembrane glycoproteins that mediate cellular interactions that are calcium dependent. Like CAMs there are several cadherins that are tissue related, and they are important in different cell types during development. The most widely studied cadherins are epithelial cadherins or E-cadherins. The extracellular membrane receptor contains a His-Ala-Val sequence and a $Ca^{2+}$-binding region that serves as the interaction site. Like focal adhesions and integrins, cadherins are linked to intracellular kinases of the src family. The intracellular portion of cadherin binds proteins such as a-, b-, and g-catenin and armadillo it to the cytoskeleton via a-actinin. E-cadherin function is frequently disrupted in cancer by alterations in b-catenin and the tumor suppressor adenomatous polyposis of the colon gene (APC), which regulates b-catenin levels. [321] E-cadherin–mediated cell-to-cell interaction results in contact inhibition, and loss of contact inhibition is a hallmark of epithelial tumor cells. Loss of E-cadherin function can occur through mutational inactivation of E-cadherin or b-catenin, transcriptional repression, or enhanced proteolysis. Phosphorylation of b-catenin and E-cadherins by src has been associated with decreased adhesiveness. [322]

**Angiogenesis, Metastasis, and Cancer**

Tumor cells have developed multiple mechanisms to stimulate angiogenesis. Malignant transformation of cultured cells is often accompanied by induction of VEGF. Oncogenic forms of ras and raf and mutated p53 upregulate VEGF mRNA. [323] Tumor cells can also induce stromal elements to produce VEGF. Increased VEGF mRNA expression can also occur in hypoxic conditions associated with uncontrolled cell proliferation. Conversely, tumor cells may also downregulate the production of angiogenesis inhibitors during their transition to the angiogenic phenotype. The net balance of inhibitors and stimulators of angiogenesis is thought to influence angiogenesis and tumor growth. [324]

Increased microvessel density is associated with poor prognosis in a number of cancers. There is an increase in microvessel density in brain tumors with an increasing grade of malignancy, [325,326] and microvessel density and VEGF expression also predict a poor prognostic subgroup in low-grade astrocytoma. [327] In NB tumors, tumor angiogenesis correlates with metastatic disease, Nmyc amplification, and a poor outcome. [328]

CD44 has been determined to be a poor prognostic marker in NB and correlates with Nmyc amplification. [329] In a small study of rhabdomyosarcoma tumors, however, CD44 was expressed in more favorable tumors. [330] Although a rigorous analysis has not been performed in brain tumors, high-grade gliomas expressed CD44 whereas meningiomas, medulloblastomas, and normal brain did not. [331]

The basic tenets of treating solid tumors with anti-angiogenic therapy arise from the observations that solid tumors will not grow beyond a few millimeters without new blood vessels, tumors are partially responsible for stimulating new vessel formation, and the endothelial cells that line the newly formed vessels express molecules distinct from those in mature vessels. Table 5-5 lists a number of clinical trials using anti-angiogenic approaches to cancer treatment. Current clinical studies are in adult patients; however, preclinical studies in pediatrics are promising. TNP-470 has been shown to inhibit the growth of small but not large NB tumors in an animal model. [332]

Clinical metastases present in several patterns: (a) the primary tumor and metastases are present at diagnosis; (b) metastases are present, but the primary tumor is occult; (c) only primary tumor is present at diagnosis but, after removal, metastases appear (within months to years), and (d) metastases disappear after removal of the primary tumor. Folkman has proposed that the majority of the presenting patterns of metastases may be influenced by the balance of angiogenic factors in the milieu of the metastases. [333] Angiostatin, a 38-kd fragment of plasminogen, is a potent anti-angiogenic factor that was identified while studying the ability of a primary tumor mass to inhibit the growth of remote metastases. Excision of the primary tumor led to the growth of distant metastases. This indicated that even though the primary tumor may secrete factors locally that stimulate angiogenesis and support its growth, it may also secrete into the circulation anti-angiogenic factors that suppress the growth of distant metastases. [334] Other anti-angiogenic approaches have centered on blocking pro-angiogenic signal transduction pathways. Antibodies to VEGFR, inhibition of VEGF, and bFGF production by interferons and, finally, blocking the VEGF, FGF, and PDGF kinase activity using small molecule inhibitors, such as SU5416 or SU6668, are in various stages of clinical trials in adult patients ( Table 5-5). [335]

Preclinical studies indicated that TIMPs block tumor cell invasion and metastasis. [336] Furthermore, in a transgenic animal overexpressing TIMP-1 in the liver, SV40 large T antigen–induced hepatocellular carcinoma development was blocked, indicating that proteolysis is important for the process of tumor initiation. [337] This has led to the development of a number of clinical trials using synthetic and natural inhibitors of TIMPs ( Table 5-5). It is unclear whether these approaches alone in humans will be as successful as they are in preclinical models. However such biologic approaches will amplify the number of strategies available to clinicians to use in combination with current cancer treatment modalities.

## APOPTOSIS

Apoptosis is an orderly, programmed, energy-dependent mode of cellular death that occurs in response to a variety of stimuli, including irradiation or chemotherapy, viral infection, growth factor or hormone withdrawal, and cytotoxic lymphocyte killing. Apoptotic responses to some of these stimuli are cell-type dependent. Cells dying by this mechanism exhibit characteristic morphologic (nuclear condensation and fragmentation, cell shrinkage, and relative sparing of the cellular membrane and internal organelles) and biochemical (DNA fragmentation and selected proteolysis) features. [338] Apoptotic cell death is a critical event in normal development and in normal tissue homeostasis, playing a role, for example, in nervous system development and in lymphocyte selection processes in the immune system.

A decrease in apoptosis tendencies also appears to be a key step in the development of tumors. An increase in tissue cell number is a pathognomonic feature of malignant growths, and for many years this abnormal cellular growth was attributed simply to an increase in cellular proliferation and dysregulation of the cell cycle. However, the discovery of the overexpression of the anti-apoptotic bcl-2 gene product in follicular lymphomas [339] raised awareness of the potential importance of decreased cell death in the process of tumor formation. Current concepts now suggest that the increased tissue cell number in tumors arises from a combination of increased cellular proliferation and decreased cellular death. The genetic abnormalities that increase cellular proliferation, such as loss of function of RB or overexpression of c-myc, also lead to increased apoptotic cell death. [340] Thus, for these pro-growth mutations to lead to a net increase in absolute cell number, additional mutations resulting in decreased cell death must occur for tumor growth to occur efficiently. Dysfunction of p53 or overexpression of bcl-2 are examples of genetic changes that could inhibit the death response initiated by c- *myc* overexpression or RB mutation. Subsequent genetic changes in these cells could then contribute to other phenotypic changes associated with tumors, such as invasiveness and metastasis.

In addition to pro-growth genetic changes providing a selection pressure for loss of apoptotic signals during tumor development, the tumor microenvironment can also provide a pressure favoring acquisition of antideath mutations. As the number of cells in a tumor mass grows, significant cellular stresses are usually present, such as hypoxia, intermittent oxidative stress, acid pH, and deprivation of nutrients and glucose. Growth of the tumor mass also results in cellular detachment from normal tissue basement membranes. Such microenvironmental stresses would normally be expected to kill the exposed cells. For a tumor mass to grow beyond a certain size, it must develop mechanisms to survive in such a harsh microenvironment. Similar to the mechanisms a developing tumor uses to survive the growth-promoting stresses discussed previously, mutations in death signaling pathways would allow the developing tumor to survive these microenvironmental stresses. Thus, mutations in survival signaling molecules or gene products involved the apoptosis machinery, and alterations in growth factor or cytokine exposure favors continued development of a tumor mass. Because the goal of anticancer therapies is to selectively kill malignant cells, these selection pressures to acquire antideath mutations also negatively impacts on the success of therapy (discussed in the section Therapy Aimed at Modulating Apoptosis).

## Mechanisms of Apoptosis

Clarification of the molecular events involved in cell death signaling pathways has advanced considerably in the past few years. Although it is almost certainly an oversimplification, there are now considered to be two major types of pathways involved in programmed cell death; those that involve signaling through the mitochondria and those that do not appear to involve mitochondria. As a generalization, stress-induced cell death, such as that initiated by chemotherapy or radiation therapy, involve signaling through mitochondria. The bcl-2 family of proteins are critical components of these signaling pathways. In contrast, cell death initiated by certain cytokines, such as TNF and related proteins, appears to occur by a different signaling pathway. It is noted that both pathways appear to converge on the same effector mechanisms of actually executing the cell through degradation of intracellular macromolecules, such as the DNA ( Fig. 5-8).

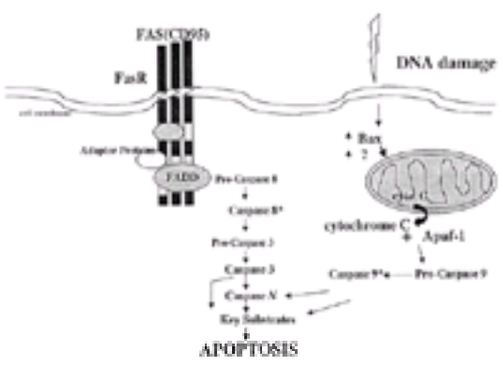

**FIGURE 5-8.** Schematic representation of critical steps in the current models of the two major apoptosis pathways. Cytotoxic stresses, such as that induced by DNA damage, result in the induction of the protein Bax and presumably other gene products. By mechanisms that remain poorly understood, cytochrome C is subsequently released from mitochondria into the cytosol where it associates with Apaf-1 and pro-caspase-9, the latter of which becomes cleaved and activated. Activated caspase-9 then activates caspase-3 and other effector caspases, resulting in destruction of cellular macromolecules, such as DNA, and cell death. The second pathway is initiated by death ligands binding to death receptors, exemplified by the Fas pathway. Binding of ligand to receptor at the cell surface results in recruitment of adaptor proteins (FADD in the case of Fas) that causes cleavage and activation of caspase-8. Activated caspase-8 then activates effector caspases, such as caspase-3, and the terminal phase of apoptosis is similar to that initiated by the cytotoxic pathway. Asterisks represent activation of caspases.

The first insight into control of apoptosis arose from identification of the anti-apoptotic gene, bcl-2, during the molecular characterization of the t(14;18) chromosomal translocation commonly seen in follicular lymphomas.[339] The follicular lymphoma model was that the abnormal lymphoid cells grow initially because of loss of cell death tendencies due to bcl-2 overexpression caused by the translocation of the bcl-2 gene from chromosome 18 to the actively transcribed Ig gene on chromosome 14 in B-lymphoid cells. At this point, such lymphomas are rather indolent, but are difficult to cure with chemotherapy. At some later stage, however, they develop other genetic changes and become more aggressive. A model has been proposed in which the bcl-2–like protein, bax, can drive the cell toward apoptosis when it forms complexes with itself.[341,342] If the bcl-2 protein is expressed at high levels, however, it can form a complex with bax, preventing bax homo-dimerization and inhibiting cell death. A family of other anti-apoptotic proteins with homologies to bcl-2 and bax, such as bcl-$x_L$ and mcl-1, have been identified.[343,344] The list of anti-apoptotic and pro-apoptotic gene products continues to grow, and it is suggested that members of this family of gene products related to bcl-2 interact with each other to influence apoptotic tendencies and that the utilization of a particular family member is a cell-type–dependent process.

Death of the cell during apoptosis is dependent on a series of highly regulated proteolytic cleavages that result in selected activation or inactivation of certain molecules and eventually result in the highly ordered internal destruction of the cell. The critical proteases involved are a family of cysteine-directed proteases, referred to as *caspases*.[345] After genotoxic damage, as would be induced by many chemotherapeutic agents, the release of cytochrome C from the mitochondria and its association with the Apaf-1 protein is a requisite event for cell death. [345,346] This release of cytochrome C appears to be dependent on the appropriate modulation of the activity of bcl-2 family members, which are localized in the mitochondrial membranes. [342,347,348 and 349] Once cytochrome C is released, this complex of cytochrome C and Apaf-1 combines with and initiates the specific cleavage of caspase-9, and activated caspase-9 initiates the cleavage of other specific caspases, such as caspase-3 (Fig. 5-8). These activated caspases then carry out the final steps of macromolecular destruction in the cell.

In addition to this pathway of cellular suicide initiated by genotoxic stress, a group of extracellular molecules can also act as death-inducing signals by interaction with selected cell-surface receptors (called *death receptors*). This process of cell death in this situation occurs via activation of a different caspase-dependent pathway, one that does not appear to be critically dependent on mitochondria ( Fig. 5-8).[342,350] In this scenario, a specific cytokine binds to its cognate receptor and the receptor undergoes a trimerization event and binds to adaptor proteins that ultimately activate caspase-8. This particular caspase does not require cytochrome C or Apaf-1 to activate downstream caspases, such as caspase-3, but the subsequent mechanics of macromolecular destruction can proceed more directly in a manner like that described above for the caspase-9–dependent pathway. Fas-ligand and Fas receptor are examples of an extracellular molecule and death receptor that initiate programmed cell death in this way, and this pathway appears to be particularly important in the regulation of cell death in lymphoid cells. TNF and the recently described TRAIL family[350] are additional examples of cytokines that act via this type of pathway. Although genotoxic stress and Fas- or TNF-induced cell death appears to primarily utilize two different signaling pathways, recent data have suggested that these distinctions are an oversimplification and that cross-talk between these pathways probably occurs.

## Apoptosis Modulation and Human Tumor Development

These apoptotic pathways do not operate in isolation in the cell. Other signaling pathways can influence the activation of one or more steps in apoptosis signaling. For example, growth factors, such as IL-3, which provide survival signals to cells, appear to act via modulation of one or more steps in these pathways. [349,351] One particularly interesting mechanism along these lines is the IL-3–induced phosphorylation of the pro-apoptotic protein, BAD, which causes the release of the anti-apoptotic protein, Bcl-$X_L$, promoting cell survival.[352] It is likely that mutations leading to activation or overexpression of growth factors or growth factor receptors in tumors arise because of their ability to inhibit death signals. This could include overexpression or mutation of EGF, HER2/neu, and IGF-1, all of which have been reported to be abnormal in multiple tumor types, including a number of pediatric malignancies. Similarly, mutation of gene products downstream of these receptor kinases (e.g., activation of Akt), can also be activated in tumors and provide similar anti-apoptotic signals. It is likely that certain chromosomal translocations found in pediatric malignancies fall into this category. It appears that the bcr-abl translocation found in Philadelphia chromosome–positive leukemias contributes to leukemia formation via its role as an anti-apoptotic signal. [353] Similarly, the E2A-HLF translocation found in the highly resistant pro-B cell leukemias appears to provide significant protection from apoptosis.[354] Similar findings are likely to be found in some of the specific translocations seen in sarcomas and other tumors in the pediatric population. Blockade of the survival signals resulting from overexpression or activation of these receptors or from these specific translocations is one potential approach to enhancing the efficacy of tumor therapies (see the section Therapy Aimed at Modulating Apoptosis).

p53 is the most commonly mutated gene in human cancers identified to date[355] and the propensity of human tumors to mutate p53 is likely due to its role in apoptosis signaling. In certain cell types, such as lymphoid cells, p53 is absolutely required for genotoxic stress, such as that induced by ionizing irradiation, to induce rapid apoptotic cell death.[356,357] However, p53 protein is not an integral component of the apoptotic machinery; rather, it signals to the apoptotic machinery. One mechanism by which p53 can influence apoptosis in certain cell types after certain stimuli appears to be via transcriptional induction of the bax protein. [358] However, p53 activation does not induce bax in many cell types and, even under the best of circumstances, bax is only partially responsible for p53-induced apoptosis. [359] It has been recently demonstrated that p53-mediated apoptosis is dependent on both Apaf-1 and caspase-3, [360] but how p53 activates these components of the apoptotic machinery remains unknown. One of major selection pressures for tumors to mutate p53 appears to be because of its critical role in hypoxia-mediated apoptosis. [361] Although the mechanism by which p53 causes apoptosis after hypoxia also remains to be elucidated, it has recently been suggested that it does not even involve transcriptional activation by p53.[362]

Mutations of p53 are relatively common in the majority of carcinomas found in adults, but most pediatric malignancies rarely mutate p53. [363] For example, p53 mutations are rare in acute lymphocytic leukemia, primary AML, and most of the embryonic tumors seen in childhood. However, p53 mutation can be seen in either

resistant variants of some of these tumors or after relapse. For example, p53 mutations rarely occur in T-cell leukemias at diagnosis, but they can be seen in relapsed cases, and these cases have very poor prognoses.[364] Although favorable-histology Wilms' tumor rarely, if ever, has p53 mutations, p53 mutation is associated with anaplastic Wilms' tumor.[365] It should also be noted that the p53 pathway can be inactivated by mechanisms other than p53 mutation, such as mdm2 overexpression or expression of certain viral gene products like human papillomavirus 16 E6.[366] Thus, some tumors can partially or totally inactivate p53 function even without mutating the gene itself. Mdm2 overexpression is found in some cases of osteosarcoma, and human papillomavirus is associated with cervical carcinomas.[367,368]

Mutations in proteins that are integral components of the apoptotic machinery appear to be less common than mutations in these “signaling” gene products. Bcl-2 overexpression occurs in follicular lymphomas and a smattering of other tumor types, but is not a commonly mutated gene in human cancers. Similar statements can be made about other bcl-2 family members, both pro-apoptotic and anti-apoptotic. There is little information implicating alterations in caspases themselves in tumorigenesis. In contrast, death receptor signaling pathways have been intensively studied in human tumors. For example, TNF receptor has been examined in human tumors, and there are many reports implicating Fas in apoptosis signaling after genotoxic stress and examples of alterations in Fas signaling pathways in tumor cells. Finally, the selective absence of “decoy” receptors for the death ligand, TRAIL, on malignant cells has led to significant interest in TRAIL-like compounds as a mechanism to selectively kill tumor cells.[350,369,370] In NB, any strategies aimed at targeting death receptors or compounds whose mechanism of action utilizes death receptors is compromised, as the caspase-8 gene is hypermethylated and not expressed in a number of NB tumors, particularly those that contain amplified Nmyc.[371] However, NB may be sensitive to ligands that activate death receptors if used in combination with compounds that would inhibit methylation or relieve transcriptional repression and induce caspase-8 expression.

### Therapy Aimed at Modulating Apoptosis

A major limiting factor for cancer cures at this time is the toxicity of chemotherapy and radiation therapy to normal tissues. The doses of current anti-neoplastic agents that would be required to kill resistant tumors would also lead to patient mortality. The selection pressures for loss of apoptotic pathways during tumor development only serve to make this selective killing of tumor cells with cytotoxic agents more difficult. Thus, the more we understand about the molecular and cellular differences between tumor cells and normal cells, especially with regard to survival and death signaling pathways, the more likely we will be able to achieve tumor cell selectivity. One can envision two primary ways to enhance tumor cell kill through modulation of apoptosis tendencies: Either the apoptotic machinery or survival signaling pathways could be targeted. Alteration of apoptotic tendencies with either of these approaches could then either be used in combination with cytotoxic agents to enhance tumor cell responses, or it is conceivable that they could enhance tumor cell death on their own without a requirement of an additional apoptosis stimulus.

In general, it is perhaps more difficult to selectively target the apoptotic machinery in tumor cells. If some functional aspects of a bcl-2 family member are altered, then it is likely that normal cells would also be affected. The same could be argued for direct modulation of caspases. However, because it is likely that tumor cells are more dependent on survival signals than normal cells, it is conceivable that direct inhibition of the apoptotic machinery could have a selective effect on tumor cells. As mentioned, there is also already significant interest in modulation of death receptor pathways because there is reason to believe that tumor-cell selectivity could be achieved.[350,369,370]

It is not difficult to envision how inhibition of signaling pathways, alone or in combination with cytotoxic agents, could lead to enhanced and more selective tumor cell kill. Development of a drug that inhibits the bcr-abl Tyr kinase in chronic myelogenous leukemia has already provided the proof-of-principle for selective inhibition of a chimeric protein resulting from a tumor-specific alteration.[372] It is likely that this inhibitor is working in chronic myelogenous leukemia because of its blockade of the anti-apoptotic effects of bcr-abl. Although it appears to have activity used as a single agent, it is quite conceivable that it will be even more effective in combination with cytotoxic agents. This synergy would be expected because the cytotoxics kill tumor cells by engaging the apoptotic machinery, and blockade of survival signals would theoretically make such agents more effective killers of tumor cells. Similar targeting of specific translocations in other tumors, most of which are found in the pediatric population, could similarly result in novel and effective approaches to treatment of a variety of pediatric tumors. Blockade of growth factor receptors, such as EGF, IGF-1, and HER2/neu, has also been shown to have clinical benefit, perhaps most dramatically in combination with other cytotoxic agents. Optimal utility of such inhibition in the treatment of pediatric tumors would require significant characterization of these various survival pathways in these tumors. Although some information exists, more complete characterization would be highly desirable for effective design of clinical trials using such inhibitors.

## SUMMARY

As we continue to learn more about intracellular signaling proteins and the mechanisms by which they regulate decisions of normal and tumor cells to proliferate, differentiate, stimulate angiogenesis, metastasize, or die, it is certain that new and improved therapies will be forthcoming. The complexities and intricacies of these processes may appear daunting, but unifying concepts should emerge. Like the development of multimodality treatments and combination chemotherapy, it may be necessary to use several of these compounds in conjunction, increasing therapeutic options.

# TUMOR IMMUNOLOGY AND PEDIATRIC CANCER

PAUL M. SONDEL
CRYSTAL L. MACKALL

## INTRODUCTION

The human immune system is a complex network of distinct cell types with remarkable and varied functions. Its mission is to maintain the physiologic and functional integrity of an individual by providing an anatomic and functional barrier to invasion by foreign, pathogenic organisms. Its hallmark is the ability to differentiate foreign from self and to remember that difference. An effective immune system eliminates the growth of invading foreign pathogens and prevents their entry when possible. Individuals who have inherited or acquired severe immunodeficiency are susceptible to potentially lethal infections that should have been controlled by the missing component of their immune system. Because fatal infection remains one of the more frequent terminal events for many children and adults who die of cancer or its sequelae, there is an important interface between clinical oncology and immunology.

This chapter delineates the molecular, cellular, and clinical interactions between the immune system and neoplastic disorders. It focuses on the cells of the immune system and their functions, with specific emphasis on abnormalities that are particularly relevant to children with cancer. These include immune dysfunction leading to or found at the time of cancer diagnosis and immune dysfunction occurring as a result of cancer treatment. Of greatest potential importance to the discipline of tumor immunology is the characterization of the two-way interaction between an individual's immune system and the cancer. The growing discipline of cancer immunotherapy is based on the hypothesis that controlled manipulations of the immune mechanisms involved will provide clinically meaningful antitumor therapy. These immunotherapeutic approaches were stimulated by several historical observations, establishing a link of uncertain strength and mechanism between the immune system and the prevention of human tumor growth.

## ANTITUMOR IMMUNITY IN HUMANS: A HISTORICAL PERSPECTIVE

The primary focus of the discipline of tumor immunology has been to characterize the mechanisms whereby immune reactions can recognize neoplastic tissue and to take advantage of this process in the form of preventive or curative therapy. Several sources of historical evidence suggested a potential role for the immune control of tumor growth. Histologic examinations of many tumor types have revealed a ring of inflammatory cells at the tumor's edge, suggesting an ineffective immune response under way against the tumor.[1] Certain patients, particularly those with melanoma or renal cell carcinoma, experienced well described, but rare, spontaneous regression.[2] Similar regressions of residual pediatric neuroblastoma (particularly in infants) were observed more frequently [3] in certain patient groups after surgical resection (see Chapter 31). Occasional “spontaneous” regressions (e.g., in children with leukemia) occurred during concurrent systemic bacterial or viral infections. Thus, some initial approaches at immunotherapy intentionally used bacteria or their toxins to try to induce immunologic tumor regressions; these approaches met with some success, but the mechanisms involved remain in question.[4]

Children with inherited immunodeficiency diseases, organ allograft recipients, and individuals receiving immunosuppressive therapy show high frequencies of certain cancers. A similar increase in the incidence of certain cancers (particularly lymphomas and Kaposi's sarcoma) was later identified in adults with human immunodeficiency virus (HIV)–induced acquired immunodeficiency. These observations suggested to some researchers that an intact immune system might play a strong surveillance role in destroying incipient cancers and thereby protect against development of malignancy. Certain well-studied patients showed that immune reactions could somehow be involved in tumor control. In 1964, Woodruff published the clinical details for a 47-year-old woman who had a solitary, isolated melanoma of the right foot excised with wide margins and no evidence of deep invasion or metastasis. No further therapy was given. [5] Three years later, a breast nodule was found, surgically resected, and found to be adenocarcinoma of the breast, clearly distinct histologically from the prior melanoma. Postoperative radiation therapy was then given to the chest wall and regional nodes. Within 1 month, thousands of subcutaneous melanoma nodules were observed in the irradiation field. Large visceral metastases of melanoma soon developed and proved fatal. This case strongly suggests that host immune mechanisms were keeping melanoma micrometastases in check for 3 years and that the local radiation therapy inhibited those mechanisms, allowing local outgrowth and further spread. Although other hypothetical mechanisms may also (or alternatively) be involved, an immune component seemed to be playing a role.

Another clinical experience argued strongly that an immune reaction could play an important role in controlling or preventing tumor growth. Analysis of data from a variety of bone marrow transplant (BMT) teams suggests an immunologically mediated antileukemic effect can prevent leukemia relapse ( Fig. 6-1) after allogeneic bone marrow transplantation for acute leukemia.[6,7] Three observations were derived from these clinical data. [8] First, leukemia recurrences were observed less frequently in patients who developed immune-mediated graft-versus-host disease (GVHD). Second, more leukemia recurrences developed in the recipients of marrow that had been depleted of T cells. Third, more relapses occurred among the recipients of syngeneic (identical twin) marrow (i.e., no alloantigens would be immunologically recognized) than among HLA-identical siblings (i.e., in whom minor histocompatibility alloantigens could stimulate immune responses), even in the absence of clinically detectable GVHD. These data strongly suggested that T cells from the donor marrow were involved in allorecognition and were also playing a role in destroying microscopic residual leukemia after transplantation, thereby preventing recurrence. Thus, several forms of anecdotal evidence suggest the presence of potentially therapeutic immune reactivity to human tumors. However, converting these observations into meaningful, testable treatment approaches requires a thorough characterization of the components of the immune response that may be involved and the mechanisms by which these responses are regulated.

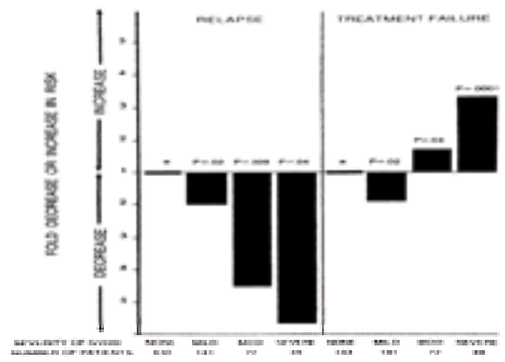

**FIGURE 6-1.** Actuarial probability of relapse after bone marrow transplantation for early leukemia according to the type of graft and development of graft-versus-host disease (GVHD). (From Horowitz MM, Gale RP, Sondel PM, et al. Graft-vs-leukemia reactions following bone marrow transplantation. Blood 1990;75:555, with permission.)

## IMMUNE SYSTEM

Critical examination of the immune system generally requires dividing immune responses into a variety of parts, thus emphasizing distinctions of the various components. Although such models in many ways artificially divide interconnecting members of this elaborate host defense network, they also serve to ease the ability to understand and to study this very complex system. One such division is shown in Figure 6-2, wherein the immune system is divided into “innate” versus “adaptive” immunity. In this model, *innate immune responses* are those that are not antigen specific and for which there is no evidence of immunologic memory, whereas *adaptive responses* refer to the classical, antigen-specific responses carried out by B cells and T cells. Innate immunity comprises responses carried out by neutrophils; phagocytes, including monocytes; and tissue macrophages, eosinophils, natural killer (NK) cells, and the complement cascade. These components generally serve as the first line of defense against infectious pathogens. The central role of innate immune responses in controlling bacterial infection in cancer patients is well known and is reviewed in the Chapter 41. In this chapter, we focus primarily on adaptive responses and their potential role in antitumor immunity.

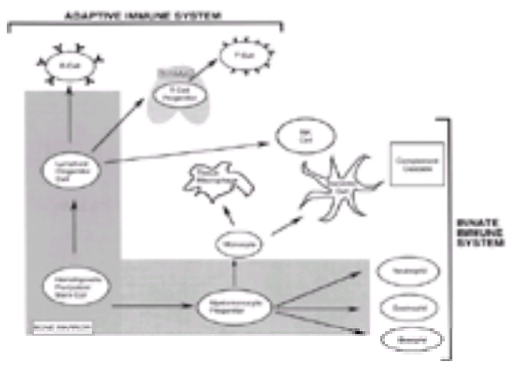

**FIGURE 6-2.** Innate and adaptive immune systems. All cells of the immune system are ultimately derived from pluripotent stem cells. These give rise to two distinct progenitors, one for lymphoid cells and the other for myeloid cells. The common lymphoid progenitor has the potential to differentiate into T, B, or natural killer (NK) cells, depending on the microenvironment to which it homes (i.e., the thymus or bone marrow). Immune cells derived from primitive myeloid progenitors include phagocytic effectors (e.g., macrophages, neutrophils, and monocytes) as well as dendritic cell populations. It should be emphasized that the distinction between these systems is somewhat artificial because there is significant crosstalk between innate and adaptive immune effectors during the initiation and completion of the immune response.

More recent research has shown that cells contained within the innate immune response network play important roles in initiating, amplifying, and potentially directing adaptive immune responses, thus emphasizing the interconnectedness of the entire system. For example, interleukin-12 (IL-12) produced by activated monocytes in response to a variety of stimuli induces interferon (IFN)-g production by NK cells, which then serves to direct T-cell responses toward a T helper 1 (Th1) phenotype.[9] A second example is the evolving role of antigen-presenting cells (APCs) in immune response induction. It is now clear that APCs can be derived from monocyte populations as a result of exposure to a variety of inflammatory stimuli.[10] These cells then serve to initiate adaptive immune responses by providing critical costimulation for T cells. Finally, in the later stages of the adaptive immune response, T cells and B cells recruit a variety of effector cells and molecules typically relegated as components of the innate immune system to carry out immune responses. One example of this is the role that can be played by eosinophils in eradicating tumors, which was recently shown in a tumor transplant model.[11] Therefore, although this chapter emphasizes the basic biology of T and B cells and the mechanisms by which their adaptive immune responses may relate to antitumor immunity, other leukocytes (e.g., NK cells, dendritic cells, and monocytes) that directly or indirectly contribute to antitumor immunity are discussed as well.

### T Lymphocytes

T lymphocytes (designated *T* for their thymic origin) function primarily to eradicate viral infections. Therefore, these cells evolved primarily to optimize their capacity to recognize and eradicate infected cells based on the recognition of intracellularly produced viral products. In modern medicine, however, T-cell responses are also important for their central role in autoimmunity, rejection of transplanted tissues, and potential for antitumor responses. Clearly, many of those features that render T cells efficient for recognizing and eradicating virally infected cells are those same features that are central to the generation of antitumor immune responses. In this section, we review currently accepted models for T-cell recognition, activation, and effector function as a basis for framing discussions of the theory behind immune-based antitumor strategies discussed later in this chapter.

#### *Role of the T-Cell Receptor in the Generation of T-Cell Receptor Diversity*

The first of the unique characteristics of T cells is the fine specificity of antigen recognition by the T-cell receptor (TCR) complex. T cells are defined by the presence of the TCR complex, which is comprised of the invariant CD3 molecule associated in most T cells with the ab heterodimer.[12] The CD3 component of this complex (Fig. 6-3) is a multimolecular cell-surface glycoprotein (comprised of g, d, e, and z chains) that is responsible for transmitting activation signals to the interior of T cells after interaction with antigen. This is accomplished via activation of protein kinase C and release of intracellular calcium stores via activation of phosphatidylinositol-3 kinase, which generate a series of intracellular tyrosine phosphorylation signal–based events, eventually resulting in cell division and cytokine production. The CD3 molecule is identical on all human T cells. Therefore, although the CD3 portion of the TCR is absolutely essential for transmitting activation signals, it plays no role in endowing T cells with the very high level of antigen specificity for which they are very well known.

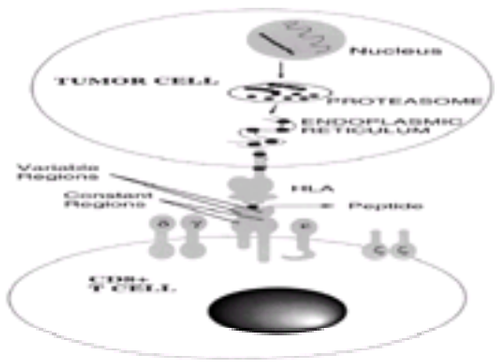

**FIGURE 6-3.** Peptide recognition by the T-cell receptor (TCR) complex. The a and b polypeptide chains of the TCR form a heterodimer anchored in the T-cell membrane. The heterodimer recognizes and binds to peptide associated with an HLA molecule on the surface of a presenting cell (shown in the figure as a tumor cell). The nonpolymorphic CD3 polypeptides (g, d, e, and z) are assembled together with the abTCR and are involved in signal transduction. Peptides presented by HLA class I molecules are typically derived from the intracellular processing of endogenous proteins that are degraded in the proteasome and subsequently are transported to the endoplasmic reticulum where they bind nascent major histocompatibility complex molecules before transport to the cell surface. (Adapted from Krensky AM, Weiss A, Crabtree G, Davis M, Parham P. T lymphocyte-antigen interactions in transplant rejection. N Engl J Med 1990;322:510.)

Rather, for most T cells, the fine specificity of the immune response to individual antigens is endowed by the abTCR heterodimer. Indeed, studies have shown that peptides that differ in only one amino acid can show widely disparate activation potential for a given abTCR. [13] This 95-kd molecule is expressed on the cell surface in close association with the CD3 complex. Its expression is controlled by genes, which are similar in structure to immunoglobulin (Ig) genes. [14] The germline cells and nonimmune cells of a given individual all contain an identical pattern of abTCR genes maintained in germline configuration, which include a linear arrangement of segments termed *variable* (V), *diversity* (for b chain only) (D), *junctional* (J), and *constant* (C) regions. The TCR genes for both the a chain and b chain of the abTCR undergo rearrangement during T-cell differentiation within the thymus, resulting in estimated $10^{12}$ different possible combinations. This combinatorial diversity is then further extended by posttranslational modifications of the abTCR (N segment additions), which yield an enormous variety of TCRs (estimated $10^{15}$), which can potentially exist within any individual. Importantly, after the process of TCR rearrangement is completed within the thymus, each individual T cell expresses only one form of the rearranged abTCR, and all subsequent progeny of this T cell also express the identical rearranged abTCR.

From this enormous T cell repertoire, a highly sophisticated series of positive and negative selection events occurs within the thymus, resulting in the survival of T cells bearing only a mere fraction of the abTCR specificities that are possible in any given individual. Based on current concepts, those T cells that survive thymic selection are those bearing TCR specificities that show enough affinity for self-major histocompatibility complex (MHC) molecules to be positively selected but show a relatively low affinity toward antigens expressed within the thymus, as these TCRs are predicted to be able to recognize foreign pathogens in the context of self-MHC but have a low probability of inducing autoimmunity (reviewed in ref. 15).

Molecular analysis of the TCR DNA within T-cell populations can distinguish individual T-cell clones from one another by their unique TCR DNA gene rearrangement patterns. Such analyses are useful in distinguishing polyclonal reactive processes (i.e., a T-cell response to a viral antigen) from monoclonal malignant expansions (i.e., a T-cell malignancy). Furthermore, the molecular monitoring for the presence of clonally derived malignant T cells in T-cell acute lymphoblastic leukemia and T-cell lymphoma using polymerase chain reaction techniques can allow for the sensitive detection of minimal residual neoplastic disease by amplifying TCR gene patterns that match those expressed on the original leukemia cells (see Chapter 8, Chapter 19, and Chapter 24).

Although most mature T cells use the abTCR, approximately 5% use a less well-characterized gdTCR dimer. [16] The gd genes are similar in structure to the ab genes but have fewer variable segments. The function of these gdTCR–bearing cells remains incompletely characterized. One unique aspect is that gdTCR+ cells generally reside in the gut and do not circulate. It is postulated that these cells contribute to the first line of defense against some infectious pathogens, as they show evidence for cytolytic capacity and recognition of virally infected cells. However, the gdTCR recognition of viral pathogens differs from abTCR recognition in that it is not virus specific (reviewed in ref. 17).

In summary, TCR gene rearrangement occurs early in ontogeny and gives rise to a diverse repertoire of T cells that are poised to respond to the enormous variety of antigens that are encountered throughout the lifetime of the host. On encounter with foreign or potentially dangerous antigens, a highly sophisticated surveillance network serves to ensure that even rare T cells bearing appropriate abTCR specificities will come into contact with antigen to which they can respond, leading to amplification of clones with appropriate TCR specificities. This model, now termed the *clonal selection theory*, was initially postulated in 1900 by Ehrlich and has been shown to be the basis for both T-cell and B-cell arms of the adaptive immune response. Clearly, the appreciation of the fine specificity of the TCR is one feature of T-cell immunity that could potentially be exploited for antitumor effects as it gives rise to the prediction that even minor point mutations in tumor-specific or tumor-associated molecules could potentially be recognized by TCRs and form the basis for an antitumor immune response.

### *Effector Functions of T Cells*

T cells activated to participate in immune responses mediate their immunologic roles through two distinct pathways. One involves direct killing of other cells through direct contact with the target cell that is to be destroyed. The second involves inducing other cells to undergo specific changes, which are dictated by the soluble molecules released by the activated T cell. In general, these distinct functions are performed by distinct subpopulations of T cells.

The cytotoxic T cells (CTLs) are characterized by their surface expression of the CD8 differentiation marker (a listing of all of the CD molecules referred to in this chapter is included in Table 6-1). These CTLs recognize the target cells that they are about to kill through their T-cell antigen receptor molecules (see the previous section) and then cause rapid cellular destruction by two distinct molecular mechanisms (Figure 6-4).[18] Granules present in the cytoplasm of activated CTLs contain molecules involved in causing cell lysis. These include perforin and granzymes. When the CTL contacts the target cell, the granules exocytose into the intermembrane space, where perforin (a complement-like molecule) causes the creation of pores in the target membrane. This initiates membrane destruction, which leads to an osmotic death associated with target cell necrosis. It also facilitates penetration into the target cell of the granzyme molecules released by the CTLs, leading to programmed cell death (apoptosis) of the target cell. In addition, some CTLs also express cell surface effector molecules that specifically interact with cellular death receptors. The best characterized of these is the Fas-Fas ligand system wherein activated CTLs express Fas ligand, which ligate the Fas receptor on target cells and induce apoptosis. Recently, other members of the Fas ligand family have been described. One of these, termed *TRAIL* for tumor necrosis factor (TNF)–related apoptosis-inducing ligand, is of particular interest in oncology because the TRAIL receptors (TR1 and TR2) appear to be restricted to neoplastic tissues. Recent work has shown that Ewing's sarcoma is particularly susceptible to death by TRAIL. [19]

**TABLE 6-1. CLUSTER DESIGNATIONS (CD) ASSIGNMENTS USED IN THIS CHAPTER**

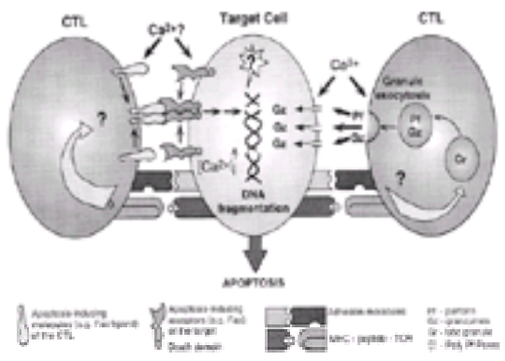

**FIGURE 6-4.** Mechanisms of lymphocyte-mediated cytolysis. Shown is a schematic diagram of the nonsecretory, receptor (e.g., Fas and TRAIL)-mediated (*left*) and the secretory, perforin/granzyme-mediated (*right*) mechanisms of lymphocytotoxicity. CTL, cytotoxic T cell; MHC, major histocompatibility complex; TCR, T-cell receptor. (Adapted from Berke G. Unlocking the secrets of CTL and NK cells. Immunol Today 1995;16:334.)

All T cells, including CTLs, can secrete soluble mediators (see section on cytokines). Nevertheless, a distinct population of T cells, designated helper T cells (Th), can be distinguished from CTLs, as Th cells express the CD4 surface molecule, instead of the CD8 molecule expressed on the surface of CTLs. When Th cells are activated, through recognition of antigen through their T-cell antigen receptors, they become metabolically activated, begin to proliferate, and secrete cytokines. Th cell populations can be further subdivided based on the cytokines they preferentially secrete and their distinct “helper” roles. Th1 helper T cells play a prominent role in helping the activation of CTLs and cellular immune reactions, and primarily secrete IL-2 and IFN-g. Th2 cells are involved in helping activation of B cells and can regulate (downmodulate) certain cellular responses. They secrete primarily IL-4, -5, and -10.

### *Targets of T-Cell Recognition: Role of the Major Histocompatibility Complex in Recognition by the T-Cell Receptor and the CD4/CD8 Cell Surface Receptors*

Elucidation of the molecular mechanisms responsible for rendering TCRs diverse enough to respond to the vast array of antigens, which they may encounter during the lifetime of the host, represented a seminal advance in the field of immunology. However, equally important were the observations made by cellular immunologists who gradually identified the targets of the recognition of these highly diverse abTCRs. Initially, it was erroneously assumed that, like antibodies, T cells recognized intact macromolecules present on the surface of the cells they recognize, designated *target cells* by immunologists. Since that time, a series of experimental observations by many investigators provided the critical insight that instead, the abTCRs of virtually all T cells recognize protein fragments (termed *peptides*) that are held by peptide-binding molecules (the MHC structures) that exist on the surface of virtually all cells. For $CD8^+$ cells, the peptides are generated intracellularly within the proteasome and are subsequently processed into small peptide units in the endoplasmic reticulum before their presentation on the cell surface by MHC class I molecules. For $CD4^+$ cells, the peptides are generated in the endosome of cells after ingestion of exogenous protein and then presented on the cell surface by MHC class II molecules.

This insight began in 1974 with the seminal observations by Zinkernagel and Doherty. They showed that T cells reactive to viral infection with lymphocyte choriomeningitis virus could only recognize virus in two different cells if MHC antigens were shared by the cells, even if the virus was identical in both systems. [20] This general property, wherein identical T cells can only recognize targets that share both the same viral infection as well as the same MHC molecule, was termed *MHC restriction* and was subsequently confirmed in a variety of other viral systems.[21,22] For some time, however, the mechanisms responsible for MHC restriction remained unclear. Initial explanations suggested that CTLs recognized whole proteins inserted alongside the membrane-bound MHC molecules. This proposed mechanism was found to be incorrect, as nuclear proteins that were not expressed on the cell surface could also be recognized by certain MHC-restricted T cells. [23,24] Indeed, in the extensively studied model of T-cell–mediated responses to influenza virus, cytoplasmic and nuclear proteins, rather than cell surface glycoproteins, were the preferred target antigens recognized by T cells. Furthermore, influenza-infected target cells recognized by antigen-specific CTLs showed no evidence for surface expression of the full influenza protein when assayed via binding by antiinfluenza monoclonal antibody. [25]

Subsequent studies confirmed that CTLs could specifically kill target cells that were not infected with influenza, but instead were first treated with exogenous administration of peptides 9-25 amino acids in length derived from whole influenza protein. This was followed by crystallographic analysis of the common HLA molecule, HLA-A2, which revealed a peptide-binding groove that could bind peptides of this size. [26] The HLA class I molecules (i.e., HLA-A, B, and C) and HLA class II molecules (i.e., the HLA-D region molecules, consisting of HLA-DP, -DQ, and -DR) have similar three-dimensional structures on the surface of the cell membrane. They consist of two a helices protruding parallel to one another and above a b-pleated sheet. This conforms to a large protein with a groove. To be visible to a reactive T cell, a peptide must fit exactly into the groove of an HLA molecule.

Progress in the understanding of the biochemistry and cell biology of antigen presentation has been on the forefront of immunologic advances in recent years (reviewed in ref. 27). Current paradigms hold that endogenous cellular proteins undergo proteolysis and processing in the proteasome ( Fig. 6-3). Peptide fragments are then transported into the endoplasmic reticulum via specialized molecules, which bind and transport peptides across the membrane of the endoplasmic reticulum via an energy-dependent process. These molecules have been termed *transporters of antigen processing*. The transporters of antigen processing molecules transfer their peptides to associated unstable MHC class I /$b_2$-microglobulin dimers. The binding of peptide to the MHC class I/$b_2$-microglobulin dimer gives rise to a stable trimolecular complex that is transported to the surface of the cell and is presented within the peptide-binding groove of MHC class I. Although the factors that determine the extent to which individual peptides bind to MHC molecules remain incompletely understood, it is clear that the extensive polymorphism that exists among MHC molecules results in substantial differences in the binding of individual peptides across individuals (reviewed in ref. 28).

Importantly, the MHC molecule also plays a critical role in directing peptides of appropriate affinity to $CD4^+$ versus $CD8^+$ cells. This is because the nonpolymorphic region of the MHC class I molecule binds to the CD8 molecule on T cells whereas the nonpolymorphic region of MHC class II binds to the CD4 molecule on T cells. In this way, $CD8^+$ T cells are brought into proximity of MHC class I expressing cells to recognize antigen whereas $CD4^+$ T cells only recognize antigen in the context of class II expression. Furthermore, class II molecules receive peptides in large part via the endosome that is generated as a result of pinocytosis and endocytosis of exogenous protein by class II expressing APC populations. In contrast, class I molecules receive peptide via transfer of peptides from the proteosome into the endoplasmic reticulum as noted. In this way, MHC class II primarily presents “exogenous” proteins to T cells, whereas MHC class I primarily presents endogenously generated peptides. Another critical difference between class I and class II MHC molecules is the limited distribution of MHC class II. Although MHC class I is expressed on essentially all nucleated cells, MHC class II expression is typically limited to professional APCs that have evolved specialized capacities to interact with the immune system (monocytes, dendritic cells, B cells, activated T cells, and endothelial cells).

The identification of the targets of T cell recognition were of considerable importance to the general immunology community because it provided a means to explain how the T-cell arm of the immune system evolved to eradicate viral pathogens that generate intracellular antigens as a result of target cell infection. [22] With regard to tumor immunology, the paradigm also suggested that a wide array of tumor-specific or tumor-associated proteins, even those restricted in distribution to the cytoplasm or nucleus, could potentially serve as targets for cell-mediated immune responses.

### *Critical Role of Costimulation: Antigen-Presenting Cells*

The model described paints a picture wherein enormous arrays of potentially recognizable self-peptides are continually presented on the surface of cells via binding to MHC molecules throughout the life of the host. To prevent autoimmunity, it is clear that mechanisms to control the reactivity of T cells bearing potentially autoreactive TCRs must exist. Experimental evidence accumulated in the 1990s has provided new insights into the processes that regulate T-cell activation. The primary concept that has evolved is that T-cell activation requires not only the interaction of an appropriate TCR with its cognate antigen (i.e., the first signal), but also requires a second “costimulatory” signal. This second signal is most frequently provided by direct interaction with costimulatory molecules present on the peptide-bearing cell. The best characterized, and the most potent, of the costimulatory signals involves the B7 family of molecules, which are expressed on the surface of professional APCs. B7-1 (CD80) and B7-2 (CD86) are surface glycoproteins that interact with CD28 on the surface of T cells. [29] Cross-linking of CD28 during T-cell activation enhances proliferation of responding T cells in part by upregulating IL-2 production. An important negative regulatory system also is incorporated into the CD28/B7-1/B7-2 interaction ( Fig. 6-5). Here, CTLA4, a molecule with very high affinity for both B7-1 and B7-2, competes with CD28 for binding

with these molecules. Rather than transmit activation signals to T cells as CD28 does, CTLA4 ligation results in downregulation of T-cell activation. [30] Under normal circumstances, this downregulation functions to limit the magnitude of the immune response, thus diminishing the likelihood of autoimmunity and lymphoproliferation. It has been shown in mouse models that if blockade of CTLA4 is induced during the course of an immune response, significant enhancement of antigen-specific responses occurs indirectly due to an enhanced interaction between CD28 and B7-1, B7-2. This approach has been used to induce primary responses to otherwise nonimmunogenic tumors in mouse models and could provide a therapeutic approach toward human cancer in the future. [31,32]

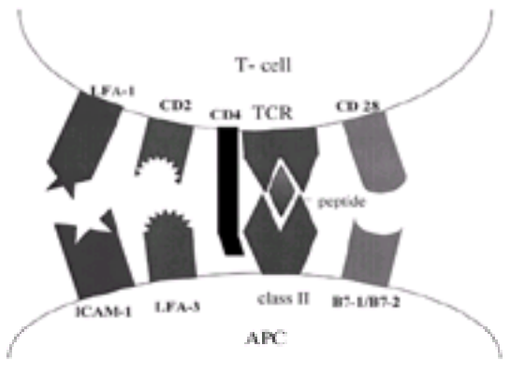

**FIGURE 6-5.** Costimulatory interactions between $CD4^+$ T cells and antigen-presenting cells (APCs). APCs express class-II HLA molecules, with antigenic peptides in their groove. These are recognized by the T-cell receptors (TCRs) on T cells. Additional interactions occur between the CD4 molecule on the T cell and the nonpolymorphic region of the class II HLA molecule. In addition, binding interactions occur between leukocyte factor antigen-1 (LFA-1), CD40 ligand, and CD28 molecules on T cells; and intercellular adhesion molecule-1 (ICAM-1), CD40 and CD80 (B7-1), and CD86 (/B7-2) molecules on APCs, respectively. CTLA4 acts as a negative regulator of T-cell activation and competes with CD28 for binding to CD80 and CD86 on APCs.

CD40 also appears to be a particularly important costimulatory molecule expressed on APCs. Ligation of CD40 via CD40 ligand expressed on activated $CD4^+$ T cells leads to upregulation of a multitude of other molecules on the APCs, including B7-1, B7-2, and MHC molecules. [33] Other accessory molecules present on the surface of professional APCs, such as intercellular adhesion molecule-1 and -2 and function associated antigen-3 (LFA-3) can also provide costimulatory requirements. [34] The two-signal model has also been described as the "danger" model wherein the expression of costimulatory molecules on APCs is induced via a variety of "danger" stimuli, including lipopolysaccharide and IL-12 production via cells of the innate immune system. In this model, the innate immune system provides a critical role by responding to a variety of "danger" signals by upregulating costimulatory molecules on appropriate APCs with subsequent activation of T cells bearing appropriate TCR specificities. [35]

This "two-signal" or "danger" model provides an explanation for why autoimmunity does not occur regularly despite the plethora of peptides expressed throughout the body in the context of MHC. With regard to tumor immunity, elucidation of the requirement for the second signal in immune response induction also provides an attractive explanation for the inability of tumors to induce immune responses in the host despite the existence of tumor-specific proteins, such as fusion proteins, which result from chromosomal rearrangement. This hypothesis generated the testable prediction that if tumor-associated antigens or tumor-specific proteins were expressed on the surface of professional APCs, which are capable of providing costimulatory requirements, then immune responses would be generated. Indeed, it has now been shown that in many experimental systems, effective antitumor immunity can be induced by enhancing costimulation of tumor-associated proteins. This has been accomplished via transfection of tumor cells themselves with various cytokines or costimulatory molecules, [36,37,38] and [39] or by immunization with professional APCs that have been manipulated to express tumor antigens. [40]

The same effect also occurs if large numbers of professional APCs are brought into proximity with tumor, as shown by Dranoff and co-workers. [38] Here, a process termed *cross-priming* results in pickup of tumor-associated peptides by infiltrating APCs, which are activated to respond to "danger." Indeed, it is possible that the phenomena of cross-priming is a critical process *in vivo* for inducing immune responses to dead and dying cells because recent work suggests that professional APCs acquire peptides from dead and dying cells via ingestion and subsequent presentation. [41,42]

The importance of costimulation for the induction of immune responses has fueled great interest in the study of cell populations capable of antigen presentation and costimulation. Of all APCs, dendritic cells are the most potent for inducing immune responses, [43] and they are unique among APC populations for their ability to induce responses from naive T cells to antigen. [44] Indeed, because a prevailing paradigm holds that the primary factor limiting antitumor responses is a lack of appropriate costimulatory molecules in the initial phases of the host-tumor interaction, much of the enthusiasm in tumor immunology today rests on the ability to isolate and activate large numbers of dendritic cells for use in the context of immunotherapy. Dendritic cells are normally found in trace amounts (1% to 2%) in blood and bone marrow, and are typically lacking in expression of T-cell, B-cell, and myeloid markers (e.g., CD3, CD14, CD16, and CD19). They express high levels of MHC class I and class II and generally express B7-1 and/or B7-2. Recent studies [45] have shown that large numbers of dendritic cells can be generated after incubation of peripheral blood monocytes with granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-4. This leads to a nonproliferative differentiation of monocytes into cells with dendritic-like processes and modest upregulation of costimulatory molecules. These cells have been termed *immature dendritic cells*. They continue to possess the ability to ingest and process proteins (similar to monocytes), but they also show some increase in the ability to present antigen. After further stimuli (e.g., TNF-a, monocyte-conditioned media, lipopolysaccharide, and exposure to CD40 ligand) the immature dendritic cells undergo irreversible differentiation into cells with very high levels of costimulatory molecules. These cells have been termed *mature dendritic cells*. Substantial numbers of mature dendritic cells can also be generated *ex vivo* from $CD34^+$ hematopoietic pluripotential cells after culture with GM-CSF and TNF-a. This occurs via proliferation and differentiation of myeloid progenitors into a dendritic cell phenotype. Another approach for generating large numbers of dendritic cells involves *in vivo* treatment with flt3 ligand. Systemic treatment with this molecule also induces the differentiation of early myeloid progenitors into cells bearing a dendritic cell phenotype, thus resulting in the accumulation of large numbers of dendritic cells throughout the organs of flt3-treated hosts. [46] Properties of the various dendritic cell populations are shown in Table 6-2, and important costimulatory interactions between APCs and T cells are shown in Figure 6-5. Ongoing work is attempting to clarify the optimal dendritic cells for induction of T-cell–mediated immune responses for ultimate use in antitumor immunotherapy.

**TABLE 6-2. PROPERTIES OF ANTIGEN-PRESENTING CELL POPULATIONS**

## B Lymphocytes

B lymphocytes (designated *B* from their bursal origin in fowl and bone marrow origin in mammalian species) are characterized when mature by having a surface membrane receptor composed of the antigen-binding component of an Ig molecule. The primary role of B lymphocytes is the production of intact Ig molecules, which are soluble molecules able to recognize protein, glycoprotein, and carbohydrate antigens and trigger other cellular and molecular responses on effective binding of

antigens they recognize.[47] As such, B lymphocytes are primarily designed to recognize and respond to soluble intact antigens, and the Igs they produce bind to epitopes that are available on the surface of whole circulating molecules. This is to be distinguished from T cells, which do not recognize intact proteins, but rather peptides that must be presented on the cell surface of MHC-bearing cells. Each Ig molecule consists of light (k or l) chains and heavy (M, G, A, D, or E) chains. Intact Ig molecules have an antigen-binding (Fab) end and an end that can fix and activate components of the complement cascade (Fc) and can bind to membrane-bound Fc receptors when the Fab end of the antibody is engaged with the appropriate antigen.

Like the genetic control of T-cell diversity, germline and nonimmune cells all contain the same pattern of germline Ig genes. As immune stem cells begin differentiating into B-lymphocyte lineages, Ig gene rearrangements involving selection from multiple segment possibilities within V, D, and J regions are rearranged. [48] When these possibilities are coupled to the different major types and subtypes of heavy and light chain constant regions that can be selected, the genetic control of an individual's immune repertoire may allow $10^{11}$ different combinations of Ig (Table 6-3). At any time, a single B cell and its progeny can secrete many copies of a single specific Ig molecule. Different B cells, having different Ig gene rearrangement patterns, make distinct Ig molecules. Efficient activation of B cells to secrete Ig molecules requires interactions with antigen-specific T cells that have also become activated during the course of immune response induction. Although some of this T cell “help” is accomplished via secretion of cytokines, such as IL-2, it is now clear that much of the help provided by T cells is in the form of the cell-associated molecule, CD40 ligand. This ligand, expressed on the surface of activated CD4 T cells, can activate CD40 on the surface of B cells to direct them to generate antigen-specific IgG-producing cells. Indeed, humans lacking CD40 have a defect in isotype switch resulting in an accumulation of IgM molecules, known as the *hyper IgM syndrome*.

| | Immunoglobulin | | αβTCR | | γδTCR | |
|---|---|---|---|---|---|---|
| | H | L | α | β | γ | δ |
| Variable segments | 250–1,000 | 250 | 100 | 25 | 7 | 10 |
| Diversity segments | 10 | 0 | 0 | 2 | 0 | 2 |
| Joining segments | 4 | 4 | 50 | 12 | 2 | 2 |
| Variable region combinations | 62,500–250,000 | | 2,500 | | 70 | |
| Junctional combinations | $10^{11}$ | | $10^{11}$ | | $10^{11}$ | |

Note: Estimated amino acid sequence diversity in immunoglobulin and TCR genes without allowance for somatic mutation. Estimates for the number of amino acid sequences that might result from diversity within the junctional region are contrasted for immunoglobulin and TCRs. Mechanisms for diversity generation within the junctional region include usage of different diversity (D) and junctional (J) gene segments, junctional N region additions, variability in the joining position of variable and J gene segments, and translation of D regions in different reading frames.

**TABLE 6-3. DIVERSITY IN T-CELL RECEPTOR (TCR) AND IMMUNOGLOBULIN GENES**

Just as molecular characterization of TCR gene patterns can differentiate polyclonal from oligoclonal or monoclonal T-cell populations, the same is possible for Ig gene rearrangement patterns among B-cell populations. This information has been of use in characterizing a variety of B-cell tumors. Because mature B cells express Ig on the cell surface corresponding to the Fab type of the Ig they are genetically programmed to secrete, monoclonal B-cell tumors consist of a population that all express the identical surface Ig Fab type. That pattern on a monoclonal population of malignant B cells [49] allows those cells to be distinguished from normal B cells not expressing the same Ig surface receptor (i.e., the Ig idiotype). This distinction has enabled idiotypes to function as tumor-specific markers, and these idiotypes have been the target for immunologic therapy.[50] Here the peptidic immune target for the T cell is the idiotype portion of the antibody itself; T-cell responses are generated that attack any cell bearing this idiotype.

Of tremendous importance to diagnostic and clinical immunology was the hybridoma technique that used murine B-cell tumors to make large quantities of monoclonal antibodies.[51,52] A hybridoma is formed by fusing a malignant B cell (Fig. 6-6) that is a poor Ig secretor with a normal B cell that makes an Ig of interest. [53] With current genetic engineering techniques, molecularly modified antibodies are being created with a number of laboratory designer improvements. Genes controlling the antigen-binding component of an Ig molecule can be fused to genes controlling constant regions for other Ig molecules. Chimeric antibodies are being created that allow mix and match combinations of antigen binding and constant regions using genes from different cells or even different species to provide the desired antigen recognition and biologic function.[54] The technology is moving toward *in vitro* gene recombination and cyclical, sequential mutation and recombination to generate Igs that may not be readily found in immune cells. The generation[55] of such *in vitro* generated and modified molecules can provide specificities and functions not found in nature, and these may have multiple clinical uses.

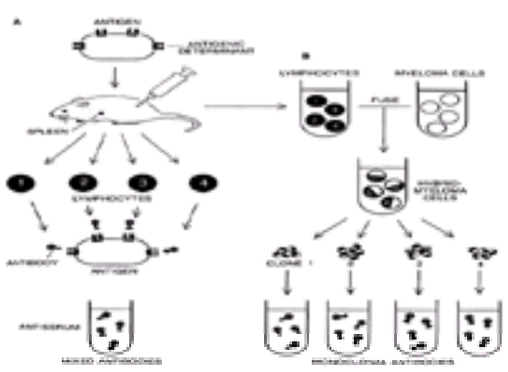

**FIGURE 6-6.** Generation of monoclonal antibodies. Immune response is initiated **(A)** when an antigen molecule carrying several different antigenic determinants enters the body of an animal. The immune system responds, and lines of B lymphocytes proliferate, each secreting an immunoglobulin molecule that fits a single antigenic determinant or a part of it. A conventional antiserum contains a mixture of these antibodies. **B:** Monoclonal antibodies are derived by fusing lymphocytes from the spleen with malignant myeloma cells. Individual hybrid cells are cloned, and each of the clones secretes a monoclonal antibody that fits a single antigenic determinant on the antibody molecule. (From Milstein C. Monoclonal antibodies. Sci Am 1980;243:66, with permission. Reprinted in Paul WE. Immunology: recognition and response. New York: WH Freeman, 1991:125.)

## Natural Killer Cells

Morphologic evaluation of peripheral blood leukocytes enables easy separation of mononuclear cells from polymorphonuclear leukocytes and relatively clear distinction of lymphocytes from monocytes within the mononuclear cell fraction. Within the population of peripheral blood mononuclear cells that appear to be lymphocytes by standard hematologic smear analysis and by standard flow cytometric techniques, there is a relatively small population of circulating cells that does not express mature T- or B-cell markers (CD3 or Ig). This third population of lymphocytes ( Fig. 6-2), initially designated *null cells*, has now been found to be comprised predominantly of a cell type termed *NK cells*. NK cells are notable for their ability to spontaneously destroy some tumor cells lines and virally infected populations *in vitro*.[56]This cytolytic capacity is mediated via the same molecules used by cytolytic T cells (i.e., perforin, granzyme, and Fas-Fas ligand interaction), as shown in Fig. 6-4, in inducing target cell lysis. Unlike T cells, however, which require preactivation to induce expression of their perforin and granzyme containing granules, NK cells constitutively express cytolytic granules and thus can kill appropriate targets very rapidly. Indeed, the observation of such granules histologically has historically led to the phenotypic description of NK cells as large granular lymphocytes.

The molecules responsible for signaling NK cells to recognize and then kill their targets have been difficult to characterize. It is clear that NK cells do not express the TCRs or Ig molecules that are present on T and B cells, respectively. [57] Furthermore, experimental evidence has shown that rather than requiring MHC expression on target cells for induction of cytolysis (as is the case for T cells), NK cell lysis is actually inhibited by the presence of MHC molecules on the targets they recognize. This has given rise to the current model for NK cell recognition, termed the *missing self hypothesis*.[58] In this model, under normal circumstances NK cells are prevented from granule release by ongoing “tonic” engagement of inhibitory receptors on the surface of NK cells that occurs via their interaction with self-MHC. Indeed, substantial progress in the identification of such inhibitory receptors has been made in the last several years. NK inhibitory receptors generally belong to one of at least three major families: first, the killer inhibitory receptors (KIRs), which are most well characterized in humans and that are comprised of an Ig-like molecule;

second, the CD94/NKG2 family of lectin type molecules that is predominantly characterized in humans; and finally, the Ly49 family, which is seen in mice and is comprised of type II transmembrane protein dimers (reviewed in ref. 59). Importantly, however, there appears to be great diversity within these systems of NK receptors, with a large diversity of KIRs expressed on individual NK cells and specificity for individual KIRs for individual MHC alleles. Furthermore, in some cases, molecules contained within these families of inhibitory receptors can also activate NK cells.

The current “missing self” model explains why NK cells may preferentially attack neoplastic cells that are known to downmodulate MHC molecules. In theory, such a model suggests that NK cells would provide an “immune surveillance” mechanism selectively targeting tumor cells or virally infected cells that downmodulate MHC molecules. Concurrently, the T-cell arm of the immune system would be poised to lyse MHC-bearing cells, which express foreign antigens. Importantly, however, recent work has shown that certain subpopulations of T-cell populations show many features of NK cell reactivity and also express KIRs, suggesting the potential for downmodulation of such NK/T-cell populations via MHC-bearing cells. With regard to tumor immunology, one could envision a scenario wherein downmodulation of one MHC allele that may be responsible for presenting a particular tumor-specific peptide may diminish the tumor's capacity to be recognized by classical T cells, whereas maintenance of another allele, reactive with the KIR receptors, could turn off NK-cell–mediated cytolytic responses. In this way, the tumor could subvert both the T-cell and NK-cell immune response.

The physiologic roles for NK cells are likely to be manifold. [56] First, these cells appear to contribute to a first line of defense against viral pathogens because hosts that are deficient in NK function show a great susceptibility to infection with herpes viruses. In addition, NK cells serve a unique position as communicators between innate and adaptive immune responses. To this end, NK cells are highly responsive to IL-12 production by monocytes and other tissue macrophages and respond with the production of high levels of IFN-g. Such IFN-g expression appears to play an important role in directing Th cell responses toward a Th1 phenotype. The Th1 phenotype has been proposed to be responsible for the induction of cell-mediated immunity and in some models is required for protection against a variety of infections. Furthermore, because of their capability for tumor lysis, it has long been postulated that NK cells contribute to a system of immune surveillance wherein the accumulation of cells lacking self-MHC molecules (such as tumor cells) would be eradicated. Indeed, in animal models, it is clear that abrogation of NK-mediated killing greatly facilitates the ability of tumor cell lines to grow in immunodeficient mice.

Importantly, NK cells also express the CD16 molecule, which is the low-affinity FcRIII that can bind to the Fc end of Ig molecules, provided the antibody is in the process of recognizing the appropriate antigen with its Fab end. Through this receptor, NK cells can potently mediate destruction of other cells that are coated with antibody via antibody-dependent cellular cytotoxicity (ADCC). This process is predicted to be of central importance for the efficacy of tumor-directed monoclonal-based therapy, and recent approaches integrating IL-2 into chimeric monoclonal antibodies have attempted to enhance ADCC by increasing the binding of monoclonal antibodies to NK cells via the IL-2 receptor. [60]

Finally, NK cells also show striking responses to IL-2, a cytokine released by Th cells ( Table 6-1). *In vitro* and *in vivo*, exposure to IL-2 causes activation and proliferation of NK cells, producing changes readily detectable by molecular and morphologic techniques. [61,62] Functionally, these IL-2–activated NK cells mediate *in vitro* destruction against an even broader range of tumor cell lines (compared to that killed by fresh NK cells). [61] Some lesser degrees of killing are observed by these IL-2–activated NK cells on certain fresh normal tissues, including monocytes and endothelial cells. [63] These IL-2–activated NK cells are largely responsible for the beneficial effects of lymphokine-activated killer (LAK) cell therapy seen in some patients with renal cell carcinoma and melanoma (see Chapter 14). [64,65]

## Cytokines

### *Intercellular Immunoregulation by Soluble Signals*

The complete *in vivo* immune response involves a tightly orchestrated interaction of all of the previously described cell types, requiring a coordinated activation or inhibition of each component of the response at the correct place and time. Many of these interactions involve direct cell contact between different cell types or different cells of similar types. However, most interactions occur through the use of soluble mediators, designated *cytokines* or *lymphokines* when produced by lymphoid cells. Because these molecules provide communication between different leukocytes, some have been given the designation of *IL*. [66] More than 18 different ILs have been characterized (Table 6-1). The family of IFNs and hematopoietic growth factors reflect protein molecules that are made by cells of the immuno-hematopoietic system and also have direct regulatory effects on the immuno-hematopoietic response. [67,68] A separate class of cytokines are those that are involved in the attraction of leukocytes to areas of inflammation. As this “chemical mediated” process of cellular attraction has been designated *chemotaxis*, the cytokines involved in this process are known as *chemokines*. [69] Synthesis of each of these molecules is regulated by cellular activation, and these molecules are specifically recognized by cell membrane receptors that trigger cellular differentiation and nuclear activity by receptor-bearing cells. The molecular pathways involved in these activation steps are somewhat analogous to that of T-cell triggering through the CD3 triggering molecule.

### *Interleukin-2 and Its Receptor*

Initially described as T-cell growth factor, IL-2 is a 15-kd protein that has been studied in greater depth than any of the other ILs. It is produced by Th1 cells after specific antigen recognition and produces differentiation and proliferation of other immune cells, specifically Th cells, CTLs, and NK cells, as well as less striking effects on B cells and monocytes. [69,70] IL-2 is able to activate cells of the immune system if they bear a functional IL-2 receptor. At a minimum, the IL-2 receptor consists of three distinct membrane receptor components, the a, b, and g chains. The intermediate-affinity IL-2 receptor consists of the 75-kd b chain that has extracellular, transmembrane, and cytoplasmic domains, as well as a 65-kd g chain that also has extracellular, transmembrane, and cytoplasmic components. The high-affinity receptor is composed of one b chain, one a chain, and one g chain, which is a 55-kd molecule with only a minute cytoplasmic domain. [68,69 and 70] Most T cells and NK cells express low amounts of the b and g chains and virtually no a chain. After recognition of specific antigen, T cells are activated to synthesize the a chain, enabling formation of a heterotrimer consisting of an a, b, and g chain that provides for high-affinity IL-2 receptor signal transmission ( Fig. 6-7). Activated T cells express the a/b/g trimolecular complex. This expression has been used to identify T cells that have recently recognized antigen, and immunosuppressive approaches directed against cells expressing this IL-2 receptor (IL-2R) complex are being used to treat autoimmune disease and allograft rejection episodes. [69] Similar approaches are being initiated for treatment of T-cell malignancies.

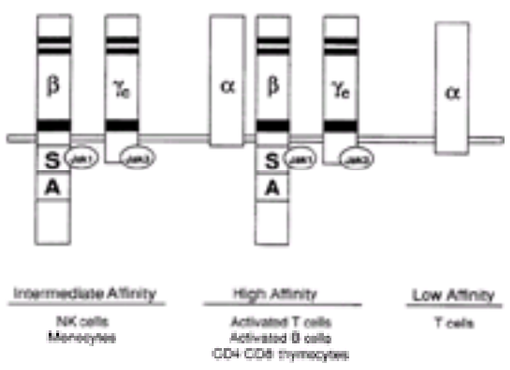

**FIGURE 6-7.** Interleukin-2 receptor (IL-2R) forms and the immune cells that express them. Individual subunits that compose the three forms of IL-2Rs are as indicated. JAK1 is a JAK family kinase that associates with the S (serine-rich) region on IL-2Rb and is a primary kinase associated with IL-2 signaling. JAK3 is a JAK family kinase that associates with IL-2Rg and is required for IL-2 signaling. The acidic (A) region is also required for proper signaling to occur. Immune cell subsets that express each IL-2R form are listed below the receptor schematics. (From Farner NL, Hank JA, Sondel PM. Molecular and clinical aspects of interleukin 2. In: Friedland JS, Remick DG, eds. Cytokines in health and disease, 2nd ed. New York: Marcel Dekker, 1997;29–40, with permission.)

In addition to expressing the a/b/g IL-2R complex on the cell surface, activated T cells, while synthesizing the a IL-2R molecule, also secrete this molecule in large quantity. Its release into the serum can be quantified and correlates with the degree of immunologic activation under way. NK cells also respond to IL-2 using what appear to be the same IL-2R molecules. “Resting” NK cells appear to have more of the 75-kd b chain than do resting T cells. [71] Although some NK cells can activate a IL-2R expression after immune activation (particularly activation with IL-2), others appear to increase their b chain expression but do not express IL-2R a chains. Functional studies with these NK cells document that the g chain plays a critical role in IL-2 binding and signal transduction. This same g chain receptor molecule is

also essential as a receptor involved in the response to a number of other interleukins (e.g., IL-2, -4, -7, -9, -13, and -15). [52,72] This is evident from the critical role this common g chain receptor molecule plays in immune development. Individuals unable to produce a normal functioning common g chain are afflicted with X-linked severe combined immunodeficiency, most likely related to a deficiency in IL-7 signaling. [71]

### *Other Cytokines*

Although IL-2 has been studied most extensively, the diverse array of other cytokines that have been identified indicates the complexity of intercellular communication through soluble mediators used by the immune system. Some of these are described briefly in Table 6-4. A detailed description of the known functions, physiologic roles, and potential immunotherapeutic implications for each is beyond the scope of this chapter. **TABLE 6-4. HUMAN CYTOKINES**

## IMMUNODEFICIENCY IN CANCER PATIENTS

### Immunodeficiency and Cancer Predisposition

Since the mid-1980s, experimental oncology has been enriched by techniques allowing highly sophisticated analyses of malignant cells and the genes within them. Numerous investigations have demonstrated that malignant differentiation is a multistep process involving expression of abnormal genes heralded by characteristic structural changes in the proteins and other molecules expressed by many malignant cell populations. Delineation of this complex multistep process of neoplastic differentiation has been used to argue against the immune surveillance hypothesis, which holds that, in health, numerous neoplastic or pre-neoplastic cells arise spontaneously and are destroyed by an effective immune system before progressing to cancer. The association of increased incidence of malignancy in patients (particularly children) with severe immunodeficiency disorders was cited to support the immune surveillance concept.

Despite the currently controversial status of the immune surveillance hypothesis, the clinical facts remain: Patients with severe immunodeficiency disorders show dramatic increases in the incidence of certain neoplasms. Because many of these immunodeficiency diseases are extremely rare, the identification of a neoplasm in a pediatric patient suggested an increased risk of cancer was associated with immunodeficiency, but it was based largely on the anecdotal observation of two rare diseases in the same patient. Establishment of the Immunodeficiency Cancer Registry has provided important data regarding the incidence of these immunodeficiency disorders and of neoplasms that arise in patients with these rare diseases. [91] Within the pediatric population, the severe immunodeficiency disorders associated with increased risk of malignancy include inherited forms of immunodeficiency such as severe combined immunodeficiency, [91] Wiskott-Aldrich Syndrome, [91] X-linked lymphoproliferative syndrome, [92] ataxia telangiectasia, and selective IgA deficiency. Increased incidence of malignancy is also observed for patients with acquired forms of immunodeficiency such as patients with organ allografts, HIV and acquired immunodeficiency syndrome, prior treatment with cytotoxic drugs for a primary malignancy, and certain chronic viral infections. [93]

If loss of immune surveillance was the entire explanation for the increased incidence of cancer in these populations, the spectrum of neoplasms developing in immunodeficient pediatric patients should correspond to the spectrum developing in an age-matched pediatric population. Despite the increased incidence of neoplasms in these immunodeficient children, [91,94] the fraction that are lymphoid malignancies (particularly non-Hodgkin's lymphomas) is strikingly greater than the incidence of these diseases in the general population of pediatric oncology patients, whereas the fraction that are primary central nervous system malignancies is less than that of the general pediatric oncology population (see Chapter 1 and Chapter 2). However, the statistical association of immunodeficiency and neoplastic disease remains clear. Rather than proving or disproving the immune surveillance hypothesis, these clinical associations of immunodeficiency and cancer susceptibility suggest that several cellular and molecular mechanisms may be simultaneously at work.

First, molecular defects associated with genetic damage may simultaneously cause immune dysfunction and independently cause DNA damage associated with an increased susceptibility to neoplastic transformation. For instance, the neoplasms and immunodeficiency associated with diseases such as ataxia telangiectasia may have a common molecular cause, without a direct correlation between the immune dysfunction and neoplastic disease. Second, dysfunction of any physiologic system is often associated with a compensatory attempt to stimulate the missing function. Patients undergoing nephrectomy show hypertrophy of the remaining kidney. Patients with bone marrow hematopoietic stem cell dysfunction often show excessive levels of erythropoietin. Patients with end-organ failure of their T- and B-cell immune systems probably are experiencing some degree of lymphocyte and stem cell overdrive, attempting to ineffectively induce repopulation of the immune system. Indeed, recent evidence for increases in serum levels of IL-7 in association with chronic T cell depletion could provide a plausible mechanisms for the increased incidence of B-cell neoplasms because mice transgenic for IL-7 show a high rate of lymphoma development. [95] Third, a dysfunctional immune system may also be ineffective at providing immune control of infectious agents that are associated with or stimulate neoplastic differentiation (e.g., Epstein-Barr virus as the central factor in inducing posttransplant lymphoproliferative disorder or lymphoma, or both). [96]

Finally, it still remains a possibility that immune surveillance may play a part in preventing the development of cancer, even within the context of a multistep neoplastic differentiative process. Indeed, recent work in murine models has shown that mice that have been genetically engineered to have a predisposition to cancer (via disruption of the p53 gene) as well as to be deficient in IFN-g develop cancers earlier than IFN-g–producing mice. These results suggest that IFN-g, which is clearly produced by the innate immune system and a central player within the effector arms of the adaptive immune system, could contribute to immune surveillance in these mice. Similarly, mice treated with mutagenic agents develop tumors earlier when IFN-g is absent compared to mice with normal IFN-g production. [97] These results suggest a role for a least some component of immune surveillance in controlling tumors that arise as a result of genetic aberrations.

### Immunologic Effects of Cancer and Cancer Therapy

The most common infectious complications observed in cancer patients are bacterial infections occurring in the setting of neutropenia. [98] Bacterial infections are also commonly observed as a result of the breakdown of barriers (e.g., mucosal surfaces, indwelling central catheters, instrumentation, and surgery). In these settings, alterations in the innate immune system play a central role, with depletion of neutrophils being the most significant predisposing risk factor. Although acute depletion of neutrophils is clearly associated with a very high risk of infection, rapid recovery of these populations is generally observed. Indeed, as noted in Figure 6-8, neutrophils and monocytes recover rapidly after successive cycles of dose intensive chemotherapy, despite deep nadirs. Mechanistically, we know that hematopoietic cells (i.e., red blood cells, neutrophils, monocytes, and platelets) are short-lived, post-mitotic, terminally differentiated cells, which are continuously replenished throughout life via repetitive cycles of hematopoietic stem cell differentiation. As a result, when these cells are acutely depleted by cytotoxic antineoplastic therapy, complete repopulation generally occurs within 14 to 21 days via hematopoietic stem cell differentiation.

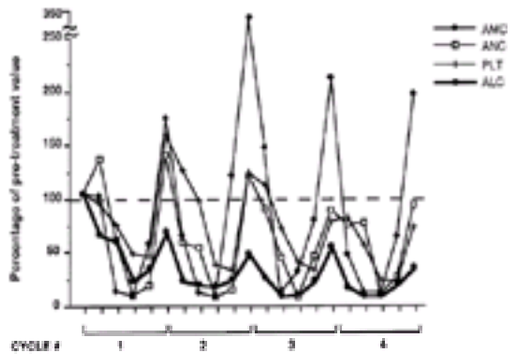

**FIGURE 6-8.** Peripheral blood lymphocytes show limited recovery after successive cycles of intensive chemotherapy. Temporal recovery of hematopoietic populations after successive cycles of dose-intensive chemotherapy as administered for pediatric sarcomas. Cycles were guided by recovery of neutrophils, which show baseline values before initiation of successive cycles. The graph displays an overshoot of the monocyte compartment. Platelet recovery is modestly reduced with successive cycles. The most limited recovery is seen in the absolute lymphocyte count (ALC), which does not return baseline at any time during successive cycles of chemotherapy. AMC, absolute monocyte count; ANC, absolute neutrophil count; PLT, platelet count. (From Mackall CL, Fleischer TA, Brown MA, et al. Lymphocyte depletion during treatment with intensive chemotherapy for cancer. Blood 1994;84:2221–2228, with permission.)

In contrast, T cells are comprised of a heterogeneous group of short- and long-lived cells, which are themselves capable of substantial mitotic expansion. Under normal circumstances, the long-lived cells, typically contained within the “naïve” subset, are quiescent, remaining in a noncycling state for months to years while awaiting encounter with cognate antigen.[99,100] The short-lived cells, generally contained within the effector and memory subsets, undergo variable levels of cell cycling in response to antigen encounter, resulting in ongoing modulation of their relative contribution to the overall T-cell repertoire.[101] Hence, in healthy hosts, ongoing hematopoietic stem cell differentiation plays only a minor role in maintaining peripheral T-cell populations. Furthermore, unique microenvironmental conditions present within the thymus are required for efficient T-cell differentiation from hematopoietic stem cells. Because age-, therapy-, and disease-related changes diminish the capacity of the thymus to produce new T cells, stem cell differentiation pathways for T-cell regeneration are frequently limited after T-cell depletion. It is therefore not surprising, that the acute depletion of T cells induced by cytotoxic antineoplastic therapy is often followed by a period of slow and incomplete restoration of peripheral T-cell populations.

For these reasons, cancer patients are also predisposed to a variety of nonbacterial infections with viral, fungal, and parasitic pathogens during the course of therapy and for some time after completion of antineoplastic therapy. Unraveling the precise contribution of specific alterations in innate versus adaptive immunity to specific infections is difficult. Nonetheless, it is clear that a deficiency in T-cell immune competence contributes to a susceptibility to viral infection as well as the development of other complications such as transfusion-associated GVHD and even Epstein-Barr virus–related lymphoproliferative disorder after allogeneic BMT.

Interactions between cancer and the immune system are complex. It is widely accepted that cancer patients display varying degrees of generalized immunosuppression at the time of clinical presentation before initiation of antineoplastic therapy. This appears to be most pronounced in patients with acute leukemia and other conditions associated with pancytopenia who frequently have infections at the time of presentation.[102] In this population, the susceptibility to infection is typically exacerbated by prolonged and intensive chemotherapy administered with or without corticosteroids.[103]

Similarly, patients with newly diagnosed Hodgkin's disease also frequently show impaired lymphocyte proliferation to a variety of antigens,[104] and patients with Burkitt's lymphoma have been reported to show variable levels of lymphocyte depletion that relate to the stage of disease.[105] Even patients with sarcoma sometimes show reduced peripheral blood T-cell populations at the time of presentation.[106] Despite these abnormalities in T-cell populations that are seen in cancer patients at the time of initial presentation, clinically profound T-cell immunosuppression is relatively uncommon before initiation of cytotoxic antineoplastic therapy.

After initiation of cytotoxic antineoplastic therapy, however, complications related to T-cell immunodeficiency are observed in a variety of clinical settings. Clearly, this is most severe and most frequent after allogeneic bone marrow transplantation when a variety of factors contribute to a high incidence of opportunistic complications (reviewed in ref. 107). Among these is the underlying disease, as patients with hematologic neoplasms who are referred for BMT have typically undergone intensive and prolonged therapy. Second, preparative regimens for allogeneic BMT are designed to be immunoablative. Indeed, it is clear that a primary factor necessary to allow engraftment of allogeneic hematopoietic stem cells is sufficient immunoablation to avoid host-versus-graft rejection. For this reason, common preparative regimens are highly immunosuppressive and frequently include a combination of cyclophosphamide and total body irradiation. More recently, the use of fludarabine has been shown to add enough to immunosuppression to allow engraftment without true myeloablation. Because of the profound lymphocyte depletion induced by fludarabine, it is anticipated that the risk for opportunistic complications will remain quite high in patients who receive this agent. T-cell depletion of the marrow graft also plays a significant role in enhancing immunosuppression by eliminating one potential pathway for T-cell regeneration ( Fig. 6-9). Finally, GVHD plays a pivotal role in adding to the immunosuppression associated with BMT. Not only does GVHD impact significantly on immune reconstitution, but the medications used to treat GVHD are potently immunosuppressive. Indeed, the most common cause of death in patients with GVHD is related to infectious complications. Therefore, recipients of allogeneic BMT are in general the most highly immunosuppressed group of cancer patients. For this reason, systematic approaches to prevent and treat opportunistic infection are indicated in the clinical management of these patients as discussed in Chapter 16 and Chapter 41.

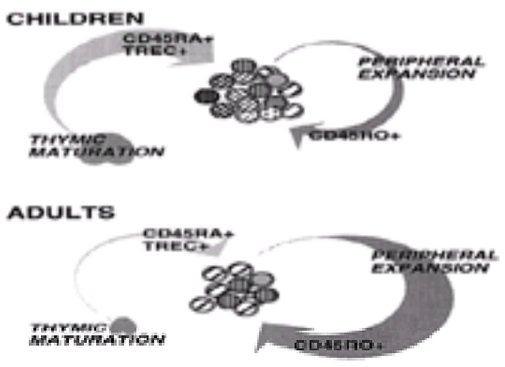

**FIGURE 6-9.** Pathways of T-cell regeneration after cytotoxic chemotherapy. Shown is a schematic representation of the two primary routes for $CD4^+$ T-cell regeneration. Children primarily regenerate T cells via thymic-dependent pathways as evidenced by normalization of peripheral $CD4^+$ T-cell numbers, a diverse T-cell receptor (TCR) repertoire, and the presence of rising numbers of $CD45RA^+/CD62L^+$ cells in the peripheral blood. In contrast, adults primarily regenerate $CD4^+$ T cells via the peripheral expansion of residual cells. This results in chronically reduced $CD4^+$ T-cell numbers, the accumulation of activated $CD4^+$ T cells ($CD45RA^+$, $HLA\text{-}DR^+$), a skewed TCR repertoire, and a propensity for programmed cell death. (Adapted from Mackall CL, Hakim FT, Gress RE. T-cell regeneration: all repertoires are not created equal. Immunol Today 1997;18:245–251.)

Notably, immunosuppressive complications of autologous BMT are generally less severe despite generally similar levels of initial T-cell depletion,[108,109] emphasizing the important role that GVHD and immunosuppressive medications used to control GVHD play in inducing allogeneic transplant-related immunosuppression. More recently, as the dose intensity of antineoplastic regimens has increased, opportunistic infections have also emerged as complications of cytotoxic antineoplastic therapy outside of the realm of bone marrow transplantation.[106,110,111] The agent most commonly implicated in antineoplastic therapy–induced immunosuppression is cyclophosphamide, which is capable of profound immunosuppression when administered as a single agent at high dose intensity.[112] In one study conducted at the National Cancer Institute (NCI) investigating single-agent dose escalation of cyclophosphamide, repetitive cycles with doses of 3.6 to 4.5 g per $m^2$ were administered in combination with GM-CSF. Sequential cycles were administered as rapidly as possible after myeloid recovery, which was unusually rapid, often within 14 days. In this study, neutropenic bacterial infections were uncommon, but opportunistic infections emerged as the dose-limiting toxicity. Therefore, although myeloid growth

factors allowed compression of the cycle length by minimizing myelotoxicity, the paradoxical result was an increase in regimen-related immunodeficiency. Similarly, recent results have shown that the use of autologous peripheral blood progenitor cell infusions can ameliorate myelosuppression after high-dose or myeloablative therapy; however, such infusions (at least in the autologous setting) do not lead to more rapid recovery of T-cell populations. [113] These results emphasize the distinctions in the regenerative pathways for myeloid versus T-cell populations after cytotoxic antineoplastic therapy. Although myeloid cells typically recover within 21 days after even dose-intensive therapy, lymphoid populations are reduced for a much longer period ( Fig. 6-8).

Clinically apparent immunosuppression has also been reported in patients enrolled on multiagent dose-intensive regimens administered for solid tumors and lymphoma. In one study, the dose intensity of the treatment regimen was shown to have a significant influence on the incidence of *Pneumocystis carinii* pneumonia, independent of other factors such as disease histology and stage at presentation. [114] Quantification of lymphocyte populations in the peripheral blood of patients treated on such dose-intensive protocols reveals significant T-cell depletion with a more profound effect on $CD4^+$ versus $CD8^+$ T-cell populations, resulting in a significantly reduced CD4:CD8 ratio. Although the relationship between the degree of $CD4^+$ depletion and the incidence of opportunistic infections has not been as extensively studied in cancer as it has in HIV infection, [115] there appears to be a general correlation between the degree of CD4 depletion and the risk for opportunistic infection in cancer patients as well. In HIV infection, it has been shown by many investigators that the risk for opportunistic infection rises substantially when the CD4 count falls below 200 cells per $mm^3$. Based on these data, the relationship between CD4 counts and opportunistic infection was compared among patients treated on three NCI protocols that showed variable levels of CD4 depletion. The rate of opportunistic infections was 0% with a mean posttherapy $CD4^+$ count of 120 ± 38 per $mm^3$, 33% when the mean posttherapy CD4 count was 68 ± 16 cells per $mm^3$, and 67% when the mean posttherapy CD4 count was 9 cells per $mm^3$.[106] Although the numbers of patients studied in this series was too small to definitely identify a threshold level of CD4 depletion that results in clinically significant immunosuppression, these results clearly show that chemotherapy as administered in the context of dose-intensive protocols for solid tumors in children can induce severe CD4 lymphopenia with a heightened susceptibility to opportunistic infection. This risk seems greatest when CD4 counts fall below 100 cells per $mm^3$.

As noted, the purine nucleoside analogs (2'-deoxycoformycin, 2-chloro-2'-deoxyadenosine and fludarabine monophosphate) represent another class of agents with a predilection for lymphocyte depletion. [116],[117],[118] and [119] These agents have a remarkable capacity for depletion of both dividing and resting lymphocytes, which likely contributes to their utility in the treatment of hairy cell leukemia and indolent lymphomas. Not surprisingly, however, these agents also induce profound depletion of normal lymphocyte populations, resulting in clinical complications related to opportunistic pathogens. As discussed, these agents are currently under investigation as the central components of new immunosuppressive preparative regimens used to allow hematopoietic stem cell engraftment in the setting of nonmyeloablative BMT.

Another clinical scenario wherein a substantial incidence of opportunistic complications occurs in the context of antineoplastic therapy involves chemotherapy regimens administered to patients with brain tumors.[120],[121] In this case, the combination of the T-cell depleting effects of chemotherapy and the functional alterations in cell-mediated immunity due to systemic corticosteroids results in significant immunosuppression. In addition, although radiation therapy in and of itself has modest immunosuppressive effects, one report suggests that the combination of radiotherapy and paclitaxel results in severe lymphocyte depletion when administered concurrently.[122] One regimen, which appears to be notable for the lack of immunosuppression, is the combination of vincristine and actinomycin D, as used in the treatment of Wilms' tumor.

The mechanisms by which classical cytotoxic agents induce T-cell depletion have not been well studied, but the effects are quite rapid. Within 1 day after initiation of cyclophosphamide therapy, there are already substantially reduced numbers of $CD3^+$ T cells in the peripheral blood that persist throughout the duration of therapy. Although classical models would suggest that alkylating agents primarily induce cell death through interference with cell division, chemotherapy induces a preferential depletion of naïve ($CD45RA^+$) $CD4^+$ T cells.[106] This subset has been shown to cycle at a diminished rate compared to memory ($CD45RO^+$) $CD4^+$ T cells,[100] suggesting that the lymphotoxic effect of these agents may not be dependent on cell cycling. Indeed, *in vitro* studies have shown that chemotherapy agents and radiation can induce spontaneous apoptosis in lymphoid cells, and clinical observations suggest that this may occur *in vivo* as well.[123]

With regard to other lymphocyte populations, B cells also sustain profound depletion in the context of dose-intensive multiagent chemotherapy. Generally however, this is accompanied by only modest reductions in serum IgG levels. In contrast, serum IgM and serum IgA levels undergo significantly greater depletion as a result of dose-intensive cytotoxic antineoplastic therapy. [113] NK cells, in contrast, appear to be relatively resistant to cytotoxic antineoplastic therapy, raising the possibility that they serve an important second line of host defense against viral pathogens in this setting and may be amenable to antitumor immunotherapeutic strategies, even in the face of chemotherapy-induced T-cell dysfunction.

Many of the current studies in this field have focused on changes in T-cell number, which are clearly a predominant feature of cytotoxic antineoplastic therapy–induced immunosuppression. There is also evidence to suggest, however, that important functional alterations may occur after cytotoxic antineoplastic therapy. After chemotherapy, we have observed a preponderance of activated T cells *in vivo*, which appear to have a heightened susceptibility for activation-induced programmed cell death.[124] Such functional alterations could significantly limit the capacity for response to antigen *in vivo*. Furthermore, restrictions in TCR repertoire diversity are likely to limit immune competence in hosts who have regenerated T cells predominantly via thymic-independent peripheral expansion. [125] Finally, recent studies have suggested that monocyte populations that are contained within peripheral blood stem cell harvests, and that frequently expand *in vivo* after cytotoxic antineoplastic therapy, may contribute to T-cell immunosuppression by the production of suppressive factors that inhibit T-cell function. [126],[127] Therefore, functional alterations in recovering T-cell and mononuclear populations may also contribute to cytotoxic antineoplastic therapy–induced immunosuppression.

In summary, the experience thus far suggests that although cancer patients have variable levels of immunosuppression at the time of presentation, the intensity of the antineoplastic therapy plays a central role in determining the risk for opportunistic complications. Clearly, such complications are most common in the setting of bone marrow transplantation; however, the use of immunosuppressive agents as part of dose-intensive regimens can lead to profound immunodeficiency in the non-BMT setting as well. The immunodeficiency induced by anticancer therapy appears to be primarily related to lymphocyte depletion and, perhaps most important, to CD4 depletion wherein increased depletion is associated with a higher incidence of opportunistic complications.

**T-Cell Regenerative Pathways**

When absolute lymphocyte counts are monitored after cessation of cytotoxic antineoplastic therapy, recovery to baseline values generally occurs within 3 months. NK-cell populations typically normalize immediately after cessation of therapy, [128] and these are followed by total B-cell populations, whose numbers generally normalize within 1 to 3 months.[129],[130] B cells often exhibit an overshoot such that supranormal values may be observed for a prolonged period after completion of cytotoxic chemotherapy. Restoration of total numbers of peripheral blood $CD8^+$ T cells generally occurs within 3 to 6 months after completion of cytotoxic antineoplastic therapy, with supranormal values for this subset also frequently observed during the initial phase of regeneration. [128] Such normalization of total lymphocyte counts belies the fact that recipients of cytotoxic antineoplastic therapy frequently experience prolonged CD4 lymphopenia. To understand the processes at work during this complex process of lymphocyte repopulation, we first review the various pathways of T-cell regeneration, with an emphasis on the implications of each, for the restoration of host immune competence.

The ontogenic or primary developmental pathway of T-cell development involves progeny of the pluripotent hematopoietic stem cells, which home to the thymus where they undergo an elaborate process involving expansion, differentiation, and selection. These newly produced cells are exported from the thymus bearing a naïve phenotype, and they subsequently travel throughout the peripheral lymphoid tissues awaiting encounter with antigen. Although a definitive marker for such thymic emigrants does not exist, they are contained within the $CD4^+CD45RA^+$ CD62hi subset.[131] Recently, a new method has been used to quantify recent thymic emigrants by employing polymerase chain reaction–based enumeration of cells that contain remnants of TCR rearrangement termed *TCR rearrangement excision circles*.[131] Thus far, however, available technology does not allow direct analysis of thymic emigrants because analysis of cell surface expression and intracellular TCR rearrangement excision circle expression cannot be performed simultaneously.

Importantly, T-cell populations can be regenerated in hosts in the absence of a thymus, primarily via a process that has been termed *peripheral expansion*.[132] Very simply, this involves the mitotic division of mature T cells themselves, thus increasing their cell number. Although peripheral expansion dramatically increases total body T-cell number, it is generally unable to completely normalize T-cell numbers, and it cannot restore TCR repertoire diversity. Indeed, because the process of peripheral expansion is driven by antigen encountered in the periphery, it is expected that contraction of the peripheral TCR repertoire will occur during the course of this process. Hence, it is not difficult to understand why thymic-dependent pathways are preferred for restoration of T-cell immune competence. When vigorous, the thymic-dependent T-cell regenerative pathway can both efficiently restore normal T-cell number and provide TCR repertoire diversity. When less vigorous, thymic-dependent pathways may still play an important role in the gradual replenishment of TCR repertoire diversity over time.

In the clinical setting, the degree of $CD4^+$ depletion induced by cytotoxic chemotherapy occurs in an age-independent fashion and is related to the intensity of

therapy. Importantly, however, the recovery of $CD4^+$ T-cell populations is highly age related, at least when comparing children to young adults. Here, recovery of $CD4^+$ T-cell populations 6 months after completion of cytotoxic antineoplastic therapy is inversely related to age in a more or less linear fashion such that children have brisk recovery, young adolescents show modest recovery, while older adolescents and young adults show poor CD4 recovery. [133] Furthermore, children typically show brisk recovery of the naïve ($CD45RA^+CD4^+$) subset coincident with recovery of total $CD4^+$ T-cell populations, and these rises are temporally associated with radiographic evidence of thymic enlargement post-chemotherapy (Fig. 6-10). Importantly, the gradual diminution in the ability to recover CD4 populations throughout childhood suggests that rather than a precipitous drop in thymic function occurring at the time of puberty, more likely there is a gradual diminution in thymic function that parallels the gradual reduction in thymic mass that is known to occur in humans during the first two decades of life. In contrast, adults generally show a slow, variable rise in $CD4^+$ populations over the first year after cessation of antineoplastic cytotoxic therapy. In this setting, $CD4^+$ cells predominantly display the memory ($CD45RO^+CD4^+$) phenotype.[124] During subsequent years, it is not uncommon to see gradual rises in naïve $CD45RA^+CD4^+$ cells in adults as well, although obvious radiographic evidence of thymic enlargement is rarely observed. Therefore, thymic-dependent pathways appear capable of restoration of $CD4^+$ T cells in children during the first 6 months after cessation of antineoplastic chemotherapy, whereas $CD4^+$ T-cell recovery in adults is dependent on the relatively inefficient thymic-independent pathways and perhaps variable degrees of low-level thymopoiesis ( Fig. 6-9). The clinical implication is that although children typically experience a relatively short period of immunosuppression associated with cytotoxic antineoplastic therapy, this period may be prolonged in older adolescents and adults. Importantly, however, if children are experiencing complications that may further impair thymic function, such as GVHD, they experience prolonged $CD4^+$ depletion similar to that observed in adults.[134] Similarly, prolonged CD4 depletion in excess of 30 years has been observed in recipients of mediastinal irradiation for Hodgkin's disease, suggesting that thymic function may be irreversibly impaired after local radiation therapy. [135] Finally, even in children, the initial months after completion of chemotherapy are likely predominated by thymic-independent pathways as recovery generally takes 3 to 6 months even in the youngest of patients.

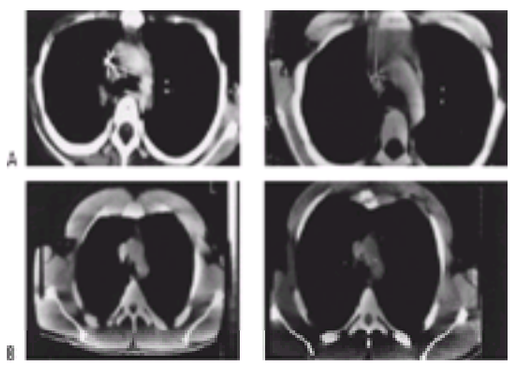

**FIGURE 6-10.** Thymic rebound after intensive chemotherapy. **A:** A contrast-enhanced computed tomography scan taken pre-therapy and 6 months after completion of dose-intensive chemotherapy in an 11-year-old treated for large cell lymphoma. Enlargement of the thymic shadow compared to baseline is observed. This was associated with a rise in peripheral blood total $CD4^+$ T-cell counts as well as $CD45RA^+CD4^+$ T cells. Biopsy of the thymus at this time point revealed normal thymic tissue. The hyperplastic organ subsequently returned to baseline size over the ensuing months. In contrast, enlargement of the small amount of thymic tissue present at baseline is not observed in the 19-year-old patient shown in **B**. Left: Baseline before chemotherapy. Right: 6 months after completion of chemotherapy. (From Mackall CL, Fleisher TA, Brown MR, et al. Age, thymopoiesis, and CD4+ T-lymphocyte regeneration after intensive chemotherapy. N Engl J Med 1995;332:143–149, with permission.)

With regard to $CD8^+$ T cells, the story is complicated by the existence of multiple $CD8^+$ T-cell subsets, many of which recover in an age-independent fashion after cessation of cytotoxic chemotherapy. In a study of children recovering from intensive chemotherapy, it was noted that unlike $CD4^+$ cells, no such relationships exist between age, thymic enlargement, and $CD8^+$ T-cell regeneration after chemotherapy.[128] Typically, within 3 months after cessation of cytotoxic chemotherapy, total $CD8^+$ numbers generally return to baseline regardless of patient age. Careful analysis of such populations, however, show that the bulk of the $CD8^+$ T cells contained within the recovered populations are atypical and represent the expansion of a normally minor subset of $CD8^+$ T cells that lack the CD28 co-receptor. Indeed, recovery of the $CD8^+CD28^+$ subset generally does not occur until approximately 1 year after cessation of therapy. The $CD8^+CD28^-$ cells that tend to predominate after chemotherapy are poorly responsive to mitogenic stimuli and may function primarily as negative regulatory or suppressor populations. [136,137] Several lines of evidence also suggest that such cells may be derived via thymic-independent pathways.[138,139] Therefore, although total $CD8^+$ T-cell numbers normalize rapidly after cessation of cytotoxic chemotherapy, it appears that abnormalities in the $CD8^+$ arm of the immune system also persist for a prolonged period after cessation of cytotoxic chemotherapy due to the expansion of a normally minor subset with abnormal functional capacity.

Therapeutic modalities for enhancing immune reconstitution are sparse at the present time. Although GM-CSF has been reported to improve immune reconstitution for patients treated with autologous BMT for lymphoma,[140] we observed prolonged T-cell depletion post-chemotherapy and post-BMT despite the use of GM-CSF in our patient populations.[113,133] Other potential cytokines include the use of IL-2, which has been shown to improve immune reconstitution in murine models and to increase $CD4^+$ counts in patients with HIV infection.[141] Alternatively, the provision of large numbers of cryopreserved autologous peripheral blood (mature) T cells is predicted to enhance immune reconstitution by contributing to thymic-independent peripheral expansion. It appears, however, that such T cells may be limited in their capacity to contribute to immune reconstitution if they are harvested after the initiation of chemotherapy, perhaps due to a susceptibility to programmed cell death.[113,124] Current studies are under way to ascertain whether the combination of systemic IL-2 therapy and infusion of chemotherapy-naïve mature T cells can rapidly reconstitute T-cell populations after chemotherapy. Future approaches are likely to involve the administration of agents that can modulate programmed cell death in expanding T cells, including the use of IL-7, which has been shown to be a potent modulator of immune reconstitution in animal models. [142]

## CANCER AS AN IMMUNE TARGET

Although the principal role of the immune system is protection from infectious pathogens, oncologists have sought to manipulate immunity to control cancer for at least 100 years. Although these efforts have yet to be translated into clinically effective therapies for the majority of human tumors, many lines of evidence suggest that immunotherapy for neoplastic disease may ultimately become a therapeutic reality. In this section, we review work spanning several decades that forms the basis for this hypothesis and emphasize current approaches for targeting human tumors, with a particular focus on issues of relevance to pediatric tumors. Specific immunotherapies and clinical trials are discussed in detail in Chapter 14.

### Animal Models

Early investigators used mouse models to study the ability of hosts to generate immune responses toward tumors. By necessity, this involved transplanting tumors from one mouse to another to evaluate the ability to reject transplanted tumors. To better evaluate potential mechanisms, spontaneously arising and experimentally induced neoplasms in animals were transplanted to other animals of the same species to evaluate immunization protocols and potential immune responses. Initially, the success of this approach was thought to be overwhelming. Virtually all transplanted tumors, if transplanted in small enough aliquots, were readily destroyed by immunologic mechanisms. Although severely immunodeficient or irradiated mice did not control even small transplanted tumor fragments, immunologically intact mice could readily destroy most allogeneic transplanted tumor fragments. However, these studies were undertaken before the development of an understanding of allogeneic immune responses, which are fully capable of eradicating tissues (either benign or malignant) that are transplanted between genetically disparate hosts within the same species. Indeed, as described by Sir Peter Medawar in his review of this literature in 1965, he noted the “immunologists who attempted to use transplantation to study tumors were instead using tumors to study transplantation.” Regardless, these studies did provide proof of the principle that immune effectors can eradicate tumor cells, although even in this setting this could be overwhelmed by large tumor burdens. Furthermore, these studies pointed out that a primary requirement for the generation of clinically relevant immunotherapies is the identification of antigens that could be used to target the immune response to syngeneic tumors.

Fortunately for the sake of scientific clarity, the fallacy of this approach of transplanting tumors was rapidly clarified. The ability to reject allogeneic transplanted tumors was readily documented by Gorer, Snell, and others to be the result of recognition of genetically inherited distinct transplant antigens (reviewed elsewhere[143,144,145] and [146]). Major and minor histocompatibility antigens expressed on all tissues of the tumor donor were the targets of T-cell recognition when the host rejected the transplanted allogeneic tumor. Indeed, it was the very weak to nonexistent immune response detected against syngeneic tumors of identical

histocompatibility type that enabled Gorer and Snell to identify the genes responsible for allograft rejection reactions and to generate congenic resistant strains differing only for these transplant-related genes. Despite the importance of these studies for clarification of the basic biology of transplant rejection, these results suggested that immune responses to syngeneic tumor were negligible.

### Tumor-Specific Transplantation Antigens

Independent studies evaluated another approach wherein the development of tumors within an individual mouse could be induced using viruses or chemical carcinogens. Prehn and Main induced murine tumors with the carcinogen methylcholanthrene (MCA). These tumors were fatal in the tumor-bearing host and were fatal when transplanted to syngeneic animals owing to local tumor growth and invasion. These tumors, unlike most clinical cancers, did not metastasize. Animals bearing a rapidly growing transplanted syngeneic tumor could have the tumor entirely resected surgically and be rendered tumor free. Such animals would survive tumor free. On rechallenge with the same tumor that had been growing in them originally (and that would have proved fatal), a clear immunologic response was mediated against the tumor (Fig. 6-11). Provided the rechallenge with the initial tumor used a small enough tumor transplant, the immune response could completely reject the transplanted tumor and provide protection.[147] This immune-mediated rejection was used as evidence for recognition of tumor-specific transplant antigens (TSTAs) that could not have been alloantigens because the tumors were derived from syngeneic animals.[144] Similar results were obtained with most experimental carcinogens used to cause chemically induced murine cancers. Although the nature of the TSTA in these chemical carcinogen-induced tumors remains somewhat uncertain, these data provided functional evidence for TSTA distinct to individual tumors.

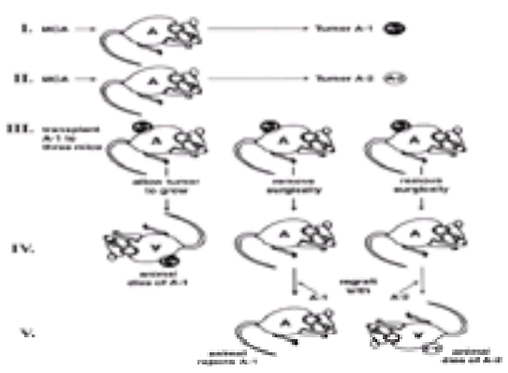

**FIGURE 6-11.** Rejection of chemically induced tumors. All mice shown (A) are strain AA mice (homozygous, syngeneic animals, with two identical strain A alleles at each genetic locus). The animal at the top in line I was treated with methylcholanthrene (MCA) to generate a fibrosarcoma-designated A-1. The animal in line II was treated with MCA and tumor A-2 developed. Line III shows grafting of a small amount of tumor A-1 onto three syngeneic AA animals. This tumor will grow progressively, and the animal will die (first mouse on line IV) if it is not removed. If the tumor is removed surgically, both animals will survive. If one of these mice is regrafted with some of tumor A-1, an immune reaction will develop and destroy tumor A-1 (left hand animal in line V). However, if the mouse is regrafted with a separate tumor (even a separate syngeneic tumor, such as A-2) it will not be rejected and will grow progressively (animal on R in line V). [Adapted from Prehn RT, Main JM. Immunity to methylcholanthrene-induced sarcomas. JNCI 1957;18:769; and from Sondel, PM, Rakhmilevich AL, DeJong JLO, Hank JA. Cellular immunity and cytokines. In: Mendelsohn J, Howley PA, Israel MA, Liotta LA, eds. The molecular basis of cancer. Philadelphia: Saunders, 2001 (in press).]

For virally induced tumors, research by Gross and by several other laboratories documented analogous TSTAs.[145] One difference, however, was that syngeneic tumors induced by the same virus in the same strain appeared to show cross-reactive TSTA with one another, suggesting a shared antigen on the surface of tumors caused by the same virus.

Three decades of *in vitro* and *in vivo* work with these experimental models have documented that the principal responding component of the immune system in all of these tumor rejection models are the T cells.[148] CTL and Th lymphocytes are typically involved and are most effective when working simultaneously against a transplanted tumor. In some model systems, the immunoprotective effect can be transferred by injecting T cells from a single-cell–derived clone (i.e., all cells in the clone express the same TCR gene rearrangement pattern), which provides specific recognition of the transplanted tumor.[149] In such models, administering IL-2 (Fig. 6-12) to the adoptively transferred tumor-bearing host can enable further *in vivo* growth and activity of the tumor-specific T cells.[150] Molecular analyses in some of these systems have clarified the nature of the tumor antigens recognized. For example, in the potent protective T-cell response to the murine leukemia caused by the Friend leukemia virus, a specific class II MHC molecule on the murine antigen-presenting cells presents a peptide contained within the virus's coat envelope protein (ENV) controlled by the viral ENV gene. These ENV-specific Th cells collaborate with CTL that recognize a nuclear peptide controlled by the GAG viral gene as expressed on the leukemia cell surface through its presentation in the groove of a specific class I MHC allele.[151] These animal models have formed the basis for a large number of ongoing preclinical efforts by many laboratories to identify appropriate molecules on human tumors, which could be used as T-cell targets. In the next section, we review current approaches for identifying and targeting such human tumor antigens.

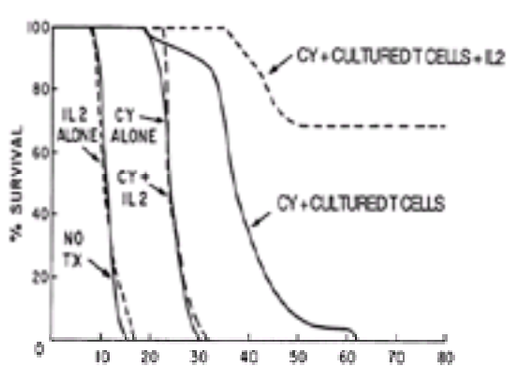

**FIGURE 6-12.** Efficacy of purified interleukin-2 (IL-2) *in vivo* as an adjunct to long-term cultured T lymphocytes in adoptive chemoimmunotherapy. C57BL/6 mice inoculated intraperitoneally with $5 \times 10^6$ FBL-3 on day 0 received no therapy (no Tx), treatment with 80 U per day of IL-2 on days 5 through 9 (IL-2 alone), treatment on day 5 with cyclophosphamide (CY) at a dose of 180 mg per kg (CY alone), treatment with CY on day 5 plus IL-2 on days 5 through 9 (CY + IL-2), treatment on day 5 with CY and $5 \times 10^6$ long-term cultured T lymphocytes immune to FBL-3 (CY + cultured T cells), or treatment on day 5 with CY plus C57aFBL (cultured) plus IL-2 on days 5 to 9 [CY + C57aFBL (cultured) + IL-2]. ### Identification of T-Cell Tumor Antigens

#### *Tumor-Reactive T-Cell–Defined Tumor Antigens*

Careful histologic analysis of a variety of human tumors reveals the presence of a lymphocytic infiltrate in a large number of tumor types. Investigators studying immune responses to malignant melanoma and renal cell carcinoma have attempted to identify the targets of these so-called tumor-infiltrating lymphocytes (TILs). Identification of tumor antigens by cloning the targets of TILs rests heavily on the assumption that tumor growth evokes a natural, endogenous immune reaction, at least a portion of which is directed toward tumor-associated molecules. Most commonly, this approach begins with the extraction of TILs from immune-responsive tumors such as malignant melanoma or renal cell carcinoma. Individual T-cell clones that are capable of lysing autologous tumor targets are generated, and the HLA-presenting allele on the target cell is identified. To identify the molecular target of the tumor-specific cytolytic T cells, complementary DNA libraries from the autologous tumor are cloned into cell lines that express the HLA-presenting allele. Identification of those clones that result in lysis is carried out sequentially until the

gene that is targeted by the T-cell clone is identified. [152,153]

This approach has led to the identification of several melanoma-associated tumor antigens that, when used as immunogens, have been shown to induce antitumor activity in clinical trials. [154,155] In general, the targets identified using this approach can be grouped into three main families. The first are the so-called cancer-testis antigens, which include molecules of the MAGE, BAGE, GAGE, PRAME, PAGE, and XAGE families. They are called *cancer-testis antigens* because they are expressed in a wide array of cancer tissues but are restricted in their normal tissue distribution to testes. Because human germ cells lack class I expression and are generally inaccessible to the immune response, it is hypothesized, and has now been experimentally proven, [156] that immune responses directed toward such antigens would spare all normal tissues. Importantly, although many molecules within the cancer-testis antigen family were initially identified using TILs derived from malignant melanomas, most of the antigens identified within this family are also expressed in other, nonrelated tumors. Presumably, this is related to demethylation of cancer-testis antigen promoters that occurs commonly in neoplastic tissues and that can induce the expression of these molecules in normal tissues. [157,158] Therefore, study of the targets of natural immune responses, particularly immunoresponsive tumors, such as malignant melanoma and renal cell carcinoma, has surprisingly led to the identification of potential public tumor antigens that could also be used as targets for immune response induction in a variety of histologically unrelated tumors.

With regard to pediatric tumors, the GAGE-1 molecule has been identified in 82% of neuroblastomas and 100% of stage IV tumors. [159] Indeed, the use of GAGE-1 as a target for monitoring minimal residual disease in neuroblastoma has been pioneered by Cheung and colleagues. [160] Although studies are limited in other pediatric tumors, GAGE-1 has also been seen in five of five Ewing's sarcomas,[159] and GAGE-1,2 is observed in 25% of other sarcomas. [161] GAGE-3,6 molecules are expressed in 78% of pediatric glioblastomas and 47% of medulloblastomas. [162] Molecules of the MAGE family are also expressed in pediatric tumors with reports of 50% to 80% of neuroblastomas expressing at least one of the four identified MAGE genes. [160,163,164 and 165] Osteosarcomas express MAGE-1, -2, -3, and -6 in approximately 50% of cases.[166] In one report, 11% of pediatric glioblastoma multiforme tumors and 60% of medulloblastomas expressed MAGE-2 whereas 13% of medulloblastomas expressed MAGE-3 and -6.[162] PRAME, another molecule identified by screening T cells reactive against autologous melanoma, has been found in a wide variety of human cancers, including sarcomas, head and neck tumors, and renal carcinomas.[167] This molecule is also observed on approximately 25% of acute leukemia samples, with 100% of those expressing the t(8;21) also expressing the PRAME molecule.[167] Using a computer-based approach to identify homologues of the GAGE family of genes, Brinkmann et al.[168] recently identified a new family, termed *XAGE*. XAGE-1 and XAGE-2 proteins were observed in Ewing's sarcoma and alveolar rhabdomyosarcoma. Therefore, identification of targets of T cells reactive against unrelated tumors has allowed the identification of multiple families of genes that occur across a wide spectrum of malignancies, some of which have been observed in pediatric cancers. Clearly, a great deal more work is required to fully characterize the range and extent of expression of these molecules in pediatric tumors. It is clear, however, that peptides derived from these molecules display significant binding to several common HLA alleles, raising the possibility that they could serve as targets for T-cell–mediated immune responses in some pediatric tumors.

The second family of molecules identified using this approach has been termed *melanocyte differentiation antigens*, as they are expressed on melanoma cells and also on normal melanocytes. These molecules include gp100/pmel17, melan-A/Mart-1, tyrosinase, TRP-1, and TRP-2. [161] Although expression of these antigens on cancers appears to be restricted to melanoma, their identification provided an important conceptual advance that is potentially of interest for the development of a wide variety of immune-based cancer therapies. Immunologic dogma has generally held that tolerance toward “self” molecules (such as differentiation antigens) occurs early in life, and that attempts to generate immune responses to such proteins would likely be unsuccessful. In clinical trials using immunization strategies targeting melanocyte differentiation antigens, however, not only have clinical antitumor responses been observed, but they are frequently associated with vitiligo, thereby providing evidence that such responses are also directed toward normal melanocytes. [169,170 and 171] These results provided the important observation that although immune tolerance toward “self” proteins is normally maintained in healthy individuals, immunotherapies can break tolerance and induce immune responses directed toward proteins that are not tumor specific, but rather tumor associated (i.e., also expressed on normal cell populations). The corollary of this observation is that autoimmunity is a potential risk of any antitumor immunotherapy directed against molecules that are not tumor specific; therefore, clinical complications related to autoimmunity must be monitored closely as such clinical trials evolve. Furthermore, the most attractive tumor-associated targets for immunotherapy development are those for which expression in normal tissues is limited to “nonvital” tissues such as melanocytes. Clearly, a better understanding of the mechanisms by which host T cells are tolerized to tumor antigens *in vivo* remains an important area of research and is central to generating immune therapies aimed at tumor-associated molecules.[172]

With regard to pediatric malignancies, it remains a possibility that classical oncofetal antigens or other molecules expressed during normal fetal development and also within neoplastic tissues could serve as targets for a T-cell–mediated immune response. Examples might include alpha-fetoprotein in hepatoblastoma, PAX-3 in rhabdomyosarcoma,[173] or chromogranin A or neuropeptide Y in neuroblastoma.[174,175] Potential drawbacks of targeting such molecules include the possibility that the selection against self-reactive T-cell clones of high avidity, which does occur early in life, results in a T-cell repertoire containing only T cells of relativity low avidity for such differentiation antigens. Indeed, TCRs with low avidity have been shown to function less well in clearing viral infection and tumors *in vivo*.[176,177] Furthermore, because expression of both cancer-testis antigens and differentiation antigens are generally not critical for viability of the tumor cell, the possibility of tumor escape by immune selection of antigen negative clones remains a real possibility. [155]

More recently, tumor antigens identified via the study of TILs have also included mutated forms of normal “self” molecules. Although the normal “self” molecule should not be recognized immunologically, the specific mutation of the molecule within the tumor allows the mutated form to be recognized as “foreign.” In one example, a mutated form of b-catenin was identified via subtractive cloning of melanoma-reactive TILs. [178] Similarly, a mutated form of the cyclin-dependent kinase, CDK-4, has been identified as a target of TILs.[179] Such molecules are particularly attractive as potential targets as they directly contribute to the neoplastic state and are therefore theoretically less susceptible to further mutation, hence diminishing the potential for immune escape by selection of antigen-negative targets. Indeed, a great deal of ongoing work by many laboratories currently using directed approaches to target such oncologically relevant, tumor-specific mutations is discussed in the following section.

### *Induction of Immune Responses Toward Independently Characterized Tumor-Specific Molecules*

The second approach for identifying potential targets for T-cell–based therapy of cancer rests heavily on the assumption that the rate-limiting factor in the generation of natural, endogenous immune responses to tumors is not the dearth of unique or aberrant molecules expressed by tumors, but rather the absence of secondary, costimulatory signals that are critical for activation of the immune system. A central theme in basic immunology holds that for T cells to become activated toward a particular antigen, two requirements must be met. First, the antigen must be presented as a peptide by a MHC molecule in a form that is recognizable to the T cell—signal one. Simultaneously, however, a second signal must be provided to the T cell, preferably via the same cell delivering signal one. The second signal is required to fully activate the signaling pathway within the T cell. [35] Because tumor cells in general lack costimulatory molecules that are capable of delivering the second signal, it remains possible that a great many antigens are presented on the surface of tumors, but in the absence of the second signal, the result is T-cell tolerance, rather than T-cell activation. Based on this model, one of the most critical components of immunotherapy development is the provision of adequate costimulation during the induction phase of the immune response. Currently, this can be achieved through immunization using dendritic cells, which were discussed earlier in this chapter in the section Critical Role of Costimulation: Antigen-Presenting Cells. Based on this model, many tumor immunologists are currently attempting to target tumor-specific molecules that have been identified during the course of investigations into the molecular mechanisms of neoplastic transformation. Although most of these molecules are intracellular, rather than cell surface molecules, it is now clear that intracellular molecules can serve as potential targets for T-cell–mediated immune responses as a result of the normal processes of protein breakdown, antigen processing, and presentation of antigenic peptides by surface MHC molecules.[27]

Examples of tumor-specific mutations that have been targeted immunologically include mutations in the Ras protein in which immune responses to mutant Ras peptides have been shown in mouse and human models.[180,181] Ras mutations occur commonly in adult lung and gastrointestinal carcinomas, whereas in pediatrics, Ras mutations are much less common. Similarly, experimental models have shown successful immunologic targeting of mutant p53, which is known to occur in a variety of adult tumors.[182,183 and 184] The difficulty associated with immune targeting of p53, however, is the requirement for sequencing and producing individualized p53 peptides for each patient because alterations in this molecule are highly variable.

In pediatric oncology, characteristic chromosomal translocations occur in a variety of tumors and provide potential targets for T-cell–mediated immune responses. This is because peptides that span the breakpoint region of the translocation represent novel epitopes that do not exist in normal tissues and hence may be susceptible to immune targeting (Fig. 6-13). Recent studies have attempted to target the breakpoint regions of the t(2;13) and the t(11;22) found in alveolar rhabdomyosarcoma and the Ewing's sarcoma family of tumors, respectively. For this approach, 15 to 18 amino acid peptides were synthesized that spanned the breakpoint region of the t(2;13) and the t(11;22) type 1 and type 2 in Ewing's sarcoma. Using computer-based models, several of the nonamers derived from these peptides were predicted to bind to mouse and human APC. The peptides were then pulsed onto murine APCs, and the irradiated pulsed APCs were administered to mice. Animals sensitized in this manner generated cytolytic T cells that were specific for the peptide and also specifically recognized and killed CT26 adenocarcinoma

cells transfected to express the full-length t(2;13) fusion protein. Therefore, these results demonstrated that breakpoint region peptides could be processed and presented on the cell surface in the context of murine MHCs. Furthermore, immunized mice were protected *in vivo* against a subsequent tumor challenge with transfected CT26 adenocarcinoma cells, and adoptive transfer of immunized cells led to antitumor responses in hosts bearing transfected CT26 adenocarcinoma cells. Based on this preclinical work, current clinical trials are under way to test whether peptides derived from the breakpoint region of t(2;13) and t(11;22) are capable of eliciting immune responses and antitumor effects in high-risk patients with alveolar rhabdomyosarcoma and Ewing's sarcoma.

**FIGURE 6-13.** Generation of a tumor-specific T-cell epitope as a result of a chromosomal translocation. Shown is the amino acid sequence of the breakpoint region of the t(2;13)(q35;q14) found in alveolar rhabdomyosarcoma. The peptides derived from the wild-type PAX3 and FKHR genes would be predicted to be recognized as self-peptides and therefore ignored by the immune system. However, the generation of the chromosomal translocation results in a series of eight breakpoint region peptides (designated bp 1 to 8) nine amino acids in length (optimal size for binding to major histocompatibility complex class I), which could potentially be recognized as novel tumor-specific epitopes by T cells.

Other chromosomal translocations that have been shown to provide peptide sequences at the breakpoints that can serve as targets for immune-mediated responses include the t(9;22), which is seen in essentially all patients with chronic myelogenous leukemia and approximately 5% of pediatric patients with acute lymphoblastic leukemia.[185] Peptides derived from the breakpoint region of the t(9;22) can induce immune responses in healthy people, as well as in chronic myelogenous leukemia patients, and such T cells have been shown to be capable of lysing chronic myelocytic leukemia targets that express the HLA-presenting allele. Similar results have been observed for the t(12;21), which occurs in approximately 25% of acute lymphocytic leukemia patients.[186] Recent studies have also shown evidence for binding of breakpoint peptides derived from t(X;18) in synovial cell sarcoma as well as t(11;22) in desmoplastic small round cell tumor to common HLA alleles, suggesting that these peptides could also potentially serve as immunogens in these tumors.

Although targeting such eminently tumor-specific molecules as chromosomal translocations is attractive due to their penultimate specificity, potential drawbacks include the relatively narrow immune response that is likely to be generated toward the limited number of epitopes that make up the breakpoint region. Similarly, because peptide-based therapies require HLA binding of individual peptide epitopes, it is possible that sufficient HLA binding of breakpoint peptides will only exist for a limited number of HLA alleles. This limitation is particularly relevant to pediatric tumors that are rare enough in the general population to limit the practicality of conducting trials and developing therapies limited to patients with unique HLA alleles (as has been possible for testing of these vaccine strategies in the more common malignancies in adults with cancer).

***Whole Tumor Cell Vaccination***

A third approach for targeting T cells toward tumor cells is to exploit the antigen processing and antigen-presenting capacities of professional APCs by supplying the entire array of antigens that may be contained within the whole tumor cell to the APC. This approach rests heavily on the assumption that the HLA makeup of each individual is a primary factor in determining which molecules are most immunogenic for any individual. Therefore, it may be less important to identify individual antigens than to devise methods to allow each individual's own antigen-processing machinery to present HLA-binding molecules present within the tumor to the individual's immune system. This approach also theoretically would induce the development of a broad, polyclonal immune response rather than focusing the immune response on one particular antigen, thus potentially amplifying the number of lymphocytes capable of responding to the tumor and diminishing the likelihood of tumor escape via immune selection. Indeed, the clinical use of whole tumor cell vaccines would not require the identification of individual target antigens for individual tumors and even assumes that different molecules will prove to be more or less immunogenic in different individuals. Such an approach could be particularly useful in pediatric oncology wherein the practical issues surrounding the development of distinct antigens as clinical products for each HLA allele in rare tumors are substantial.

Currently, there are a variety of means under study to present the complete antigenic array of a given tumor cell to T cells via dendritic cells. Fusing tumor cells to autologous dendritic cells has recently allowed the tumor-dendritic cell hybrid to be used as an effective vaccine for inducing antitumor responses in patients with renal cell cancer.[187] Another method comes from a recently published report wherein it was shown that dendritic cells preferentially ingest apoptotic and necrotic cells and can subsequently present antigenic peptides derived from such cells to autologous T cells.[41,42] Theoretically therefore, apoptotic necrotic tumor cells could be fed to dendritic cells as immunogens. Similar results have been obtained using RNA that has been fed to dendritic cells wherein the induction of tumor-specific CTLs has been shown.[188,189] This technique has the advantage of requiring only limited amounts of tumor tissue in cases in which cell lines are not available, which could be particularly pertinent to the development of such therapies in pediatrics. Tumor lysates [190] as well as acid-stripped antigenic peptides have also been shown to be capable of inducing tumor-specific immune responses.[191] Tumor-cell–derived heat shock proteins, which presumably function as molecular chaperones within the tumor cell and are thus a rich source of endogenously processed peptides, can also potently induce tumor-specific immune responses by providing an array of immunogenic peptides to autologous T cells.[192]

These advances in our understanding of the function of T cells, antigen processing, and presentation by APC, and the molecules that are selectively expressed on human tumor cells, have set the stage for the potential clinical development of effective active immunotherapy. Current goals of research in this area are to identify the optimal approaches to induce a patient's own T cells to selectively recognize and destroy autologous tumor cells. Separate immunotherapy strategies are based on tumor recognition by cells of the innate immune system and by Ig molecules produced by B cells.

**Antitumor Potential of the Innate Immune System**

Cells of the innate immune system are not as effective at mediating tumor cell destruction as are activated, antigen-specific CTLs. However, when activated, certain cells of the innate immune system, particularly NK cells and macrophages, can mediate potent destruction of tumor cells *in vitro* and in animal models. Thus, several clinical strategies have been pursued whereby activators of the innate immune system (IFNs or IL-2 to activate NK cells, muramyl-tri-peptide-phosphatidyl-ethanolamine to activate macrophages) have undergone clinical testing with some signs of clinical benefit in treating spontaneously arising tumors in companion animals or in patients. However, the actions of these activated cells do not seem to be sufficiently tumor specific. A variety of "nonspecific" toxicities (e.g., fever, rash, capillary leakage, and rigors) are associated with these approaches, and may reflect the systemic effects of the downstream "cytokine storm" induced by these activators of the innate immune system. More recent approaches are trying to utilize T- or B-cell tumor recognition mechanisms to enhance the antitumor capabilities of the innate immune system (see following section).

**Tumor-Specific Selective Antibodies**

Although the T-cell component of the immune system appears to be pivotal in many experimental and therapeutic immune responses to tumors, efforts directed at B-cell reactivity to tumor have also been pursued. For several human tumors, particularly melanoma, renal cell carcinoma, neuroblastoma, and head and neck cancers, biochemical separation of molecules found in human patient sera can demonstrate, in some patients, Ig molecules or immune complexes that appear to react with the patient's autologous tumor.[193] The possibility that these molecules may be mediating an antitumor effect or somehow masking the tumor surface from cellular immune recognition and destruction has been suggested, and additional data are needed. Nevertheless, the presence of human antibodies against human tumors promotes the possibility of generating antibody molecules that recognize tumor-specific or tumor-selective molecules to enable their use in the preferential binding *in*

*vivo* to tumor cells.

Since the creation of monoclonal antibodies in 1975 ( Fig. 6-6), labs worldwide have been immunizing mice with human tumor tissue and screening for antibodies that specifically recognize human cancer cells, but not any normal human tissues. Although rare antibodies of this type (“tumor specific”) have been described, most antibodies produced by this approach have been shown to recognize both neoplastic and normal human tissues. Some of these, which may be clinically useful, recognize molecules that are highly overexpressed on certain human tumors and expressed weakly on only a small histologically distinct subset of normal human tissues. Examples of such tumor-selective antigens that have been important in clinical pediatric oncology are: the CD19 molecule expressed on pre-B leukemia and lymphoma, and on certain precursor B cells; the CD33 molecule found on acute myeloid leukemia cells, as well as certain normal myeloid precursors; and the GD2 disialoganglioside, which is overexpressed on neuroblastoma and most osteosarcomas, but also expressed weakly on peripheral nerves. [194] Multiple molecular modifications of these and other similar tumor selective monoclonal antibodies are being pursued for diagnostic and therapeutic purposes. These include *in vitro* purging of tumor cells from hematopoietic stem cell and several strategies involving direct *in vivo* administration of these tumor-reactive antibodies.

The infusion of tumor-reactive antibody without directly activating antitumor recognition by the host's own immune system has been designated “passive” immunotherapy, to differentiate it from the “active” immunotherapy directed at inducing the host's own immune system to recognize the cancer directly. In fact, there may not be such a clear distinction between these active and passive approaches, as both may be working together. [195] For example, 35 years ago, Jerne proposed an “immune network hypothesis” whereby any immune response turns on a compensatory regulatory response. For example, in an immune response to a tumor antigen (e.g., GD2), an antibody against GD2 may be produced ( Fig. 6-14). This is designated as “antibody-1” (Ab-1). The unique peptide sequence of that Ab-1's antigen-binding component (generated through the somatically derived Ig gene rearrangement process) can be considered as an antigen itself for the immune system and is designated the “idiotype” of the Ab-1 molecule. Jerne proposed that this could induce the immune system to create an antiidiotype antibody (Ab-2), which recognizes the idiotype as foreign. Because the antigen-binding portion of the anti-GD2 antibody can specifically interact with the GD2 molecule, and can also specifically interact with the Ab-2 molecule, this implies that the antigen-binding portion of the Ab-2 molecule and the GD2 molecule may have some structural similarity. This concept becomes even more complex when considering the host's immune response against the unique peptide sequence of the antigen-binding portion of the Ab-2 molecule. The anti-Ab-2 molecule (in early descriptions referred to as an *anti-antiidiotypic antibody*) made by the host should recognize the antigen-binding portion of Ab-2 (which has molecular structural similarity to the GD2 itself); thus, the Ab-3 molecule may have direct antitumor recognition capabilities. Sufficient data in a variety of systems have now documented the validity of this concept. Thus, clinical trials providing passive treatment to patients with antitumor antibody (i.e., Ab-1) suggest antitumor effects may be influenced by the induction of Ab-3. [196] Furthermore, separate clinical trials are intentionally treating patients with antiidiotypic antibodies (i.e., Ab-2) to induce an Ab-3 response. [195] In such trials, the Ab-2 molecule is actually functioning as the antigenic component of a “tumor antigen vaccine.” Furthermore, it seems that some patients being “immunized” with Ab-2 molecules are also generating T-cell responses against the initial tumor antigen that had been recognized by the Ab-1 that was the “target “ of the Ab-2 molecule.

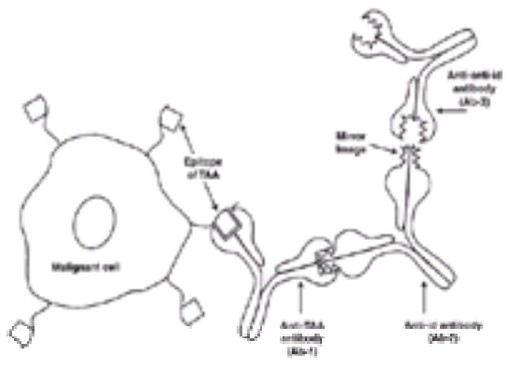

**FIGURE 6-14.** Mimicry of tumor-associated antigens (TAA) by anti-id antibodies. An epitope of a TAA is shown schematically by the box attached to a glycoprotein on the membrane of the tumor cell. A monoclonal antibody (Ab) was made in mice against this TAA. This anti-TAA antibody (Ab-1) has antigen-binding ends (Fab) that allow tight binding of the TAA epitope. When Ab-1 is used as an immunogen, it can induce an antibody directed against it. This antiidiotypic antibody (Ab-2) has antigen-binding sites that can bind to the antigen-binding sites of Ab-1. As such, the antigen-binding sites of Ab-2 may interact with the antigen-binding sites of Ab-1 in the same way that the antigen-binding sites of Ab-1 interact with the TAA itself. Thus, the antigen-binding sites of Ab-2 and the TAA are both recognized by Ab-1, and the antigen-binding sites of Ab-2 may be immunologically similar in structure to the TAA of the malignant cell. This similarity in structure is referred to as *internal image*. If the Ab-2 molecule is recognized as an antigen, the antibody directed against it is an “anti-anti-id antibody” (Ab-3). As the Ab-3 recognizes the internal image of the TAA found on Ab-2, the Ab-3 antibody may directly recognize the TAA itself. This is the rationale behind using an anti-id (Ab-2) to induce an immune response (Ab-3) able to recognize a TAA. [Adapted from Mittelman A, Wang X, Matsumoto K, Ferrone S. Anti-idiotypic response and clinical course of the disease in patients with malignant melanoma immunized with mouse anti-idiotypic monoclonal antibody MK2-23. Hybridoma 1995;14:175–181; and from Sondel PM, Rakhmilevich AL, DeJong JLO, Hank JA. Cellular immunity and cytokines. In: Mendelsohn J, Howley PA, Israel MA, Liotta LA, eds. The molecular basis of cancer. Philadelphia: Saunders, 2001 (in press).]

### Combined Approaches

Clinically effective antitumor immunotherapy remains a goal not yet fully achieved, despite many effective preclinical strategies and several promising clinical approaches currently being pursued. As we obtain a better molecular and cellular understanding of the immune system, and of the tumors we wish to eradicate through immune recognition and destruction, more effective strategies will likely become possible. These may well involve combined approaches that add immunotherapy to conventional antitumor treatments or combine distinct immunotherapies attempting to obtain additive effects. For example, activation of the innate immune system with GM-CSF (neutrophils and macrophages) and IL-2 (NK cells) may have some antitumor activity, and is known to activate cells expressing Fc receptors. Infusions of tumor-reactive monoclonal antibodies can target the antibodies to sites of tumors *in vivo*, but tumor destruction may be limited by the ability of the antibody to use effector cells (cells with Fc receptors) to selectively destroy the tumor. Thus, combined treatment with cytokines such as GM-CSF and IL-2 together with tumor reactive monoclonal antibody [197] may allow these distinct mechanisms to work additively, allowing the activated effector cells to selectively recognize the tumor through *in vivo* ADCC. Ongoing progress with this and other forms of clinical cancer immunotherapy is presented in Chapter 14.

## ACKNOWLEDGMENTS

Research summarized in this chapter reflects experiences of various laboratory and clinical research teams worldwide, but this review does not attempt to cite comprehensively the massive body of literature in this expanding field. Work cited from our research teams are supported by National Institutes of Health (NIH)-NCI Intramural funds and NIH grants CA-32685, RR-03186, CM-87290, CA-53441, and CA-20432; NIH support to the University of Wisconsin General Clinical Research Center; GCRC; and the Midwest Athletes for Childhood Cancer Fund. Gratitude is given to our colleagues J. A. Hank and L. Helman, who have been involved in most aspects of these studies, and to editors Pizzo and Poplack for inviting us to provide this revised chapter.

# CLINICAL ASSESSMENT AND DIFFERENTIAL DIAGNOSIS OF THE CHILD WITH SUSPECTED CANCER

TERESA J. VIETTI
CHARLES PHILIP STEUBER

## SIGNS AND SYMPTOMS IN THE CHILD WITH CANCER

It is usually difficult to diagnose childhood cancer in its early stages because most of the signs and symptoms are relatively nonspecific and may mimic a variety of other, more common childhood disorders. For a pediatric oncologist, the index of suspicion of cancer is high; for the primary care physician, the opposite is true. The early manifestations are vague, childhood malignancies are rare (see Chapter 1), and there may be a reluctance to suggest such a diagnosis on the basis of indefinite signs and symptoms because of its ominous implications to the family. However, even though the patient or parents may not directly express it, they are often worried about whether an unexplained fever or lump represents a serious illness such as a malignancy. It is therefore appropriate that the possibility of cancer should be mentioned when the initial signs and symptoms are suspicious. The time to diagnosis of pediatric cancer is variable and ranges from a median time of 31 days for neuroblastoma to 136 days for Hodgkin's disease (Table 7-1).[1]

| Diagnosis | n | Mean | Median | 25th percentile | 75th percentile |
|---|---|---|---|---|---|
| Brain | 194 | 211 | 93 | 38 | 237 |
| Ewing's | 82 | 182 | 127 | 79 | 255 |
| Hodgkin's | 143 | 223 | 136 | 49 | 270 |
| Leukemia | 908 | 109 | 52 | 20 | 129 |
| Non-Hodgkin's lymphoma | 184 | 117 | 62 | 25 | 141 |
| Neuroblastoma | 237 | 120 | 58 | 15 | 164 |
| Osteosarcoma | 67 | 127 | 98 | 40 | 191 |
| Rhabdomyo-sarcoma | 126 | 127 | 55 | 25 | 161 |
| Wilms' | 223 | 101 | 31 | 9 | 120 |

**TABLE 7-1. DISTRIBUTION OF LAG TIME IN DAYS BY DIAGNOSIS OF COMMON CHILDHOOD CANCERS**

Obtaining the history is the first step in the diagnostic process, with the chief complaint being the most important initial clue. Some of the signs and symptoms that the public associates with the much more common adult-onset malignancies are rare in children. These include hoarseness, difficulty in swallowing, breast mass, chronic cough, a non-healing skin lesion, difficulty in voiding, bleeding from the rectum, and a change in bowel habits.

The signs and symptoms that are common to many childhood illnesses and possible malignancies are listed in Table 7-2. Initial evaluation for a malignant neoplasm is usually not warranted. If these signs or symptoms do not subside within a reasonable period, then a telephone consult with a pediatric oncologist or other specialist is warranted. There are exceptions to this generalization. For instance, a soft tissue mass on the torso or extremities in a child younger than 1 or 2 years of age warrants early evaluation and biopsy unless it is known that there was some traumatic event that could have caused such a bump.

| Symptom/sign | Possible malignancy |
|---|---|
| Generalized malaise, fever, adenopathy | Lymphoma, leukemia, Ewing's, NBL |
| Head and neck | |
| Headache, nausea, vomiting | Brain tumor, leukemia |
| Febrile seizure | Brain tumor |
| Earache | STS |
| Rhinitis | STS |
| Epistaxis | Leukemia |
| Pharyngitis | STS |
| Adenopathy | NBL, thyroid, STS, lymphoma, leukemia |
| Thorax | |
| Extrathoracic | |
| Soft tissue mass | STS, PNET |
| Bony mass | EWS, NBL |
| Intrathoracic | |
| Adenopathy | Lymphoma, leukemia |
| Abdomen | |
| External soft tissue | STS, PNET |
| Internal: diarrhea, vomiting, hepatomegaly, and/or splenomegaly | NBL, lymphoma, hepatic tumor, leukemia |
| Genitourinary | |
| Hematuria | Wilms', STS |
| Trouble voiding | Prostatic or bladder STS |
| Vaginitis | STS |
| Periscrotal mass | STS |
| Musculoskeletal | |
| Soft tissue mass(es) | RMS, other STS, PNET |
| Bony mass/pain | Osteosarcoma, EWS, NHL, NBL, leukemia |

EWS, Ewing's sarcoma; NBL, neuroblastoma; NHL, non-Hodgkin's lymphoma; PNET, primitive neuroectodermal tumor; RMS, rhabdomyosarcoma; STS, soft tissue sarcoma, including rhabdomyosarcoma.

**TABLE 7-2. SYMPTOMS AND SIGNS OF CHILDHOOD CANCER MIMICKING NORMAL CHILDHOOD ILLNESSES; INITIAL EVALUATION FOR CANCER USUALLY NOT WARRANTED**

There are signs and symptoms that are cause for alarm and concern (Table 7-3) and that warrant immediate evaluation to establish the diagnosis. If at all possible, these children and their families should be referred to a pediatric cancer center. There are multiple reasons for this. In addition to evaluation of the physiologic status of the child, the extent of disease should be evaluated by appropriate laboratory and imaging studies. In addition to a pediatric oncologist and surgical specialist, all of the other disciplines that may be involved in the initial evaluation, diagnosis, and subsequent management should be consulted. For instance, if the lesion is located on an extremity, a radiation oncologist should be consulted to make sure that subsequent radiation therapy (if required) will not be compromised by an inappropriately placed incision.

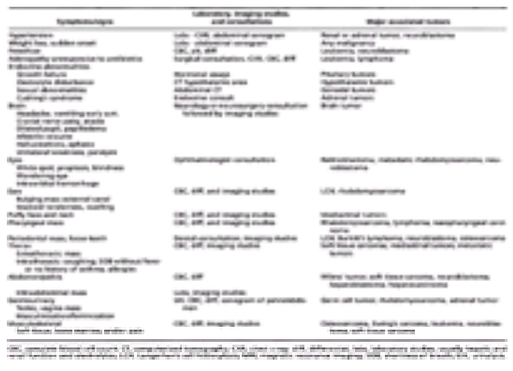

**TABLE 7-3. UNUSUAL SYMPTOMS AND SIGNS THAT WARRANT IMMEDIATE LABORATORY AND/OR IMAGING STUDIES AND CONSULTATION**

A pathology consult is absolutely essential. He or she will make sure at the time of surgery that enough appropriate material is obtained to establish the diagnosis. Studies will include not only routine histochemical and immunochemical stains but also immunotyping, cytogenetics, molecular genetics, electron microscopy, and, when warranted, anaerobic, aerobic, fungal, and other cultures for fastidious organisms. If the pathologist can confirm while the child is still asleep that the lesion is malignant, other suspicious lesions can be biopsied or excised. A bone marrow aspirate and lumbar puncture can be performed and a central venous access inserted.

At least 85% of pediatric cancers are associated with the presenting signs and symptoms listed in Table 7-2 and Table 7-3. The remaining 10% to 15% of tumors are those associated with unusual signs and symptoms that can make early diagnosis even more difficult. The pediatric tumor most commonly associated with unusual signs and symptoms is neuroblastoma (Table 7-4). Table 7-5 lists unusual presentations that have been reported for other pediatric malignancies.

| |
|---|
| Unusual signs and symptoms not related directly to tumor growth |
| Chronic diarrhea[2] |
| Polymyoclonus-opsoclonus[3] |
| Cog-wheel erythrocytes[4] |
| Failure to thrive[5] |
| Cushing's syndrome[6] |
| Unusual signs and symptoms related directly to tumor growth |
| Horner's syndrome[7] |
| Superior vena cava syndrome[8] |
| Hydrocephalus |
| Meningeal involvement[9] |
| Cavernous or lateral sinus involvement[10] |

| Heterochromia[16] |

**TABLE 7-4. UNUSUAL PRESENTATIONS OF CHILDHOOD NEUROBLASTOMA**

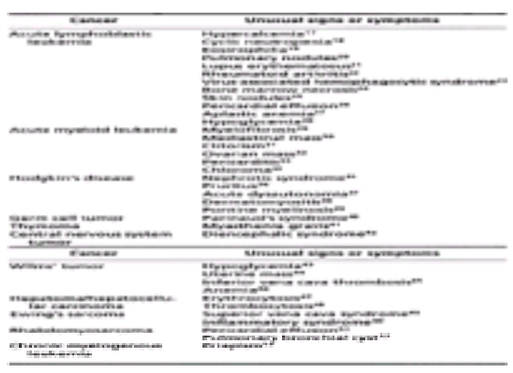

**TABLE 7-5. UNCOMMON PRESENTATIONS OF CHILDHOOD CANCERS OTHER THAN NEUROBLASTOMA**

The family medical history is of paramount importance when the diagnosis of malignancy is a possibility. Detailed histories of the parents, siblings, and first cousins should be noted on a family tree or family group record. The minimal data collected should include a list of serious illnesses, family members' ages, congenital anomalies, and the cause of death for deceased members. The occurrence of any malignancy should be documented with as much demographic data as are available on the diagnosis.

When dealing with pediatric tumors, genetic factors may be important. Established associations with genetic traits and other neoplasms or disorders are summarized elsewhere (see Chapter 3). The major categories of disease linked with an increased risk of cancer are immunodeficiency disorders, metabolic disorders, disorders of chromosomal instability, and the phakomatoses. Certain familial and genetic diseases, such as autoimmune diseases, neurofibromatosis, and familial polyposis are associated with an increased incidence of cancer.

Because outcomes for children with cancer have improved, there is a growing cohort of survivors of childhood cancers who have increased risk for development of a second malignancy.[54],[55] and [56] The association of osteosarcoma and bilateral retinoblastoma[57] and that of acute lymphocytic leukemia (ALL) and brain tumors[58] are good examples of such high-risk populations (see Chapter 2 and Chapter 49).

Environmental factors also are associated with increased risk for childhood cancer. Of the recognized oncogenic environmental factors, exposure to ionizing radiation[59] and oncogenic viruses (e.g., human immunodeficiency virus, Chapter 25, and possibly Epstein-Barr virus, Chapter 5) are the most commonly reported.

## DIFFERENTIAL DIAGNOSIS

The following sections discuss some of the more common signs and symptoms seen with pediatric cancer and suggest a method of workup for each one. Table 7-3 lists these signs and symptoms and the differential diagnoses and suggested diagnostic studies.

### Headaches

Headache is a common symptom seen in a pediatric practice. Although few of these headaches are caused by intracranial tumors, it is always important to rule out a brain tumor when dealing with complaints of repeated headaches (see Chapter 27).

The diagnosis of a brain tumor is initially suspected on the basis of a symptom complex that reflects the site of the tumor. Pediatric brain tumors are frequently situated so that they interfere with cerebrospinal fluid circulation, and increased intracranial pressure is a common occurrence. An analysis of the early prominent symptoms in a group of children with brain tumors revealed that with supratentorial tumors vomiting occurred in 46% of patients and headache in 43%, whereas with infratentorial tumors, 59% of patients had coordination difficulties, 76% experienced vomiting, and 56% complained of headache. [60]

Computed tomography (CT) and magnetic resonance (MR) with or without contrast imaging offer precise, noninvasive means to investigate the possibility of a brain tumor (see Chapter 9 and Chapter 27). However, these tests cannot be recommended routinely for all children with headache or vomiting. Honig and Charney [61] analyzed the history, physical examination findings, and skull radiographs of 72 children with headaches secondary to brain tumors. Their findings suggest that the best method of screening for a brain tumor in a patient with a headache is a careful neurologic examination, because approximately 95% of children with a headache and a brain tumor had abnormal neurologic findings on clinical examination. [61]

Obtaining a good clinical history is extremely important. The following variables should be determined: duration of symptoms and their location, timing, severity, precipitating events, and mode of onset. The study by Honig and Charney [61] indicated the importance of the following symptoms in suggesting a brain tumor: recurrent morning headache; headaches that awaken the child; intense and incapacitating headache; and changes in the quality, frequency, and pattern of the headaches. The conditions that suggest the need for further radiologic examination are outlined in Table 7-6. These examinations should be combined with a thorough neurologic examination.

| |
|---|
| Presence or onset of neurologic abnormality |
| Ocular findings such as papilledema, decreased visual acuity, or loss of vision |
| Vomiting that is persistent, increasing in frequency, or preceded by recurrent headaches |
| Change in character of headache, such as increased severity and frequency |
| Recurrent morning headaches or headaches that repeatedly awaken child from sleep |
| Short stature or deceleration of linear growth |
| Diabetes insipidus |
| Age of 3 yr or younger |
| Neurofibromatosis |
| Cured of acute lymphoblastic leukemia with irradiation of central nervous system as part of initial treatment |

**TABLE 7-6. CONDITIONS SUGGESTING THE NEED FOR COMPUTED TOMOGRAPHY IN CHILDREN WITH HEADACHE**

### Lymphadenopathy

Lymphadenopathy is a common complaint and physical finding in children. The size of the lymph nodes rapidly increase in size during the first 12 years of the child's life to such an extent that the total lymph node mass will be twice the size of that seen in an adult ( Fig. 7-1).[62] The size of the nodes in children vary markedly because the child is continuously exposed to new viruses and bacteria. The lymphocytes react to this exposure by markedly increasing their number to combat any invasion. A lymph node is considered enlarged if it is more than 10 mm in its greatest diameter. Exceptions are epitrochlear nodes, for which 5 mm is considered abnormal, and inguinal nodes, which are not considered abnormal unless they are larger than 15 mm. Most children have palpable, small cervical, axillary, and inguinal nodes, but adenopathy in the posterior auricular, epitrochlear, or supraclavicular area is definitely abnormal. Most enlarged nodes in children are related to infections.

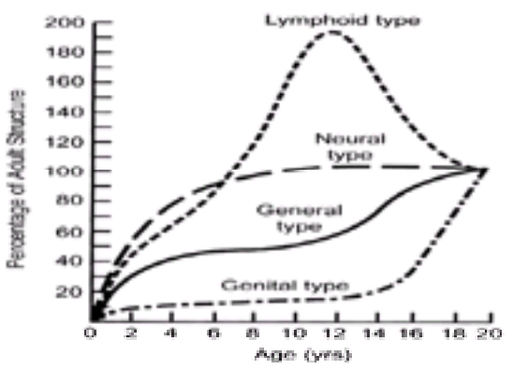

**FIGURE 7-1.** Growth of lymphoid tissue, neural cells, and supporting structures in the central nervous system; general somatic growth; and growth of secondary sex characteristics in a child from birth to adulthood. (Redrawn from Harris JA, et al: Measurement of man. University of Minnesota Press, 1930.)

A thorough physical examination and history are essential to the initial evaluation of lymphadenopathy. One of the first determinations to be made is whether the nodal enlargement is regional or generalized. Conventionally, lymphadenopathy is considered generalized when nodes are enlarged in two or more noncontiguous lymph node areas. It would be unusual to have generalized adenopathy without associated findings. Ordinarily, there is no problem in categorizing generalized lymphadenopathy fairly quickly after a thorough history and physical examination and a few radiographic and blood tests. For example, although ALL and acute myeloid leukemia (AML) often present with generalized lymphadenopathy, the enlarged nodes are usually not the sole presenting complaint and are only one of multiple abnormal clinical and laboratory findings. Although it is impossible to generalize enlarged lymph nodes secondary to malignant tumors, they are usually firm, rubbery, and matted. Cancerous nodes are usually not associated with tenderness, erythema, warmth, or fluctuance. Over the course of several examinations, an increase in nodal size is typically noticed by the examiner in malignant conditions.

Regional lymphadenopathy that predominates in noncervical areas is more suggestive of a malignancy than is node enlargement in the area of the head and neck. Any asymptomatic node larger than 2.5 cm merits further investigation and early consideration for excisional biopsy. Non-Hodgkin's lymphoma and neuroblastoma are two of the more common malignant conditions that manifest with regional lymphadenopathy. Even though the nodal enlargement is localized, there is often other evidence of systemic disease, such as a chest mass, an abdominal mass, or peripheral blood changes.

The differential diagnosis of localized node enlargement in the head and neck area is more difficult because acute and chronic infections are frequent causes of node enlargement. The most common bacterial causes of acute cervical adenopathy are *Staphylococcus aureus* and b-hemolytic *Streptococcus*.[63] Acute bacterial adenitis is usually associated with local signs of inflammation. Other infectious causes of cervical node enlargement include cat-scratch disease, nontuberculous mycobacterial infection, toxoplasmosis, infections with Epstein-Barr virus, cytomegalovirus, or human immunodeficiency virus. Isolated enlargement of the supraclavicular nodes usually signifies diseases transported by the thoracic ducts arising in the abdomen (Virchow's node) if on the left side, or from the chest if on the right.

With chronic, persistent, or progressive lymphadenopathy in the head and neck, malignancy becomes a more likely diagnosis. The primary malignant tumors that involve the head and neck in children are most often lymphomas. The child's age offers important diagnostic information and direction in evaluating enlarged nodes of the head and neck region for possible cancer. In children younger than 6 years of age, the most common cancers with head and neck involvement are neuroblastoma, rhabdomyosarcoma, non-Hodgkin's lymphoma, and leukemia. From 7 to 13 years of age, Hodgkin's lymphoma and lymphosarcoma are the most common and are seen with equal frequency. Thyroid cancer and then rhabdomyosarcoma follow in frequency. Over 13 years of age, Hodgkin's disease is the most frequent neoplasm.

Lymphadenopathy in the mediastinum presents a diagnostic problem. In a report by Bower and co-workers of 173 cases of mediastinal masses, 41% were malignant neoplasms.[64] At the University of Minnesota, of 68 anterior or middle mediastinal masses, 43% proved to be Hodgkin's lymphoma, 25% were non-Hodgkin's lymphoma, 17% were leukemia, and 9% were histoplasmosis.[65]

The diagnostic workup for lymphadenopathy should include the important clues from the clinical presentation as a guide. In general, if a lymph node is unresponsive to antibiotics and continues to increase in size over a 2-week period, it should be biopsied. Children with mild to moderately enlarged nodes at the first visit can be followed by serial examinations. Within 2 or 3 weeks, most noncancerous nodes should have regressed toward normal size. For localized cervical adenitis with

moderate inflammation and fever, the child should be started on oral antibiotic therapy empirically. The antibiotic should cover *Streptococcus* and *Staphylococcus*, and anaerobic coverage should be considered if a dental source is suspected. [63] A complete blood cell count (CBC) and a throat culture are indicated in these situations.

When a child does not respond to antibiotic therapy or has a fluctuant lymph node or a node larger than 2.5 to 3.0 cm, a more extensive workup is indicated. This may include a tuberculin purified protein derivative skin test, chest radiograph, CBC with differential and platelet count, and cultures from other sites that may be the source of an infection. Viral, bacterial, and fungal serologies are useful only if indicated by the history and physical examination. A bone marrow biopsy and aspiration are indicated if the chest film is abnormal, if the blood work shows thrombocytopenia or anemia, if there is significant hepatosplenomegaly, or if there is a combination of these parameters.

The need for lymph node biopsy is suggested by the following signs and symptoms:

- An enlarging node or nodes that remain enlarged after 2 to 3 weeks of antibiotic therapy
- Nodes that are not enlarging but that have not diminished in size after 5 to 6 weeks, or that do not return to normal size by 10 to 12 weeks, especially if associated with unexplained fever, weight loss, or hepatosplenomegaly (enlarged supraclavicular or lower neck nodes should be biopsied earlier)
- Enlarged nodes associated with any abnormal chest film finding

The largest and firmest node should be taken for evaluation. As mentioned previously, before this procedure is done, the child should be referred to a pediatric cancer center. If this is not possible, a pediatric oncologist and pathologist should be consulted by telephone. When suspect, material should be cultured for aerobic and anaerobic bacteria and for mycobacteria. In endemic regions, fungal cultures (e.g., for *Histoplasma* or *Cryptococcus*) should be done. The node should also be examined by light and electron microscopy and portions should be sent for chromosomal analysis and for analysis of cell markers. When possible, extra material should be frozen to have available if other tests become necessary.

**Thoracic Masses**

Almost all of the primary intrathoracic neoplasms develop within the mediastinum. Anatomically, the mediastinum is divided into three regions, and the localization of a mass in one of these compartments imparts important clues about its nature. The anterior mediastinum is bounded by the first rib superiorly, by the posterior surface of the sternum anteriorly, by the anterior border of the upper dorsal vertebra posteriorly, and by a curved line along the anterior cardiac border, extending back to the border of the dorsal vertebra. The posterior mediastinum is bounded posteriorly by the anterior surface of the curve of the ribs, anteriorly by the posterior border of the pericardium, and inferiorly by the diaphragm. The middle mediastinum occupies the area between the other two regions, with its base on the diaphragm.

The common lesions in the anterior mediastinum are lymphomas, masses of thymic origin, teratomas, angiomas, lipomas, and thyroid tumors. In the middle mediastinum, lymphomas, metastatic or infection-related lesions involving lymph nodes, direct extension of abdominal malignant lesions, pericardial cysts, bronchogenic cysts, esophageal lesions, and hernias through the foramen of Morgagni are found. In the posterior mediastinum, neurogenic tumors are some of the most common tumors, accounting for approximately 20% of all primary mediastinal tumors and cysts.[66] These lesions arise from the nerve roots and sympathetic ganglia in the paravertebral sulcus. The types seen are neuroblastomas, ganglioneuroblastomas, neurilemomas, neurofibromas, ganglioneuromas, and pheochromocytomas (rare). The other masses seen in the posterior mediastinum include enterogenous cysts, thoracic meningocele, and malignant tumors such as Ewing's sarcoma, lymphoma, and rhabdomyosarcoma.

Patients with mediastinal tumors may be asymptomatic or may present with symptoms secondary to compression or erosion of adjacent organs such as the respiratory tract (e.g., cough, stridor, and hemoptysis; see Chapter 39). Commonly, the mass is discovered during routine chest radiographs. Tomography, barium swallow, fluoroscopy, ultrasound, CT, and MR scans may be helpful in localizing and identifying mediastinal tumors (see Chapter 9). In all cases, the final diagnosis must await histologic definition.

A bone marrow aspiration and biopsy are frequently indicated for evaluation of possible tumor or infection. If marrow test results are negative, more invasive diagnostic procedures, such as bronchoscopy, mediastinotomy, or open biopsy, are necessary to obtain tissue for histologic study.

A common diagnosis made by analysis of tissue from the mediastinum is that of a small round cell tumor (see Chapter 8). This category includes Ewing's tumor of bone and soft tissue, rhabdomyosarcoma, lymphoma, and leukemic mass. Electron microscopy, histochemical evaluation, cell membrane studies, cytogenetics, and polymerase chain reaction studies may be necessary to establish a definitive diagnosis. If one is in doubt, and a portion of a rib is involved, resection of the rib above and below the lesion, as well as resection of the involved rib and intercostal muscle along with the tumor, is justified. This procedure satisfies the criteria for initial treatment of Ewing's tumor, rhabdomyosarcoma, and other small blue round cell tumors of thoracopulmonary origin (see Chapter 31, Chapter 32, Chapter 33, Chapter 34 and Chapter 35).

**Bone and Joint Pain**

Most pain associated with cancer is caused by bone, nerve, or visceral involvement or encroachment (see Chapter 43). The early symptoms of childhood cancer rarely include pain, except for malignancies involving bone or bone marrow, such as leukemia and primary bone cancers, or metastatic diseases to bone or bone marrow (e.g., neuroblastoma). Bone pain is common for the two most common malignant bone tumors in children, osteogenic sarcoma and Ewing's tumor. In a series of 229 patients with Ewing's tumor, 89% had pain as a presenting symptom (see Chapter 33 and Chapter 35).[67] This pain tends to be intermittent at first, and increases in severity with time. A peculiarity of the pain associated with Ewing's tumor is that it often disappears spontaneously for weeks or months. A similar incidence of bone pain is seen with osteogenic sarcoma, with pain as a presenting symptom for 79% of the cases. [68] For osteogenic sarcoma and Ewing's tumor, the median time between the onset of symptoms and the diagnosis was 3 months and 4 months, respectively (see Table 7-1).

Bone pain or arthralgias may be prominent presenting features of acute leukemia, and leukemic joint pain can be mistaken for various rheumatic diseases. For a child with suspected arthritis, the presence of leukopenia or nondiagnostic bone scan should prompt the physician to examine the bone marrow (see Chapter 19). Clinical findings and constitutional complaints do not help to differentiate the causes of bone pain. Bone pain as a presenting complaint of leukemia has been reported in 27% to 33% of cases.[69] Most of the cases are related to ALL rather than to acute nonlymphocytic leukemia. A review of 107 consecutive children presenting with ALL reported 21% with bone pain and 44% with radiographic bone changes. [70] A significant correlation was found between the severity of the bone pain and the number of bones demonstrating radiographic involvement. There was no significant correlation between the presence or absence of bone pain and the prognosis.

If a child complains of persistent bone or joint pain, especially if the pain is abrupt in onset, occurs at night, and is associated with swelling, mass, or limitation of motion, a radiograph should be obtained promptly and examined by an experienced radiologist. Although the films are extremely important in judging the extent of the abnormality and the behavior of the skeletal lesion, they should not be used to make a definitive diagnosis of the cause, because there are no pathognomonic radiographic signs of malignant bone lesions. Biopsy and pathologic studies are absolutely necessary to establish the diagnosis.

**Abdominal Masses**

A palpable abdominal mass is one of the most common presenting finding of malignant solid tumors in children. Although there are a variety of benign or pseudotumorous entities that may manifest as abdominal masses, all masses require workup to ensure that an early proper diagnosis is made.

In obtaining the history, it helps to determine whether symptoms have been referable to the abdominal mass and, if so, their type and duration. Because of the high incidence of renal cause for an abdominal mass, a thorough history that focuses on the urinary tract is particularly important.

The age of the patient is a helpful clue. For an abdominal mass in a newborn infant, a renal cause is most common. If the mass turns out to be malignant, it will most likely be a Wilms' tumor or a neuroblastoma ( Table 7-7). In older children, a mass is more likely to be secondary to leukemic or lymphomatous involvement of the liver and spleen.

| Retroperitoneal tumors (462 cases) | Number of patients |
|---|---|
| Kidney | |
| Wilms' tumor | 202 |
| Other malignant tumors | 10 |
| Benign tumors | 18 |
| Sympathetic tumors | |
| Neuroblastomas with metastases at presentation | 125 |
| Neuroblastomas without metastases | 60 |
| Neuroblastomas (Pepper's syndrome)[a] | 15 |
| Ganglioneuromas | 5 |
| Adrenocortical tumors | 7 |
| Malignant lymphomas | 65 |
| Liver | |
| Benign tumors | 9 |
| Malignant tumors | 14 |
| Ovary | |
| Dysgerminomas | 4 |
| Teratomas | 27 |
| Embryonic sarcomas | 22 |
| Other | 9 |

Data from the Institut Gustave-Roussy as presented in Shweisguth O, ed. Solid tumors in children. New York: John Wiley & Sons, 1982, with permission.
[a]"Pepper's syndrome" eponym for neuroblastoma of adrenal gland (usually right) with hepatic metastases.

**TABLE 7-7. RELATIVE INCIDENCE OF RETROPERITONEAL TUMORS**

For the child with a mass, a thorough abdominal examination is frequently not easy. Every attempt should be made to have the child relaxed before palpating the abdomen. Attempting to divert the child's attention is perhaps the best method but does not always work. For a younger child, a bottle or pacifier can be helpful. When examining the abdomen, it is important to remember that a number of structures (i.e., liver edge, spleen, kidneys, aorta, sigmoid colon, feces, and/or spine) are palpable in normal children. Further studies depend on whether the child has a normal CBC. If the abdominal mass is suspected of being feces, it may be practical to give an enema and reexamine the patient. Similarly, if the mass is suspected to be the bladder, it may be necessary to catheterize the patient and repeat the examination. A rectal examination is indicated if the child has a normal absolute neutrophile count. Vaginal and pelvic examinations are important in the older adolescent girl, but bimanual abdominal and rectal examinations are preferred to vaginal examinations in infants and younger girls. Pelvic examinations should be performed by an experienced physician. Although much has been written about the importance of the size, mobility, and consistency of a mass, such information is unrewarding in determining its nature. Histologic confirmation is always necessary.

After the physical examination has been completed and routine laboratory studies obtained, the workup should proceed to sonography of the abdomen and a chest film. The results may suggest the need for any further tests such as abdominal CT with or without contrast and intravenous urography, tumor marker assays, and bone marrow examination.

## Pancytopenia and Leukocytosis

### *Pancytopenia*

Anemia, leukopenia, and thrombocytopenia occur alone or in combination as a common presenting sign in acute leukemias of childhood, both ALL and AML (see Chapter 19 and Chapter 20). Among 936 untreated children with newly diagnosed ALL, 51% presented with a hemoglobin concentration of less than 7.5 g per dL, 73% presented with platelet counts less than 150,000 per $mm^3$, and 30% presented with a total peripheral white blood cell count (WBC) of less than 5,000 per $mm^3$.[71] A similar analysis of 171 children with AML revealed that 82% presented with platelet counts less than 100,000 per $mm^3$, and 39% presented with a total WBC of less than 5,000 per $mm^3$.[72]

Any malignancy that involves the marrow can produce pancytopenia or depression of only one of the cell lines. After leukemia, the childhood malignancies that most often involve the bone marrow are neuroblastoma, lymphoma, and, less commonly, Ewing's tumor and rhabdomyosarcoma. These cytopenias are primarily attributed to replacement of the bone marrow by tumor, although such replacement often does not completely explain the degree of pancytopenia. There are alternative explanations for anemia associated with various malignancies. The anemia may be typical of that seen in chronic disease. Autoimmune hemolytic anemias may occur with lymphoma.

Unless there is marrow involvement, leukopenia is rarely a part of primary extramedullary malignancies. This is also true of thrombocytopenia, except for the rare instance of immune-mediated thrombocytopenic purpura associated with Hodgkin's disease, or the low platelet counts seen with a disseminated intravascular coagulopathy (DIC), which may occur with tumors such as neuroblastoma that have extensive tumor necrosis.

### *Leukocytosis*

An elevated WBC (i.e., leukocytosis) is commonly seen with acute leukemia of childhood (see Chapter 19 and Chapter 20). Counts of greater than 10,000 per $mm^3$ are reported in 45% of children with ALL; 10% have an initial count of greater than 100,000 per $mm^3$.[71] Among newly diagnosed cases of AML, 21% of patients have WBCs of greater than 100,000 per $mm^3$.[72] Most nonmalignant cases of leukocytosis are caused by infections, especially staphylococcal and pneumococcal infections. Exaggerated elevations (e.g., leukemoid reactions) of greater than 50,000 per $mm^3$ may occur with septicemia, especially with infections due to *Staphylococcus*, *Haemophilus influenzae*, *Meningococcus*, and *Salmonella*.[73] Lymphoid leukemoid reactions have been observed in infectious lymphocytosis,[74] mumps,[75] varicella,[76] adenovirus,[77] cytomegalovirus,[78] and pertussis[79] infections. Peripheral WBCs greater than 100,000 per $mm^3$ almost always reflect a leukemia. A myeloid leukemoid reaction (100,000 per $mm^3$) has been reported in premature infants whose mothers received corticosteroids during pregnancy.[80] Leukocytosis, predominantly due to eosinophilia, with WBCs in the range of 20,000 to 100,000 per $mm^3$, is often seen with parasitic infections, especially visceral larval migrans.[81] Other non-malignant causes of eosinophilia include the hypereosinophilic syndrome, periarteritis nodosa, allergy, and hypersensitivity reactions. The malignant causes are Hodgkin's disease, ALL, and a rare entity described as eosinophilic leukemia (see Chapter 19 and Chapter 20).

### *Workup of Pancytopenia and Leukocytosis*

Careful assessment for an infectious cause is of paramount importance in evaluating a patient with abnormal peripheral blood counts. A bone marrow study is frequently the most appropriate means to rule out most malignant causes, and aspiration and biopsy are required to determine morphology and marrow cellularity.

The indications for bone marrow examination include

- Finding of atypical or blast cells on peripheral blood smears
- Significant depression of more than one peripheral blood cell element without obvious explanation
- Association with unexplained lymphadenopathy or hepatosplenomegaly, or a thymic mass
- Absence of an infectious cause for the blood abnormality

## Bleeding

Bleeding is an uncommon initial sign in children with cancer. When it does occur, it is usually related to thrombocytopenia secondary to marrow involvement. In a patient with newly diagnosed acute leukemia, bleeding can also be related to impaired platelet function due to the administration of aspirin or other nonsteroidal antiinflammatory drugs for fever or bone pain. High-dose penicillin, carbenicillin, ticarcillin, and moxalactam have been associated with platelet dysfunction and can add to the bleeding tendency of these patients.[82] Effective antibiotics without these side effects are available (see Chapter 41). Although coagulation abnormalities can be associated with disseminated malignancies, they rarely cause signs or symptoms unless DIC occurs. A very high incidence of coagulopathy occurs in cases of acute promyelocytic leukemia (M3) and to a lesser extent with myelomonocytic leukemia (M4) and acute monoblastic leukemia (M5a) when associated with initial leukocytosis.[83,84] This complication has also been reported for patients with ALL (especially T-cell ALL), lymphoma, and neuroblastoma.[85] When a child presents with significant bleeding and thrombocytopenia, the possibility of a malignancy, especially acute leukemia, and other causes, such as infection and immune-mediated thrombocytopenia, must be considered. The diagnosis usually requires examination of the peripheral blood with a CBC and frequently necessitates a bone marrow aspiration. Initial laboratory workup of a bleeding diathesis consists of a standard panel of tests: one-stage prothrombin time (PT), activated partial thromboplastin time (PTT), thrombin time, fibrinogen level, serum fibrin-fibrinogen degradation (split products), and platelet count. In a patient with DIC, the PT is prolonged, and the PTT usually prolonged; the thrombin time is slightly prolonged, and fibrinogen is decreased, with decreased platelet count and increased fibrin degradation products. The presence of fibrin degradation products usually separates DIC from other causes of bleeding that are associated with abnormal PT, PTT, and fibrinogen levels.

Only rarely is the bleeding associated with malignancy difficult to detect clinically. Consultation with coagulation experts assists in selecting more specialized studies.

## ESTABLISHING THE DIAGNOSIS

With the exception of the rare true emergency, optimal treatment for a malignancy can begin only after the tumor has been accurately diagnosed and the extent of disease precisely defined. Noninvasive imaging techniques, such as CT, diagnostic ultrasound, and MR imaging, have dramatically improved the assessment for cancer (see Chapter 9). Significant advances have been made in identifying cellular tumor markers. Although extra-cellular markers, such as the catecholamines and alpha-fetoprotein, have direct clinical usage, many have no direct clinical application, and, whereas they potentially provide important clues to the presence of a cancer, the only absolute way to establish the diagnosis of cancer is by pathologic confirmation.

When initiating the evaluation of a child for a suspected cancer, it is important to discuss overall plans with the parents and the child (if of appropriate age). Most families, and often referring physicians, are frustrated with the length of time that the diagnostic tests, including biopsy and interpretation, take. For example, routine processing and examining a tissue specimen usually take 2 or 3 days but may take longer if special techniques or preparations are needed to make a definitive diagnosis. The family's frustration and anxiety are heightened when the signs and symptoms have persisted for months. It helps to prospectively emphasize to the parents that enough time must be taken to ensure the correct diagnosis and to determine the extent of disease accurately. Such care helps ensure proper therapy and prevents later errors and the need to repeat examinations and biopsies after treatment has begun.

### Pathologic Diagnosis

When the results of the clinical, laboratory, and imaging studies point to the probability of a neoplasm, the next decision is selection of the quickest and most reliable method to establish the pathologic diagnosis (see Chapter 8). Before obtaining any tissue for pathologic study, the primary physician should confer with a pediatric oncologist, the surgeon, and the pathologist and discuss the site to biopsy, the amount of tissue needed, and the specimens to be obtained. It is important to plan to remove enough material initially so that additional biopsies are not necessary.

The basic principles of initial surgery for childhood tumors are outlined in Chapter 12. In general, when it appears that the mass is localized to an organ such as the adrenal gland or the kidney, and there is no evidence of metastatic disease, the approach is one of surgical exploration, with the intent of total extirpation if possible. Although an intraoperative frozen-section study may be unnecessary because an immediate diagnosis is unlikely to alter the operative management, review of the surgical margins may help determine the adequacy of the excision (e.g., in cases of a partial hepatectomy for hepatoblastoma or resection of a soft tissue sarcoma). Additionally, if the lesion is malignant, central venous access and bone marrow aspirate or biopsy can be done while the child is still asleep.

Excisional and incisional biopsies are the standard techniques for obtaining diagnostic tissue. An excisional biopsy is preferred by most pathologists, because it yields a greater amount of tissue with fewer artifactual distortions than the smaller incisional biopsy. However, if an excisional biopsy could compromise future therapy (such as an extremity lesion, which may require radiation therapy), it should not be performed. The prototypical clinical situation for an excisional biopsy is the suspicious lymph node. Too often, an accessible lymph node is removed in fragments rather than as an intact structure. If a suspicious lesion is smaller than 4 cm and located superficially in the dermis or subcutaneous tissues, an excision generally is recommended. A larger mass in a deeper location may require a more cautious approach with an incisional biopsy unless a total resection is contemplated.

Frozen-section examination is recommended during an incisional biopsy to be certain the targeted lesion has been sampled. However, if the amount of available tissue is small or if the surgeon is reluctant to remove additional tissue because of a difficult approach, a frozen section should not be performed. Disadvantages of the frozen section include artifact, exhaustion of tissue in the block through sectioning, and the loss of the opportunity to perform additional studies such as electron microscopy. On the other hand, frozen section of tissue that is subsequently fixed in formalin generally does not interfere with the application of most immunohistochemical stains.

Regardless of the particular biopsy technique, the resultant tissue should be placed in 0.9% saline and immediately transported on ice to the surgical pathology laboratory. This method ensures the most expeditious handling of the tissue for special studies such as cell markers, cytogenetics, freezing for a variety of analyses, preparation of a suspension for flow cytometry, and fixation for electron microscopy. A pathologist should be available to supervise these activities. Gross examination of the tissue is preferred beforehand so that a judgment can be made about the representative nature and adequacy of the specimen.

Aspiration, biopsy, and cytology (ABC) using needle aspirate and biopsy or a fine needle biopsy (FNB) have been increasingly recommended in some clinical situations if small amounts of tissue can suffice for the intended purpose. Because of limitations of sample size, the ABC/FNB approach as the primary diagnostic procedure does not yield sufficient material for the myriad special studies that most pediatric oncologists prefer for these tumors before initiating therapy.

However, the approach has generated much enthusiasm by virtue of its cost efficiency, low morbidity, and reliability in experienced hands. The procedure has been widely applied in adults for thyroid, prostate, or breast masses. The method also can be used for the more deeply situated mass, with the thin-needle aspirations guided by CT scan. The skill of the operator and the confidence of the cytopathologist are the critical elements for a reliable diagnosis. An ideal clinical indication for ABC/FNB is the child with a previously diagnosed and treated neoplasm who presents with a suspected recurrence. [86] The tumor type will have already been established by an earlier biopsy or excision, and histopathologic confirmation is not a consideration unless there is a question of a second primary tumor. Even then, if the histologic types of the two primary tumors are sufficiently divergent, this may be appreciated in the ABC/FNB. The recognition of a recurrent neuroblastoma or rhabdomyosarcoma by ABC is usually straightforward.

Electron microscopy, immunohistochemistry, immunophenotyping of suspected lymphomas, cytogenetic DNA analysis through flow cytometry, and oncogene amplification studies are specialized diagnostic procedures available in many laboratories (see Chapter 8). Few laboratories have all of these techniques immediately available. The point cannot be overemphasized that these studies must be prefaced by an accurate pathologic diagnosis or reasonable differential diagnosis. The pathologist is in the best position in most cases to decide the appropriate special studies in consultation with the clinician.

## SUMMARY

Throughout this chapter, the emphasis has been on the influence of presenting signs and symptoms in making the early diagnosis of cancer in children. As shown in Table 7-8, the impact of age and site is important and should be considered when evaluating a sick child. The armamentarium of diagnostic tests available to establish the diagnosis of malignant diseases is extensive. Early diagnosis can improve outcome, but if the possibility of a cancer is never considered by the physician, delayed diagnosis is the result. Although the incidence of malignant disease in children is low, the impact of cancer makes it imperative that all professionals handling children have a high index of suspicion of cancer.

# MOLECULAR PATHOLOGY OF PEDIATRIC MALIGNANCIES

TIMOTHY J. TRICHE
POUL H. B. SORENSEN

## OVERVIEW

Cancer in children is distinct from cancer in adults and requires a far different approach to diagnosis and treatment. The mere fact that most childhood tumors are mesenchymal or neuroectodermal in origin, whereas the overwhelming majority of adult cancers are of epithelial origin, clearly sets childhood cancer apart. [1,2,3,4 and 5] Furthermore, the primary treatment modality in adult cancer is surgery; in children, success was historically achieved through chemotherapy in combination with surgery and radiation therapy. The evolution of combination therapy protocols has brought with it a very real need to tailor treatment to specific types and subgroups of tumors in children, far more so than in adults. This demands far more precision and flexibility of the pediatric diagnostician. Finally, the highly organized character of childhood cancer treatment, whereby the vast majority (i.e., 90% or more of children aged 15 years and younger) is treated on cooperative group protocols, has mandated tumor-system–specific specialized diagnostics in conjunction with routine pathologic evaluation. [6] This task has been complicated by the unusual number of tumors in children that lack morphologic evidence of differentiation, and therefore histogenesis, the usual necessary first criterion for accurate diagnosis. Historically referred to as the *small round, blue cell tumors*, the problem is now well addressed with a battery of molecular and immunochemical diagnostic procedures, but only if such methods are used.[7,8] Many of these specialized diagnostic procedures are largely unknown to pathologists more familiar with adult cancer patients, and are thus frequently overlooked in the diagnostic workup of pediatric cancer patients in largely adult settings.

The net effect of these considerations in the diagnosis of childhood cancer is a need for clear, explicit guidelines for the diagnostic workup of children with tumors, as well as detailed consideration of specific diagnostic modalities required in the differential diagnosis of certain childhood cancers. In addition, certain tumor groups present particular problems in either diagnosis (such as the morphologically undifferentiated tumors) or prognostic subgrouping [as in leukemia, brain tumors, lymphoma, neuroblastoma (NB), rhabdomyosarcoma (RMS), and certain nonrhabdomyogenic soft tissue sarcomas]. This chapter sets out a set of guidelines for optimizing the likelihood of correct, specific, and clinically useful diagnosis in tumor patients, followed by a discussion of tumor systems that represent particular diagnostic or management challenges to the pathologist, oncologist, or surgeon. We hope that this information will be useful not just for the pediatric pathologist but also for anyone charged with diagnostic or management responsibilities for the child with cancer.

### Unique Challenge of Childhood Cancer Diagnosis: Age, Ethnicity, and Genetic Factors

Carcinoma is unusual in children. Retinoblastoma is unknown in adults. [9] In fact, childhood cancer bears little resemblance to adult cancer, as illustrated by a consideration of childhood tumor types in Figure 8-1. Clearly the common carcinomas (e.g., breast, lung, colon, prostate) dominate any consideration of adult cancer but are all absent from childhood cancer. In contrast, mesodermally derived tumors (e.g., hematopoietic and sarcomas) and brain tumors dominate childhood cancer, which reflects fundamental differences in the etiology of these two age groups. Many tumors seen in children are virtually unknown in adults, although due to the overwhelming preponderance of carcinoma in adults, the frequent occurrence of childhood tumors such as Ewing's sarcoma, osteosarcoma, synoviosarcoma (SS), and RMS in young adults is often overlooked. These are the same tumors, and should be recognized and treated as such.

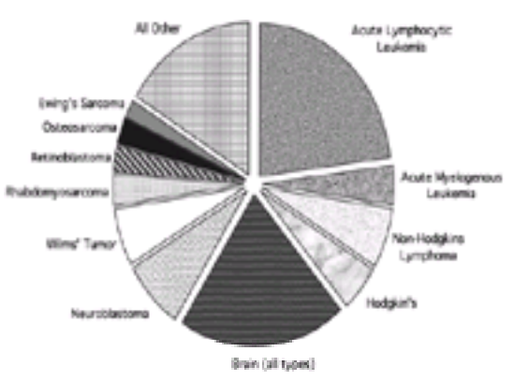

**FIGURE 8-1.** Distribution of childhood cancer. Hematopoietic malignancies (*gray textured wedges*) account for approximately one-third of childhood malignancy: acute lymphocytic leukemia and acute myeloid leukemia account for approximately 27%, and non-Hodgkin's lymphoma and Hodgkin's account for another approximately 11%. Brain tumors total approximately 21%. Neuroblastoma (approximately 7%) and Wilms' tumor (approximately 6%) follow. Rhabdomyosarcoma, retinoblastoma, osteosarcoma, and Ewing's sarcoma are each approximately 3% of the total. All other tumors account for approximately 16% of all childhood tumors in aggregate. Notably absent from the above is any significant incidence of carcinoma, the most common form of adult cancer.

#### *Age versus Tumor Type*

Beyond these obvious points lies a complex panoply of considerations that confront the diagnostician. It is difficult enough that many tumors defy simple morphologic

diagnosis. It is worse still that the occurrence of one or another type is quite age dependent, as illustrated in Figure 8-2, a graph of age versus tumor type from birth to 15 years. Overall, cancer incidence is greatest just after birth and declines to a low at age 10 years, reflecting intrauterine oncogenesis and growth for most of these tumors. However, there is also a linear increase after the first decade that extends into adulthood. This increase likely reflects the development of tumors with an etiology distinct from the largely embryonal tumors of early childhood yet still distinct from the common carcinomas of adulthood, in which environmental and lifestyle factors play a major role. No such factors are known for any childhood tumor.

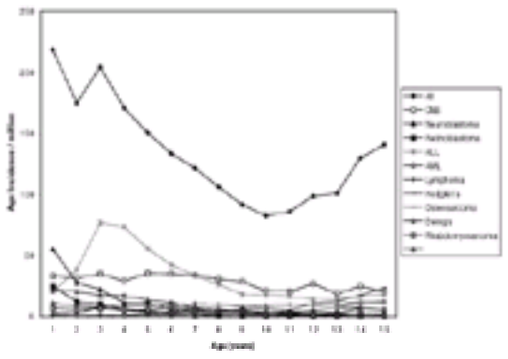

**FIGURE 8-2.** Age incidence of childhood cancer. All cancer as a group is depicted by the line with diamonds and shows a nearly linear decline from birth until approximately age 10 years, at which time the slope of the line reverses and begins to incline steadily toward greater incidence in adulthood. The large peak seen at approximately age 3 years is largely due to the peak incidence of acute lymphocytic leukemia at age 3 years ( ). The influence of other tumors is less apparent due to their lesser incidence, but here, too, striking age-dependent differences occur as well, especially with neuroblastoma ( ) and retinoblastoma ( ). ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; CNS, central nervous system.

The issues are in fact even more complicated. Specific tumors show distinct age incidence within childhood. Figure 8-3 illustrates this in connection with common neuroectodermal tumors such as NB and the Ewing's family of tumors (EFTs); they have completely different age ranges, yet the two tumors are almost, in some cases, morphologically indistinguishable. Without knowledge of the patient's age, otherwise avoidable misdiagnoses may occur.

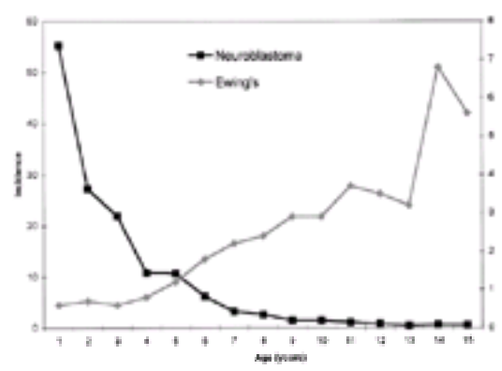

**FIGURE 8-3.** Neuroblastoma versus Ewing's sarcoma: age-specific incidence. Although the two most common neural tumors in childhood are neuroblastoma and Ewing's sarcoma, they are strikingly different in their incidence and character, despite their occasionally similar morphology. Neuroblastoma, however, is clearly a largely congenital tumor most common at birth, whereas Ewing's sarcoma is rare at birth and peaks at age 14 years. From this one would assume that the genetic origins for these two neural tumors are distinctly different (incidence = cases/million).

Even within a single tumor system, age plays a significant role. There are two dominant types of RMS, the most common sarcoma in children: embryonal (ERMS) and alveolar (ARMS). The age of occurrence between the two is quite different, however, as shown in Figure 8-4. ERMS, as the name suggests, is clearly linked to embryogenesis, with a peak incidence basically at birth, whereas ARMS shows a bimodal age incidence quite distinct from ERMS, such that in older patients, alveolar forms predominate, despite its overall lesser incidence (e.g., only one-half as common overall as ERMS). Not only does this distinction suggest a very different pathogenesis but it also complicates the diagnosis, as the two forms may appear morphologically similar (as discussed in section on classification of RMS). This has historically led to an approximate 20% misdiagnosis rate, based on cooperative group studies of this tumor. Misdiagnosis in turn has led to suboptimal treatment of many patients, as these same cooperative group treatment protocols distinguish between the two for treatment purposes.

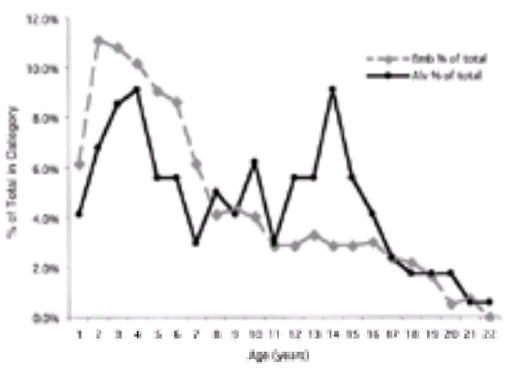

**FIGURE 8-4.** Age incidence of rhabdomyosarcoma. The two major forms of childhood rhabdomyosarcoma, embryonal (Emb) and alveolar (Alv), show distinctly different age incidences. Embryonal is most common in the first 2 years of life and declines steadily thereafter. Alveolar rhabdomyosarcoma, when plotted as a percent of total cases, shows a distinct bimodal age incidence, the first mode roughly corresponding to the peak age incidence of embryonal rhabdomyosarcoma, and the second at age 14 years, unlike embryonal forms. Recent studies indicate that the two modes are genetically and prognostically distinct as well.

### *Genetic Factors*

Age is an important consideration in the diagnostic evaluation of a patient, but it is also known that genetic factors, such as inherited gene defects, are not uncommon in childhood tumors; familial versus sporadic retinoblastoma is the prototypical example. [10] Familial patients with a mutation in one allele of the *RB* gene develop bilateral and multiple tumors when the normal allele is lost or mutated; sporadic patients generally do not. Li-Fraumeni syndrome, with a germline mutation of *p53,* is another, more pleiotropic example in which multiple tumor types throughout life can occur, presumably depending on when the normal *p53* allele is lost or mutated.[11,12]

In other cases, ethnicity can likewise be a critical determinant of cancer susceptibility. Here there is no classic mendelian gene defect as seen in retinoblastoma and Li-Fraumeni syndrome. Rather, as yet unknown, complex genetic traits are presumably responsible. The classic example of this is the EFTs. As shown in Figure 8-5, based on Surveillance, Epidemiology, and End Results network data, this tumor is virtually unknown in some African populations and is nearly as scarce in some Asian populations (e.g., in China and Hong Kong), whereas in northern Europeans it is more common than the “most” common bone sarcoma, osteosarcoma. [2,13,14]

Even more surprising, the tumor is most common in Spanish, Israeli (non-Arabic), and notably, Polynesian (e.g., Maori, Hawaiian) populations. Epidemiologic studies have documented other, less striking but nonetheless important differences in tumor type incidence among ethnic populations. [5,15] Aside from the intriguing implications for population-specific disease susceptibility, this observation implies that knowledge of patient ethnicity can be a helpful adjunct in diagnosis, particularly among the undifferentiated tumors common in childhood.

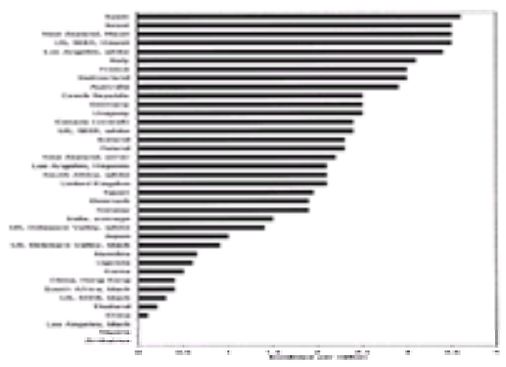

**FIGURE 8-5.** Ethnicity versus incidence—the Ewing's family of tumors. Striking differences in the incidence of Ewing's sarcoma are well documented and are graphically evident in this illustration. The well-known near-total lack of incidence in native Africans (Zimbabwe and Nigeria with no reported incidence) as opposed to a striking incidence in whites (Los Angeles, white, 3.4) fails to convey the entire story. Surveillance, Epidemiology, and End Results (SEER) network data clearly document an even greater incidence in Spain and Israel (approximately 3.5) as well as in at least two Polynesian populations, the New Zealand Maori and the Hawaiian Polynesian, with a similar incidence. At the same time, considerable variation among Asian populations is evident: China has the lowest reported incidence (0.1), Korea is intermediate (0.5), and Japan is the highest (1.0). These striking ethnic differences are not paralleled by any childhood malignancy.

## Current Approach to Childhood Tumor Diagnosis

Similar to all areas of medicine, pathology has been transformed by a rash of new techniques, equipment, and basic knowledge eventuating from the tremendous advances in biotechnology. This, in turn, has irrevocably changed the methods used to arrive at a diagnosis. No longer is gross examination and light microscopy in conjunction with clinical information the only means available to derive a diagnosis. Virtually every case of childhood cancer now requires recourse to some combination of immunochemical, molecular, or, occasionally, ultrastructural analysis. [16,17] and [18] These tools have enormously increased diagnostic precision, but most important, they allow far better correlation of tumor diagnosis with clinical behavior and response to therapy.

Examples of specific tumor types and their optimal diagnostic evaluation are discussed in the section Childhood Tumor Diagnosis. Here, mention of a few specific examples will suffice to make the point. Ideally, no child with suspected leukemia, lymphoma, or NB will fail to have ancillary diagnostic procedures performed to detect gene translocations, antigen expression, or gene amplification. This concentration of advanced diagnostic procedures common to childhood cancer evaluation is rare in adult cancer, a striking difference often overlooked by adult cancer diagnosticians. This is unfortunate, because these procedures require special handling considerations (e.g., fresh, viable tumor tissue, short-term culture, or fresh frozen tissue) that are not part of the routine workup of adult cancer. In many cases, local institutions lack the facilities to perform these studies, but the tissue is handled by prescribed protocols that ensure proper handling of tissue and shipment to a central reference laboratory to complete these studies. If these procedures are unknown to the primary pathologist, as they often are, the moment may be lost. Fresh tissue [and the high-quality, largely intact messenger RNA (mRNA) it contains] cannot be reconstituted from formalin-fixed tissue, nor can cell cultures for molecular genetic analysis or establishment of a permanent cell line be grown from fixed or frozen tissue. It is thus useful to lay out an action plan for childhood tumor diagnosis that will forestall such eventualities.

A simplified diagram, Figure 8-6, illustrates the routine handling of childhood cancer tissue as prescribed by the Children's Oncology Group, which is responsible for the diagnosis and treatment of as much as 95% of children with cancer in North America. [19] A sizable percentage of these cases is not handled by pediatric pathologists familiar with these protocols; inclusion here will hopefully assist the general pathologist confronted with childhood cancer cases. The diagram illustrates the single most important principle: *tissue must not be placed into fixative in the operating room*. This single oversight is responsible for most lost diagnostic opportunities. It is also a reason that so little tissue is available for molecular diagnostics and biomedical research. Fixed tissue has limited utility for most molecular genetic diagnostic procedures and severely limits even conventional diagnostics such as immunohistochemistry and electron microscopy (EM).

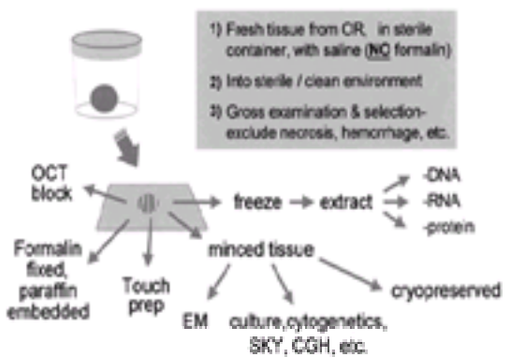

**FIGURE 8-6.** Tissue handling diagram. Tissue for optimal pathologic and biologic studies requires specialized handling, as summarized in this chart. Tissue should be collected fresh, not fixed. From a fresh or frozen specimen, virtually all important studies can be performed. Increasing reliance on specialized molecular diagnostics, especially those that detect messenger RNA, require fresh or fresh frozen tissue for routinely successful results. A version of this diagram is in wide use in the Children's Oncology Group and has contributed to significant improvements in diagnostic accuracy in childhood cancer. CGH, comparative genomic hybridization; EM, electron microscopy; OCT, optimal cryopreservation temperature compound; OR, operating room; SKY, spectral karyotyping.

The second stage of tissue handling illustrated in the diagram is simply precautionary: If tissue is divided into multiple forms, for specific use as needed in subsequent diagnostic procedures, nothing is lost. If not, the opportunity to perform the diagnostic procedure is generally lost. As a case in point: failure to set aside fresh tissue precludes reliable fluorescence-activated cell sorter (FACS) analysis routine and necessary for the diagnosis of leukemia and lymphoma. Ideally, then, cells or tissue placed in transport or culture medium for cytogenetics is important. Frozen tissue is perhaps even more important, as all manners of molecular diagnostics (particularly for RNA) are now possible. Small fragments in cryopreservative, if available, are invaluable for a “second look” in the future if needed (a nice way to compare pretreatment versus posttreatment tumor for chemosensitivity, perhaps, or especially new methods such as gene expression profiling, which is discussed under Gene Expression Profiling by DNA Microarrays). Also, a fundamental technique such as EM, still a mainstay for childhood tumor diagnosis, requires fixation in glutaraldehyde for optimal interpretation.

If these procedures are followed, virtually every diagnostic modality available now and in the future is likely to be feasible. In reality, experience to date under even the most rigorous circumstances (e.g., protocol admissibility contingent on submission of tissue in this fashion) has rarely succeeded in much more than 50% of cases. This has led to the development of diagnostic techniques that provide similar information but obtain it from routinely fixed and processed tissue. Thus, cytogenetic analysis for a chromosome translocation can now be substituted by polymerase chain reaction (PCR) analysis. [20] Gene amplification can be detected by fluorescent *in situ* hybridization (FISH). [21,22] and [23] Antigen retrieval methods allow monoclonal antibody–mediated detection of scant antigens otherwise detectable only by FACS. [24] Although vital to ensure every case can benefit from advanced diagnostics necessary for optimal therapy, these alternative methods sometimes introduce serious doubt into the results: what if the PCR is negative? What if the FISH analysis is plagued by high background formalin-induced fluorescence, obscuring the signal? What if the immunochemical results are equivocal? Most cases succeed despite these handicaps, but it is clear that adherence to a protocol, as described in

Figure 8-6, can avoid all these pitfalls.

### Interplay of Multiple Diagnostic Techniques in Tumor Diagnosis

The fundamental reason for the multiple diagnostic approaches advocated in Figure 8-6 is that no method alone suffices for all tumors. Childhood cancer diagnosis (and all pathologic diagnoses, for that matter) is better viewed as a contingency tree. *If* the initial results suggest certain alternatives, *then* appropriate ancillary diagnostics are to be used. This is especially true in the current environment of limited resources for patient diagnosis and treatment. Diagnostic procedures cannot be used for research interest alone, and most DNA or RNA diagnostics are not reimbursable from third-party payers, despite their proven utility in patient management. This state of affairs mandates frugal application of only the most relevant diagnostic methods.

The typical childhood cancer case in our institution, as in other children's hospitals, is handled as illustrated in Figure 8-6. *After* the routine formalin-fixed, hematoxylin and eosin (H&E) slides are returned and examined, the diagnosis is either clear (perhaps half the time) or more studies are required. In many cases, the diagnosis is clear, but protocol requirements mandate special studies, such as *MYCN* and ploidy studies in NB. This tissue is submitted either at the outset if the diagnosis is unequivocal or after the initial studies document the expected (or unexpected!) diagnosis. In the latter case, failure to follow the guidelines in Figure 8-6 may seriously compromise diagnosis. If diagnostic uncertainty remains, a host of methods remains that in virtually every case will result in a specific and reliable diagnosis, generally with an estimate of clinical aggressiveness. These common methods are summarized in Table 8-1. Note that these methods are used judiciously, such that only the rare diagnostic dilemma will invoke most or all of these methods. Nonetheless, the availability of these methods, especially the newer molecular genetic methods (note that five of ten are molecular), has transformed the field of childhood cancer diagnosis from one littered with misdiagnoses and misleading information to an orderly, precise, and generally correct one, tightly linked to therapeutic protocols that depend on this information for patient protocol eligibility and treatment. This is rather unique to childhood cancer and is the fundamental reason for a detailed consideration of the optimal diagnostic evaluation of the child with cancer.

| Method | Comment |
|---|---|
| Light microscopy | Mandatory for all cases |
| Immunohistochemistry | First choice ancillary diagnostic; widely used |
| Molecular generic: reverse transcriptase polymerase chain reaction | Most common molecular diagnosis; now routine |
| Molecular generic: FISH | Rapidly supplanting cytogenetics for many cases |
| Molecular generic: *in situ* hybridization | Specialized use to date (nontumor; Epstein-Barr virus typical) |
| Special stains | Still needed in some cases; useful and cheap |
| Electron microscopy | Still widely used to augment light microscopy |
| Cytogenetics | Needed when no suitable FISH probes available |
| Molecular generic: SKY, CGH | SKY soon to be a useful diagnostic; CGH maybe |
| Molecular generic: DNA sequencing | Rare case such as Li-Fraumeni syndrome (p53 mutation) and others |

CGH, comparative genomic hybridization; FISH, fluorescent *in situ* hybridization; SKY, spectral karyotyping.

**TABLE 8-1. TOP TEN DIAGNOSTIC METHODS FOR TUMOR DIAGNOSIS**

## CHILDHOOD TUMOR DIAGNOSIS

### Character of Childhood Cancer

As noted earlier, childhood cancer presents certain diagnostic challenges. In addition to the unusual variety of age-dependent tumors compared to adult cancer, the typical childhood tumor either lacks definitive morphologic evidence of lineage, or histogenesis, (e.g., small blue cell tumors) or the lineage is ambiguous (e.g., spindle cell tumors). This ambiguity in diagnosis, coupled with the need for definitive diagnosis to establish a treatment regimen, necessitates the use of a variety of diagnostic methods far beyond H&E slides. For example, a specific diagnosis, such as NB, is insufficient; the prognostic subgroup, as determined by the Shimada, now International, classification (Fig. 8-7),[25,26] as well as ancillary studies, such as *NMYC* status by PCR (Fig. 8-8) and FISH (Fig. 8-9), TRKA expression (Fig. 8-10), 1p deletions, and ploidy, are also mandated or requested for entry on current protocols. [27] But what if the simple tumor diagnosis is not possible by H&E study alone? This problem, rare among adult cancers, is frequent in childhood cancer cases and warrants some consideration.

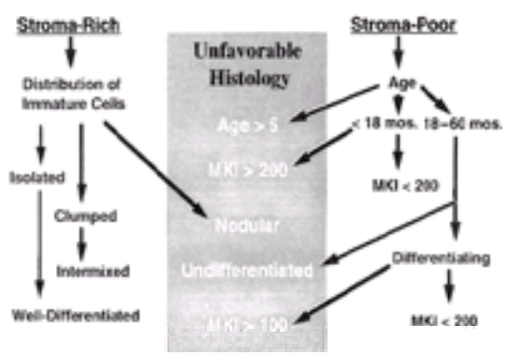

**FIGURE 8-7.** Shimada classification system. Although various versions of the standard classification of childhood neuroblastoma based on morphology and associated prognosis have been published by several authors, this version simplifies the classification by describing two basic groups, stroma-rich ( *left*) and stroma-poor (*right*). Only one stroma-rich type is associated with a poor prognosis ( *gray box*), with clusters or nodules of immature cells set against a well-developed, poorly cellular stoma. In contrast, only two forms of stroma-poor tumors have a favorable prognosis, those in patients younger than 18 months with a mitotic-karyorrhectic nuclei index (MKI) of less than 200, and those in patients aged 18 to 60 months with differentiating tumor cells and an MKI less than 200. All other types in this group are associated with a poor prognosis, as indicated. (Adapted from Shimada H, et al. Histopathologic prognostic factors in neuroblastic tumors: definition of subtypes of ganglioneuroblastoma and an age-linked classification of neuroblastomas. J Natl Cancer Inst 1984;73:405–416.)

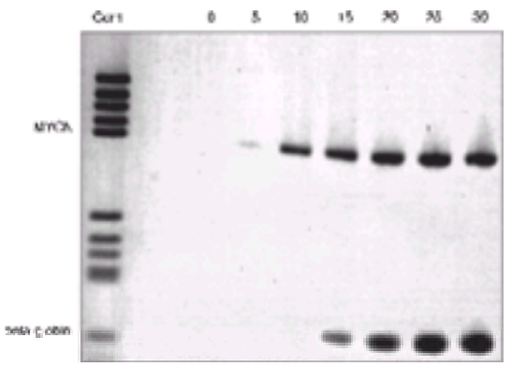

**FIGURE 8-8.** Polymerase chain reaction (PCR) analysis to detect *MYCN*. DNA from a minute patient sample was simultaneously amplified by PCR with primers for both *MYCN* and a control gene, beta globin, as indicated. Product was visible after even five cycles for *MYCN*, whereas beta globin was detectable only after 15 cycles, indicative of *MYCN* gene amplification. (Courtesy of J. Peters, Pathology Department, Children's Hospital, Los Angeles.)

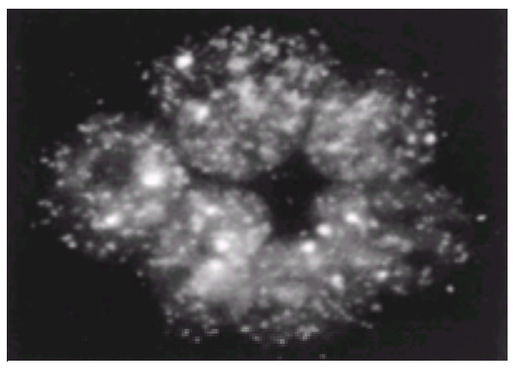

**FIGURE 8-9.** Fluorescent *in situ* hybridization analysis of *MYCN*. In this imprint of a neuroblastoma, a rosette of six cells is detectable. Each nucleus contains two or more bright signals, corresponding to copies of chromosome 2, the normal site of *MYCN*. Conversely, the multitude of fainter signals represent *MYCN* copies, numbering in the hundreds per cell. Even after the normal chromosome 2–based copies of *MYCN* are subtracted from the total, there is a gross amplification of *MYCN* in this tumor. Using this method, results are available within 1 or 2 days of biopsy, far faster than with Southern blot methodology. Fluorescein, ×630.

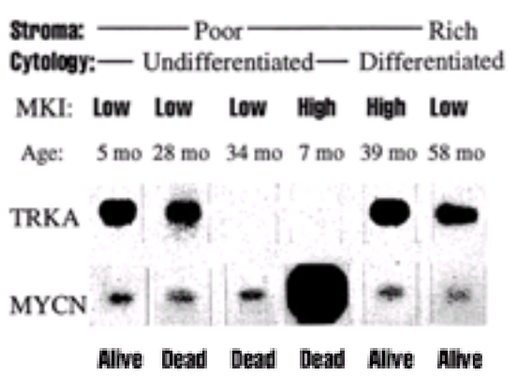

**FIGURE 8-10.** Polymerase chain reaction analysis of *TRKA* and *MYCN*. In this composite blot of *TRKA* (high-affinity nerve growth factor receptor) expression (*upper row*) and *MYCN* copy number determined by Southern blot (*bottom row*), the outcome is compared with Shimada classification. Patients with single-copy *MYCN* that express *TRKA* generally survive. The exception in lane 2 was associated with a poor-prognosis Shimada category. Sequence analysis of this *TRKA* product revealed an 18-bp deletion that rendered the gene product (a membrane tyrosine kinase receptor) biologically unresponsive to nerve growth factor, the functional equivalent to no *TRKA* expression. Conversely, patients with single-copy *MYCN* who lack *TRKA* expression (*lane 3*) have a poor prognosis, as do those with amplified *MYCN* (*lane 4*). Prognosis therefore correlates more closely with *TRKA* expression of the neuronal isoform than with *MYCN* stats and is best with the Shimada classification system. MKI, mitotic-karyorrhectic index. (Courtesy of H. Shimada, Pathology Department, Children's Hospital, Los Angeles.)

## Small Round Cell Tumors of Childhood

The name for this group of difficult-to-diagnose childhood tumors, small round cell tumors (SRCTs) of childhood, refers to the usual appearance of these lesions ( Fig. 8-11). A typical list is found in Table 8-2. Various authors might include other entities, but the point remains the same: they are often largely indistinguishable from each other histologically. As a group, they are primitive or embryonal in appearance, often present in misleading clinical situations (i.e., bone marrow metastases from an occult primary), and lack any particular morphologic features that would allow a precise diagnosis. As a result, they have engendered an entire literature on this subject.[7,8,28]

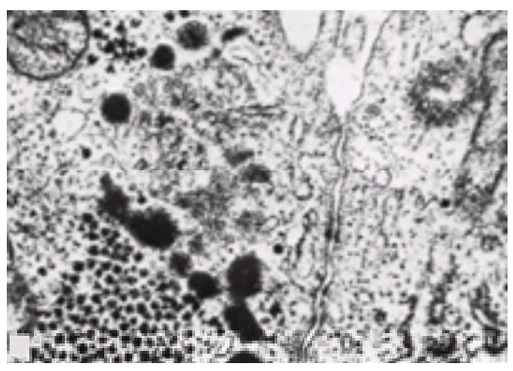

**FIGURE 8-11.** Morphology of typical small round cell tumor. Routine histologic or cytologic examination is of little value in perfectly undifferentiated tumors as illustrated here. Despite high-quality histology and staining, there are no discernible morphologic clues that would allow an unequivocal diagnosis. This so-called small round cell tumor problem is prevalent among childhood tumors and is one of the reasons for the widespread adoption of ancillary diagnostics to provide unequivocal and precise diagnosis.

RMS, rhabdomyosarcoma.

**TABLE 8-2. DIFFERENTIAL DIAGNOSIS OF PEDIATRIC BONE AND SOFT TISSUE SOLID TUMORS**

Because these tumors often cannot routinely be morphologically distinguished from one another, other diagnostic methods must be used to establish a reliable diagnosis. They are a model system that demonstrates the benefits of a multimodality approach to tumor diagnosis. These nonmorphologic techniques noted earlier and discussed in following sections in detail provide not only diagnoses but also prognostic information. By far the most interesting and informative methods to have emerged in the past several years are genetic.[7,18,29,30] and [31] Furthermore, the emerging methods, also discussed in the section Diagnostic Methodology are ever more sophisticated genetic methods that for the first time offer the prospect of predicting not only a diagnosis but also parameters such as biologic behavior, propensity for

metastasis, and drug sensitivity, to name only a few.[32,33,34 and 35] This will likely usher in an era of customized therapy based on these data.

One cautionary note is that a common belief, first espoused with the advent of “sophisticated” diagnostic methods, such as EM and immunohistochemistry, was that “conventional” diagnostic methods, such as routine H&E studies, would be eliminated in favor of these methods. To paraphrase Mark Twain, the rumors of the death of H&E pathology are greatly exaggerated. No other method returns so much information for so little expenditure of time and money. The real issue is that H&E analysis is no longer sufficient in the majority of cases. Thus, the following discussion *presumes* that the diagnostic workup begins with routine H&E studies, followed as indicated by the methods discussed. Any other sequence is generally unacceptable and leaves the diagnostician liable for medicolegal sanction. Cancer diagnosis requires an initial histopathologic tissue examination.

## Diagnostic Methodology

The basic approach to tumor diagnosis that we employ is as follows, using the methods listed in Table 8-1. A representative tissue block is submitted for formalin fixation, paraffin embedding, and routine H&E stain. If, on microscopic examination, there is any diagnostic ambiguity, a series of special studies are chosen based on the differential diagnosis. The most common secondary diagnostic procedure is immunohistochemistry. Concurrent with, or subsequently, special stains [e.g., periodic acid–Schiff (PAS)], EM, or molecular studies are used, depending on the situation. Finally, the entire set of findings are reviewed and interpreted in context with the clinical history and H&E diagnosis to arrive at a final diagnosis. In virtually every case, no matter how undifferentiated, the typical childhood tumor yields to this diagnostic armamentarium. Very few diagnoses are reversed when such an extensive diagnostic evaluation is undertaken. Conversely, H&E diagnoses are often overturned. Thus, it is prudent to use the many ancillary diagnostic methods available to the pathologist with judicious discretion.

Although most tumors require only a few of the procedures listed, some cases are candidates for all of them. This decision to proceed is generally based on the results of the routine H&E studies, although many tumor groups require specific studies that are initiated at the time of initial receipt of the specimen, regardless of diagnostic status. If this is not done, nothing is lost, as long as the procedures diagrammed in Figure 8-6 are followed at the outset.

Before proceeding to a detailed discussion of useful diagnostic methods, it is worthwhile to briefly review the basic methods required for optimal light microscopic diagnosis. With increasing emphasis on other diagnostics, an inevitable loss of attention to detail in the most fundamental workup can occur. We have seen entire specimens procured for studies, such as FACS analysis, only to discover in the aftermath that the tumor in question was never properly diagnosed, is not a leukemia or lymphoma, and never even had basic H&E pathology. This should be avoided. Some attention to the basic methods is in order.

### *Light Microscopy*

No specimen is more widely studied and available for additional analyses than the routine formalin-fixed, paraffin-embedded tissue sample. Accordingly, stringent attention should be paid to a few simple precautions. When performed properly and with attention to quality of the final product, light microscopy provides sufficient evidence for diagnosis in the majority of cases; the better the quality, the less the need for the techniques discussed in the following sections. This is illustrated in Figure 8-12, in which sections from the same case are illustrated. Initial sections were of poor quality and were nondiagnostic ( Fig. 8-12A). When additional sections were carefully cut and stained, the identity of tissue elements and therefore the diagnosis became apparent ( Fig. 8-12B). Furthermore, many new diagnostics have and are being developed to use the ubiquitous specimens. They will fail if simple procedures such as handling, fixation, embedding, and storage are haphazardly applied.

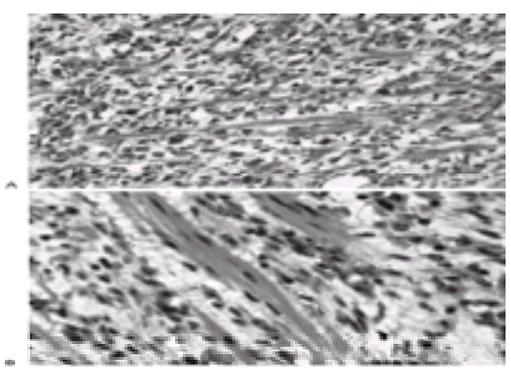

**FIGURE 8-12.** Poor and well-done histology of a typical tumor. **A:** The appearance of a soft tissue neoplasm in a 9-month-old infant. The identity of bands seen coursing across the photograph was difficult to distinguish as fibrous tissue, myofibroblastic elements, or smooth muscle. The correct interpretation only became apparent with proper fixation and embedding, as seen in **(B)**, in which the correct identity as well-differentiated smooth muscle is evident. The surrounding primitive mesenchymal tumor (embryonal rhabdomyosarcoma) is now also evident. Most diagnostic problems in childhood tumor interpretation benefit from optimal-quality histology. Morphology remains the most useful and necessary first step in diagnosis and the subsequent choice of other ancillary diagnostics.

At the outset, tissue should be handled at least in a clean environment with clean instruments, but preferably in a sterile environment such a laminar flow hood if available. *After* tissue is chosen for special studies (Fig. 8-6), including touch preparations and blocks of tissue frozen in optimal cryopreservation temperature compound, if sufficient tissue is available, routine tissue specimens should be submitted in cassettes no thicker than 3 mm. If rapid processing is required, thinner specimens are necessary. Representative sections of large specimens are important, as these tumors are frequently heterogeneous. Some pathologic studies, such as the International (Shimada) classification of NB, cannot be reliably performed on limited specimens such as needle biopsies. When tissue is available, a block for every 30 to 50 g of tissue is a prudent amount to include, although these decisions should be driven by the gross examination. Fewer blocks will suffice in large, homogeneous tumors such as Wilms' tumor. Tumors with obvious heterogeneity on cut surface should be multiply sampled to include all apparent areas, regardless of size.

Optimal fixation is mandatory for many studies, from routine H&E to immunohistochemistry and molecular genetic methods. We recommend a high-quality, buffered 4% formalin fixative for all routine light microscopic studies. If other fixatives are used, they should only be used on additional blocks of tumor tissue. Failure to fix at least one tissue fragment in formalin is a regrettable mistake, to be avoided at all costs. Given the increasing use of formalin-fixed tissue for molecular diagnostics combined with the proven utility of these tissues for diagnosis, there is no other single procedure that better guarantees successful diagnosis.

Once fixed adequately (i.e., at least several hours for any tissue fragment between 1 and 3 mm in thickness), tissues should be embedded in good quality, reasonable (i.e., low) melting point paraffin or paraffin/plastic hybrid to preserve antigenicity of the tissue. Sections should be cut onto acid-cleaned glass slides, if possible, to ensure good adherence, especially because many routine slides are not used for decidedly nonroutine purposes such as *in situ* hybridization, laser capture microscopy, and *in situ* PCR. Tissue that falls off the slides curtails successful use of these methods. Thin sections, no more than 5 µ, are important for diagnostic precision in a variety of methods. Finally, attention to precise, high-quality staining ( *not* batch-processed slides of marginal quality) is mandatory, although frequently overlooked. The wise pediatric pathologist will not accept such slide material.

Although this procedure may seem self-evident, these simple principles are too often eschewed; review of any group of cases assembled from material submitted from a variety of laboratories makes this painfully obvious. Because of this single oversight alone, many of the techniques to follow are often pursued for lack of high-quality light microscopic information. Often, however, these will have no chance of success due to poor-quality tissue; such tissues often yield little useful information.

### *Immunocytochemistry*

Currently, the most universally used ancillary diagnostic method is light microscopic immunocytochemistry. It is routinely used in the majority of childhood cancer cases to confirm presumed histogenesis (based on presumed lineage-specific markers, although this practice is fraught with exceptions—for example, muscle-“specific” desmin in vessels and myofibroblasts). Nonetheless, when used in tandem with routine H&E, this method has become the preferred adjunct to

establish a rapid (i.e., overnight), precise, and reliable diagnosis in a majority of cases.

A detailed discussion of the immunocytochemical results expected from every antibody and every tumor is obviously beyond the scope of this chapter, and is more appropriately found elsewhere. However, Table 8-3 summarizes some of the more useful and specific antibodies used in most pediatric pathology services, along with their common tumor association.

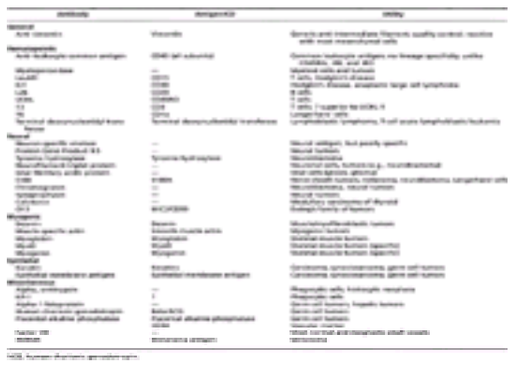

**TABLE 8-3. USEFUL ANTIBODIES IN CHILDHOOD TUMOR DIAGNOSIS**

The most important point concerning the results listed in Table 8-3 is that they are only a guide to expected results; they are not individually always reliable, and anomalous results are the rule, not the exception. The more antibodies used in a given case, the greater the probability of an untoward result. Thus, we interpret the results of immunocytochemistry only in context with light microscopy. Inappropriate results are viewed with skepticism.

A few specific comments about the behavior of some of these antibodies in specific settings are in order. The following discussion of specific genes is based on actual experience of a group of pediatric pathologists in a children's hospital. All diagnostic immunohistochemistry ordered over the course of the year 2000 was compiled and all antibodies used other than sporadically for tumor diagnosis were tallied as Table 8-3. Other pathology groups will likely use some other antibodies with different frequency, but overall this is a reasonable representation of useful antibodies for tumor diagnosis. Thirty-five antibodies are sufficient in our hands for all common tumors. Others are used in a research setting, and promising new antibodies are constantly evaluated. Nonetheless, this tabulation reflects the current state of diagnostic immunohistochemistry.

A second general point is that the overall pattern of antigen localization in a tissue depends on several factors, most notably the cellular disposition of the antigen. Three basic patterns are observed: nuclear, cytoplasmic, and cell surface. These are illustrated in Figure 8-13A, Figure 8-13B and Figure 8-13C. If a tissue shows positive staining but of an inappropriate pattern, the result is highly suspect and should be used with caution. Similarly, artifacts such as geographic staining patterns (e.g., areas of positivity and negativity across a section, independent of tumor heterogeneity), staining of acellular areas (e.g., stroma), and staining of normal cellular elements that should not stain (e.g., endothelial cells for neural markers) are routinely encountered and must be factored into the interpretation. Rarely is a section free of all artifacts. The results, then, depend on the experience and skill of the diagnostician.

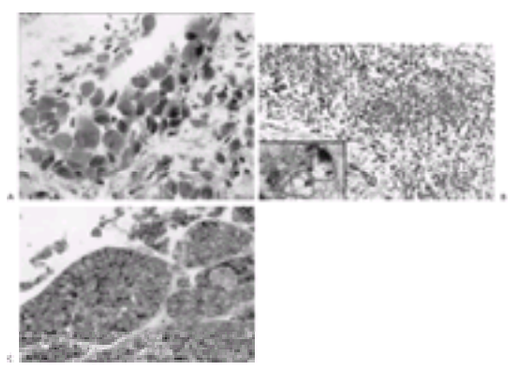

**FIGURE 8-13.** Immunohistochemistry—typical results. Immunohistochemistry is widely used in surgical pathology of adult and childhood tissues. Many classes of antigens (e.g., nuclear, cytoplasmic, and cell surface) are widely detected in the evaluation of childhood cancer. Illustrated here are three categorical examples. **A:** An example of nuclear staining for a transcription factor, myoD, used to detect extremely undifferentiated childhood rhabdomyosarcoma. **B:** Vimentin, a ubiquitous intermediate filament found in most childhood tumors, localized to the cytoplasm (*detail, see inset, lower left*). **C:** *MIC2*, a cell surface antigen found in Ewing's sarcoma and T-cell lymphoma and leukemia.

### Vimentin

Vimentin, a 10-nm intermediate filament, is expressed in all cells of the body at some developmental stage and at some level.[36,37] Antibodies to vimentin have no specific diagnostic utility. It is, however, the single most useful antibody for quality control, the most common reason for incorrect or invalid results by this methodology. Epithelia are generally negative, but most other cells are positive. Within a given section, *something* will be reactive (often blood vessels and fibroblasts, for example), thereby proving that the antigenicity of the section is intact and enabling reasonably reliable interpretation of results with other antibodies.

### Leukocyte Common Antigen, or CD45, Nonrestricted

CD45 is an abundant cell surface glycoprotein on immune cells that functions as a phosphotyrosine phosphatase.[38] All hematopoietic cells should in theory react with this antibody. That is not the case with certain lymphomas,[39] for example, possibly because loss of CD45 may be associated with the development of aggressive T-cell leukemias,[40] but most lymphomas, leukemias, and granulocytic sarcomas do react. Hodgkin's disease is poorly reactive.[41] Many commercial sources exist, generally with similar if not identical reactivity, despite the fact that most are single monoclonal antibodies (or, less often, “cocktails” of several anti-CD45 monoclonal antibodies). Because benign *and* malignant hematopoietic cells react with the antibody, it is most useful as a tool to distinguish one hematopoietic malignancy from another, nonhematopoietic tumor. It is of no value (in general) in distinguishing benign, reactive, or malignant hematopoietic cells from one another.

### Myeloperoxidase

Although myeloperoxidase activity can be detected histochemically in suitable specimens by the generation of free oxygen from peroxide, the enzyme itself, a protein, can be detected with suitable antibodies.[42,43] This detection is especially useful when discrimination between a granulocytic neoplasm (typically either acute myelogenous leukemia or granulocytic sarcoma or chloroma). Both benign and malignant myelocytic lineage cells are reactive, although highly immature myeloid precursor cells may be weakly reactive.

### LeuM1 (CD15)

Despite the name, LeuM1, reactive with the CD15 cell surface antigen, identifies predominantly T cells and Hodgkin's disease Reed-Sternberg cells.[44,45] Although useful, it does not distinguish the two. It is best used in conjunction with CD30 antibodies, with which it can reliably distinguish Hodgkin's disease (positive) from

anaplastic large cell lymphoma (ALCL; negative).

**Ki1 (CD30)**

Ki1, part of the Kiel University series of monoclonal antibodies (thus, the name, Ki1), has been most widely used to identify Hodgkin's cells in Hodgkin's disease. [46,47] and [48] However, it also reacts with ALCL in children. [49] Concurrent use of anti-CD15 antibodies (see the previous section) distinguish the two: Hodgkin's cells are reactive with both; ALCL reacts only with CD30. Because of overlapping immunophenotypic features of the two, most authors employ molecular diagnostics (see the section on molecular genetic diagnostic techniques) to detect the NPM/ALK chimeric gene found in ALCL. [50] Despite this, there are reports of Hodgkin's disease with the fusion gene, [51] or that evolve into ALCL, so this distinction may not always be possible.

**L26 (CD20)**

Recognized as a pan-B cell–reactive monoclonal antibody useful in paraffin-embedded specimens from the outset, [39,52] it was soon determined that L26 recognized a known pan-B antigen, termed *CD20*. [53] This antibody has endured as the single most useful marker of B cells in general, and neoplastic ones in particular, despite occasional staining of T cells. [54,55] and [56] In conjunction with CD45, it will stain B cells even when CD45 (LCA) is negative.

**UCHL-1 (CD45RO)**

The counterpart to the pan-B antibody L26 is UCHL-1, also recognized early on as highly specific for T-cell lineage and reactive with paraffin-embedded tissues. [57,58] and [59] It is therefore the ideal companion to L26 for T- versus B-lineage determination in hematopoietic neoplasia. The only drawback is a more frequent occurrence of negativity (i.e., 61% to 78%) in bona fide T-cell malignancies. [57,60] Despite these inconsistencies (true of all antibodies and their target antigens to a greater or lesser degree), the panel of CD45, CD20, and CD45RO is the standard set in routine use for hematopoietic and T- versus B-lineage studies.

**T3 (CD3)**

Described earlier than the other major T-cell marker CD45RO, [61,62] anti-T3 antibodies (e.g., UCHT-1, OKT3) have been used in both flow cytometry to mark T cells and subsequently in solid hematopoietic tumors as well, especially because the T3 epitope, CD3 (actually a group of transmembrane glycoproteins), [61] survives formalin fixation and paraffin embedding. [63] In practice, UCHL-1 is more often used, but anti-CD3 antibodies are valuable adjuncts, especially because a significant percent (as much as 20%) of T-cell malignancies fail to react with UCHL-1. [58]

**CD1a (T6)**

Antibodies against the CD1a epitope were originally recognized to react with lymphoid cells of T-cell lineage, specifically mid-thymocyte lineage. [64] Common acute lymphoblastic leukemia cells were also noted to be reactive in a high percentage of cases, but not sufficiently consistent to denote T-cell lineage in this malignancy. [65] At approximately the same time, it was noted that anti-T6 (CD1a) antibodies reacted consistently with the Langerhans' cells of histiocytosis X, or Langerhans' cells histiocytosis by current terminology. [66] Further investigation revealed that normal Langerhans' cells in epidermis and lymph node are also reactive (typically, $CD1a^+/HLA\text{-}DR^+$), documenting the Langerhans' cell lineage of normal and neoplastic histiocytes. Not surprisingly, malignancies of follicular dendritic cells and interdigitating reticulum cells (e.g., interdigitating reticulum cell sarcomas) were also found to be reactive, [67] although confirmation optimally requires comprehensive immunophenotyping, as some malignancies of histiocytic lineage lack the usual phenotype of Langerhans' cells. [68] At a practical level, anti-CD1a antibodies in conjunction with anti-S100 antibodies are of great value in confirming a diagnosis of Langerhans' cell histiocytosis, a not uncommon problem in childhood tumor diagnosis. $CD1a^+/S100^+$ cells are unequivocally of Langerhans' cell lineage, although specific features, such as pure lymph node involvement and sarcomatous appearance, may suggest a histiocytic sarcoma or interdigitating cell sarcoma, which are also generally positive. [68]

**Terminal Deoxynucleotidyl Transferase**

Although terminal deoxynucleotidyl transferase (TdT), a DNA polymerase, was first detected on the basis of its enzymatic activity (specifically in adding nontemplated nucleotides during T-cell receptor gene rearrangement), whereby a strong correlation with T-cell lineage was noted, [69] it was quickly realized that TdT activity is therefore a reliable index of T-cell lineage among lymphoid neoplasia. [70,71,72,73] and [74] Many studies based such detection on enzymatic assays, [71,73,74] but less cumbersome methods designed to detect the enzyme itself independently of its enzymatic activity were soon developed. [75,76] These methods were largely immunofluorescent in character, but with the general advances in immunohistochemistry true of the past two decades, these antibodies have been adapted to chromogenic avidin-biotin–based methodology, specifically for use on paraffin-embedded, formalin-fixed tissues. [77,78] and [79] Comparative studies confirmed both a close correlation with the enzymatic activity and the association with acute lymphoblastic leukemia and lymphoblastic lymphoma. [80,81] As is virtually universally the case with antigen expression on cells and tissues in general, even TdT activity has now been identified on non–T-cell neoplasia, [82] and rare cases of TdT-lymphoblastic leukemias have been reported. [83] Despite these caveats, antibody-based TdT detection remains the single most useful means of detecting T-cell leukemia and lymphoma (notably lymphoblastic lymphoma) in children.

**Neuron-Specific Enolase**

Neuron-specific enolase (NSE), the so-called neuron-specific isozyme of a family of endase enzymes, was thought to be restricted to neural tissues and tumors, and numerous studies at first appeared to support its utility as a diagnostic marker for tumors of neural lineage. [84] This apparent specificity was soon recognized to be incorrect; numerous non-neural tumors were subsequently shown to express NSE. [85] Despite these problems with nonspecificity of detection of the g subunit of NSE, it has subsequently been demonstrated that NSE is nonetheless the single most sensitive and universal marker in neural tumors, despite its proclivity to be expressed in non-neural tumors as well. [86] Although widely used to detect neural phenotype in tissues and tumors, it is generally used in conjunction with antibodies against other neural antigens such as PGP 9.5 and soluble brain-derived protein (S100). [86]

**Protein Gene Product 9.5**

Problems with nonspecificity of NSE prompted a search for other, more reliable markers of neuronal differentiation. Protein gene product 9.5 (PGP 9.5), a soluble glycoprotein isolated from brain, has been widely adopted as an alternative, or in many cases, an adjunct diagnostic antibody in the evaluation of neural tumors. [87] Its diagnostic value in NB was promptly reported [88,89] and compared to NSE staining. It has been found to be more reliably associated with neural tissues but with similar sensitivity. [86] Currently, PGP 9.5 in conjunction with tyrosine hydroxylase (TH) is widely used in the specific diagnosis of NB (other, non-sympathetic neural tissues and tumors are TH negative). [90] Thus, for general purposes, *both* NSE and PGP 9.5 are ideally used in tandem in the diagnosis of any neural neoplasm, notably NB and the EFTs. TH positive will identify the former in contradistinction from the latter.

**Tyrosine Hydroxylase**

Among the many neurotransmitter enzymes necessary for the adrenergic (catecholamine-producing) metabolic pathway, TH has proved uniquely useful as an indicator of NB. [91,92,93] and [94] Elevation of this enzyme, produced only by monoaminergic neurons of the sympathetic ganglia (the site of virtually all childhood NBs), is closely associated with serum and urinary excretion of intermediary metabolites homovanillic acid and vanillylmandelic acid. [95,96] However, not all NBs show increased expression of this enzyme. [97] Consequently, detection of TH activity may be diagnostic, but lack of activity does not preclude a diagnosis. The presence of TH has been assessed immunochemically, and a strong association between detection of the proteinaceous enzyme and TH activity has been noted. [98,99,100] and [101] Reverse transcriptase-PCR (RT-PCR) assays have also been developed, [102,103,104] and [105] but immunochemical detection appears to be at least as useful, and offers the additional advantage of tissue localization. [106] The specificity of TH expression is well documented, and thus detection of TH by immunohistochemistry is highly specific and generally positive in NB. [90,107]

### Neurofilament Triplet Protein

Neurofilament triplet protein, so called because three different transcripts and resulting different molecular weight subunits are expressed to produce the final intermediate filament of neural tissue, is routinely expressed in the classic neural tumors of childhood, NB and medulloblastoma. [108,109,110 and 111] It is also occasionally detected in the peripheral neural tumors, now collectively referred to as the EFTs, but less reliably so. [112,113] Furthermore, all intermediate filaments can show lineage-inappropriate expression in tumors; NFTP is no exception, typically being expressed in RMS and rhabdoid tumor, to name only two examples. [113,114,115,116 and 117] When used in conjunction with other neural markers like NSE and PGP 9.5, however, NFTP can be a useful marker to document neural lineage in a tumor. It represents definitive evidence of such differentiation, much as myogenic filaments in muscle tumors document myogenesis.

### Glial Fibrillary Acidic Protein

Glial fibrillary acidic protein, normally restricted in its expression to the glial cells of the brain, [118] has nonetheless been documented in a variety of tumors other than gliomas, notably NB, primitive nerve sheath tumors, and even Ewing's tumors. [119,120 and 121] Although most useful when used in concert with NFTP and vimentin, it is occasionally useful separately to document support cell differentiation (e.g., Schwann cells), in conjunction with S100, in NB (so-called stroma-rich tumors), in which its expression is inappropriate but a useful marker of non-neuronal differentiation in this tumor.

### Soluble Brain-Derived Protein

S100 immunoreactivity has long been recognized as a reliable index of neural differentiation. [122] However, it should be noted that S100 is immunoreactive in a broad range of tumors, including neural, nerve sheath, melanocytic, cartilaginous, and Langerhans' cell histiocytic. [123,124,125,126 and 127] Despite this widespread occurrence of immunoreactivity, S100 remains useful in the identification of these cell types. Positivity, then, can only be used diagnostically in context with other features of a given cell lineage in a tumor. For the most part, that is not difficult. S100 immunostaining merely provides confirmation of such lineage in most cases.

### Chromogranin, Synaptophysin, and Calcitonin

Chromogranin, synaptophysin, and calcitonin are selectively expressed in neural tissues (or neuroendocrine cells of the thyroid in the case of calcitonin) and are therefore reliable markers of neuroendocrine phenotype in normal and neoplastic cells. At first, highly selective expression was thought to correlate with neuroendocrine cell lineage alone, but more extensive experience has demonstrated many instances of lack of detectable expression in known neuroendocrine tumors and (especially with synaptophysin) expression in non-neuroendocrine tissues. Thus, although useful, this group of markers is not as widely used as those discussed previously. [128,129,130,131,132,133,134,135,136,137,138,139,140 and 141]

### O13 (p30–32 MIC2, CD99)

The otherwise often ambiguous diagnosis of EFTs was revolutionized by the recognition that an antigen on T cells involved in red cell adhesion, E2, was the product of the pseudoautosomal gene MIC2, which in turn is highly expressed in Ewing's tumors. [142,143,144,145 and 146] Within a short time, detection of the MIC2 p30–32 glycoprotein product by suitable antibodies (often either O13 or Leu 7) became the diagnostic standard for these tumors, at least for that brief period after its initial description and before the recognition of the *EWS-FLI1* fusion gene in this family of tumors. [147,148,149 and 150] Subsequent studies have documented the expression of CD99 in other tumors, most notably some desmoplastic SCRTs (DSRCTs), RMSs, brain tumors, and even angiomatoid fibrous histiocytoma. [141,151,152]

### Desmin

Desmin, a prototypical intermediate filament protein (along with vimentin, NFTP, glial fibrillary acidic protein, and keratin), is strongly associated with myogenic cell differentiation. [118,153] Consequently, it was promptly identified as a potential, easily detectable marker of early myogenesis, and in fact has become the diagnostic standard for detection of skeletal muscle differentiation in suspected RMS, despite its known occurrence in smooth muscle and even myofibroblasts. [154,155,156,157 and 158] More troubling, desmin expression has been reported in completely unrelated tumors [e.g., NB and primitive neuroectodermal tumors (PNETs) as well] thereby undermining its utility as a stand-alone marker of rhabdomyogenesis. [159,160] For these reasons, current practice is to use at least two markers, nominally desmin and muscle-specific actin (MSA). [158]

### Muscle-Specific Actin

Among the several actins (cytoplasmic, skeletal muscle, and cardiac muscle), MSA represents the single most common transcript during normal myogenesis. [161,162] It was therefore a predictable application to develop suitable antibodies against this particular actin and to use such antibodies in the diagnosis of RMS. [163] When compared to desmin, MSA antibody staining has proved a reliable adjunct, but it, too, stains nonrhabdomyogenic cells such as vascular smooth muscle. [164] As long as normal cellular components can be excluded, MSA, preferably in conjunction with desmin, is a potent diagnostic tool for the diagnosis of RMS. [165]

### Myoglobin

Myoglobin, as its name implies, is an oxygen-carrying heme protein normally localized to skeletal muscle and should therefore be a reasonable marker of skeletal muscle differentiation. This fact was recognized early in the evolution of diagnostic immunohistochemistry and used for the diagnosis of RMS. [156,166,167 and 168] Experience over many years has clearly indicated that myoglobin staining is not always reliable, however, and therefore results should never be used in isolation. Ideally, the combination of desmin, MSA, and myoglobin staining optimizes the sensitivity and specificity of immunohistochemical diagnosis of RMS. [169]

### MyoD and Myogenin (Myogenic Transcription Factors)

The exquisite, precisely orchestrated steps that eventuate in the creation of a skeletal muscle cell from an undifferentiated mesenchymal stem cell have been worked out in remarkable detail. [170,171,172,173,174,175,176,177,178 and 179] It is now clear that a few master control genes, notably myoglobin D1 (MyoD1), Myf5, and Myogenin (myf4), all members of the basic helix-loop-helix family of nuclear transcription factors, are responsible for commitment and subsequent differentiation in mesenchymal (or any other) cells. [177,178 and 179] This, then, is the critical first step leading to skeletal muscle differentiation in normal and neoplastic mesenchymal cells. [173,178,180,181] The latter property thus defines RMS at a molecular level. As such, it thus requires detection of these scant nuclear proteins. This has been accomplished, even on routinely fixed tissues, using antigen retrieval methods such that MyoD1 and Myogenin can be readily identified, a finding tantamount to a diagnosis of RMS if the tumor in question is a soft tissue sarcoma of childhood. [24,182,183 and 184] Currently, detection of MyoD or Myogenin in tumor cells is sufficient for a diagnosis of RMS, even in the absence of muscle-specific proteins such as MSA, myosin, or desmin, all of which are expressed later in muscle development.

It is tempting to ask whether there is an even more proximal determinant of muscle lineage in normal and tumor cells. There is, but it is of no value in this context, as the genes responsible, PAX3 or PAX7, are also expressed in neural tissues and certain neural tumors (e.g., the EFTs). Thus, PAX3 or PAX7 expression is not sufficiently specific, even though it is mandatory to incite myogenesis via MyoD and MYF5. [185,186 and 187]

### Keratin

Keratin is the unique intermediate filament of epithelia. [188,189] However, it is also expressed in a number of other tissues and tumors with some frequency. [36,37,190,191 and 192] Consequently, keratin alone does not reliably identify epithelial tumors. It does, however, strongly associate with epithelial phenotypic expression in a tumor in the broadest sense of the word. If one accepts that certain keratins are expressed in all ectodermal and entodermal cells, its expression in even primitive cells of such lineage, such as the EFTs, is not untoward. [193] Likewise, even tumors of clear mesenchymal origin, such as SS, with known ability to undergo glandular differentiation routinely express keratin, even before obvious glandular (epithelial) differentiation. [194,195]

### Epithelial Membrane Antigen

Confirmation of epithelial phenotype in a tumor is thought to be reliably established by concurrent use of anti-epithelial membrane antigen (anti-EMA) antibodies. Coexpression of both keratin and EMA is not observed with any frequency in any cells other than those with epithelial phenotype. In the cases in which both are expressed but no obvious epithelial cells are present, there is increasing evidence for nascent epithelial differentiation, as in monophasic SS and nerve sheath tumors.[194,196,197] Admittedly, exceptions are well known, such as the EFTs, DSRCTs, and leiomyosarcoma, but in general there is strong correlation between epithelial differentiation and coexpression of keratin and EMA.

### Alpha$_1$-antitrypsin and KP1 (CD68) (Phagocyte-Associated Antigens)

Alpha$_1$-antitrypsin (AAT) expression has been associated with phagocytic or histiocytic cells. Experience with antibodies to AAT has been somewhat unsatisfactory, however, as immunoreactivity has been found in a wide variety of cell types.[198,199] This has led to the development of more specific targets found more or less exclusively in phagocytic cells. One in particular, KP1 (anti-CD68), has enjoyed wide use as a reliable marker of phagocytes, histiocytes, and their presumed tumors.[200,201 and 202] Although useful, results are sometimes less than ideal, limiting their utility in the absence of other confirmatory information.[200,201]

### Alpha-1-fetoprotein, Human Chorionic Gonadotropin, and Placental Alkaline Phosphatase (Germ Cell Markers)

Germ cell tumors have for some time been readily diagnosed by detection of specific antigens more or less unique to this group of tumors. The three most commonly used antibodies to detect alpha-1-fetoprotein, human chorionic gonadotropin, and placental alkaline phosphatase have now been well characterized and shown to correlate remarkably well with the germ cell tumor lineage of the tumor in question. Very few exceptions occur. As a result, any tumor suspected of being a germ cell tumor or to contain even elements of germ cell tumor can be documented with a simple panel of three well characterized antibodies.[203,204,205,206,207,208,209 and 210]

### CD34 and Factor VIII (Vascular Markers)

CD34, an antigen nominally present on hematopoietic precursor cells, has also been detected on vascular (endothelial) cells and vascular tumors.[211,212] However, it has also been detected on a variety of other tumor cell types to the point that its utility as a vascular marker has been questioned.[213,214] Recent studies with laser capture microscopy and immunodetection confirm, however, that the antibody detects a genuine tumor cell product of the correct molecular weight.[215] Thus, specificity of antigen recognition is not an issue; rather, the antigen is expressed on diverse types of nonvascular cells as well, thereby undermining the utility of anti-CD34 antibodies as purely vascular markers. Most authors therefore use a combination of anti-CD34 and anti-factor VIII or ulex agglutinin in their efforts to confirm a vascular phenotype to a tumor of uncertain histogenesis. In one recent study of 80 malignant vascular tumors (angiosarcomas), all were at least focally positive for factor VIII–related antigen, whereas only 74% were positive for CD34.[212]

### HMB45 (Melanoma Antigen)

Although melanoma per se is uncommon in children, melanocytic tumors are not so rare, notably melanoma of soft parts (clear cell sarcoma of soft parts) and pigmented peripheral nerve sheath tumor [part of the spectrum of malignant peripheral nerve sheath tumor (MPNST)]. Thus, the introduction of a specific melanoma antigen antibody over a decade ago has been of great (albeit occasional) utility.[216,217,218 and 219] Other antibodies have been proposed, but HMB45 appears to be the most specific and most uniformly reactive among melanocytic lesions.[220,221] The particular value, of course, is in the diagnosis of amelanotic lesions and those with atypical histology (e.g., spindle cell lesions) with very rare false negative results and virtually no false positive results.[222,223,224,225 and 226] The latter point (i.e., specificity) is accentuated by the finding, for example, of composite melanocytic/neuroblastic tumors, wherein only the melanocytic component expresses the HMB45 antigen.[227] Thus, despite limited overall utility, the specificity of this antibody renders it highly useful when the differential diagnosis includes melanocytic lesions of any type.

It is important to remember that the preceding list represents actual everyday usage in a children's hospital. Adult institutions will likely use a very different spectrum of antibodies, reflective of the differences between adult and childhood cancers. The preceding list is of some use in a pediatric cancer setting, however. It is not all inclusive or exhaustive but will account for the bulk of childhood tumors seen in such an institution.

## *Special Stains*

The success of immunohistochemistry and EM has largely replaced the use of special stains in diagnostic surgical pathology. A few remain useful, however, and warrant at least a brief comment here.

The basic special stains in common use, especially the connective tissue stains (i.e., trichrome, pentachrome, and reticulin), are used most commonly to detect a fibrous supporting stroma. This can be useful in determining whether a given tumor is a stroma-producing tumor (e.g., a sarcoma). It can also be useful in distinguishing certain types of sarcoma: At one extreme, hemangiopericytoma generally produces an obvious stroma when stained with a silver reticulin stain, whereas the EFTs do not, providing a simple method of distinguishing the two, which occasionally resemble one another to a striking degree. It should be apparent after reading the molecular diagnostic section that molecular diagnosis has become the gold standard for diagnosis. In the absence of suitable tissue for molecular studies (such as a few submitted unstained slides), a connective tissue stain can be helpful in supporting a diagnostic impression of a stroma-poor sarcoma such as an EFT, as opposed to an hemangiopericytoma, or even a small cell osteosarcoma.

The older diagnostic literature repeatedly refers to the value of PAS, with and without diastase digestion (to remove glycogen), in the diagnosis of childhood tumors.[228,229,230,231 and 232] However, it has also become obvious that tumors that should accumulate glycogen detectable by the PAS reaction sometimes do not, and others that should not, do.[229,231] Thus, the utility of this stain has decreased, but it is still a useful adjunct in confirming the diagnosis of an EFT, for example, while ruling out most lymphomas and NBs.

Finally, myeloperoxidase activity demonstrated histochemically on tissue sections (e.g., von Leder stain) can be an invaluable diagnostic adjunct in the rare case of suspected granulocytic sarcoma, or chloroma.[233,234] Often, these cases present in unusual clinical settings, such as a periorbital mass, preceding any overt peripheral blood abnormalities suggestive of myeloid leukemia.[235,236,237,238,239,240,241,242 and 243] The distinction from more conventional solid tumors of soft tissue, such as Langerhans' cell histiocytosis, lymphoma, RMS, and NB (especially in the periorbital region), is generally easily made, as the von Leder stain is highly specific for myeloperoxidase activity. Although antibodies against myeloperoxidase have been developed,[233] the von Leder stain remains the procedure of choice.

## *Electron Microscopy*

EM no longer plays a significant role in the diagnosis of most adult tumors but is still widely used in the diagnosis of childhood tumors (and other tissues). Thus, although infrequently used in adult settings, approximately 5% to 10% of childhood tumors are studied by EM to improve diagnostic accuracy. The most common reason, beyond diagnostic uncertainty based on ambiguous morphology (the small blue cell tumor problem almost unique to childhood tumor diagnosis), is to clarify conflicting results from other studies such as immunohistochemistry. It is a valuable adjunct, but plays a subordinate role in most diagnostic settings, in which cheaper, more specific, or more rapid diagnostics are used first. Small blue cell tumors are a common setting, but most of these can now be quickly diagnosed by other methods.

Despite these caveats, EM can be indispensable in selected cases. Its greatest contribution is usually definitive evidence of histogenesis, or a tumor-specific ultrastructural feature in which no definitive morphologic or immunochemical feature is identified. Examples include basal lamina in nerve sheath tumor versus fibrosarcoma (Fig. 8-14A), cell adhesions to rule out suspected lymphoma (Fig. 8-14B), Langerhans' granules in histiocytosis X (Fig. 14C), primitive duct or gland formation (e.g., apical cell junctions and basal lamina) in monophasic SS (Fig. 8-14D) or Wilms' tumor, dense core granules and/or neurites in suspected NB (Fig. 8-14E), melanosomes in melanoma of soft parts (Fig. 8-14F) or pigmented peripheral nerve sheath tumors, and Weibel-Palade bodies (usually with numerous endocytic vesicles) in vascular tumors. The actual spectrum of findings in the common (and uncommon) tumors of childhood is of course the subject of an entire literature, too lengthy to review here.[244,245,246,247,248 and 249] Increasingly, the challenge is the availability of this technology, which is both expensive and requires

specialized training for reliable interpretation. These issues increasingly limit the utility of EM for tumor diagnosis.

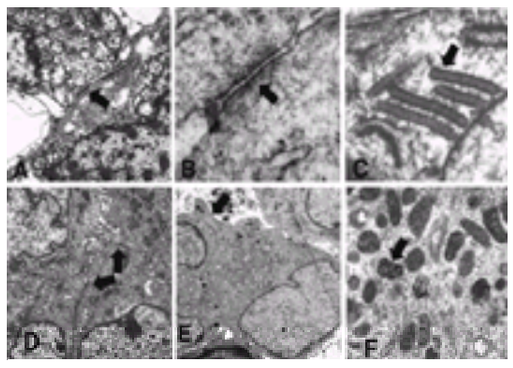

**FIGURE 8-14.** Typical ultrastructure. Electron microscopy still plays a useful role in childhood tumor diagnosis. Six typical findings useful in the diagnosis of childhood cancer are illustrated here. **A:** Basal lamina (*arrow*). Typically found in benign nerve sheath tumors, benign and some malignant muscle, and underlying the glandular elements of synoviosarcoma, basal lamina is a distinctive feature that can help in a differential diagnosis of at least these tumors. **B:** Cell adhesions (*arrow*). When lymphoma or leukemia are a consideration, the finding of any form of cell adhesion, such as that illustrated here, rules out any form of hematopoietic malignancy. This finding is especially useful given the frequent negativity of childhood lymphomas and leukemias for specific lymphoid and T- and B-cell markers. **C:** Langerhans' granules (*arrow*). These structures, of unknown function and origin, are among tumors exclusively associated with Langerhans' cell histiocytosis. They are normally found in dendritic cells in lymph node and in Langerhans' cell of skin. **D:** Gland formation. Although carcinoma is effectively not described in childhood cancer, a typical glandular epithelial formation with apical junctions ( *arrows*) is routinely found in biphasic synoviosarcoma in which islands of nascent glandular differentiation may be identified. **E:** Dense core granules and neurites (*arrow*). A common diagnostic problem in childhood tumors is neuroblastoma versus other small round cell tumors of childhood. The most common differential finding by electron microscopy is the presence of dense core granules and neurites ( *arrow*), which are virtually synonymous with neuroblastoma (although rarely they may be observed in peripheral primitive neuroectodermal tumors and Ewing's tumors). **F:** Melanosomes. Although melanoma is exceedingly rare in children, melanosomes (*arrow*) are routinely found in melanoma of soft parts. This finding can be useful in the differential diagnosis of spindle cell soft tissue tumors in which distinction between melanoma of soft parts, monophasic synoviosarcoma, malignant peripheral nerve sheath tumor, and fibrosarcoma may be problematic.

### *Molecular Genetic Diagnostic Techniques*

For lack of a better term, *molecular genetic diagnostic techniques* as used here applies to the five major methods currently in use to examine the genomic status of a cell or cells: (a) PCR, (b) cytogenetics, (c) FISH, (d) spectral karyotyping (SKY), and (e) comparative genomic hybridization (CGH). The methods fundamentally differ; PCR is applicable largely to extracted DNA or RNA converted into DNA, whereas the other four methods, directly or indirectly, detect whole chromosomal genetic status.

It is also important to note that there are innumerable variations of these methods, and even entirely different methods (e.g., arrays, discussed under Microarrays, Polymorphisms, and Whole Genome Studies). Here we focus on only those methods now in daily use to analyze childhood tumors. Furthermore, specific examples of the application of these general methods to childhood tumor diagnosis are discussed later. The purpose here is to introduce the basic methodology.

#### Polymerase Chain Reaction

PCR is now commonplace, and this discussion is not intended to review the history of this fundamental tool in genetic studies. Modern genomic analysis could not be undertaken without it, nor could most forms of tumor genetics.[250] Rather, the purpose here is to discuss how this basic method has been adapted and used to detect genomic alterations and gene expression in even single cells and paraffin-embedded material, tissue sources never envisioned by those who first used this method. As of this writing, there are at least four basic approaches to the use of this technique: (a) conventional PCR, including detection of mRNA, using reverse transcriptase to create complementary DNA (cDNA) from mRNA (RT-PCR); (b) PCR from paraffin (e.g., short primers); (c) quantitative PCR (as marketed by Roche Pharmaceuticals), and (d) *in situ* PCR on cells or tissue sections. The creative skeptic can certainly identify other methods, including gross amplification of total mRNA extracts from even single cells (as popularized by Eberwine),[250a,250b] but these are not yet in widespread diagnostic use.

Although mRNA can be readily detected and used as an index of gene expression in the analysis of childhood tumors,[251] most diagnostic PCR in childhood tumor diagnosis is used to detect genomic alterations (e.g., gene translocations, amplifications, or deletions). Although this can be performed on genomic DNA, and frequently is, the method of choice in practice is to amplify expressed mRNA sequences. This method is useful, especially when translocation variants generate huge intron sequences that may not be reliably amplified (the FKHR gene, discussed in the section *PAX-FKHR* Gene Fusions in Alveolar Rhabdomyosarcoma, is one example). This works reliably, as documented by an extensive literature on the subject (see references [252,253] and [254] for reviews). However, less than one-half of most tumors are available in a suitable physical state (e.g., fresh, frozen, or imprints) to reliably perform conventional RT-PCR. Thus, the method has been adapted to even paraffin-embedded, formalin-fixed tissues, largely by using primers designed to compensate for the widespread RNA degradation and fragmentation found in these specimens.[255,256,257] and [258]

The other major innovation in PCR diagnostics is the introduction of reliable and seemingly quantitative PCR analysis. Although quantitative PCR analysis is not new, no consensus had emerged as to a preferred method until Roche introduced a commercial platform (Taqman) that routinizes and automates the procedure. This important new tool extends the utility of PCR for detection of gene expression beyond simple presence or absence; quantitative levels can now be measured and compared, as is commonplace for NB and *MYCN* expression (as in index of amplification; see below).

Although premature to stress at this point, it is nonetheless relevant to note the emergence of amplification methods using PCR that offer the possibility of generating abundant RNA that more or less stoichiometrically parallels the abundance of these same species in the native specimen. This method, pioneered by Eberwine,[250a,250b] has been greatly improved in the recent past,[258a,258b] and may well make possible analysis of the entire repertoire of expressed genes by methods such as microarrays and serial analysis of genetic expression (serial analysis of genetic expression; see the section Microarrays, Polymorphisms, and Whole Genome Studies) from the smallest samples, perhaps even single cells.[259] It is not too far-fetched to imagine minimally invasive procedures such as radiographically directed fine needle aspiration or laser capture microscopy of single cells or small groups of target cells (e.g., pure tumor cell populations) coupled with DNA or RNA amplification as a common diagnostic sequence in the future.

#### Karyotypic Analysis (Cytogenetics)

Conventional tumor cytogenetics is in a state of rapid evolution at present. Conventional cytogeneticists are becoming molecular cytogeneticists. Nonetheless, the most common genetic analysis at a whole cell level is ordinary G-banding metaphase cytogenetics, or karyotypic analysis.[260,261] Every case of leukemia and most solid tumors avail of the technology. Most of the diagnostic translocations discussed elsewhere [such as the t(11;22) of the EFTs] are readily identified ( Fig. 8-15), and (importantly) new translocations or deletions will also be discovered, which ultimately lead to discovery of new translocations, variants, or even new genes involved in the etiology of the tumor. The negative side of cytogenetics is the success rate: perhaps only 50% of the time is diagnostic material cultured.[262,263] and [264] These cases are not negative; they are uninformative. Thus, a negative result from a lack of metaphase cells to karyotype is *not* a negative result. Even if metaphase cells are present, an occult translocation may be present, for example, and still be called “normal,” or a nonspecific abnormality. Thus, positive results by cytogenetics are exceedingly important; negative results cannot be counted on.

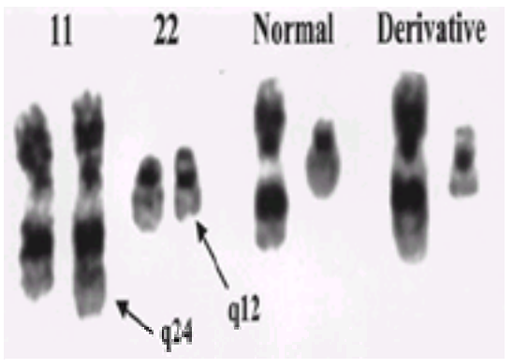

**FIGURE 8-15.** Ewing's cytogenetics. Tumor cytogenetics was the first purely genetic diagnostic analysis of tumors. A classic example, Ewing's sarcoma, routinely shows a reciprocal translocation of the long arms of chromosomes 11 and 22 [t(11;22)], resulting in the formation of derivative chromosomes 11 and 22 paired with a normal 11 and 22, as seen here. This was the first clue leading to the later identification of a specific chimeric gene in this disease.

### Fluorescent *In Situ* Hybridization

These limitations of traditional cytogenetics spawned an approach, that of interphase FISH, that requires no metaphases but which can yield exceedingly rich information from simple specimens such as frozen tissue, touch preparations, and even ordinary paraffin-embedded sections ( Fig. 8-16).[265,266,267,268,269,270,271,272,273,274,275,276] and [277] New translocations or genes cannot be found by this technique (by definition, one uses fluorescently labeled DNA probes to detect a translocation, for example). Nonetheless, the speed, specificity, and utility of this method have made it an important diagnostic tool in short order.[277,278]

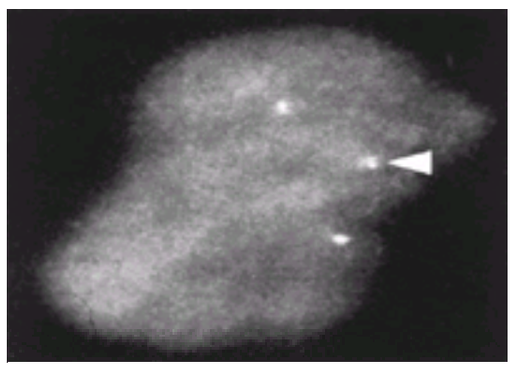

**FIGURE 8-16.** Ewing's fluorescent *in situ* hybridization (FISH). Chimeric genes, such as the EWS-FLI1 responsible for Ewing's sarcoma, are easily identified by FISH, now in routine diagnostic use, as illustrated here. Three signals are identified compared to the normal four due to the fusion of one copy of EWS and one copy of FLI1, resulting in a compound single signal (*arrowhead*), accompanied by one signal each from normal EWS and FLI1. (Courtesy of D. Lopez-Terrada, Texas Children's Hospital.)

The predominant use of FISH to date has been to detect genomic alterations, but it can also be used to detect gene expression by hybridization with mRNA in touch preparations or tissue sections. This method is less sensitive than PCR and requires better RNA preservation, and is therefore not in widespread use for diagnostic purposes, although it is an important research tool. [279]

Diagnostic use of FISH has really only begun. Refinements with new, more easily detected probes applicable to tissue sections, combined with routine *in situ* amplification of target, perhaps enhanced by secondary detection methods, such as those applied to immunohistochemistry (e.g., avidin-biotin complexes) to detect even normal gene expression in addition to gene translocations, amplification, or deletion, will likely make this technique as important as immunohistochemistry in the future.

### Spectral Karyotyping

The development of methods to label and detect individual chromosomes using spectral analysis of emitted fluorescence, thereby ascribing computer-generated false colors to individual chromosomes, is a major advance in the analysis of chromosomes, especially because metaphase and even interphase chromosomes can be visualized.[280,281,282,283] and [284] This is particularly important given the frequent failure of conventional cytogenetics to culture tumor cells, thereby obviating any chance of detecting constitutional chromosomal abnormalities (e.g., number, translocation, and deletions) as well as those tumors in which successful culture of tumor cells has uniformly failed (e.g., alveolar soft part sarcoma). [285,286]

Despite the relative youth of this technology, it is rapidly being deployed to analyze a host of tumors heretofore difficult to analyze. Cryptic inversions, translocations, numerical abnormalities, and similar chromosomal abnormalities can now be readily identified, and are, in a host of childhood (and adult) tumors, including lymphoma, NB, and RMS.[286,287,288,289] and [290] There is a very real possibility that this method will become the benchmark method for chromosomal analysis of tumors given its enormous scope of application and sensitivity to even minute abnormalities, especially when used in conjunction with derivative techniques such as locus FISH. [286]

### Comparative Genomic Hybridization

In contrast to SKY, in which intact, fresh cells or tissue are necessary for analysis of individual chromosomes, CGH (as the name suggests) can be used to detect genomic gains or losses on a comparative basis (Fig. 8-17), using a 50/50 mix of normal control and tumor differentially fluorescently (e.g., red/green) labeled DNA hybridized to normal metaphase preparations. Anything found in excess in the tumor will fluoresce more brightly with that fluor; anything lacking will fluoresce differentially with the control fluor.[291] Not surprisingly, there has been great enthusiasm in applying this method to the detection of occult amplification, deletion, and even translocation in a large variety of pediatric tumors. [292,293,294,295,296,297,298,299,300,301] and [302]

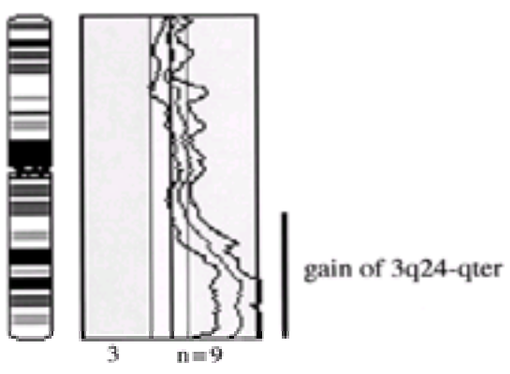

**FIGURE 8-17.** Comparative genomic hybridization analysis of chromosome 3 in malignant fibrous histiocytoma (MFH). The banding pattern of human chromosome 3 is shown on the left, and the relative hybridization levels of tumor DNA (representing nine MFH cases) versus normal DNA is shown on the right. The deviation of the

curves from the axis starting at chromosome 3q24 represents gain of genomic DNA in the MFH samples at 3q24 to the 3q terminal region ( *black bar*).

Despite the power of this method, there remains the problem that it can identify abnormalities by region, but confirmation of identity requires alternative methods. Despite this limitation, a number of novel, specific molecular defects in a variety of tumors have been identified by this method. [302,303,304,305,306,307,308] and [309] Furthermore, continued refinements of this method, such as array CGH, are generating more precise information, eventually perhaps at the single gene or locus level. [310]

### Implications for Tumor Molecular Genetics

The variety of molecular methods currently being applied or in development in cancer biology is unprecedented. Given the generally accepted truth that cancer is after all a genetic disease, this approach will undoubtedly yield a vast amount of currently unknown information about the etiology and mechanisms of cancer, including, one day, identification of fundamental mechanisms of oncogenesis within individual tumors. In the meantime, more established methods, such as PCR and correlative FISH with tumor-specific probes, are the mainstay of molecular genetic diagnosis.

## MOLECULAR GENETIC ANALYSIS OF CHILDHOOD CANCER

The identification of genetic alterations in human neoplasia is not only contributing profound insights into the oncogenic process, but it has been instrumental in the emergence of molecular diagnostics as a distinct field of pathology. Detection of tumor markers in pathologic specimens is gradually being incorporated into the diagnostic workup of tumor cases. This is necessitating changes in the way that pathologists handle tumor specimens in the surgical pathology suite to optimize the amount of information that can be derived at the molecular level. Moreover, as we begin to appreciate the specificity of these tumor markers for individual tumor types, we are forced to reevaluate the way we classify human tumors. This is particularly the case for bone and soft tissue tumors of childhood, which tend to be extremely primitive in appearance and therefore very difficult to differentiate from each other on morphologic grounds alone. [311] In fact, the detection of tumor-specific chromosomal translocations and gene amplifications in pediatric solid tumors is playing an increasingly important role in the diagnostic and prognostic stratification of these lesions. The following is a brief review of the molecular genetics of pediatric solid tumors, followed by a discussion of molecular tests currently used in the diagnostic workup of these tumors and recommendations for optimal processing of tumor tissue for such studies.

### Differential Diagnosis of Primitive Bone and Soft Tissue Solid Tumors of Childhood

Whereas organ-specific tumors of childhood, such as Wilms' tumor, hepatoblastoma, and pancreatoblastoma, are often less of a diagnostic dilemma, primitive pediatric solid tumors with a more diverse distribution remain difficult to diagnose at the time of specimen acquisition. In particular, pathologic classification in any given case of pediatric bone or soft tissue sarcoma continues to pose a frequent challenge for the surgical pathologist despite considerable histological, immunohistochemical, and ultrastructural literature on this topic. [311,312] This is not an insignificant issue because initial diagnosis often determines which treatment protocol a patient is entered on, and is therefore a critical prognostic factor. The group of malignancies known as the SRCTs are still formidable diagnostic problems, as described under Small Round Cell Tumors of Childhood, due to the relative lack of differentiation in these tumors. [311,312] Traditionally included in this group are the EFTs of peripheral primitive neuroectodermal tumors (formerly pPNETs), ARMS and ERMS, and NB. Other entities also entering this differential diagnosis include intraabdominal DSRCT (IDSRCT) and malignant lymphoma, particularly ALCL in the pediatric population ( Table 8-1). Among fibrous or spindle cell malignancies, SS, congenital or infantile fibrosarcoma (CFS), adult-type fibrosarcoma (ATFS), MPNST, and malignant fibrous histiocytoma must be considered. [311] The issue is further complicated by the fact that spindle cell lesions such as SS can sometimes have a small round cell cytologic appearance. [313]

### Molecular Genetics of Pediatric Solid Tumors

Molecular studies have contributed to an expanding list of genetic abnormalities in pediatric solid tumors, including chromosomal translocations and inversions; amplification of proto-oncogenes involved in cell growth and differentiation; loss of tumor suppressor genes by mutation DNA methylation, or deletion; abnormalities of genomic imprinting; alterations in DNA repair mechanisms; telomerase activity; and other abnormalities. From a clinicopathologic perspective, however, it only makes practical sense for a diagnostic molecular pathology laboratory to screen for those recurrent genetic changes that have been rigorously correlated with specific pathologic or clinical subgroups. The following discussion, therefore, focuses only on genetic abnormalities with well-established diagnostic or prognostic relevance, including chromosomal translocations leading to tumor-specific gene fusions in pediatric sarcomas, and gene amplifications and other genomic alterations in NB (Table 8-2). It remains to be determined whether some of the other alterations listed earlier in this section will eventually also show clinicopathologic correlations useful in clinical practice.

#### *Gene Fusions in Pediatric Solid Tumors*

Cytogenetic studies of several childhood sarcomas have identified reciprocal chromosomal translocations that are correlated with specific tumor types. Molecular cloning of the translocation breakpoints have identified in-frame fusions between genes located at the breakpoints of each partner chromosome; these gene fusions result in the expression of chimeric oncoproteins that appear to function in transformation by dysregulating gene transcription or altering cellular signal transduction pathways. [31,314] Known gene fusions in pediatric solid tumors are now reviewed.

#### *EWS-ETS* Gene Fusions in the Ewing's Tumor Family.

The diagnosis of Ewing's tumor and other EFTs, which can occur in bone or soft tissues, has traditionally depended on clinical features along with demonstrable intracellular glycogen accumulation, variable evidence of neural differentiation, and staining for the MIC2 antigen using the O13 antibody (reviewed elsewhere [312]). Aside from the latter, however, none of these features is particularly specific. In fact, even MIC2 staining, although present in greater than 95% of EFTs, [142,147] has been described in other tumors such as RMS, NB, and lymphoblastic lymphoma. [149,315] One feature of EFTs that does appear to be consistent is that they share common genetic rearrangements, with approximately 85% of cases showing a t(11;22)(q24;q12) chromosomal translocation ( Fig. 8-15). [316] Molecular cloning of the translocation breakpoint has identified an in-frame fusion of the *EWS* gene from chromosome 22q12 with *FLI1* from chromosome 11q24, a member of the *ETS* family of transcription factors ( Fig. 8-18A). [317,318] An additional 10% to 15% of cases carry a variant t(21;22)(q22;q12) translocation in which *EWS* is fused to another *ETS* gene, *ERG* from chromosome 21q22. [319] More rarely (likely in 1% or less of tumors), *EWS-FEV*, *EWS-EVI1*, and *EWS-ETV1* gene fusions resulting from t(2;22), t(7;22) and t(17;22) translocations, respectively, have been reported. [320,321] and [322] It is now thought that virtually all EFTs carry some form of *EWS-ETS* gene fusion, and that these rearrangements are pathognomonic of the EFTs. [323]

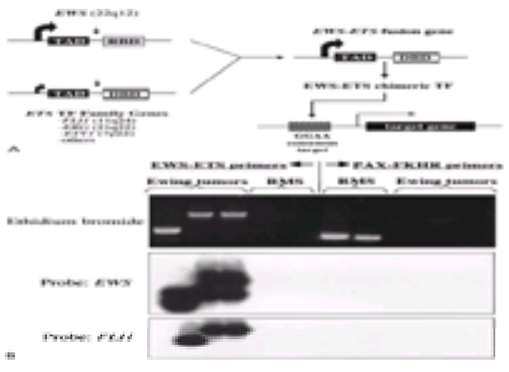

**FIGURE 8-18. A:** Schematic diagram of *EWS-ETS* gene fusions in Ewing's family tumors. As a result of chromosomal translocation breakpoints (*small downward arrow*), the *EWS* gene on chromosome 22q12 becomes fused to one of several ETS family genes, most often *FLI1* on 11q24 or *ERG* on 21q22. This fuses the transcriptional activation domain (TAD) of EWS with the DNA-binding domain (DBD) of the respective *ETS* gene and places the resulting *EWS-ETS* fusion gene under the control of the strong *EWS* promoter. This rearrangement replaces the RNA-binding domain (RBD) of EWS with the ETS DBD, creating a chimeric transcription factor (TF) that binds to ETS consensus GGAA sites on DNA and activates transcription of ETS target genes thought to be involved in

EWS-ETS–induced transformation. **B:** Reverse transcriptase-polymerase chain reaction (RT-PCR) analysis of Ewing's family tumors. Consensus primers for *EWS-ETS* fusion transcripts are used in RT-PCR experiments (*left side*) to demonstrate *EWS-FLI1* transcripts in the three Ewing's tumor samples but not in the two rhabdomyosarcoma (RMS) samples by ethidium bromide staining of agarose gels (*top panel*). This is confirmed by probing the amplification products with oligonucleotide probes for *EWS* (*middle panel*) and *FLI1* (*bottom panel*). On the right side, primers for the *PAX-FKHR* gene fusions of alveolar rhabdomyosarcoma are found in the RMS cases but not in the Ewing's tumor samples.

Expressed *EWS-ETS* chimeric proteins are oncogenic in NIH3T3 cells[318] and appear to function as aberrant transcription factors binding to ETS consensus sequences of target genes (Fig. 8-18A).[318,324,325,326 and 327] A number of potentially interesting target genes of EWS-ETS–mediated transcriptional activation have been described,[328,329,330 and 331] including stromelysin 1, cytochrome P-450 F1, cytokeratin 15, manic fringe, and E2-C, a cyclin-selective ubiquitin-conjugating enzyme involved in degradation of cyclin B. How these putative EWS-ETS targets are involved in oncogenesis remains unknown. An interesting possible role for EWS-ETS chimeric oncoproteins is suggested by the recent observation that EWS-FLI1 and other EWS-ETS proteins down-regulate expression of the TGF-b type II receptor TGF-b RII), a putative tumor suppressor gene.[332,333] TGF-b signaling through this receptor induces apoptosis in many cell types, and therefore repression of TGF-b RII expression may provide Ewing's tumor cells with a mechanism to elude a major pathway leading to programmed cell death. Another intriguing finding is that inactivation of the *p16* INK4a locus occurs frequently in EFTs, suggesting that loss of the pRb pathway may be important in Ewing's tumor oncogenesis.[334] These tumors also appear to use a number of autocrine growth factor pathways. Insulin-like growth factor-1 (IGF-1) is expressed by EFTs,[335] and oncogenicity of EWS-FLI1 requires the presence of an intact IGF-1 receptor pathway.[336] Moreover, Ewing's tumor cells have been found to express neural peptides such as the bombesin homolog gastrin-releasing peptide,[337] although the role of gastrin-releasing peptide in tumorigenesis remains unclear.

### Other *EWS*-Associated Gene Fusions in Small Round Cell Tumors of Childhood

IDSRCT is a recently described aggressive malignancy in late adolescent males that coexpresses skeletal muscle, neural, and epithelial antigens.[312] This tumor most commonly occurs in association with serosal surfaces, and as such can be confused with extraosseous pPNETs. A characteristic t(11;22)(p13;q12) translocation in IDSRCT fuses *EWS* with the *WT1* tumor suppressor gene from 11p13.[29,338] Another *EWS*-associated gene results from the t(12;22)(q13;q12) translocation of malignant melanoma of soft parts,[339] in which *EWS-ATF1* gene fusion transcripts are expressed in tumor cells. This melanin-producing tumor, also known as clear cell sarcoma of tendons and aponeuroses, mostly occurs in limbs of young adults.[312] The epithelioid appearance of tumor cells can sometimes cause confusion with SRCTs. Both EWS-WT1 and EWS-ATF1 chimeric products appear to be DNA-binding proteins and likely function as aberrant transcription factors.

### *PAX-FKHR* Gene Fusions in Alveolar Rhabdomyosarcoma

Childhood RMS is generally subdivided into ERMS (approximately 65%) and more primitive forms including ARMS (approximately 20%), and so-called undifferentiated sarcoma (approximately 15%).[340] The diagnosis of RMS is based on morphology and demonstration of myogenic differentiation in tumor cells (reviewed elsewhere[312]), including desmin and MSA immunostaining and expression of the MyoD family of myogenic transcription factors.[341,342] However, these markers can be expressed in other tumor types.[311,343,344] Of RMS subtypes, only ARMS is characterized by a diagnostic rearrangement. Approximately 60% of cases demonstrate a t(2;13)(q35;q14) translocation, which fuses the *PAX3* gene from 2q35 with the *FKHR* gene from 13q14; a smaller proportion of approximately 15% to 20% have t(1;13)(p36;q14) translocations that fuse *PAX7* from 1p36 with *FKHR*.[345,346] *PAX3* and *PAX7* are members of the PAX family of transcription factors, whereas FKHR is a member of the forkhead family of developmentally regulated transcription factors.[347] Resulting *PAX3-FKHR* and *PAX7-FKHR* fusion transcripts can be detected in tumor tissue by RT-PCR (Fig. 8-18B).[345,346] Although several molecular studies indicate that *PAX3-FKHR* and *PAX7-FKHR* gene fusions are present in greater than 85% of ARMS cases,[20,29] others have reported that significantly higher percentages of ARMS cases lack these fusions,[348] indicating that a proportion of ARMS cases have molecular alterations that are yet to be defined. In studies by Kelly et al.[349] comparing clinical features of ARMS cases with either *PAX3-FKHR* or *PAX7-FKHR* gene fusions, it was reported that *PAX7-FKHR* rearrangements are associated with younger age and extremity disease, and in these studies there was a trend toward improved overall survival in the *PAX7-FKHR* group. These studies have been extended to a larger series of ARMS cases as will be discussed below.

### *NPM-ALK* Gene Fusion in Anaplastic Large Cell Lymphoma

ALCL, also called *Ki-1 lymphoma*, is a distinct clinicopathologic subtype of intermediate-grade non-Hodgkin's lymphoma that can occur in children (see also Chapter 24)[350] ALCL has a wide range of morphologic appearances, although it is most often described as having large pleomorphic cells expressing the CD30 (Ki-1) antigen. An as-yet undetermined proportion of ALCL cases have a t(2;5)(p23;q35) translocation, which has recently been cloned.[351] A gene fusion is formed that encodes the N-terminal portion of a nonribosomal nucleolar phosphoprotein, nucleophosmin (NPM), fused to the tyrosine kinase domain of a novel transmembrane tyrosine-specific protein kinase, anaplastic lymphoma kinase (ALK).[351] A variant *NPM-ALK* fusion has also been described.[352] The incidence of the *NPM-ALK* gene fusion in ALCL is somewhat controversial and remains under investigation. The situation is complicated by the fact that ALCL as originally described appears to be a heterogeneous disease morphologically, cytogenetically, and clinically. This is reflected in the literature by a wide range (12% to 100%) in the incidence of this gene fusion in ALCL (reviewed elsewhere[353]). Current estimates are that approximately 70% of cases overall and almost 90% of childhood cases of ALCL express this gene fusion.[353,354] Neither anaplastic morphology nor the expression of CD30 appears to accurately predict the presence of this molecular genetic subtype of lymphoma. Some authors contend that immunostaining for the p80 NPM-ALK chimeric protein is a reliable diagnostic method for identifying cases with the t(2;5)(p23;q35) translocation.[354] Recently, several variant translocations in which ALK is fused to other partners have been reported.[355,356] The incidence of these rearrangements in ALCL remains to be determined.

### Gene Fusions in Childhood Spindle Cell Tumors

Gene fusions associated with pediatric solid tumors have mainly been identified and characterized in lesions with SRCT morphology. Tumor-specific translocations and resulting gene fusions have also been reported in several spindle cell tumors occurring in childhood, however—namely SS, CFS, and congenital mesoblastic nephroma (CMN). SS is a malignant neoplasm of children and young adults showing variable combinations of spindle cell and epithelial components. The latter stains positively for cytokeratin and EMA,[312] causing diagnostic confusion with epithelial tumors if SS is not suspected. A specific t(X;18)(p11.2;q11.2) translocation is present in greater than 90% of either biphasic or monophasic forms of SS (Fig. 8-19A).[357] Molecular cloning of the translocation breakpoints actually identified two different rearrangements—namely the fusion of the *SYT* gene from 18q11.2 with either of two closely mapped Xp11.2 genes, *SSX1* or *SSX2* (Fig. 8-19B).[358,359] It has been suggested that the *SYT-SSX2* gene fusion is associated with a monophasic phenotype,[360] but this has not been confirmed in other studies.[359] *SYT-SSX1* or *SYT-SSX2* fusion transcripts can be detected in more than 90% of SS,[359,361] and therefore assays to screen for these fusions provide a sensitive tool for the diagnosis of SS.

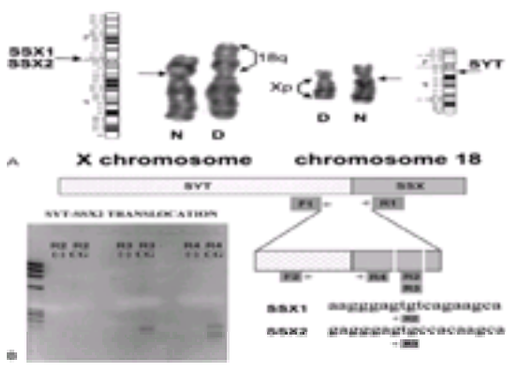

**FIGURE 8-19.** Synoviosarcoma cytogenetics and molecular genetics. **A:** Synoviosarcoma fusion cytogenetics. In this disease, the short arm of the X chromosome near the centromere (at a gene, SSX 1 or 2) is translocated to the near centromeric long arm of chromosome 18 (at another gene, SYT), as illustrated by the arrows labeled 18q and Xp, respectively. This results in the formation of derivative chromosomes X and 18 and a fusion gene, SYT-SSX, paired with a normal chromosome X and 18, as also labeled here. **B:** Fusion gene detection using polymerase chain reaction (PCR). Two common break points occur on the X chromosome, resulting in

the creation of two forms of the chimeric gene, identified as SSX1 and SSX2, respectively. Both can be amplified with universal PCR primers, labeled F1 and R1 here, which amplify sequence flanking the break point. This can be specifically amplified using sequence-specific primers, as illustrated here (R2 and R3 for SSX1 and SSX2, respectively). In the case of paraffin-embedded material in which messenger RNA is highly fragmented, the resulting specific amplified signal can be further amplified by nested PCR (here illustrated using another primer pair, F2 and R4), resulting in detection that might not otherwise be possible, as illustrated in the accompanying PCR gel. (Courtesy of Deborah Schofield, Children's Hospital, Los Angeles.)

CFS is a cellular spindle cell tumor of the soft tissues that generally presents before age 2 years. [362] As the name implies, many cases are congenital. Although CFS shows frankly malignant cytology and a high recurrence rate, it has a very good prognosis with an 80% to 90% overall survival and only a 10% metastatic rate. [362] It must therefore be differentiated from so-called ATFS of older children, which appears to have poor prognosis similar to fibrosarcoma occurring in adults. [363] Knezevich et al.[364] recently identified a t(12;15)(p13;q25) translocation in CFS that fuses the *ETV6* (*TEL*) gene from 12p13 with the 15q25 neurotrophin-3 receptor gene, *NTRK3* (*TRKC*) (Fig. 8-20A). *ETV6-NTRK3* fusion transcripts were not present in ATFS and appear to be specific for CFS among childhood soft tissue tumors ( Fig. 8-20B). The predicted chimeric product contains the helix-loop-helix (HLH) dimerization domain of ETV6 fused to the protein tyrosine kinase (PTK) domain of NTRK3. ETV6-NTRK3 has potent transforming activity in NIH3T3 cells, which requires both the HLH and PTK domains of the fusion protein. [365] Homodimerization through the HLH domain leads to activation of the NTRK3 PTK domain, which appears to dysregulate NTRK3 signal transduction pathways in tumor cells. Several groups [364,366,367] have recently demonstrated identical *ETV6-NTRK3* gene fusions in another pediatric solid tumor, CMN. CMN is an infantile spindle cell tumor of the kidney that is subdivided into “classical,” “mixed,” and “cellular” forms based on the degree of cellularity and mitotic activity. The histogenesis of CMN remains obscure, but a relationship between cellular CMN and CFS has been postulated based on morphologic and ultrastructural similarities. [368] This is supported by similarities in clinical behavior: whereas both classical and cellular forms of CMN occur in very young children and are generally thought to have an excellent prognosis, reports of local recurrences and metastatic spread are almost exclusively associated with the cellular variant. [369,370,371] and [372] To test this relationship at a molecular level, Knezevich et al.[373] screened CMN cases for *ETV6-NTRK3* gene fusions: eight of nine cellular CMNs and two of two mixed CMNs were fusion positive but all four classical CMNs tested were negative (Fig. 8-20B). Other studies did not find these transcripts in the mixed form. [366] Taken together, these studies indicate that classical and cellular CMN have different genetic features, and support the concept that cellular CMN is histogenetically related to CFS. Virtually all CFS and cellular CMN cases with the *ETV6-NTRK3* gene fusion were found to carry an extra copy of chromosome 11 (Fig. 8-21).[367,373] Trisomy 11 has been previously described for these lesions. [374,375,376] and [377] Although there are numerous explanations as to why tumor cells might select for both the *ETV6-NTRK3* gene fusion and trisomy 11, one intriguing possibility is that this provides cells with an additional copy of the insulin-like growth factor 2 gene ( *IGF-2*), which localized to chromosome 11p15.5 and is known to induce anti-apoptotic signaling by binding to the IGF-1 receptor. [378]

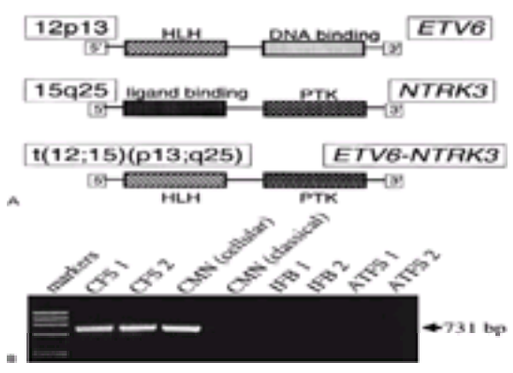

**FIGURE 8-20. A:** Schematic diagram of *ETV6-NTRK3* gene fusions in congenital fibrosarcoma (CFS) and cellular congenital mesoblastic nephroma (CMN). As a result of t(12;15)(p13;q25) translocations, exons encoding the helix-loop-helix (HLH) dimerization domain of the 12p13 *ETV6* (*TEL*) transcription factor gene are fused to exons encoding the protein tyrosine kinase (PTK) domain of the *NTRK3* (*TRKC*) neurotrophin-3 receptor gene on 15q25. This results in expression of a chimeric tyrosine kinase that undergoes ligand-independent dimerization and PTK activation. **B:** Reverse transcriptase-polymerase chain reaction (RT-PCR) analysis of the *ETV6-NTRK3* gene fusion in CFS and CMN. With primers from 5' sequences of the *ETV6* gene and 3' sequences of the *NTRK3* gene, RT-PCR is used to amplify a 731-bp amplification product in CFS and cellular CMN, but not in classical CMN, infantile fibromatosis, or adult-type fibrosarcoma.

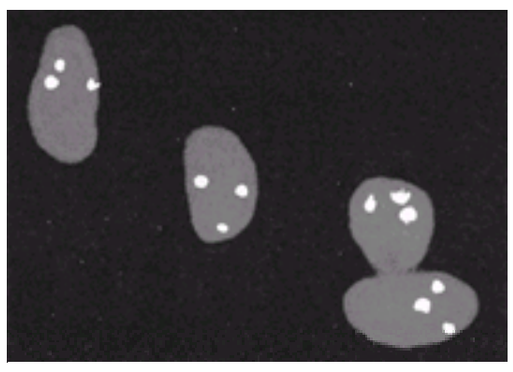

**FIGURE 8-21.** Trisomy 11 in congenital fibrosarcoma and cellular congenital mesoblastic nephroma (CMN). Four interphase cells from a case of cellular CMN are shown after probing with a centromeric probe for human chromosome 11. Three copies of chromosome 11 are demonstrated for each cell.

### *Molecular Genetic Alterations in Neuroblastoma*

The diagnosis of NB is generally less problematic than that of other SRCTs given the usual occurrence of a catecholamine-secreting tumor arising in the adrenal gland of a young child and the distinctive neural phenotype of virtually all cases. [311] The marked variability in clinical behavior of this tumor, however, ranging from spontaneous regression to metastatic growth and early death, has prompted an intense search for reliable predictors of prognosis in NB. A number of genetic abnormalities have been identified in NB that correlate to varying degrees with clinical outcome, including *MYCN* amplification, deletion of distal chromosome 1p, deviations from diploid DNA content, expression of neurotrophin receptors (particularly TRKA), amplification of 17q, and detection of telomerase activity (reviewed elsewhere[30,379]). Of these, *MYCN* amplification (Fig. 8-9) and 1p deletions—each present in approximately 30% to 50% of NB primary tumors—have in recent years been regarded as the best predictors of poor prognosis. A strong correlation has been found between these two prognostic markers. [380] Brodeur et al.[379] have suggested that NB should be classified into three distinct subsets based on biologic and clinical features. The first includes hyperdiploid tumors that express TRKA, do not overexpress *MYCN*, and are low-stage, favorable-prognosis tumors occurring in very young children. The second group is made up of near-diploid, non- *MYCN* amplified tumors with 1p deletion and low TRKA expression; they tend to present as higher-stage lesions in older children and have an intermediate outcome. The third group includes *MYCN*-amplified, near-diploid tumors with 1p deletions and low or absent *TRKA* expression; these tumors present as advanced-stage disease in older children and have a very poor prognosis. This is summarized for *TRKA* and *MYCN* in Figure 8-10. Further studies are necessary to confirm the clinical utility of this classification scheme, but it is proposed that the three different subsets represent genetically distinct forms of NB. [379] More recently, it has become apparent that gains of chromosome 17q21-qter may be the most frequent cytogenetic abnormality (greater than 50%) in NB. [381,382] and [383] This abnormality has been associated with advanced disease, age older than 1 year, deletion of chromosome arm 1p, and amplification of the *MYCN* oncogene, all of which have previously been associated with an adverse outcome. In fact, Bown et al.[381] have recently shown that gain of this region was the most powerful prognostic factor in multivariate analysis of a series of NB patients, strongly indicating that gain of 17q is an important prognostic factor in children with NB. As discussed below, we currently limit our analysis to screening for *MYCN* amplification and deletions of 1p in primary NB cases, although we are considering adding 17 gains to the analysis of NB.

## Molecular Genetic Tests for Pediatric Solid Tumor Diagnosis

Detection of the discussed tumor markers in pathologic specimens holds great promise as a diagnostic modality and, in fact, molecular genetic testing is already standard practice in many centers. However, it is important to note that these techniques place new requirements on the initial handling of specimens arriving in the surgical pathology suite. It cannot be emphasized enough that for many of the molecular assays described below, the most critical factor for success is the proper initial tissue processing. The following is a summary of the tests we routinely perform at the Children's and Women's Health Center of British Columbia and a discussion of some practical issues for the optimization of these tests.

### *Molecular Assays for Pediatric Solid Tumor Gene Fusions*

The development of RT-PCR assays to detect specific gene fusions now offers a sensitive and reliable diagnostic modality for the identification of SRCTs and other pediatric solid tumors.[29,31,359,384,385] These assays have been applied to the detection of minimal residual disease in pediatric patients diagnosed with solid tumors.[386,387,388 and 389] This specific application consists of the screening of bone marrow or peripheral blood samples from patients with previously identified gene fusions as a means for detecting residual tumor cells in these specimens. This is increasingly requested by oncologists at our institutions both for staging purposes and for evaluation of remission before bone marrow transplantation. We have also tested autologous bone marrow samples to screen for the presence of tumor cells before transplantation. The specific tests we perform and references for the methods are included in Table 8-4, but a number of general points can be made that apply to all the gene fusion assays.

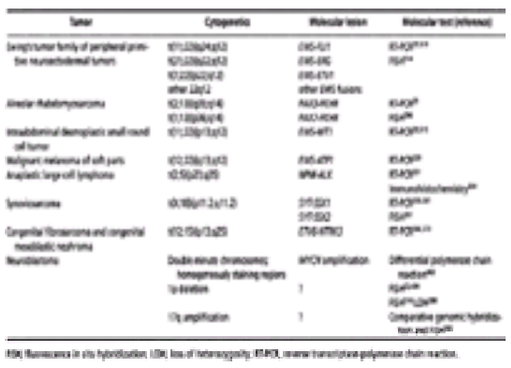

**TABLE 8-4. MOLECULAR TESTS USED IN THE DIAGNOSTIC WORKUP OF PEDIATRIC SOLID TUMORS**

### Reverse Transcriptase-Polymerase Chain Reaction from Frozen Tissue

Each RT-PCR assay depends on the successful isolation of RNA from representative tumor tissue. Far and away the best source of intact RNA is snap-frozen tissue stored at –70$^{o}$C or colder, as many of the commonly used fixatives result in appreciable RNA degradation and unacceptably low yields. Tissue should be frozen as soon as possible after surgery or biopsy to minimize autolysis. It is also essential that the presence of viable tumor and minimal necrosis is present in the tissue to be analyzed. We therefore routinely snap-freeze tissue fragments in optimal cryopreservation temperature medium, allowing us to easily cut a frozen section on a cryostat for H&E staining before further processing of the sample.[385] We find that total RNA isolated using the acid guanidinium-phenol/chloroform method of Chomczynski and Sacchi[390] or a related method provides adequate RNA quality. A number of commercially available reagent kits such as Trizol (Gibco/BRL) are very useful for RNA isolation from primary tumor tissue. At least 100 to 200 mg of primary tumor tissue is required, which corresponds to five to ten 5-µm sections (depending on the size of the tissue block) cut on a cryostat equipped with clean cryostat blades.[385] These sections should be placed directly into denaturing solutions such as solution D.[390] RNA is subsequently converted to cDNA using random primers. The resulting cDNA mixture is then subjected to PCR using primer pairs from coding sequences of each of the involved partner genes. An example of this process is shown for detection of *ETV6-NTRK3* fusion transcripts of CFS and CMN in Figure 8-20B. These assays have been optimized to maximize specificity and to minimize the number of false-positives (reviewed elsewhere [29]). Positive controls, usually consisting of cell lines expressing the gene fusion in question, are always included, as are negative controls lacking these hybrid genes. Alternatively, previously tested positive primary tumors can be used, but this of course may quickly deplete sample material. In extenuating circumstances, amplified PCR fragments from specific assays can be cloned into and used as positive controls,[385] but this is not recommended, as cloned products will be readily amplified even if assay conditions are suboptimal for primary tumor tissue. PCR fragments are separated by gel electrophoresis using 2% agarose gels and visualized by ethidium bromide staining. For confirmation of identity, PCR products are blotted onto nylon filters and probed with labeled oligonucleotides specific for each gene fusion.[29]

Several pediatric solid tumors are characterized by more than one variant of a distinct family of gene fusions, making the use of consensus primers that amplify multiple fusion types within each family particularly useful. We therefore use consensus primers that will amplify both *EWS-FLI1* and *EWS-ERG* gene fusions in EFTs, and use *FLI1*- or *ERG*-specific oligonucleotides as probes to distinguish between these fusion types.[29,319] An example of this process is shown in Figure 8-18B. A similar strategy is used to differentiate *PAX3-FKHR* and *PAX7-FKHR* gene fusion in ARMS,[29] and between *SYT-SSX1* and *SYT-SSX2* gene fusions in SS.[361] Some authors have advocated the use of multiplex RT-PCR assays that amplify more than one family of gene fusions simultaneously.[20]

In terms of sensitivity, *EWS-ETS* gene fusions are thought to be present in virtually all EFTs.[323] Similarly, *ETV6-NTRK3* transcripts appear to be expressed in at least a large majority of CFS and cellular CMN, as is reported for *EWS-WT1* and *EWS-ATF1*, as well as for *SYT-SSX1* and *-SSX2* gene fusions in IDSRCT, malignant melanoma of soft parts, and SS cases, respectively. These assays can therefore be regarded as true diagnostic tests for each tumor subclasses. As mentioned above, however, in our clinical experience it appears that as many as 20% to 30% of cases with ARMS phenotype lack detectable *PAX3-FKHR* or *PAX7-FKHR* gene fusions.[391] Therefore, although these rearrangements are specific for ARMS, they may not be expressed in all cases of suspected ARMS, as this tumor subclass may be more heterogeneous than previously appreciated. The same can be said for ALCL, in which *NPM-ALK* gene fusions do not appear to be present in all cases analyzed, and the incidence of variant gene fusions remains to be determined.

### Reverse Transcriptase-Polymerase Chain Reaction from Archival Tissue

It is well known that fixation of tissue and embedding in paraffin results in significant RNA degradation, which has previously mitigated against the use of archival tissue in RT-PCR assays. However, recent improvements in the recovery of mRNA from paraffin-embedded tissue have resulted in a reevaluation of this application. A number of reports have described the detection of SRCT- or spindle cell–associated gene fusions using formalin-fixed, paraffin-embedded tissue.[366, 391a,391b,391c and 392] In our own studies, several general factors appeared to be critical for successful recovery of amplifiable RNA amenable to RT-PCR analysis (unpublished results). First, alcohol fixation gave the best results followed by formalin; Bouin's and B5 solutions did not yield usable nucleic acid. Second, minimizing the time of fixation to less than 24 hours generally gave better results. Third, optimal results were obtained when the size of the expected amplification products was reduced to less than 200 bp, as has been reported by others.[366, 391a,391b,391c and 392] Fourth, it was often necessary to hybridize the PCR products with specific oligonucleotide probes to detect positive reactions. Our current success rate is approximately 60% to 70% in terms of deriving amplifiable RNA from paraffin-embedded tissue, as assessed using RT-PCR assays for the phosphoglycerate kinase gene (*PGK*).[392] For the specific gene fusion assays, the relative success rates depend on the specific assays, with RT-PCR detection of *EWS-ETS*, *EWS-WT1*, *SYT-SSX*, and *ETV6-NTRK3* being quite robust in paraffin-embedded tissue. In contrast, detection of *PAX-FKHR* gene fusions in paraffin-embedded tissue from ARMS cases is generally less successful and, at least in our institutions, remains an experimental tool. Clearly the optimization of this approach will greatly facilitate the application of RT-PCR to the diagnosis of pediatric solid tumors, and further studies are warranted in this regard.

### Gene Fusion Detection Using Fluorescence *In Situ* Hybridization

The cloning of fusion gene partners and subsequent availability of FISH probes for those genes have made FISH a natural alternative method to study the genetics of solid tumors.[393,394 and 395] Several strategies are currently used to screen for solid tumor gene fusions: (a) one-color FISH with a probe or probe cocktail that spans one of the fusion partners; probing would then be expected to show three signals in tumor cells (including two derivative chromosomes and one normal copy) as opposed

to two copies in normal cells; (b) two-color FISH in which flanking probes from each side of one of the partner genes are labeled with different fluors; normal cells will demonstrate two overlapping or fusion of the signals, whereas tumor cells will demonstrate splitting of the one of the signals to each derivative chromosome; and (c) two-color FISH in which probes from each of the involved genes is labeled with different fluors; in this case normal cells will show two separate signals for each fluor representing the normal loci, whereas tumor cells will show a fusion signal representing the derivative locus in addition to one separate signal for each fluor. These approaches can be used not only for metaphase cells from routine cytogenetic preparations [396] but also for interphase cells from touch preparations [314,396,397] or from paraffin-embedded sections.[22,398,399,400 and 401] In our opinion, the only major drawbacks to the application of this technique to tumor diagnosis are the limited availability of probes and the high degree of technical expertise required for successful reproducible FISH compared to RT-PCR technology.

***Molecular Testing in Neuroblastoma***

We currently screen all new NB cases for evidence of *MYCN* amplification, and we screen selected cases for deletions of distal chromosome 1p. At the time of writing, only the presence or absence of *MYCN* amplification more than ten copies, among available molecular tests, is incorporated into therapeutic stratification for NB protocols at Children's Oncology Group (the former Children's Cancer Group and Pediatric Oncology Group) institutions. [27] As discussed, several other molecular parameters may also ultimately be used in this regard.

We test for *MYCN* amplification using two approaches. The first is the technique of semiquantitative differential PCR in which genomic DNA from NB tumor samples is amplified using primer sets for *MYCN* and simultaneously for a control single copy gene such as b-globin. [402] PCR products are then resolved using agarose electrophoresis, and *MYCN* amplification is identified by visual or densitometric comparison of the *MYCN* band intensity with that of the single-copy control band ( Fig. 8-8). NB cell lines such as IMR-32,[403] with known levels of amplified *MYCN*, are run for comparison, as are normal samples that function as controls for single-copy *MYCN*. This approach is particularly useful, as the assay can be run with as little as 25 to 50 ng of DNA. Moreover, the assay works well using DNA isolated from paraffin-embedded, formalin-fixed tissue blocks. A major caveat of this technique is that if the tissue fragment being tested consists of less than 25% tumor cells, then amplification will not be readily evident. Therefore frozen sections should be stained for histology before analysis. This caveat is also the reason we use FISH as an independent approach to screen NB cases for *MYCN* amplification. We use a commercially available *MYCN* cosmid probe (Oncor, now Ventana Medical Systems, Tucson, AZ) for FISH studies performed on metaphase or interphase cells from fresh NB samples, detecting either double minute chromosomes or homogeneously staining regions containing *MYCN* amplicons.[404] This technique has been adapted to isolated nuclei from paraffin-embedded tissue. [7,23] We find an excellent correlation between the results of differential PCR and FISH studies, and we do not routinely perform Southern blot analysis for *MYCN* amplification.

Deletions of distal 1p are analyzed by two-color FISH using an a-centromeric probe for chromosome 1 in conjunction with a telomeric probe for chromosome 1p, D1Z2 (Fig. 8-21) (Oncor, now Ventana). This approach requires metaphase cells, which we obtain from routine cytogenetic cultures, if available. The caveat of such a strategy is that it may miss small interstitial deletions of 1p36 as well as point mutations in the putative tumor suppressor gene involved in NB.

**Molecular Genetic Testing from Paraffin-Embedded Tissues**

Knowledge of the types of molecular genetic tests that are available for the diagnostic workup of pediatric solid tumor samples is essential for proper handling of tumor specimens. Although FISH and genomic PCR techniques have been well adapted to paraffin-embedded archival tissues, studies requiring mRNA analysis, such as the detection of fusion transcript expression, are still problematic. Until, and if, RT-PCR can reliably be performed from fixed tissues, it remains the responsibility of the pathologist to ascertain that tissue is frozen at the time of biopsy of a pediatric solid tumor, as illustrated in Figure 8-6. This ensures that all molecular tests are possible for that case, whether performed at local institutions or in molecular pathology reference laboratories.

## MICROARRAYS, POLYMORPHISMS, AND WHOLE GENOME STUDIES

As informative as single-gene analyses have been in the study of childhood cancer, technologic advances have opened up an entirely new approach to analysis of the functional genome, a point of considerable interest to oncologists and cancer biologists alike. [405,406] Increasingly, it has become obvious that the power of this technology to elucidate the multiplicity of genomic defects inherent in oncogenesis, and to potentially identify diagnostic, prognostic, and therapeutics targets, is unprecedented. For that reason alone, it is worth examining the basic technology and assumptions in some detail, as these methods will certainly come to play an increasing role in the evaluation of human malignancy and disease (and health) in general.

Although biotechnology is an area of intense development, with nearly constant innovation and development of new methods, there are currently several well-characterized approaches to analysis of the entire genome. Methods like high-throughput direct DNA sequencing (as recently used to complete the sequence of the human genome) as applied to expressed sequence tags and batch processes for detection of many, but not all, expressed genes, such as serial analysis of genetic expression, are well known. Here, we focus on promising new developments in this area. Three particularly interesting methods are discussed:

1. Patterns of gene expression, usually identified by gene expression arrays
2. Patterns of nucleotide base changes related to gene function, usually screened genome-wide by DNA resequencing arrays
3. Patterns of gene product (e.g., protein) expression, assessed by multiple technologies ranging from mass spectroscopy to protein arrays, generically referred to as *proteomics*, to emphasize the parallels between DNA or RNA and protein assays.

The nearly universal interest in the power of these technologies to exploit the information derived from sequencing of the entire human genome has engendered an enormous development effort to create many forms of these three basic platforms. Many of these are seemingly unrelated to the current technology (all-in-one nanomachines capable of DNA, RNA, and protein analysis come to mind). None is currently well developed enough to warrant detailed discussion here. Rather, we consider the current and imminent contributions of mature technology to childhood cancer diagnosis (and ultimately treatment), noting only that the specific technology will likely diverge strikingly over the lifetime of this writing. The goal remains the same, however: a genetic explanation for the occurrence, behavior, and treatment responsiveness of a given tumor.

**Gene Expression Profiling by DNA Microarrays**

The basic technology for gene expression profiling is not new, however; it is simply enormously expanded. It is generally referred to as *microarray* or *gene chip* technology.[407,408 and 409] In essence, the same basic technique used for years to identify expressed genes on filter papers (e.g., slot blots and dot blots) has been reversed (i.e., the sample is applied to the substrate, which contains identified genes of interest) and scaled up from one or a few genes to thousands of genes, soon to encompass the entire human genome, estimated at approximately 30,000 to 40,000 discrete genes.

Two basic methods have been developed. So-called spotted microarrays use full-length cDNA clones, often expressed via phage in bacteria, cut out, and attached either covalently or via a charged moiety (e.g., poly- L-lysine) to a glass substrate (generally an ordinary glass slide with treated surface). [409] The alternative arrays use photolithography technology to synthesize short (approximately 24mer) oligonucleotides *in situ*.[407] To fairly represent genes that may be thousands of bases long, multiple oligonucleotides are chosen throughout the length of the expressed gene sequence and represented as separate “tiles” adjacent to one another. Thus, a single gene may have 20 or more short oligos represent various regions from 5' to 3' along the length of the gene. An example is illustrated in Figure 8-22. Here, each “tile” represents an oligomeric sequence chosen from exons arrayed from 5' to 3' throughout the length of the gene. To control for nonspecific hybridization, tiles with a single base mismatch are arrayed just below the matching “perfect match” tile. Hybridization intensity is compared between the two and along the length of the gene. These values are compiled and a determination of “present” or “absent” is calculated and reported, along with a quantitative value.

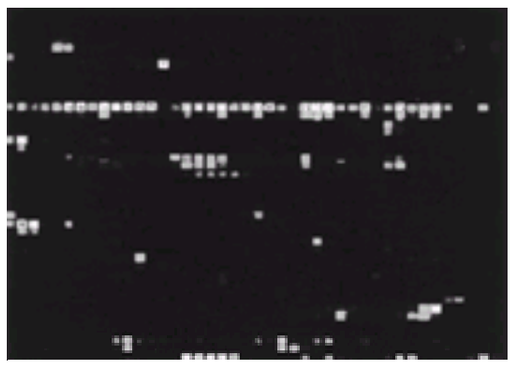

**FIGURE 8-22.** DNA gene-expression chip. DNA chips produced by the synthesis of 25-base oligomers have been popularized commercially. In these chips, a single gene is represented as a series of tiles, as seen here, each representing a 25-base stretch of the gene in question. In some versions of these chips, the genes are physically arrayed left to right, representing the gene 5' to 3' tiles, as seen here in the upper portion of the figure. When a gene is expressed at high levels, complementary RNA will hybridize and yield a bright fluorescent signal, as seen in the series of brightly fluorescent tiles. Single tiles, as seen elsewhere, are meaningless, and as is clear from this illustration, many genes are not expressed at any given moment in time.

A variant technology has also been developed, wherein spotting technology is used to spot short sequences (often approximately 50mers) on glass slides. In addition, multiple oligos, representing different regions of the gene, analogous to the photolithography arrays described above, can be spotted in adjacent spots, also often chosen from multiple stretches of the entire coding sequence of the gene of interest. [410] An example is shown in Figure 8-23. This approach combines some of the performance features of both technologies—specifically, the economy of spotted arrays with the predictable performance of short oligonucleotides as synthesized on the photolithography arrays. In addition, this method (and the photolithography arrays), unlike cDNA arrays, should enable detection of splice variants, alternate exon usage, message truncation, and related phenomena (such as chimeric genes formed from the fusion of two normal genes as a result of chromosomal translocation, as discussed in the section Gene Fusions in Pediatric Solid Tumors). This presumes, of course, that the oligos chosen are a fair representation of exon-by-exon sequences within the gene of interest. An additional challenge is representation of some genes that use the same coding DNA sequence but out of frame, such as p16 and p19/ARF. [411,412] Ultimately, the goal by any of these variants is to detect or monitor genome-wide gene expression as an index of total gene activity and, with suitable data mining tools (see below), use that information to better estimate the three cornerstones of oncology: diagnosis, prognosis, and therapy. The general paradigm is equally applicable to any disease state, or biologic function, for that matter.

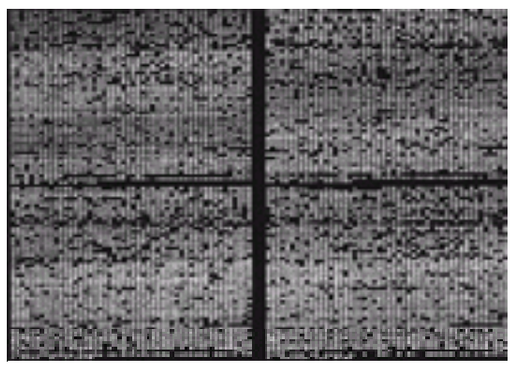

**FIGURE 8-23.** DNA gene expression chip [spotted complementary DNAs (cDNAs)]. An alternative technology, widely used in many research labs, employs full-length cDNAs spotted on glass slides, as seen here. Similar to the technique illustrated in Figure 8-22, tens of thousands of genes can be analyzed in one pass in this fashion. Notably different, however, is the need for the user to define the content of these arrays, as well as the need for competitive hybridization between two samples, one of interest and the other a reference standard. An advantage of the spotted technology is the relative speed whereby final data can be obtained in a matter of hours. A relative disadvantage is the general need for greater amounts of RNA. In reality, both methods are useful and are in widespread use.

Regardless of the specific method used, the information returned is the same: a somewhat quantitative measure of the amount of any given gene being expressed in the sample of interest. When scaled to thousands of genes accessed simultaneously, as current arrays do, a snapshot of the activity of the genome in question is obtained. [413,414] It is increasingly clear that microarray data may be the embodiment of the axiom, “be careful of what you wish for, because you may get it.” Biologists and physicians have yearned for such all-encompassing information about disease states; it is now a reality, but with an enormous caveat: how does one practically use this information? Therein is the conundrum that currently faces everyone who presumes to use this technology. [405]

The great power of this new technology lies in its ability to provide a complex, all-encompassing image of the biologic activity of the cells or tissue at hand. [415] The challenge is to meaningfully analyze the enormous amount of data generated. [416,417,418 and 419] The rapid adoption of this technology by life science researchers has necessarily fostered a parallel effort to develop suitable data mining tools to distill useful information from these arrays. [33,409,414,417,420] Simple scatter analyses with a list of “outlier” genes that are up- or down-regulated in a disease state have limited utility ( Fig. 8-24). In contrast, clusters of genes statistically associated with a given disease, stage, or clinical behavior can be a powerful analytic tool. [32,34,35,419,421,422 and 423] For example, comparisons of three genetic variants of alveolar RMS, PAX3-FKHR, PAX7-FKHR, and translocation negative, have shown a greater similarity of translocation-negative cases to PAX3 cases than to PAX7, which parallels the observed clinical behavior. [349] This observation suggests that these arrays have the inherent potential not only to identify (or “diagnose”) specific diseases but also to identify prognostic groups within a given tumor group. This information, gleaned from analysis of pretreatment biopsy tissue, offers the prospect of predicting clinical course, and therefore optimal therapy, even in the absence of other diagnostic or prognostic markers, before therapy or evolution of the disease.

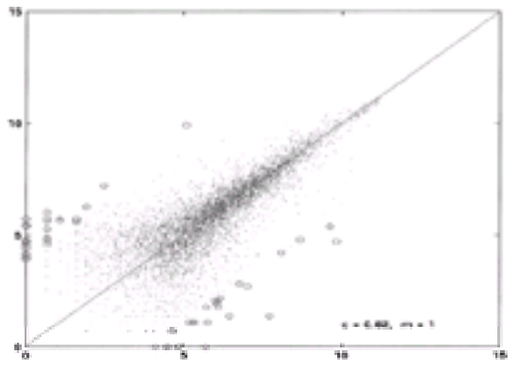

**FIGURE 8-24.** Scatter analysis of expressed genes in rhabdomyosarcoma. Gene expression data can be represented in many forms. A common method is scatter analyses, wherein the quantitative expression value for the same gene for each of two samples is plotted as an x-y coordinate. If all genes were identical in expression between the two, a perfect straight line through the origin with a slope of 1 would result (e.g., a linear regression line). The tendency for two such samples in this illustration is very clear (in fact this represents two physically different portions of the same tumor-analyzing parallel). There is near identity, as indicated by the regression line slope of 1 and a correlation coefficient of 0.82. Note, however, the wide variation in expression of genes expressed at low levels, seen in the lower left portion of the diagram. Distinction between biologic or other noise and true differences in gene expression are difficult to assess in this region. However, the ability to assess effectively all active genes in the human genome simultaneously is a powerful tool that is enjoying increasing acceptance for research and (soon) clinical prognostic purposes.

This is a rapidly evolving field and the next several years will almost certainly demonstrate many clinically useful applications of this technology. Likewise, the current prohibitive cost or technical obstacles will likely be subsumed by facile, inexpensive, and specific diagnostic/prognostic arrays produced from a knowledge of critical genes that dictate clinical behavior in a given disease. If true, these DNA arrays will revolutionize the evaluation of the cancer patient.

### Nucleotide Polymorphisms

Beyond DNA expression arrays lies a vast new arena of genomic analysis, focused on normally occurring genetic polymorphisms, often referred to as *single nucleotide polymorphisms* (SNPs).[407,424,425] These "normal" variants are thought to be associated with variably functional gene products, especially when they occur within coding regions or within 5' promoter/suppressor elements of genes, which in turn may be associated with disease susceptibility, unique drug responsiveness, or clinical evolution of a disease state.[424] The recent sequencing of the entire human genome will result in a vast amount of information regarding normal sequence variation within individuals, which can be represented on so-called SNP chips. These arrays are currently capable of identifying more than 1,500 SNPs, and the number will certainly increase by orders of magnitude shortly as information from the human genome project is used to create vast numbers of SNP arrays. This information, correlated with clinical behavior, will provide yet another picture of clinical behavior in a patient, independent of, but perhaps associated with, their gene expression profiles.[424] Only preliminary studies have been published to date, but the promise of this new technology is clear; when combined with expression and other data, the impact may be staggering.[426,427]

### Proteomics

Finally, the next generation of gene expression profiling will likely be based on protein expression, or proteomics. [428,429 and 430] Although no technology comparable to DNA hybridization currently exists, many competing technologies are being evaluated to accomplish the same result. [431,432,433 and 434] Here, in addition to the basic presence or absence of a gene/protein, one will also be able to assess posttranslational modifications such as glycosylation and phosphorylation, both known to potentially dramatically alter the functionality of a given gene product. These parameters cannot be addressed by a purely nucleic acid method such as the current expression arrays—thus the interest in proteomics.

Whatever the result, a similar picture to gene expression profiles will emerge, but now specifically and quantitatively linked to the amount of effecting protein. Initial studies of tumors have been of some interest, but fundamental insights will require further maturation of the technology, which is still in its early stages. [435,436 and 437] An additional caveat relates to informatics; the vast amount of information from genomics is paralleled with that from proteomics, with comparable challenges, especially when attempts are made to correlate the two.[430,438,439]

## TOPICAL ISSUES IN THE DIAGNOSIS OF CHILDHOOD CANCER

Many tumor-specific issues have been overlooked in the preceding general discussion of childhood tumor diagnosis. A brief consideration of the unique features of specific tumors, particularly where notable breakthroughs or challenges have been described, is warranted. This is intended to give a perspective on the issues of interest as they relate to diagnosis, and in some cases, prognostic relevance. More detailed discussions are found in the chapters dealing with these specific tumors.

### Are Fusion Genes Diagnostic among Childhood Tumors?

The widespread occurrence of chimeric genes associated with specific leukemias and solid tumors of childhood superficially suggests that these tumor-associated aberrant genes are perhaps causative and therefore diagnostic.[253,254,440,441] This assumption rests on two basic premises: (a) the specific gene occurs in a given tumor on a more or less one to one basis, and is therefore tantamount to diagnostic, and (b) the gene is functional and drives phenotypic features that are the basis of historical and current tumor diagnosis. Examples of the first case are well known: *SYT-SSX* in SS; *EWS-WT1* in DSRCT; *EWS-FLI1* or equivalent in EFTs.[442,443,444 and 445] It is, however, important to consider the veracity of this basic assumption as a universal rule, as all diagnoses, and therefore therapy, may be predicated on it. Diagnosis, after all, is the necessary first step in patient management, and the relative precision of molecular diagnostics is therefore of some importance, particularly if information from these molecular diagnostics, as described above, is to supersede that from more conventional methods. In essence, if morphologic diagnostic criteria are in conflict with molecular information, which do you believe?

A consideration of the accumulated literature to date suggests caution in blind faith acceptance of molecular data as primary diagnostic criteria. Two specific problems arise: (a) certain tumor-specific translocations occur only in some percentage of tumors within the group, and (b) in some cases, the same translocation occurs in another tumor, phenotypically distinct from the common type. The first example is epitomized by ARMS, in which the two common fusion genes, *PAX3-FKHR* and *PAX7-FKHR*, are detected in approximately 75% of cases; the remaining 25% of cases show no detectable *PAX-FKHR* fusion (although a novel FKHR analogue may be involved in rare cases) (Sorensen et al., in press). This is echoed in many leukemias, in which the specific chimeric gene may be present in many but not all cases of a defined phenotype (e.g., *TEL-AML1* in 22% acute lymphocytic leukemia).[446]

The second situation occurs when a known fusion gene occurs in an appropriate setting. Examples of this include three different reports of various EWS fusion genes in DSRCT, in one case "resulting" in a mixed DSRCT/EFT tumor phenotype.[447,448 and 449] Note that these examples are not to be confused with those found in certain biphenotypic tumors with a myogenic phenotype and a EFT translocation.[343] These tumors may well be functionally associated with the known common PAX3/7 role in normal and perhaps neoplastic development of both skeletal muscle and primitive neural tissue.[450]

Another example is the appearance of the similar or identical chimeric gene in tumors of different histogenesis. Inflammatory myofibroblastic tumors, which are benign or low-grade malignant neoplastic mesenchymal proliferations with an inflammatory component that can occur in children, demonstrate fusion of tropomyosin 3 or 4 (*TPM3* or *TPM4*) to the *ALK* gene on chromosome 2.[451] *TPM3-ALK* gene fusions have also been described in ALCL.[354, 355] This is reminiscent of *ETV6-NTRK3* fusion transcripts, which in addition to being expressed in CFS and cellular CMN as described, have been reported in a case of acute myelogenous leukemia occurring in a 59-year-old adult patient.[452] Therefore ETV6-NTRK3 and TPM3-ALK, both of which are chimeric PTKs, each appear to be able to transform both mesenchymal and hematopoietic human cell lineages.

What, then, is the relative value of gene translocation analysis in the diagnosis of these often phenotypically undeveloped tumors? The answer is a resounding confirmation of their enormous value in the differential diagnosis of this difficult tumor group.[252,253] The exceptions are so rare as to be reportable and would generally be detected by a simple review of the morphologic appearance. This is a far better accuracy than is normally associated with the conventional diagnosis of these tumors. In fact, in most studies careful review of the "aberrant" cases reveals an incorrect initial diagnosis, not an invalid molecular diagnostic.[252,323] Fusion gene analysis in childhood solid tumors therefore should be viewed as superior to any other diagnostic means to date—although this information should always be used in context with conventional diagnostic criteria. Otherwise, one will draw easily avoidable incorrect conclusions in at least a minority of cases.

### Does Fusion Gene Subtype Analysis Provide Prognostic Information?

It can be said that by virtue of providing a more definitive diagnosis for a given tumor subtype and hence facilitating early institution of appropriate therapy, molecular detection of tumor-specific gene fusions is by definition prognostically relevant. In addition, however, a number of studies suggest that different fusion subtypes within classes of gene fusions might also be independently predictive of outcome.

#### *Ewing Family Tumors*

Virtually all EFTs express some form of *EWS-ETS* gene fusion. Detection of these rearrangements by RT-PCR assays is, as discussed above, very useful as a diagnostic modality for the pathologic workup of EFTs. Further diversity of *EWS-ETS* gene fusions is conferred by different combinations of exons from *EWS* and its partner genes, giving rise to variably sized fusion products.[339] A recent analysis limited to *EWS-FLI1*–positive cases revealed a significantly better prognosis in patients with the more common type 1 gene fusion (*EWS* exon 7 fused to *FLI1* exon 6) in comparison to cases with larger, less common fusion types (Fig. 8-25).[453,454] This difference was only seen among cases with localized disease. In another recent study, no association with outcome was found when *EWS-FLI1*-expressing tumors were compared to *EWS-ERG*-expressing tumors.[455] Further studies will be necessary to determine whether the prognostic significance of smaller versus larger

*EWS-ETS* fusion types also extends to the less common variant fusions such as *EWS-ERG*, in which the number of cataloged cases with clinical follow-up for each fusion subtype is small and difficult to interpret with regard to meaningful outcome analysis.

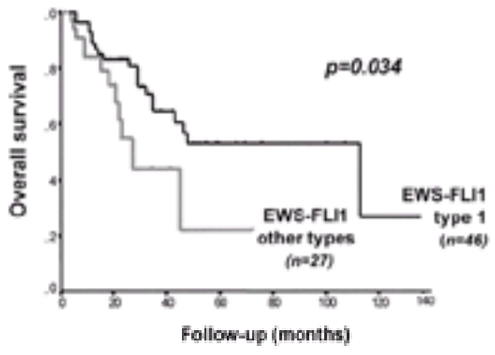

**FIGURE 8-25.** Ewing's survival by fusion gene type (type 1 versus others). Differences in clinical behavior observed in Ewing's sarcoma patients whose tumors express an EWS-FLI1 type 1 translocation as opposed to all other types of EWS-FLI1 translocations have been reported by two authors. [456,457] Data showing a more favorable survival for patients with an EWS-FLI1 translocation with a *p* value of .03 in this study of 73 patients are reproduced here. [457] (Reproduced with the permission of Mark Ladanyi. de Alava E, et al. EWS-FLI1 fusion transcript structure is an independent determinant of prognosis in Ewing's sarcoma [Published erratum appears in J Clin Oncol 1998;16:2895] [see comments]. J Clin Oncol 1998;16:1248–1255.)

### *Synoviosarcoma*

In a recent study of SS, *SYT-SSX1* and *SYT-SSX2* fusion transcripts were detected in 64% and 36%, respectively, of a series of 45 SS cases. [456] There was a significant relationship between histological subtype: all 12 biphasic SS had a *SYT-SSX1* fusion transcript, and all 16 tumors that were positive for *SYT-SSX2* were monophasic. Furthermore, patients with *SYT-SSX2* had significantly better metastasis-free survival than did patients with *SYT-SSX1*; histological subtype alone was not prognostically important.[456] Similar findings have been reported by others.[457] Therefore it appears that the type of *SYT-SSX* fusion transcript correlates with both the histological subtype and the clinical behavior of SS. A new variant *SYT-SSX* gene fusion, *SYT-SSX4*, has recently been reported[458]; it will be interesting to determine its incidence in SS and how it relates to outcome in this tumor class.

### *Alveolar Rhabdomyosarcoma*

ARMS remains a devastating disease clinically and a formidable challenge for the pathologist attempting to make the diagnosis. The poor outcome for ARMS has led to an intense search for prognostic indicators useful for therapeutic stratification. As described above, t(2;13) and t(1;13) chromosomal translocations resulting in the expression of two related fusion genes, *PAX3-FKHR* and *PAX7-FKHR*, respectively, are characteristic of ARMS. Detection of *PAX3-FKHR* and *PAX7-FKHR* fusion transcripts in tumor specimens by RT-PCR assays is widely accepted as a useful tool in the diagnostic workup of ARMS. However, up to now, the incidence of these abnormalities and their specificity for ARMS have not been examined in a large cohort of centrally reviewed RMS cases. In a very recent report, RT-PCR analysis of *PAX3-FKHR* and *PAX7-FKHR* gene fusions in 171 RMS cases from Intergroup Rhabdomyosarcoma Study-IV (IRS-IV) detected fusion transcripts only in ARMS (Sorensen et al., in press). No ERMS cases or tumors diagnosed as undifferentiated sarcoma were fusion positive, confirming the specificity of these alterations for ARMS. Interestingly, 23% of the 78 ARMS cases tested were fusion negative, suggesting that other genetic abnormalities such as *PAX-FKHR* variant gene fusions may characterize at least a subset of ARMS. Consistent with an earlier preliminary report, [349] this study also found a correlation between fusion status and clinical outcome. Among ARMS cases presenting with metastatic disease there was a striking association between *PAX3-FKHR* expression and poor outcome (Sorensen et al; in process citation). The estimated 4-year overall survival rate was more than 70% for *PAX7-FKHR* versus less than 10% for *PAX3-FKHR* in cases presenting with metastatic disease. Multivariate analysis confirmed this finding: there was a significantly increased risk of relapse and death in patients with metastatic disease if their tumors expressed *PAX3-FKHR*. This was coupled to a very intriguing difference in the pattern of metastatic disease between *PAX3-FKHR*– and *PAX7-FKHR*–positive cases: more than 50% of metastatic *PAX3-FKHR*–positive ARMS patients had bone marrow metastases, whereas none of the metastatic *PAX7-FKHR*–positive cases demonstrated bone marrow involvement. Therefore expression of *PAX3-FKHR* and *PAX7-FKHR* gene fusions identify high-risk and low-risk subgroups, respectively, among ARMS patients presenting with metastatic disease.

## What Is Poorly Differentiated Rhabdomyosarcoma?

Two major issues surround the diagnosis of RMS: is the tumor in question a RMS, and if so, what type? These questions, as it turns out, are not trivial, because the answer is frequently wrong in both cases, with unfortunate consequences for the patient. Historical experience has shown that these tumors are best treated on the protocols developed over the past quarter century by the former Intergroup Rhabdomyosarcoma Study Group. Patients with RMS treated otherwise often fare less well.

### *Rhabdomyogenesis*

Morphologic methods of detecting skeletal muscle differentiation in a sarcoma fail with alarming regularity, as became clear when better methods such as immunohistochemistry for muscle proteins became available. For several years now, the standard repertoire has included two main antibodies (as discussed in more detail previously): desmin and muscle actin. However, neither is unique to skeletal muscle; desmin occurs widely in nonrhabdomyogenic cells (including myofibroblasts), and muscle actin routinely reacts with smooth muscle. Thus, myogenesis may be assumed, but *rhabdo*myogenesis cannot. What, then, to do? Developmental studies of transcription factors have documented the critical and pivotal role these genes play in normal skeletal muscle development; the same is true of rhabdomyogenic tumors. MyoD and Myogenin in particular are useful markers of incipient rhabdomyogenesis; MYF5 is as well but is less widely used as a marker. A typical diagnostic method has been RT-PCR to detect these rare mRNA transcripts. PCR can be disastrously misleading, however; even the most minute contamination from normal skeletal muscle (a likely event in a sarcoma, it should be noted) will yield a false-positive result in nonmyogenic sarcomas. Antibodies have been developed against MyoD and Myogenin that are able to detect even these scant transcription factor proteins in the nucleus, either on frozen tissue sections or on imprints. This is illustrated in Figure 8-13A. More recently, antigen retrieval methodology has extended this to ordinary formalin-fixed, paraffin-embedded tissue sections as well.[24] A positive result here it should be noted, especially if localized to tumor cell nuclei, is unequivocal evidence of rhabdomyogenesis, unlike the ambiguous results given by desmin and muscle actin antibodies. This, then is the preferred diagnostic marker for this tumor.

### *Classification*

Having established that a questionable tumor is RMS, the next challenge is often how to subclassify the tumor. Such cases are generally *not* typical examples or they would not have been subjected to such scrutiny in the first place. Although some are spindle cell tumors, the more common variety is a round cell tumor, the same round cell tumor problem discussed earlier. In this case, the issue is which category of RMS, referencing the recently published International Classification of Rhabdomyosarcoma summarized in Table 8-5. The single most important change from historical systems (for the purposes of this discussion) is the recognition that alveolar RMS need not display an alveolar pattern. The diagnosis of this type of RMS is more cytologic and molecular genetic (although approximately 25% of cases will be translocation negative, necessitating reliance on morphology for their diagnosis when no alveolar pattern is present). Strikingly, the major reviews of IRSG study material that developed this schema documented both a failure to recognize alveolar cytology in nearly one-third of alveolar RMS cases and a marked increase in the different prognoses of these two tumors when this mistake was corrected. After review, the number of alveolar RMS cases increased nearly 50%, to one-half as common as the more common ERMS, from one-third, as was common by historical criteria. At the same time, survival differences became statistically significant, with alveolar RMS faring worse, as long suspected. A typical example of the cases incorrectly identified as ERMS, but now recognized as a variant of alveolar RMS termed *solid alveolar RMS*, is shown in Figure 8-26.

| Diagnosis | Histology | Prognosis |
|---|---|---|
| Botryoidal embryonal | Favorable | Superior |
| Spindle cell embryonal | Favorable | Superior |
| Embryonal, not otherwise specified | Favorable | Intermediate |
| Alveolar | Unfavorable | Poor |
| Solid alveolar | Unfavorable | Poor |
| Anaplastic/pleomorphic embryonic | Unfavorable | Poor |
| Undifferentiated sarcoma | Unfavorable | Poor |

**TABLE 8-5. INTERNATIONAL CLASSIFICATION OF RHABDOMYOSARCOMA**

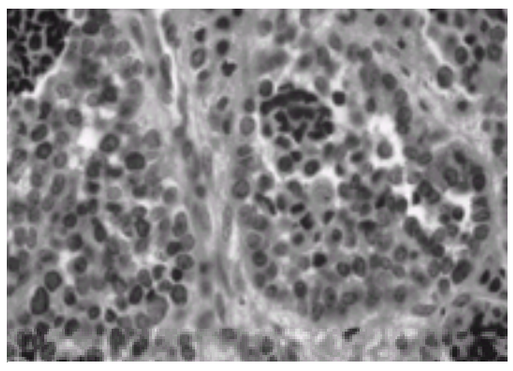

**FIGURE 8-26.** Solid alveolar rhabdomyosarcoma. This tumor in the Intergroup Rhabdomyosarcoma Studies was routinely misdiagnosed as a form of embryonal rhabdomyosarcoma for nearly 25 years. As a result of the new international classification scheme, 10% to 20% of all cases have now been correctly reclassified as alveolar rhabdomyosarcoma. As a group they have histology similar to that seen here, composed of round, poorly adherent cells that may begin to form a nascent alveolar pattern (*right side*). The true alveolar character of these lesions has been documented: they show a similar incidence (i.e., approximately 75%) of a PAX3- or PAX7-FKHR translocation, as observed in conventional forms of the disease.

***Lineage Fidelity and Fusion Gene Status***

We have previously identified *EWS-ETS* gene fusions identical to those found in EFTs in a series of myogenic solid tumors occurring in the soft tissues of children and young adults.[343] These tumors had an SRCT morphology with histological features suggestive of ARMS. Moreover, they expressed myogenic cell intermediate filaments. In one case, the initial presentation was indistinguishable from an EFT, but after therapy both Ewing's-like and frankly rhabdomyoblastic elements were detected (Fig. 8-27A, Fig. 8-27B and Fig. 8-27C). This case tested positive for EWS-FLI1 fusion transcripts ( Fig. 8-28), documenting the EFT lineage; the frank myogenesis documented the rhabdomyogenic lineage.

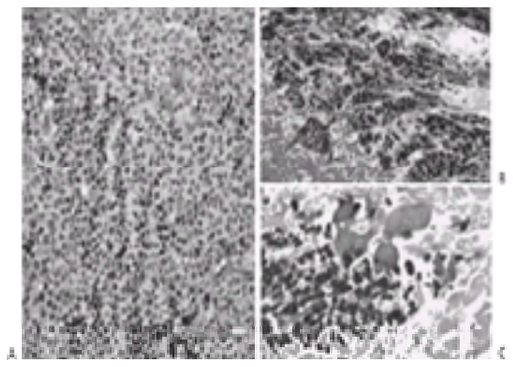

**FIGURE 8-27.** Biphenotypic sarcoma (Ewing's plus rhabdomyosarcoma). The three panels in this illustration show **(A)** the pre-therapy appearance of the tumor, which was composed entirely of round, undifferentiated cells that appeared to be those of Ewing's sarcoma. After treatment and subsequent excision, the tumor now showed evidence of two cell types: **(B)** continued to resembled Ewing's sarcoma, whereas some portion of the tumor **(C)** now showed unequivocal evidence of terminal rhabdomyoblastic differentiation. Thus the original tumor was too undifferentiated to identify as a mixed Ewing's and rhabdomyosarcoma tumor, but the treatment-induced differentiation revealed the unequivocal dual phenotypic character of the tumor.

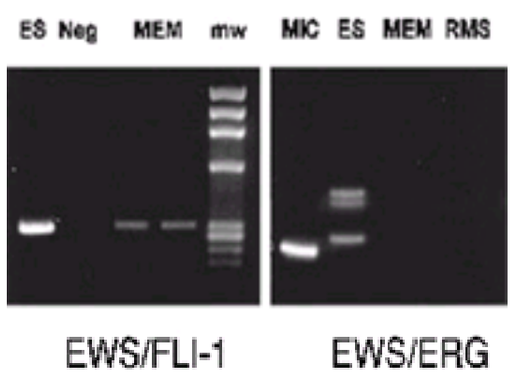

**FIGURE 8-28.** Polymerase chain reaction (PCR) confirmation of the Ewing's translocation. To confirm the distinction between simply primitive or undifferentiated rhabdomyosarcoma versus a true biphenotypic tumor, PCR analysis of the tumor along with control samples, such as rhabdomyosarcoma, is illustrated here. A positive band for *EWS-FLI1* is readily detected, confirming the Ewing's family character of the tumor, but here unquestionably a component of a rhabdomyosarcomatous tumor, as documented in Figure 8-27. This has been termed *biphenotypic sarcoma* by the authors, and is considered a primitive form of the conventional malignant ectomesenchymoma (MEM). ES, Ewing's sarcoma; mw, molecular weight; Neg, negative; RMS, rhabdomyosarcoma.

We have hypothesized that these biphenotypic tumors represent examples of malignant ectomesenchymomas (MEMs), defined as soft tissue tumors having neural sarcomatous elements in addition to a malignant mesenchymal (rhabdomyoblastic) component[459,460 and 461] and that these tumors are members of the pPNET family, now EFTs.[343] This finding is potentially of importance diagnostically as at least some *PAX3-FKHR* or *PAX7-FKHR* fusion–negative ARMS cases may represent MEMs. In a recent analysis of approximately 200 cases originally submitted to IRS-IV for molecular studies and possible inclusion on IRS-IV therapeutic protocols, we did identify one case out of approximately 50 cases with ARMS morphology that was *PAX3-FKHR* or *PAX7-FKHR* fusion–negative but which expressed an *EWS-FLI1* gene fusion (P.H.B. Sorensen, F.G. Barr, and T. Triche, *unpublished results*). Therefore, although rare, at least some ARMS cases may actually represent MEMs with

EWS-ETS gene fusions. Alternatively, some ARMS cases lacking ARMS-associated gene fusions may represent cases of IDSRCT in which either neural or epithelial markers are difficult to detect. It is therefore recommended that SRCTs with ARMS morphology but that lack *PAX3-FKHR* or *PAX7-FKHR* gene fusions should be assayed for *EWS-ETS* or *EWS-WT1* gene fusions as part of the diagnostic workup.

**Cellular Fibroblastic Lesions of Early Childhood**

A considerable source of controversy for both pathologists and clinicians is the occurrence of cellular, mitotically active spindle cell tumors in very young children, which have the morphologic appearance of ATFS.[462] Fibrosarcoma is known to occur in children, but there appears to be a bimodal age distribution to this entity. Those occurring before age 5 years (with most occurring in children younger than 1 year) are known as *CFS*.[362] A second peak occurs in patients aged 10 to 15 years, and these are referred to as *ATFS*. ATFS is histologically identical to CFS, and the lower end of the pediatric age range in ATFS is not well defined, making the distinction from CFS potentially problematic in young children. This is an important distinction; whereas CFS generally has an excellent prognosis and is often treated with surgery alone, ATFS is an aggressive lesion with a poor prognosis similar to that of adult fibrosarcoma. [462] Both CFS and ATFS may be confused with fibromatosis, a less cellular proliferation of benign-appearing fibroblasts with a more collagenous matrix ( Fig. 8-29).[362] This lesion most commonly occurs in children aged 2 years or younger and is therefore often referred to as *infantile fibromatosis* (IFB). When IFB cells show contractile elements ultrastructurally or stain for muscle actin suggesting myofibroblast derivation, the term *myofibromatosis* is used.[362,463] This lesion often demonstrates multifocal sites of involvement. Aggressive fibromatosis is a clinical term for an otherwise histologically indistinguishable form of IFB that shows increased local invasion or recurrence rates. [462] Therefore CFS may be confused with a number of both benign and malignant entities. Unfortunately, standard pathologic examination often does not readily distinguish these conditions from each other.

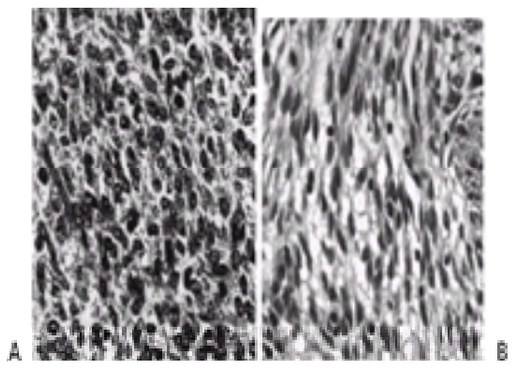

**FIGURE 8-29.** Light microscopic appearance of fibrosarcoma and fibromatosis. **A:** A typical fibrosarcoma, with characteristic darkly basophilic nuclei and disorderly growth pattern contrasts strongly with the spindle cells of fibromatosis. **B:** The striking dichotomy seen here is not present in all cases, and overlapping appearances sometimes render the two forms indistinguishable. Hematoxylin and eosin, ×400.

As described, a novel t(12;15)(p13;q25) chromosomal translocation has recently been described in CFS that gives rise to an oncogenic *ETV6-NTRK3* gene fusion.[364] RT-PCR assays can detect *ETV6-NTRK3* fusion transcripts in CFS frozen[364] or paraffin-embedded tumor.[366,464] In a recent series of 62 predominantly pediatric soft tissue spindle cell tumors, including 11 CFS cases, 13 malignant spindle cell tumors (including ATFS) and 38 benign spindle cell tumors (including IFB and myofibromatosis), Bourgeois et al.[464] found that *ETV6-NTRK3* was expressed only in the CFS cases. In this study, the authors also examined whether immunohistochemistry with an antibody to the NTRK3 PTK domain could detect ETV6-NTRK3 proteins in paraffin-embedded tissue blocks; however, this technique did not reliably detect chimeric proteins in tumor specimens. Therefore RT-PCR detection of the *ETV6-NTRK3* gene fusion in pediatric spindle cell tumors appears to be the modality of choice for identification of *ETV6-NTRK3* gene fusions in the diagnostic workup of CFS. It is hoped that further genetic characterization of other pediatric spindle cell tumors will provide better markers for these diseases as well.

**Nonrhabdomyogenic Spindle Cell Sarcomas of Older Children**

A common problem in older children is the distinction of fibrosarcoma, monophasic SS, and malignant nerve sheath tumors from one another. These tumors, all nonmyogenic spindle cell sarcomas, are conceptually quite distinct. Further, the biologic or clinical behavior is also allegedly quite different; most MPNSTs are considered to be of low-grade malignancy, ATFS is a full-blown malignancy, and SS is generally a high-grade malignancy. In reality, the distinction between these entities has increasingly been questioned in view of recent data linking at least some proportion of these three tumors.

ATFS, unlike the congenital form discussed previously, generally occurs in adolescents and young adults, is not a variant of the common malignant fibrous histiocytoma of adults, and requires aggressive surgery and potentially adjunctive therapy (although well-accepted, multimodality therapy protocols are not widely used).[465,466 and 467] No diagnostic gene fusion or other marker has been identified, unlike the histologically similar but pathogenetically unrelated and only recently recognized as malignant (albeit low-grade) soft tissue tumor, inflammatory myofibroblastic tumor. [451,468] For some years, then, fibrosarcoma has been a seemingly clear cut entity, a bona fide member of the nonRMS soft tissue sarcomas.[467]

SS has for years been recognized in its classic biphasic form, as well as the less typical monophasic form, which can be difficult to distinguish from fibrosarcoma ( Fig. 8-30).[469,470] Remarkably, a consistent chromosomal translocation unique to this tumor was identified in 1986 by Turc-Carel et al. [357] and subsequently confirmed by a number of others.[471,472,473,474 and 475] Within a short time, the breakpoint was cloned and shown to involve two unique genes, *SYT* on chromosome 18 and a novel gene, *SSX*, on chromosome X.[476,477] Shortly thereafter, two gene transcripts were identified on chromosome X, identified as *SSX1* and *SSX2* (Fig. 8-19).[358,359,478,479] This number has now been expanded to *SSX4*, but only if *SYT* in involved from chromosome 18.[458] Remarkably, this fusion gene has only been found in SS, and in all SS studied to date in which adequate material has been available. [358,359,444,476,477,478,479 and 480] Thus, the presence of an *SYT-SSX* gene fusion is thought to be 100% predictive of a diagnosis of SS.

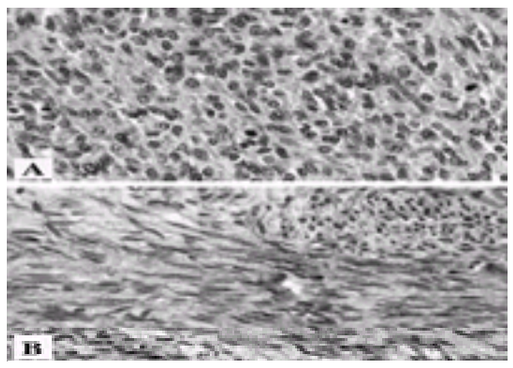

**FIGURE 8-30.** Fibrosarcoma versus monophasic synoviosarcoma. Spindle cell tumors, even when clearly malignant, can be difficult to distinguish. Here a typical fibrosarcoma **(A)** and a typical monophasic synoviosarcoma **(B)** are illustrated. At first glance, it is frequently difficult to distinguish the two; before the advent of molecular methods (Fig. 8-19), monophasic synoviosarcomas were routinely identified as fibrosarcoma due to their typically fibroblastic appearance as seen here. When compared to a conventional fibrosarcoma **(A)**, however, striking differences are evident, notably the wavy nuclei and fibrillar stroma of synoviosarcoma.

The third entity to be considered here is MPNST. Historically, this was often termed *neurofibrosarcoma* or *malignant schwannoma*, particularly when it occurred in

adults.[481,482,483,484,485 and 486] In children, unlike adults, there is no association with von Recklinghausen's disease or abnormalities of NF1. Numerous features, from EM evidence of perineural cell differentiation with basal lamina formation to S100 immunoreactivity by immunohistochemistry, appeared to distinguish this tumor from fibrosarcoma or SS (Fig. 8-31A, Fig. 8-31B).

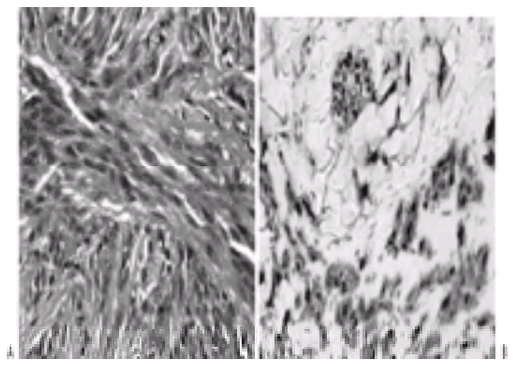

**FIGURE 8-31.** Malignant peripheral nerve sheath tumor. It is increasingly recognized that malignant peripheral nerve sheath tumor **(A)** can be difficult to distinguish from fibrosarcoma and synoviosarcoma. Immunohistochemistry for S100 protein **(B)** will generally identify malignant nerve sheath tumor, is only rarely reactive with synoviosarcoma, and should be nonreactive with fibrosarcoma. Increasingly, however, these analyses are being augmented with *SYT-SSX* analysis for synoviosarcoma. However, exceptions to this dichotomy (e.g., *SYT-SSX*–positive synoviosarcoma with S100-positive cells) have been reported.

The diagnostic overlap central to this discussion first appears with the description of tumors that appear to be nerve sheath tumors but with divergent differentiation, forming skeletal muscle (so-called Triton tumors) or glandular elements (or glandular differentiation in MPNST).[487,488 and 489] This then raises the question of how to distinguish a malignant nerve sheath tumor with glandular differentiation from a biphasic SS. The presence of the diagnostic *SYT-SSX* translocation can potentially distinguish the two. However, as more of these tumors are analyzed, particularly those spindle cell tumors expressing neural markers but lacking glandular differentiation, examples with the same SS-specific translocation have been encountered.[194,490,491]

Either there is a link between these three tumors or there is inappropriate expression of neural markers by some SS and fibrosarcomas. In either case, molecular genetic analysis has provoked a reconsideration of the classification of these seemingly unrelated tumors. This is particularly unexpected given the general association of SS with a highly unique and possibly pathogenic chromosome translocation, in contrast to the common association of malignant nerve sheath tumor with NF1 mutations or loss. Given the seemingly different behavior between these tumors, it will be important to use phenotypic and molecular genetic methods to resolve this ambiguity. In the meantime, an *SYT-SSX* translocation analysis is needed in every suspected case of SS, and ATFS and MPNST as well.

**Is the Rhabdoid Tumor a Tumor or a Phenotype?**

The rhabdoid tumor was first described as an unusual variant of Wilms' tumor in early National Wilms' Tumor Study Group studies.[492] Notable features were an extraordinarily prominent nucleolus, and to a lesser extend, brightly eosinophilic cytoplasm resembling that of RMS cells (hence the name) ( Fig. 8-32A). These features are easily confirmed by EM as well (Fig. 8-32B). At first, these tumors were thought to be limited to the kidney, but within a short time they were identified in almost every anatomic location.[493,494,495,496,497,498,499 and 500] Worse, they often occurred superimposed on bona fide tumors of otherwise known lineage, or at least diagnosis, such as SS, leading some to suggest such tumors were not a tumor per se, but rather a particularly poor prognosis form of any sarcoma (as almost all such patients died in early reports).[498,501,502]

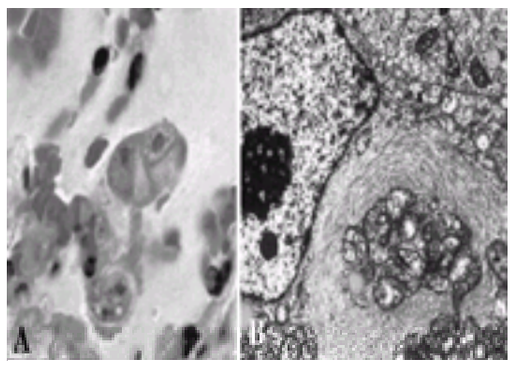

**FIGURE 8-32.** Rhabdoid tumor—cytology and electron microscopy (EM). This “tumor” has been historically identified based on unique histiologic and cytologic characteristics. Typically the cells show a prominent nucleolus and a cleared area of adjacent cytoplasm, often with eosinophilic inclusions **(A)**. By EM **(B)** the cytoplasmic inclusion is found to be a whorl of intermediate filaments. The prominent nucleoli are also evident by EM. Recent description of a common *SNF5* (*INI1*) mutation in this tumor suggests that it is a recurring genomic alteration in a tumor, but the frequent occurrence of the phenotype in other well-characterized tumors suggests that the phenotype can exist independent of the tumor type (e.g., rhabdoid phenotype in synoviosarcoma with a characteristic SYT-SSX chimeric gene).

With time, a unique chromosomal translocation involving the short arm of 11 and the long arm of 22 was described [and thus distinct from the Ewing's tumor t(11;22), which involves the long arm of each chromosome], although the chromosome 22 breakpoint in the rhabdoid tumor was exceedingly close to the EWS breakpoint of Ewing's tumor.[503,504] Numerous attempts to identify a chimeric gene analogous to that described in RMS or Ewing's, for example, failed.[505,506,507,508,509,510 and 511] Recently, however, a unique genetic defect has been described, specifically the loss or mutation of snf5 (or INI1), a member of a family of genes important in chromatin remodeling.[512,513] The common and necessary finding of a single prominent nucleolus would thus seem to be linked in some fashion to defective function of this gene complex in these tumors, although a specific functional relationship between this genetic abnormality and the ubiquitous prominent nucleolus is currently unclear. Why most tumors also accumulate unique cytoplasmic whorls of intermediate filaments is even less clear. Nonetheless, the alteration at the moment appears restricted to rhabdoid tumors, but this, too, may prove illusory, as have most “tumor-specific” gene abnormalities. (B. Weissman, *personal communication*, 2000) Despite this, SNF5 mutations appear to be found in most if not all rhabdoid tumors, suggesting an etiologic role for this defect. Widespread diagnostic testing awaits further clarification of the common defect in all such tumors; no specific translocation or mutation akin to those in other sarcomas has yet been described.

## A FINAL WORD

It should be apparent from the foregoing that diagnosis of tumors and tumorlike conditions, or even the exclusion of the same, is uniquely difficult in children, with disproportionate consequences for an incorrect diagnosis. Presumably for this reason, many of the most specialized diagnostic modalities introduced into medicine have been first applied to childhood tumors. Molecular genetic analysis of hematopoietic malignancies (notably leukemia and lymphoma) is not routine as is gene amplification and quantitative gene expression analysis in NB. PCR is now ordinary, used in almost every case of RMS, EFT, SS, DSRCT, melanoma of soft parts, and others suspected of being any of the above. FISH is also routine for translocations in all of the above.

This is hardly the case in adult tumor diagnosis. Why, and why does it matter? In part, the high frequency of mesenchymal tumors (leukemia, lymphoma, Wilms' tumor, and sarcomas in particular) with their extraordinary frequency of reproducible genetic abnormalities (translocations, deletions, amplifications, and imprinting) clearly contribute to the utility of molecular genetic diagnostics among these tumors. But that only speaks to utility. The real reason is that the results of these diagnostic procedures make a difference in patient management and outcome. Fortunately, many of these diagnostics are closely linked to specific prognoses. *NMYC*

amplified NBs are associated with a poor prognosis, as are *PAX3-FKHR* alveolar RMSs and *SYT-SSX1* SSs.

What comes next will be perhaps the most interesting chapter in this continuing story. Identifying not just single- (or two-) gene abnormalities but wholesale genomic and expression features, as promised by DNA microarrays and similar emerging technologies, offers the real prospect of, for the first time, identifying diagnostic, prognostic, etiologic, and therapeutic target features in a given tumor all at once. This will indeed usher in a new understanding of childhood cancer and likely cancer (and disease) in general.

The rate at which new understanding has come to oncology in general and pediatric oncology in particular within the past decade or so is unprecedented. It will only increase disproportionately with the recent successful sequencing of the human genome and the vast amount of knowledge that will flow from there. With that knowledge comes the responsibility to apply it in a clinically meaningful, useful, and responsible manner. The preceding commentary offers at least some direction for doing so in the diagnostic evaluation of the child with cancer.

# IMAGING STUDIES IN THE DIAGNOSIS AND MANAGEMENT OF PEDIATRIC MALIGNANCIES

RICHARD M. BRAVERMAN
BRUCE R. PARKER

## INTRODUCTION

The past three decades have seen a remarkable improvement in the survival rate of children with malignant disorders and witnessed a technologic explosion in the field of diagnostic imaging that has made accurate assessment of tumor size and spread more precise than ever before possible. These advances in imaging technology, however, entail increased knowledge and sophistication on the part of the imaging specialist, greater cost of technologically advanced equipment, and increased difficulty in choosing the appropriate imaging modality for the quickest, most accurate, and least expensive patient evaluation at the lowest possible radiation dose. Since the previous editions of this book were published, improved technologic sophistication rather than wholly new technology has characterized the field of diagnostic imaging. This chapter discusses the innovations of the past several years and explores in greater detail the contributions of increasingly sophisticated computerized imaging procedures. The relative merits of the imaging procedures currently available are considered, and recommendations are made concerning the evaluation of general problems in pediatric oncology. The imaging characteristics and the imaging evaluation of patients with specific tumors are dealt with in the appropriate specific chapters of this text.

## RELATIVE MERITS OF IMAGING PROCEDURES

### Plain Film Radiography

At a time of remarkable advances in sophisticated imaging modalities, the plain film radiograph continues to play a significant role in the diagnosis, evaluation, and follow-up of children with malignant disease ( Table 9-1). Although less sensitive than computed tomography (CT), plain film chest radiography is the examination of choice for short-term interval evaluation of both primary intrathoracic tumors and of pulmonary metastases ( Fig. 9-1). The examination is fast, technically easy to perform, inexpensive, requires no anesthesia or sedation, and delivers minimal radiation to the thyroid, breast tissue, bone marrow, and gonads. The chest film also continues to be the initial procedure of choice for evaluating complications of therapy such as drug reactions and pulmonary infections in the immunocompromised host.

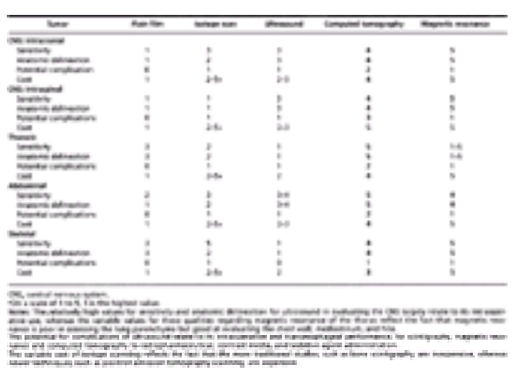

**TABLE 9-1. COMPARATIVE VALUE OF IMAGING PROCEDURES ON A SCALE OF 1 TO 5[a]**

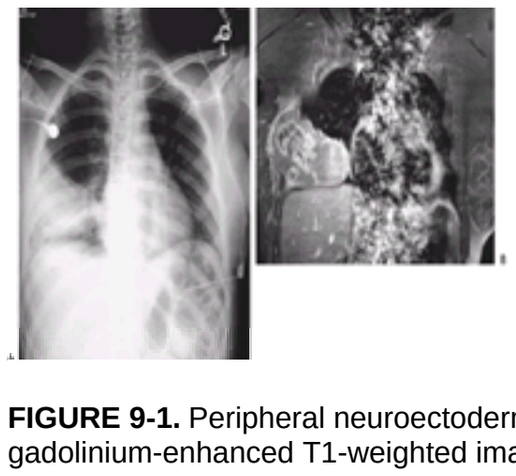

**FIGURE 9-1.** Peripheral neuroectodermal tumor. **A:** Posteroanterior chest radiograph demonstrates a large mass at the base of the right hemithorax. **B:** Coronal gadolinium-enhanced T1-weighted image confirms the presence of the lesion and shows areas of diminished signal within it consistent with intratumoral necrosis.

Plain films of the abdomen have to a great extent been superseded by more technologically advanced procedures for evaluation of abdominal masses and other problems found in pediatric oncologic patients. Nevertheless, sufficient information can often be gleaned from abdominal plain films to warrant their performance before more sophisticated imaging procedures are undertaken. Specifically, although not as sensitive as CT for finding calcification within tumors, the plain film of the abdomen does depict most calcifications and many intraabdominal masses. Finally, and perhaps most significantly, conventional radiography of the abdomen

constitutes the best simple means to evaluate for bowel obstruction and pneumoperitoneum.

Excretory urography is seldom performed to evaluate patients with oncologic disease. Instead, various combinations of nuclear scintigraphy, ultrasound, CT, and magnetic resonance (MR) are used to evaluate retroperitoneal disease, both intrinsic and extrinsic to the genitourinary system.

Barium studies are a simple and sensitive means of evaluating gastrointestinal (GI) tract lesions ( Fig. 9-2). However, with the exception of lymphoma, primary neoplastic involvement of the GI tract is rare in children and, in the case of lymphoma, CT offers the advantage over barium studies of not only demonstrating the bowel but of also depicting the mesentery, the mesenteric lymph nodes, and the solid abdominal viscera ( Fig. 9-3). Mucosal lesions of the GI tract are better seen with traditional barium studies than by any of the more advanced imaging studies available. Esophagitis, duodenal ulcer, drug-induced colitis, and radiation enterocolitis are, for example, best identified by barium studies. Contrast enemas must, however, always be used with caution and are generally contraindicated in neutropenic patients because of the bacteremia that invariably occurs during the procedure ( Fig. 9-4). Contrast studies performed after oral ingestion of contrast agents are generally safe even in immunocompromised children.

**FIGURE 9-2.** Burkitt's lymphoma manifesting as ileocolic intussusception in a 4-year-old boy. Barium enema demonstrates the typical coiled-spring appearance of intussusception.

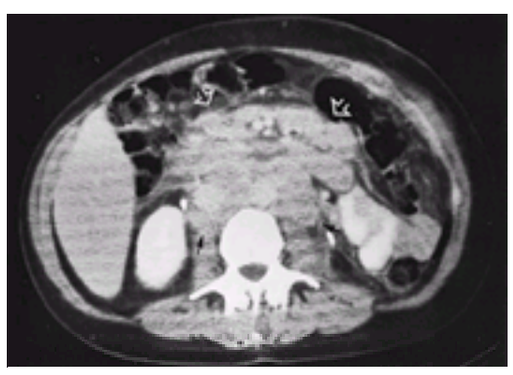

**FIGURE 9-3.** Non-Hodgkin's lymphoma in a 17-year-old girl. Computed tomography demonstrates mesenteric lymphadenopathy (*open arrows*) and retroperitoneal lymphadenopathy (*closed arrows*).

**FIGURE 9-4.** Radiation colitis in 6-year-old boy presenting 2 years after therapy for pelvic rhabdomyosarcoma. Barium enema shows rigidity, narrowing, and mucosal effacement of the sigmoid colon.

Barium is an inexpensive, convenient, and safe contrast medium for the evaluation of the GI tract. Its use is contraindicated, however, when perforation of the intestine or bowel obstruction is suspected. In such circumstances, water-soluble contrast material should be used. Historically, derivatives of meglumine and diatrizoate salts have been used, but these hyperosmolar agents have been largely abandoned due to their propensity to cause dangerous fluid shifts when administered in large quantities, pneumonitis when aspirated, and peritonitis when spilled from the GI tract. Newer, nonionic low-osmolar agents, though expensive, are safer, provide better detail of the GI tract mucosa, and remain undiluted within the GI tract for longer periods.

Skeletal radiographs are reasonably sensitive in detecting bony abnormalities, although most neoplastic and infectious processes are apparent on radionuclide bone scans and by MR imaging before they are evident on plain films. Nevertheless, by the time most patients with primary bone tumors are symptomatic, the plain film image is abnormal and should be used as the first screening modality in a patient with bone pain. MR has proved to be better than plain films, radionuclide studies, or CT in determining the osseous and extraosseous extent of bone neoplasms (Fig. 9-5) and is currently the mainstay for the evaluation of primary bone tumors. MR can be used to assess for metastatic disease but total-body MR imaging is cumbersome and, with the exception of Langerhans' cell histiocytosis [1] and neuroblastoma, in which radiographic skeletal surveys can serve an important complementary role, nuclear scintigraphy is generally the preferred modality for the detection of bony metastases. Of great importance, however, is the fact that, although MR and radionuclide scanning are highly sensitive, these modalities, and especially bone scintigraphy, are considerably less specific than plain film imaging, and thus abnormalities detected by MR or by scintigraphy should be correlated with conventional skeletal radiographs.

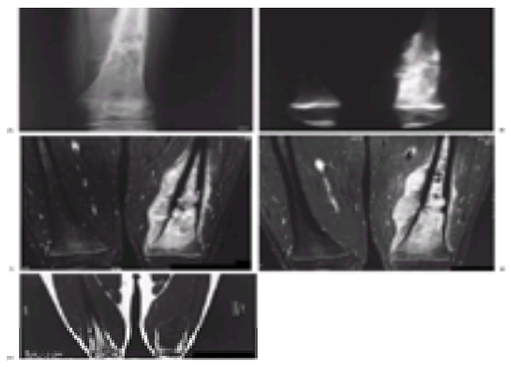

**FIGURE 9-5.** Imaging evaluation of primary bone tumors. **A:** Anteroposterior radiograph of the left femur shows a mixed sclerotic and lytic process in the left femoral shaft with “sunburst”-type periosteal reaction medially, a classic appearance for new bone production in this osteosarcoma. **B:** Anteroposterior 99-m technetium methylene diphosphonate bone scintigram shows increased uptake at the site of the tumor. **C:** Coronal short t inversion recovery magnetic resonance (MR) image shows increased signal at both the intramedullary and extraosseous portions of the tumor. **D:** Coronal T1-weighted MR image shows the signal from the intramedullary tumor to be less intense than that of the normal fatty marrow within the distal portion of the right femur. The extraosseous soft tissue tumor has T1-weighted signal similar to that of normal muscle. **E:** Coronal fat-saturated T1-weighted MR image shows increased enhancement of both the intra- and extraosseous portions of the tumor.

Skull radiography, in the era of CT and MR, is rarely useful. [2] A skull film should always be included as part of a radiographic metastatic survey to detect calvarial metastases, but virtually any other abnormality, including lesions of the sella turcica, sphenoid wings, and the skull base, is better seen on CT or MR. [3,4] Even as a screening mechanism, plain skull radiography adds nothing but cost to the evaluation of the patient and can always be obtained after the CT or MR if there is reason to think it might add some information.

Spinal radiographs are valuable as a screening examination for metastatic disease and for compression fractures secondary to disease-induced or drug-induced osteoporosis. Radioisotope bone scanning, however, is more sensitive for the early detection of metastatic disease or occult bone tumor, and CT or MR gives better definition of bony spinal lesions and of associated abnormalities of the intraspinal contents.

Conventional fluoroscopic myelography was initially largely supplanted by spinal CT performed after intrathecal contrast injection and was subsequently nearly completely replaced by MR imaging, the current study of choice for the evaluation of lesions of the spinal cord and its coverings. [5] MR studies are more diagnostic, are obtained without the intrathecal injection of contrast material, and are generally better tolerated by patients. Of particular importance for children is the fact that MR is extremely sensitive to the encroachment of paraspinous neurogenic tumors through the neural foramina into the spinal canal ( Fig. 9-6).[6] As both MR[7] and CT images can be significantly degraded by the presence of metallic hardware on occasion, conventional myelography can be helpful in evaluating patients with such hardware.

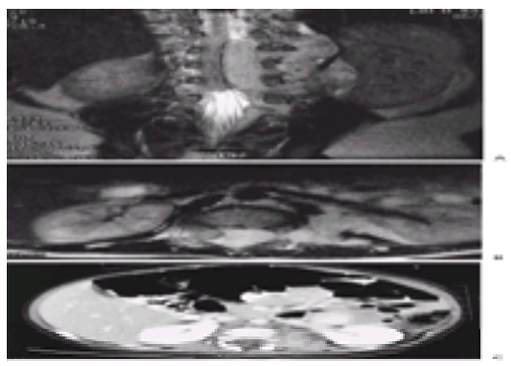

**FIGURE 9-6.** Left paraspinal neuroblastoma invading the spinal canal through several thoracic and lumbar neural foramina and displacing the thecal sac rightward as depicted on **(A)** T2-weighted coronal and **(B)** T2-weighted axial magnetic resonance images and on **(C)** axial computed tomography scanning performed with oral and intravenous but without intrathecal contrast.

## Angiography and Lymphangiography

Although invasive vascular imaging is currently performed in the context of image-guided interventional procedures, such as tumor embolization and intraarterial chemotherapy delivery, invasive vascular imaging for purely diagnostic purposes has been largely supplanted by the newer imaging modalities and is currently rarely indicated. Inferior vena cavography was initially replaced by lymphangiography and subsequently by CT and MR for evaluation of retroperitoneal lymphadenopathy, and by ultrasound, CT, and MR for the evaluation of intravascular spread of malignancy as in cases of Wilms' tumor [8] and hepatoblastoma. Although angiography is occasionally performed to evaluate tumor vasculature, particularly in some institutions when partial hepatectomy or limb salvage procedures are contemplated, most tumors, including hepatic neoplasms, can be adequately studied by noninvasive cross-sectional imaging. Although its spatial resolution is less than that of CT, MR provides a generally superior depiction of vascular anatomy. [9,10]

Invasive diagnostic neuroangiography for the evaluation of tumors has also been superseded by CT and MR. Invasive arteriography, however, is still the best way to evaluate small-vessel disease within the central nervous system (CNS), an uncommon problem in children that nonetheless can occur as a rare complication of antitumor therapy.

Lymphangiography remains a somewhat controversial issue in the diagnostic evaluation of patients with lymphoma ( Table 9-2).[11] The procedure is technically difficult in inexperienced hands, invasive, expensive, has a small but definite incidence of complications, and usually requires deep sedation or general anesthesia of preadolescent children. On the other hand, it is the only imaging procedure that allows evaluation of intrinsic lymph node architecture ( Fig. 9-7) and has been performed successfully in children as young as 14 months of age by experienced personnel. [12] Body CT, when performed with appropriate use of intravenous and oral contrast agents, is capable of identifying lymph nodes larger than a few millimeters in diameter. However, CT is not able to determine whether a lymph node is enlarged because of tumor involvement or because of reactive hyperplasia. Because reactive hyperplasia is present in 12% of children younger than 16 years of age and 19% of children younger than the age of 11 years, [13] the specificity of CT is low. The accuracy of lymphangiography approaches 95%. [14] Nonetheless, CT evaluation of the retroperitoneal lymph nodes has replaced lymphangiography in most institutions, and in those few institutions where lymphangiography is still performed, it is often reserved for patients with negative CT scans who will not receive chemotherapy. MR can demonstrate retroperitoneal lymph nodes but, like CT, cannot, at least at this time, differentiate reactive hyperplasia from malignant disease. Measurement of relaxation times and *in vivo* MR spectroscopy (MRS) (or both) may in the future, however, enable this procedure to definitively identify malignant lymph node disease.

| | Lymph-angiography | Computed tomography | Ultra-sound | Magnetic resonance |
|---|---|---|---|---|
| Accuracy | 4 | 3 | 2 | 3 |
| Technical skill required | 4 | 1 | 3 | 2 |
| Invasiveness | 4 | 1–2 | 0 | 0–1 |
| Potential complications | 3 | 1–2 | 0 | 0–1 |
| Cost | 4 | 2–3 | 1 | 3–4 |

*On a scale of 1 to 4, 4 is the highest value.
Notes: The invasiveness, potential for complications, and cost of computed tomography and magnetic resonance vary with the need for sedation.

**TABLE 9-2. RETROPERITONEAL LYMPHADENOPATHY: COMPARISON OF UTILITY OF IMAGING PROCEDURES ON A SCALE OF 1 TO 4[a]**

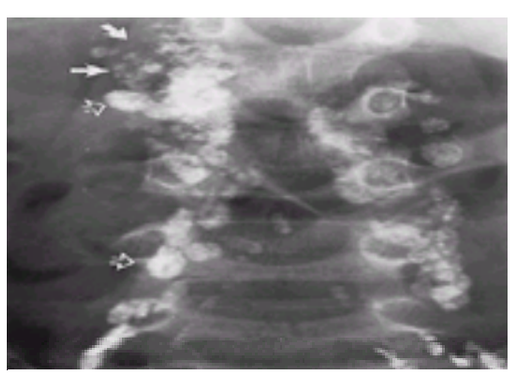

**FIGURE 9-7.** Hodgkin's disease. Bipedal lymphangiogram in 11-year-old boy demonstrates areas of tumor involvement ( *closed arrows*) and reactive hyperplasia (*open arrows*) documented at staging laparotomy. The nontumorous nodes are at least as large as the involved nodes, making differentiation by computed tomography, ultrasound, or magnetic resonance techniques difficult.

**Nuclear Medicine**

Nuclear medicine studies, especially when performed by imaging specialists with a particular interest in and experience with pediatric diseases, can be an effective diagnostic tool. Although they yield considerably less morphologic data than do other advanced imaging procedures, they can provide information regarding the metabolic status of pediatric tumors that is not available by others means.

Bone scanning is of less value than CT or MR in the evaluation of extent of involvement by primary bone tumors, but, as stated above, with the exception of Langerhans' cell histiocytosis and neuroblastoma in which the examination is commonly supplemented by radiographic skeletal surveys, bone scintigraphy is the screening examination of choice for the identification of bony metastatic disease. [15] Positive bone scans can, however, result from abnormalities other than metastases, and typically any area that is positive on bone scan should undergo radiography for further evaluation.

Liver scans are generally not as sensitive as ultrasound or CT for the detection of intrahepatic metastases or abscesses. Infiltrating diseases, such as leukemia and lymphoma, can however occasionally be better defined by radioisotope liver scans than by other imaging modalities.

Gallium-67 scanning is frequently used in the detection of infections and tumors. In children, it has been most useful in detecting rhabdomyosarcoma and lymphoma (Fig. 9-8).[16,17] In some institutions, thallium-201 has been used in the diagnosis and management of patients with brain tumors, osteogenic and Ewing's sarcoma, lymphoma, rhabdomyosarcoma, and germ cell neoplasms.[18,19]

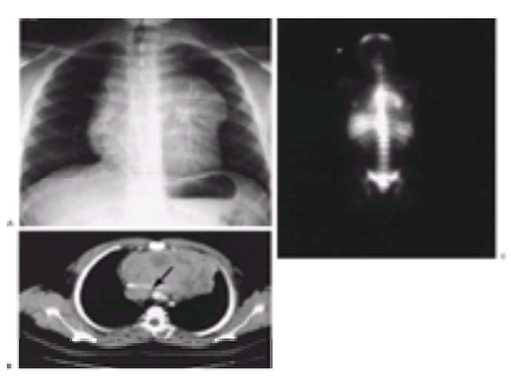

**FIGURE 9-8.** Hodgkin's disease. **A:** Posteroanterior chest radiograph shows a large mediastinal mass. **B:** Intravenous contrast–enhanced axial chest computed tomography scan confirms the presence of the mass and demonstrates compression of the left brachiocephalic vein by the tumor ( *arrow*). **C:** Gallium-67 citrate total body imaging shows physiologic tracer uptake by the liver, spleen, and bone marrow, as well as uptake by the mass.

As a further aid to the detection of focal infectious processes in the immunocompromised patient, scans using indium-111– and technetium-99m–labeled white cells have shown an ability to localize involved organs. For children, an accuracy of 86% has been reported for indium-labeled white cell imaging. [20] Although as many as one-third of patients with occult infections may show false-negative results, the lack of false positives makes a positive scan a reliable indication of a focal infectious process.[21] It may be necessary to follow labeled white cell scintigraphy with ultrasound, CT, or MR to better define a lesion, but the white cell scan offers the advantage of imaging the entire body at a lesser cost than is possible with other modalities.

The use of iodine-131 metaiodobenzylguanidine (MIBG) as a radioisotope marker in neuroblastoma is finding more adherents despite its cost and logistical difficulties.[22,23] and [24] The agent, which is also accumulated by pheochromocytomas, has been used in neuroblastoma primarily to diagnose and localize primary, metastatic, and residual disease. The potential for targeted treatment of neuroblastoma with a therapeutic doses of radiolabeled MIBG is under investigation.

Nuclear imaging has been widely used to monitor cardiac function in patients receiving cardiotoxic chemotherapy.

Recent advances in nuclear medicine imaging have been highly dependent on computer-aided technology. Single-photon emission CT uses the same computationally intense mathematical algorithms as are used in radiographic CT scanning to produce tomographic reconstructions of gamma emission data. Positron emission tomography (PET) uses so-called “coincidence imaging” to document the distribution of positron-emitting isotopes within the body and has significant potential for the depiction of physiologic and metabolic activity not evaluable by more traditional scintigraphic studies. [25] Especially useful has been the ability of PET imaging to distinguish metabolically active and therefore viable tumor from necrotic neoplasm and scar tissue. Labeling of tumor-avid agents with positron emitters may in the future permit localization of neoplastic tissue using the technique. Initially, the availability of PET imaging was significantly limited by the fact that as a research tool there was no financial reimbursement provided for PET studies and the fact that an expensive dedicated PET camera was required for imaging.

Currently, PET studies are, in many instances, reimbursed by private insurance, Medicare, and Medicaid. In addition, the cost of dedicated PET units has decreased considerably. There are also units available that can be used for both general-purpose nuclear medicine imaging and PET imaging and, in some cases, also CT scanning. An ongoing difficulty with PET imaging, however, arises from the fact that most positron emitters require a cyclotron for their production, an expensive proposition, and that most have quite short, on the order of seconds or minutes, half-lives, necessitating that a cyclotron be sited in close proximity to the PET unit. However, fluorine-18, the most widely used positron-emitting isotope at present and the isotope used to produce labeled glucose [fluoro-2-deoxyglucose (i.e., $^{18}$F-FDG)], has a relatively long half-life of 110 minutes, permitting its production at a central site and distribution throughout a community to multiple end users, a process commonly used with nuclear pharmaceuticals. Initially, the major use of PET scanning had been in neuropsychiatric and cardiovascular studies. The technique has, however, been found to be useful in evaluating lung and colon cancer, lymphoma, melanoma, and brain tumors, and investigation of its use in the diagnosis and management of neuroblastoma, bone tumors, and rhabdomyosarcoma is ongoing.[26,27]

**Ultrasound**

Although high-frequency sound was first used for diagnostic purposes more than 30 years ago, its true value has only been realized in the past two decades with the rapid development of advanced technology.[28] The ultrasound procedure uses sound waves in the range of 1 to 20 million cycles per second (1 to 20 MHz), well above the 20,000 Hz that is the upper limit of aural perception by human beings. Higher frequency sound permits greater imaging resolution but penetrates tissues to a lesser depth than does lower frequency sound. Thus, high-frequency transducers are used for high-resolution imaging of superficial structures such as the skin, testes, thyroid gland, and breast tissues. Lower frequency transducers are used for imaging of the intraabdominal organs. The sound waves are generated by a handheld transducer that contains a piezoelectric crystal. This crystal vibrates when an electric current is passed through it, propagating sound waves at a specific frequency. The sound can be directed toward a particular body part and can be focused to greater or lesser degrees depending on technologic factors. The transducer's crystal also acts as a receiver for sound waves reflected from internal structures. The vibrations generated in the crystal by these echoes produce electrical signals that can be digitized, processed, and displayed, typically in real time on a video monitor. The number and strength of the echoes depends on the quantity and nature of tissue interfaces within the insonated structure. Because there are no interfaces in a fluid-filled cyst, for instance, no echoes within it are seen, and the structure is known as *sonolucent* or *anechoic*. Tissue interfaces, such as those found in solid tumors, produce echoes of variable number and intensity. The resulting image is described as *echogenic*. Interfaces between air and soft tissues produce such strong echoes that depiction of anatomy beyond such interfaces is typically not possible. Bone attenuates sound waves to such a degree that anatomic detail beyond it is largely obscured.

Ultrasound examination, particularly when performed with the newest computerized equipment, is an excellent tool in the evaluation of the abdomen, pelvis, thyroid, breasts, and scrotal contents of children. Its utility in examining other areas of the body, such as the chest and CNS, depends on the amount of bone or gas present in or near the structure to be imaged. Because ultrasound examinations are relatively quick and inexpensive, use no ionizing radiation, have no known complications or side effects, and usually do not require sedation or anesthesia, they represent an ideal screening examination of the abdomen after plain film imaging. Technically successful ultrasound examinations are easier to perform in infants and young children than in older children and adults because of the relative paucity of abdominal fat in younger patients.

Ultrasound is particularly useful in evaluation of the liver, the gallbladder, the spleen, the kidneys, and the pelvic organs. In children, the pancreas, the aorta, and the inferior vena cava are typically well imaged. Retroperitoneal lymphadenopathy can frequently be identified but not as routinely as with CT. Intraperitoneal abnormalities may be difficult to image, especially if small, because of the presence of intraluminal intestinal gas. Ultrasound can easily and accurately differentiate solid from fluid-filled masses and can usually distinguish the organ of origin of an abdominal mass ( Fig. 9-9). During open surgery, high-resolution sonographic imaging can be performed by placing a sterile dressed ultrasound probe in direct contact with the surface of an organ of interest. Such intraoperative ultrasound has proven helpful in localizing tumors within the brain, spinal cord, pancreas, liver, and kidneys that are inapparent to physical inspection.

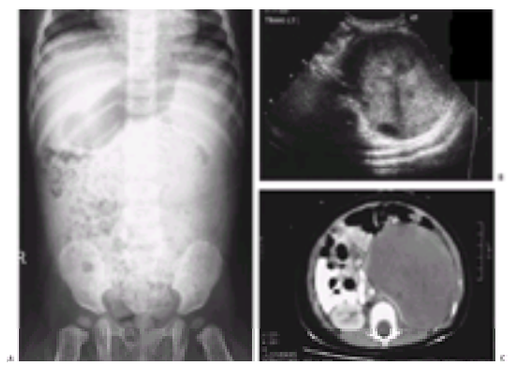

**FIGURE 9-9.** Wilms' tumor. **A:** Supine abdominal radiograph view demonstrates mass effect in the left side of the abdomen. **B:** Ultrasound confirms the presence of a solid left-sided tumor of renal origin. **C:** Axial computed tomography scan with oral and intravenous contrast shows the mass with a slender rim of enhancing renal tissue at its posterior margin.

The major disadvantages of ultrasound are that the resolution is poor compared with CT or MR; the examination depends on the skill, experience, and expertise of the sonographer; and the presence of bone or gas interferes with image production, limiting its utility in many anatomic areas.

Technologic advances in ultrasound have led to improved image resolution and greater diagnostic capability. Doppler imaging for blood flow improved markedly in the early 1990s, and, although the utility of Doppler waveform analysis in distinguishing malignant from benign disease has been limited, the ability of the method to detect intravascular thrombus, both malignant and benign, has proven to be quite valuable in tumor staging, [29] in assessing for complications of thrombogenic chemotherapeutic agents, and in providing guidance for placement of central lines.

**Computed Tomography**

A CT image represents a display of a thin section of anatomy. However, rather than being produced as are conventional plain films by radiation from a stationary x-ray tube striking a piece of film after passing through the patient, with CT the x-ray source is a fan-shaped beam produced by an x-ray tube that rotates 360 degrees around the body part being examined. Instead of film, the x-rays strike a series of small detectors that convert the energy into electrical signals. These thousands of signals are fed into a computer, which analyzes and constructs an image that can be displayed on the computer console. By changing various settings on the console, the radiologist can manipulate the image to bring out those features of particular interest. For instance, the images can be viewed to highlight the details of the highly radiodense bones or the largely radiolucent lungs. The image can be photographed on film for interpretation and storage or can be archived on tape or disc and accessed electronically.

The patient is placed on a movable table and the body part to be examined is positioned within the gantry of the CT unit, a structure that looks like an elongated doughnut. Because the geometry of satisfactory image production necessitates a relatively small diameter for the gantry, most scanning must be performed in transaxial cross-section, the images being oriented perpendicular to the long axis of the body.

Studies performed with iodinated intravascular contrast are typically more informative than those performed without such contrast. In the head, intravenous contrast material typically increases the conspicuity of brain pathology be it neoplastic, inflammatory, or ischemic in nature and, in the case of tumors, is particularly helpful in differentiating neoplastic tissue from surrounding edema. In the body, intravenous contrast is useful for optimal assessment of the parenchyma of the liver, spleen, kidneys, and adrenal glands, evaluation for intratumoral necrosis, and differentiation of vascular from nonvascular structures, including lymph nodes ( Fig. 9-10). Although there is a small but definite incidence of morbid and even fatal reactions to traditional hyperosmolar ionic iodinated contrast material among adults, the incidence of such reactions is so low in children that ionic material can be used with a high degree of safety in the pediatric population. [30] Nevertheless, the increased safety of non-ionic, low-osmolar contrast materials has persuaded most pediatric radiologists to use them despite the considerably greater financial cost of the non-ionic agents. The primary concern about the use of intravenous contrast material in children is potential compromise of renal function; this can be obviated by having patients well hydrated before the procedure and maintaining the total intravenous dose of iodinated contrast material generally at a level not greater than 2 to 3 mL per kg of body weight, with a maximum dose of 250 to 300 mL. (Of note, although such high total doses may be necessary for angiography, most CT

examinations, even in large patients, can be accomplished with less than 200 mL of contrast.) Iodinated contrast material is relatively but not absolutely contraindicated in patients with anuria, renal failure, combined liver and hepatic dysfunction, severe thyrotoxicosis, myeloma, and suspected or known pheochromocytoma.

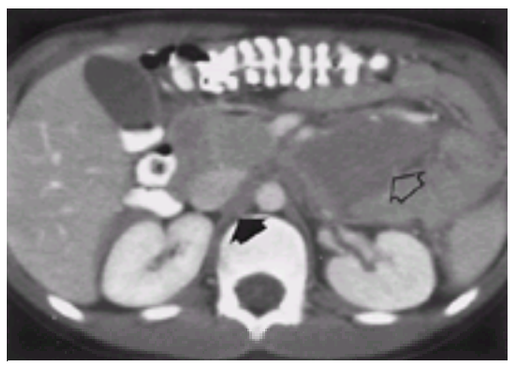

**FIGURE 9-10.** Burkitt's lymphoma. Scanning electron beam computed tomography demonstrates mesenteric tumor (*open arrow*) and also retroperitoneal lymphadenopathy (*solid arrow*), which is easily distinguished from the contrast-enhanced inferior vena cava anterior and to the right of the tumor and the aorta to the left of the tumor.

Appropriate use of oral contrast material in abdominal and pelvic scanning is critical to differentiate intestinal loops from lymph nodes and soft tissue masses. In children, the use of such material is especially important because of the lack of retroperitoneal and mesenteric fat that in adults surrounds and separates structures, increasing their conspicuity.[31]

Disadvantages of CT include its cost, its relatively high radiation dose, and the need for conscious sedation or general anesthesia in the young patient. Initially, one of the additional disadvantages of CT was its inability to produce images in planes other than the transaxial one. Advances in computer technology, however, now permit the production of computer-reconstructed images in any plane desired. Reconstructing the CT data, however, is cumbersome, and the resulting images are prone to misregistration artifacts caused by patient motion; thus, the multiplanar imaging capability of CT is not quite so robust as that of ultrasound and MR imaging. Three-dimensional reconstruction of CT images is also possible, but this method is not commonly used in the evaluation of oncologic patients, except those with head and neck tumors.[32]

High-resolution CT (HRCT) has greatly enhanced the ability of radiologists to identify interstitial lung disease so mild as to be inapparent on conventional chest radiographs and CT scans.[33] For HRCT, 1-mm thick sections are obtained using the bone reconstruction algorithm on the CT computer, a technique that accentuates parenchymal detail. The major value of HRCT in pediatric oncology is the identification of pulmonary Langerhans' cell histiocytosis ( Fig. 9-11)[34] and interstitial lung disease produced by chemotherapeutic agents. Among other uses, HRCT has also been employed in the evaluation of febrile neutropenic patients and in bone marrow and blood stem cell transplant recipients to evaluate for pneumonias occult to conventional radiography. [35]

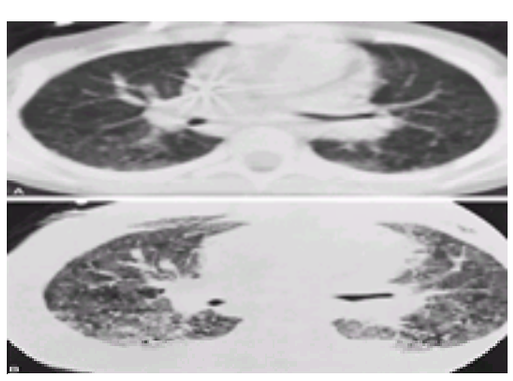

**FIGURE 9-11.** Langerhans' cell histiocytosis. Conventional **(A)** and high-resolution **(B)** computed tomography scans demonstrate diffuse interstitial lung disease with characteristic focal emphysematous changes (i.e., black holes in lungs), seen to better advantage on high-resolution computed tomography.

Spiral CT, also known as *helical* or *volumetric acquisition CT*, has decreased scanning time, reduced need for sedation, and improved resolution. [36] With conventional CT imaging, the CT table moves stepwise 1 to 20 mm at a time, and a CT slice is obtained at each table position. With helical scanning, both table motion and data acquisition are continuous during the course of the examination. Because the resulting helical data is acquired in a volumetric fashion, rather than slice by slice as in conventional CT, there are no “geographic misses” because of small lesions falling between slices. Three-dimensional reconstruction can also be performed with far greater detail than was possible with conventional CT. [37] Compared with conventional CT, spiral imaging can be accomplished more rapidly, at lesser radiation doses, and with smaller volumes of intravenous contrast. The speed advantage of spiral units has been augmented with the recent introduction of multislice CT units that use, at present, up to four detector arrays that simultaneously collect data from multiple locations along the axis of rotation with a gantry that rotates up to twice as fast as traditional gantries.[38,39]

Electron beam CT was initially introduced as a tool for cardiovascular imaging [40] but has proved useful in generalized body imaging as well. Rather than moving the x-ray source and x-ray detectors about the patient, as is done in conventional CT, an electromagnetically steered electron beam is used to generate x-rays that, like those propagated by the rotating source used in conventional CT, strike the patient from all angles, permitting tomographic reconstruction of radiographic detail ( Fig. 9-10). The method permits very rapid scanning even exceeding that possible with multislice helical units, a feature, which though it is of limited consequence for most indications, is helpful in imaging rapidly moving structures such as the lungs and especially the heart. The units are, however, costly, the advantages of the increased speed of electron beam scanning limited, and the imaging of the brain less satisfactory than that obtainable using conventional scanners; consequently, there are relatively few electron beam CT units in use.

The advantages of CT in evaluation of the cranial contents were apparent immediately after its introduction in 1972. Pneumoencephalography has disappeared from the armamentarium of the neuroradiologist, and intracranial arteriography is rarely used for pediatric patients with tumors. As the equipment has become technologically more sophisticated over the past 20 years, speed of imaging and image resolution have improved dramatically, allowing rapid identification of tumor masses, intracranial calcifications, hydrocephalus, and cerebral and cerebellar complications of anticancer therapy. Although MR has supplanted CT as the imaging modality of choice for detailed evaluation of the brain, CT imaging, because it is quicker, less expensive, and more readily available than MR and highly informative, continues to play a major role in the evaluation of intracranial pathology. Although CT, especially after administration of intrathecal contrast, was at one time an important modality for evaluation of the contents of the spinal canal, such evaluations are now almost exclusively performed with MR. MR has also superseded CT in the evaluation of bone tumors and soft tissue masses within the extremities, and within the chest, abdominal, and pelvic walls. Although MR has made inroads, CT remains the primary advanced imaging modality for studying the contents of the thoracic, abdominal, and pelvic cavities, except for the uterus and ovaries, which are optimally evaluated by a combination of ultrasound and MR imaging.

**Magnetic Resonance Imaging**

The role of MR in the evaluation of pediatric oncologic disease has expanded at a rapid pace over the last 15 years. Based on the concept of nuclear MR first described by Bloch[41] and Purcell,[42] clinical MR is based on “alignment” of the body's hydrogen nuclei in a strong, uniform magnetic field. Once aligned, these hydrogen nuclei precess or “wobble” at a frequency proportional to the magnetic field strength. When these hydrogen nuclei are bombarded with radiofrequency (RF)

waves at the precessional frequency, energy is absorbed by the nuclei. The radio waves are then turned off, and the hydrogen nuclei return to their initial alignment, releasing energy that induces voltage in a wire receiving coil. As with CT, MR images represent “slices” through the body that are made up of a specified number of volume elements, called *voxels*. Unlike CT, in which the “slices” are almost always by necessity obtained in the transaxial plane, MR imaging can be performed in any desired plane. Using the same mathematical construct, the Fourier transformation, used in CT and single-photon emission CT imaging, each MR voxel is assigned a shade of gray between white and black that reflects the amount of hydrogen and the rate at which equilibrium is reestablished with the magnetic field after RF excitation.

Three classes of magnets, permanent, resistive, and superconducting, are used for MR. The field strengths used in clinical imaging range from low (0.15 T) to medium (0.35 to 0.50 T) to high (1.5 to 3.0 T) field strengths. High field strength systems have the potential advantage of enhanced signal-to-noise ratio and therefore improved image quality, as well as the potential for MRS. Disadvantages of the high field strength systems include the need for greater shielding (which significantly increases siting costs), significant fringe fields (and therefore an increased risk for attractive force-induced accidents), and an increased potential for biologic hazard arising from the need for higher RF pulse strengths. A less hazardous environment, without significant fringe fields, is afforded by the lower field strength magnets. At lower field strengths, ferromagnetic items (including anesthesia equipment) can be used in the imaging suite without the risks involved at higher field strengths. High field systems require that the imaged body part be placed within a narrow tunnel like bore in the magnet, a condition that can preclude imaging of very large patients or of claustrophobic individuals. Lower fields can be generated with so-called “open” systems in which the imaged body part is placed between two parallel plates that are far less confining than the bore of a high field magnet. [43,44]

A variety of RF coils are used in MR. The shape of the coil, the type of wire used to form it, the number of wire turns, the net capacitance of the coil, and many other factors influence the performance. The coils are designed to maximize their response for the body part studied at the precessional frequency of the spins, thus optimizing the signal-to-noise ratio. [45]

A detailed explanation of the multiple MR sequences available for clinical use is beyond the scope of this book; the reader is referred to one of several excellent texts describing in detail the various MR sequences. [45,46 and 47] In the most commonly used sequence, called *spin echo*, the time between the subsequent RF pulses [i.e., repetition time (TR)] and the time between the initial pulse and data collection [i.e., echo time (TE)] can be manipulated so that a T1-weighted or a T2-weighted image is acquired. An image acquired with a short TR (300 to 600 msec) and short TE (10 to 20 msec) emphasizes the T1 characteristics of the tissue, and an image acquired with a longer TR (>2,500 msec) and a longer TE (>80 msec) reflects primarily the T2 characteristics of the tissue. The T1 and T2 characteristics of tissue reflect the inherent tissue relaxation times, which are exponential time constants that describe the realignment of the tissue protons with the main magnetic field after cessation of the RF pulse. The T1 relaxation time, or longitudinal relaxation time, describes the return of the signal to equilibrium (i.e., alignment with the main magnetic field); the T2 relaxation time, or transverse relaxation time, describes the exponential loss of alignment or phase coherence of the magnetization of the protons. On T1-weighted images, tissues with short T1 relaxation times (e.g., fat) are seen as bright signal intensity, and tissues with longer T1 relaxation times (e.g., water, tumor) are seen as intermediate to low signal intensity. On T2-weighted images, tissues with short T2 relaxation times (e.g., muscle, tendon) are seen as low to intermediate signal intensity, and tissues with longer T2 relaxation times (e.g., water, tumor) are seen as bright signal intensity. Images acquired with TRs and TEs that are intermediate to those used to acquire T1- and T2-weighted images are often referred to as *proton-density images*. The signal characteristics on these images reflect a complex mixture of T1 and T2 relaxation times and the proton density of the imaged tissue.

New sequences seem to appear in every issue of imaging journals. These sequences have focussed primarily on reducing scanning time, suppressing fat signal for better evaluation of lesions, and increasing conspicuity of blood flow. The latter have been so successful that a new subfield of MR imaging, MR angiography, has been created that, in the realm of pediatric oncology, has been particularly useful in the presurgical evaluation of liver tumors and of bone and soft tissue sarcomas and in assessing the central venous system before central line placement (Fig. 9-12). [48,49 and 50] In neuroimaging, considerable attention has been directed recently to diffusion imaging, a technique that characterizes tissues on the basis of the molecular motion of constituent water and which is highly sensitive for the detection of acute ischemia. [51,52]

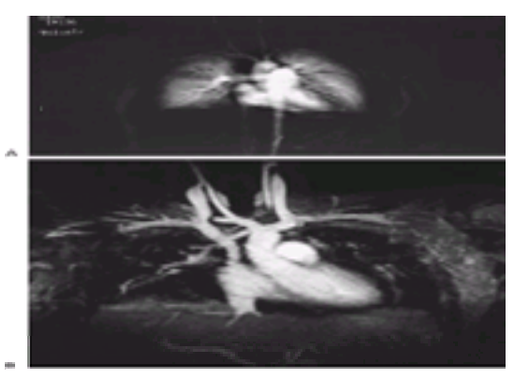

**FIGURE 9-12.** Normal magnetic resonance (MR) angiogram performed before central venous line placement in a patient who had undergone bone marrow transplant for myelodysplastic syndrome after treatment of lymphoma. **A:** Arterial phase contrast-enhanced MR angiogram shows the pulmonary arterial tree, the aorta, and the great arteries well. **B:** More delayed imaging shows both arterial and venous structures and demonstrates patency of the superior vena cava, and the innominate, subclavian, and internal jugular veins.

MR offers several advantages over CT. MR delineates normal soft tissues and discriminates abnormal from normal soft tissues better than CT and does so without the use of ionizing radiation. Iodinated contrast agents are not required, beam-hardening artifacts from bone are eliminated, and imaging can be performed in any plane desired. Disadvantages of MR include its relatively great cost and limited availability as well as its limited ability to detect calcification and to assess the pulmonary parenchyma and the bony cortices. The absence of a widely accepted GI contrast medium impedes the ability of the test to discriminate between normal bowel and intraperitoneal pathology. Finally, MR image acquisition is slower than image acquisition by ultrasound, CT, or conventional radiography, a notably unfortunate feature of the technique as MR images are also highly susceptible to degradation by normal cardiac and respiratory motion, bowel peristalsis, and vascular pulsations. In addition, gross patient motion compromises MR imaging substantially, and, as a consequence, children who would not require sedation for other imaging modalities, including CT, often require sedation for MR imaging.

MR is superior to CT in diagnosing most instances of intracranial tumors, especially in the posterior fossa ( Fig. 9-13). The spinal cord and its coverings, the surrounding intracanalicular soft tissues, the cerebrospinal fluid, and the vertebrae can all be studied without the need for myelography. Evaluation of direct coronal, sagittal, oblique, and transverse images allows more precise localization of neoplastic disease.

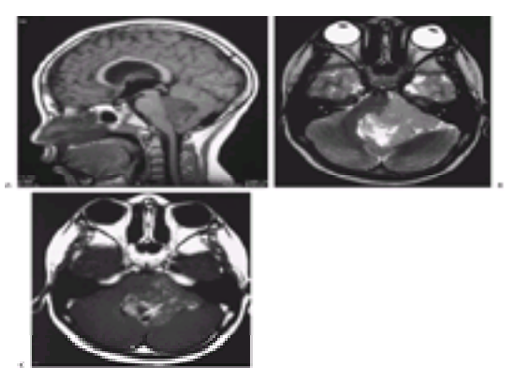

**FIGURE 9-13.** Malignant ependymoma. T1-weighted sagittal **(A)** and T2-weighted axial **(B)** magnetic resonance images demonstrate a mass within the fourth ventricle that extends left laterally through the foramen of Luschka into the left cerebello-pontine angle. **C:** T1-weighted gadolinium-enhanced image demonstrates some irregular enhancement within the lesion.

The calcification that occasionally accompanies pediatric oncologic disease, including brain tumors, has a variable appearance on MR. Although heavily calcified regions can be seen as low signal intensity on T1- and T2-weighted images, calcium that is embedded in a protein matrix or that has a speckled appearance on conventional radiography is often inapparent. The small bones of the skull and face are also often not adequately evaluated by MR. Therefore, if the identification of calcium or the precise evaluation of the small bones of the face and skull is required, CT is recommended in addition to or in place of MR. Conventional radiographs can also on occasion be helpful, especially in evaluating the facial bones and the skull.

Application of MR studies to extracranial structures has advanced rapidly. Although MR is equal to or better than CT in the anatomic definition of many mediastinal [53,54] and intraabdominal tumors,[55,56] it is the direct acquisition of images in the coronal and sagittal planes and the ability to visualize flowing blood in vessels without the need for intravenous contrast that promise an increasing role for MR in the evaluation of extracranial tumors.

MR is thought to be generally superior to CT in the evaluation and staging of musculoskeletal tumors, except in the detection of calcification, early cortical bone erosion, and the identification of periosteal reaction. [57,58,59] and [60] However, as knowledge of the MR appearance of these entities increases, examiners are finding MR equal, and in some cases superior, to CT in these aspects of musculoskeletal tumor evaluation ( Fig. 9-5). The increased accuracy of MR compared with CT in the evaluation of musculoskeletal tumors is particularly important when primary radiation therapy or limb-salvage procedures, or both, are being considered.

One of the difficulties when using MR in the evaluation of musculoskeletal lesions is the delineation of extraosseous soft tissue masses from the edema that surrounds them, as both appear as intermediate signal intensity on T1-weighted images and increased signal intensity on T2-weighted images. When present, soft tissue edema may not be as bright as soft tissue tumor on T2-weighted images and typically has a feathery appearance conforming to the local soft tissue planes. Adding to the confusion is the as yet unresolved question of whether to extend radiotherapy fields to encompass regions of suspected peritumoral edema. Intramedullary tumor is not typically associated with significant surrounding edema so that marrow space signal abnormalities detected by MR correlate closely with the gross extent of tumor at surgical resection, usually within 3 to 4 mm.

There continues to be significant progress in the use of MR for the evaluation of pediatric marrow disease. A statistically significant prolongation of T1 relaxation time in diseased vertebral marrow was first reported in 1986. This allowed differentiation of leukemic from normal marrow based solely on the comparison of T1 relaxation times (Fig. 9-14).[61] Further work using bulk T1 relaxation times[62] and chemical shift imaging[63] confirmed these findings. There is also a prolongation of vertebral marrow T1 relaxation times in relapsed leukemia compared with the T1 relaxation times of leukemia in remission. In several instances, the diagnosis of relapsed leukemia has been made using calculations of MR T1 relaxation times several weeks before the diagnosis was appreciable by bone marrow aspirate or biopsy. There are several reasons for this phenomenon, including the fact that vertebral marrow, as the primary site of hematopoiesis in children, may reflect the changes of leukemia earlier than iliac crest marrow. In addition, iliac marrow sampling error could account for some initially false-negative results. Although an initial bone marrow biopsy is still required for children presenting with new-onset leukemia, MR may ultimately obviate the need for bone marrow aspirates or biopsies during routine follow-up. MR of the marrow is also useful in the evaluation and detection of focal areas of macroscopic lymphoma in patients who are symptomatic but have negative bone scans.[64,65]

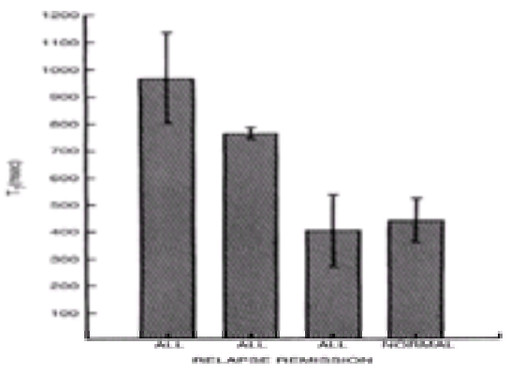

**FIGURE 9-14.** Marrow T1 relaxation times in leukemia. The histogram shows mean T1 relaxation times of the vertebral marrow for each of four groups: newly diagnosed acute lymphocytic leukemia (ALL), leukemia in relapse, leukemia in remission, and normal age-matched controls. The T1 relaxation time is significantly prolonged for children with disease compared with age-matched controls with no evidence of active disease. The standard deviation for each measurement is shown. (From Moore SG, Gooding CA, Brasch RC, et al. Bone marrow in children with acute lymphocytic leukemia: MR relaxation times. Radiology 1986;160:237.)

Despite the fact that the superior soft tissue contrast differentiation of MR permits identification of most tumors without the administration of any intravenous contrast agent and the fact that flowing blood can also be readily identified without resort to contrast administration, intravenously administered gadolinium-containing agents are used in MR much like intravenously administered iodinated contrast in CT to better assess tumor vascularity and endothelial permeability and to evaluate for intratumoral necrosis.[66] The dynamics of contrast uptake by tumors is under current investigation with the belief that a determination of the rate of contrast uptake will be helpful in predicting and documenting a given tumor's response to therapy. [67,68] Recent studies, for example, suggest that in osteosarcoma rapid and pronounced access of contrast to the extravascular space on initial pretherapy dynamic-enhanced MR imaging (DEMRI), a considerable decrease in this access as a consequence of therapy and minimal access at the conclusion of therapy confer a good prognosis. [69] In addition to intravenously administered gadolinium, other MR contrast agents include intravenously administered iron-containing compounds for liver, spleen, and bone marrow imaging, as well as a variety of orally administered materials to manipulate the signal from the GI tract, including perfluoro-octylbromide (PFOB) and agents containing barium, iron, manganese, and lipid.

*In vivo*, MRS remains a promising but unproven clinical tool. A variety of technical and physiologic factors have impeded the transfer of MRS from the laboratory to the clinic, but several major institutions have made major commitments to MRS research, which should bear fruit shortly. [70,71] Investigators have focused their attentions on proton (H) and phosphorous (P31) magnetic spectroscopic imaging (MRSI).[72] H-MRSI of cerebral neoplasms, a technique that can determine the relative concentrations of choline and *N*-acetyl-aspartate within tissues, appears to be particularly promising in predicting outcome for patients with a variety of brain tumors. [73]

There are few risks involved in MR imaging. Although there are no known adverse biologic effects on human subjects from static magnetic fields of the strengths in clinical use,[74] a number of known bioeffects may potentially cause physiologic changes at higher field strengths greater than 2 T. These result primarily from the RF and rapidly changing magnetic field gradients that are used to spatially encode the image data. This exposure to RF fields results in the generation of heat and the formation of electric current within the body tissues. Large metallic implants may absorb RF energy and heat the local area, but the temperature elevation is minimal, and the heating of these metallic implants is thought to be of no clinical consequence. [75] Ferromagnetic metals, such as iron, copper, cobalt, type 400 stainless steel, and nickel, are more likely to interact with the magnetic field than nonmagnetic materials, such as silver, tantalum, and type 300 stainless steel. Nonmagnetic material is used in orthopedic devices, surgical clips, and suture material. The interaction of ferromagnetic objects with the magnetic field can result in movement or torque of the object, induction of electric currents, heating, and MR signal distortion. Contraindications to MR therefore include exposure to ferromagnetic particles, particularly when these particles may be lodged within the eyes or CNS. In general, there is no contraindication to imaging a child with intraabdominal surgical clips. Many of the older intracranial aneurysm clips are ferromagnetic, and imaging of patients with such ferromagnetic clips is contraindicated. Most prosthetic heart valves manufactured after 1964 are not ferromagnetic, but consultation with the radiologist is recommended before ordering an MR examination for a child with a prosthetic heart valve. Most stainless steel orthopedic implants, including those used for scoliosis and internal fixation, are not significantly affected by imaging at the field strengths in clinical use. However, these nonferromagnetic metals can occasionally distort the MR image.

Cardiac pacemakers are affected by induced current caused by the changing field gradients and by the motion of the patient as she or he enters and leaves the static magnetic field. Because this can result in damage or malfunction of the pacemaker, MR examination of these patients is not recommended. As long-term studies of the effects of MR imaging on human fetuses are not available, scanning of pregnant women should be undertaken with caution. Nevertheless, MR imaging of pregnant women has been performed without apparent detriment to the mother or the fetus, and the technique has in fact been advocated for the prenatal assessment

of complex fetal anomalies inadequately elucidated by ultrasound.

The role of MR in the evaluation of pediatric malignancy has evolved rapidly. MR is unequivocally the imaging study of choice for CNS tumors, [76] musculoskeletal tumors,[77] and lesions of the chest and abdominal and pelvic walls. It is complementary to ultrasound in the assessment of the female genital tract and is currently being widely investigated for the evaluation of intrathoracic, intraabdominal, and intrapelvic malignancies.

### Interventional Radiology

During the past decade, image guided interventions have played an increasing role in the diagnosis and therapy of children with cancer. Needle biopsies of various organs under fluoroscopic observation have been done for some years, but the development of ultrasound, CT, and, most recently, MR guidance for needle biopsy has greatly increased the utility of this procedure. Recently developed ultrafast CT and MR techniques, so-called CT and MR "fluoroscopy," have further facilitated image-guided intervention. Lesions in the chest, liver, retroperitoneum, abdomen, and bone are readily accessible to biopsy procedures with appropriate imaging guidance (Fig. 9-15).[78,79,80 and 81] Diagnostic accuracy of 95% has been reported.[82] In experienced hands, the procedures are accurate and safe, although they may require anesthesia in young children. Because small-bore needles are frequently used, cytologic examination by an experienced pathologist is typically necessary to determine whether a biopsied lesion is benign or malignant. Often, the precise nature of a malignancy cannot be diagnosed, and for this reason thin-needle biopsies have been more useful for the determination of recurrent disease than for making a specific primary diagnosis. If a specific histologic diagnosis is needed from a percutaneous biopsy, larger-bore aspiration needles or cutting needles can be used. However, the use of these needles entails a higher risk of complications, especially post-biopsy bleeding. Patients undergoing such procedures often undergo a preparatory screen of clotting function, and these procedures, like all other image-guided interventions, should be performed by an experienced radiologist capable of treating potential complications.

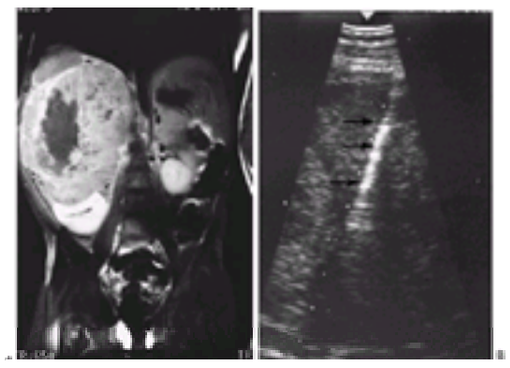

**FIGURE 9-15.** Neuroblastoma. **A:** Coronal fat-saturated, gadolinium-enhanced, T1-weighted magnetic resonance image demonstrates a centrally necrotic mass above the right kidney. **B:** Percutaneous biopsy under ultrasound guidance yielded neuroblastoma. Note the echogenic biopsy needle within the lesion ( *arrows*). (Courtesy of Dr. Taylor Chung, Department of Diagnostic Imaging, Texas Children's Hospital, Houston, TX.)

Interventional radiologists perform vascular catheterization for infusion of chemotherapeutic agents especially in cases of hepatic malignancies and for embolization of tumors.[83,84] They can also radioablate some tumors percutaneously. In many children's centers, radiologists create gastrostomies and place central lines and enteric feeding tubes.

Interventionists have also been active in the treatment of complications of tumor and of antitumor therapies. Such treatments include, but are not limited to, relief of biliary and urinary tract obstruction, endovascular stenting, percutaneous cholecystostomy, and percutaneous abscess drainage. [85]

## GENERAL CONCEPTS OF PEDIATRICTUMOR IMAGING

### Diagnosis

Although details of the diagnostic imaging of specific tumors are discussed in subsequent chapters of this text, some basic guidelines for the imaging of children with malignancies are offered at this juncture ( Table 9-3).

**TABLE 9-3. RECOMMENDED IMAGING STRATEGIES FOR PATIENTS WITH SUSPECTED MALIGNANCIES**

#### *Central Nervous System Tumors*

Although cranial CT is an excellent tool for the evaluation of the CNS in children with neurologic symptoms, MR has become the study of choice. [86] One of the particular problems with cranial CT in children has been adequate evaluation of the posterior fossa because of the bone artifacts produced on CT scans. Because most CNS tumors in childhood are located in the posterior fossa, MR should be used because of its superior imaging capabilities for infratentorial lesions ( Fig. 9-13). Although no imaging study can replace histologic diagnosis of CNS tumors, the characteristic location and imaging features of many brain tumors in children permit reasonably reliable presurgical diagnosis. MR has also become the modality of choice for identifying lesions of the spinal cord and its coverings. [87] The need for plain film myelography and for spinal CT with intrathecal contrast material has been virtually eliminated by MR. A thorough discussion of imaging studies in the evaluation of the CNS can be found in Chapter 27.

#### *Thoracic Tumors*

Primary tumors of the bronchi and lungs, such as pulmonary blastoma and adenoma, are extremely rare in children. They are commonly evaluated by a combination of conventional radiography and CT imaging. Occasionally, MR imaging can be helpful. Most malignancies involving the pulmonary parenchyma, however, are metastatic in nature and are discussed in the portion of this chapter devoted to tumor staging.

Primary tumors of the mediastinum are best defined by the compartment in which they arise. Tumors arising in the posterior mediastinum are largely of neurogenic origin. Neuroblastoma is the most common malignant tumor of the posterior mediastinum. Erosion of ribs, widening of spinal neural foramina, and calcification of the mass are plain film signs that suggest the correct diagnosis ( Fig. 9-16). Although the differential diagnosis is extensive, the common benign lesions have radiographic features that usually differentiate them from neuroblastoma, ganglioneuroma, and ganglioneuroblastoma. Neurenteric cysts for instance are always associated with

congenital anomalies of the thoracic spine whereas neurofibromas are frequently associated with acute-angle scoliosis and multiple small paraspinous masses at several levels along the spine. Calcifications are also not present in these two benign conditions.

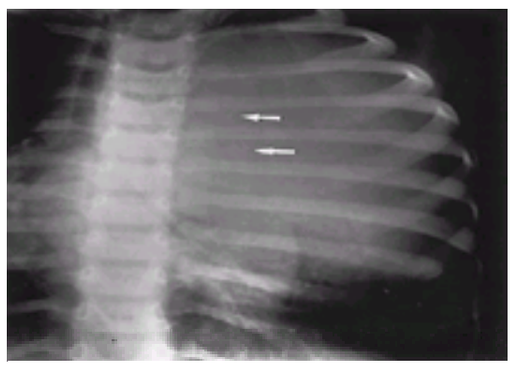

**FIGURE 9-16.** Thoracic neuroblastoma. An overpenetrated anteroposterior view of the chest demonstrates a large mediastinal mass with spreading of upper ribs, erosion of several posterior ribs, and speckled calcifications ( *arrows*).

Cross-sectional imaging is essential in the evaluation of a possible posterior mediastinal neuroblastoma. CT is typically performed, although MR yields more definitive information regarding the relationship of the mass to the neural foramina and spinal canal ( Fig. 9-6). CT can strongly suggest a diagnosis of neuroblastoma by depicting calcification within the mass (90% of neuroblastomas are calcified on CT, but only 50% are calcified on plain film radiography). [88] MR is less sensitive for the detection of intratumoral calcification than is CT. [89]

The middle mediastinum may be involved by lymphadenopathy secondary to leukemia or lymphoma, but this rarely occurs in the absence of anterior mediastinal lymphadenopathy or thymic infiltration. Acute myelogenous leukemia and chronic lymphocytic leukemia may be exceptions. Plexiform neurofibromatosis and juvenile fibromatosis may involve the middle mediastinum as a large infiltrating mass rather than the multiple paraspinous masses more typically seen in neurofibromatosis. Although histologically benign, plexiform neurofibromatosis and juvenile fibromatosis are potentially fatal because of involvement of the tracheobronchial tree or the great vessels. CT is useful for evaluation of the middle mediastinum. [89] As in any CT evaluation of the mediastinum, intravenous contrast material should always be used in an attempt to differentiate cardiovascular structures from abnormal masses. Numerous studies of MR of the mediastinum suggest that this method will likely supplant CT, [90] but CT continues to be the procedure of choice in most centers.

Evaluation of the hilar lymph nodes is particularly important in Hodgkin's disease but also may be useful for other tumors. Studies comparing MR and CT in the initial diagnosis[91] and follow-up[92] of patients with Hodgkin's disease have been performed. On MR and CT scans, lymphadenopathy is appreciated as nodal enlargement. However, no definite size criterion of nodes allows for separation of normal from abnormal mediastinal nodes in children. In adults, a lymph node exceeding 1 cm in diameter is believed to be pathologic. In infants and young children, hilar lymph nodes are not usually seen, and their presence should be considered abnormal. No signal criteria on MR examination allow accurate differentiation of benign, hyperplastic nodes from neoplastic nodes. However, MR has a distinct advantage in the evaluation of the hili because vessels can be easily distinguished from nodes without the use of intravenous contrast. Flow-sensitive cine MR studies of the mediastinum can be performed in cases of suspected compression or invasion of vessels by enlarged nodes.

The anterior mediastinum is the compartment most frequently involved by malignant disease, typically leukemia or lymphoma ( Fig. 9-8). These diseases may cause anterior mediastinal lymphadenopathy, may produce infiltration of the thymus by malignant cells, or may cause both of these processes to occur. Plain film radiographic analysis of anterior mediastinal masses in children can sometimes be difficult because of the wide range of normal thymic size. The identification of malignancy within the thymus itself is complicated by the fact that the gland can be quite big, especially in infants and young children, and be entirely normal. Also, the gland can be involved by malignancy without being strikingly enlarged. Often, the diagnosis of intrathymic neoplasm is simplified when a prominent thymus is seen in conjunction with lymphadenopathy in other areas of the mediastinum, such as the paratracheal, tracheobronchial, and hilar regions. In the absence of associated lymphadenopathy, the finding on conventional radiographs of a loss of the normal wavy contours of the thymus may suggest pathologic infiltration of the organ. Aside from potentially demonstrating heterogeneous radioattenuation and enhancement of the organ or an alteration of its typically triangular shape in cases of thymic neoplasia (Fig. 9-17), CT often does not definitively assess the thymus for tumor. [93]

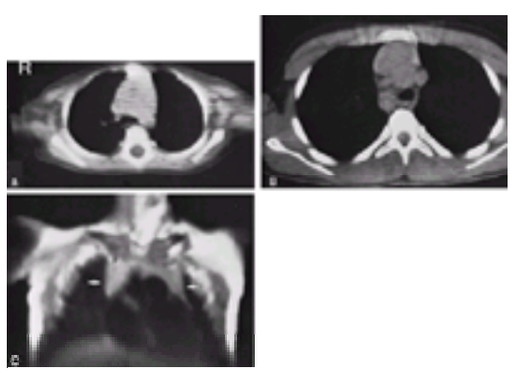

**FIGURE 9-17.** Thymus gland. **A:** Computed tomography scan through the thymus shows a normal triangular gland between the heart and sternum. **B:** A rounded, tumor-infiltrated thymus is seen in a 14-year-old girl with Hodgkin's disease. **C:** A T1-weighted coronal scan of the chest of an 8-year-old boy demonstrates both lobes of the thymus (*arrows*) to good advantage.

MR studies of the thymus may be able to differentiate thymic abnormalities from normal thymus in many instances. [94] On MR, lymphoma of the thymus can be seen as asymmetric or diffuse enlargement of the gland. There may be marked inhomogeneity of the thymus, with intermediate signal intensity on the T1-weighted image and bright signal intensity on the T2-weighted image, which may be caused by underlying necrosis or cystic degeneration ( Fig. 9-18). The normal thymus has a homogeneous intermediate signal intensity on T1-weighted images, with a homogenous mildly increased signal intensity (similar to that of subcutaneous fat) on T2-weighted images. This pattern, combined with the size and contour of the gland, often allows differentiation of normal from abnormal thymus on MR scans. Gallium and PET scanning can also be helpful in identifying malignant thymic disease and specifically in differentiating thymic rebound from recurrent tumor.

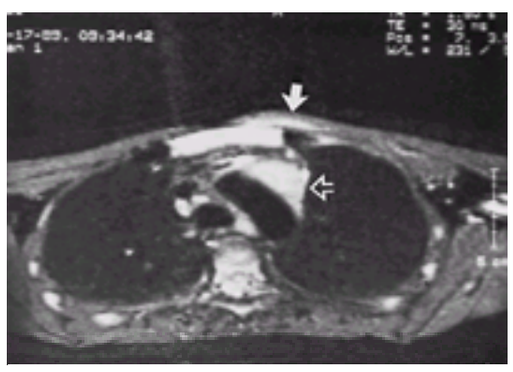

**FIGURE 9-18.** Axial short T1 inversion recovery image of a patient with lymphoma shows chest wall involvement (*closed arrow*) and paraaortic involvement (*open*

*arrow*). The sternal marrow signal is also very high. (Courtesy of Dr. Colleen Bergin, Stanford, CA.)

Pleural involvement by malignant tumors is most typically from metastatic disease and is discussed in the portion of this chapter devoted to tumor staging. Pleural involvement by lymphoma may be evaluated by MR imaging or CT.

Chest wall tumors may arise from bone or soft tissues. The most common malignant soft tissue lesions are rhabdomyosarcoma, extraosseous Ewing's sarcoma, and primitive neuroectodermal tumor or Askin's tumor. Although plain films may demonstrate a nonspecific mass, CT allows evaluation of the extent of tumor, is more sensitive for bony erosion, and may accurately determine the site of origin of tumors arising in unusual places such as the diaphragm. MR can also be used to evaluate chest wall tumors and is superior to CT in evaluating individual components of the chest wall, including muscle, fat, lymph nodes, vessels, and nerves ( Fig. 9-1). By using a surface coil, the marrow and subtle cortical detail of the ribs can usually be evaluated. However, if the cortex is not adequately seen on the MR examination, CT can be used as an ancillary examination specifically to evaluate the cortical bone. Primary bone tumors, especially Ewing's sarcoma and some osteogenic sarcomas, may arise from the ribs, thoracic vertebrae, or scapulae and manifest as chest masses. CT and MR evaluation may give specific diagnostic information as well as general information concerning the extent of tumor and the presence of mediastinal disease; CT is superior in the evaluation of pulmonary metastases.

***Abdominal Masses***

The plethora of diagnostic imaging examinations available for evaluation of abdominal masses in infants and children requires a logical and analytic approach to avoid unnecessary expense, radiation, and potential morbidity. In neonates, more than 85% of abdominal masses are nonmalignant. [95] A combination of plain films and abdominal ultrasound usually identifies the organ of origin and, if the mass is not solid, suggests its benignancy. Renal abnormalities account for more than one-half of the palpable abdominal masses in the neonatal period, with hydronephrosis and renal cystic dysplasia accounting for the majority of these. Ultrasound can usually determine a specific diagnosis in these cases.

The next most common cause of abdominal masses in the neonatal period, cephalad extension of pelvic, usually ovarian, lesions in infant girls, is also readily amenable to ultrasound diagnosis. Ultrasound has also been particularly useful in differentiating neonatal adrenal hemorrhage from neonatal adrenal neuroblastoma. Lesions that develop central hypodensity and, most important, decrease in size over time are likely evolving hemorrhages whereas those that increase in size are presumed to be neuroblastomas until proven otherwise.[96] If a combination of plain film radiography and ultrasound identifies a solid tumor arising from the retroperitoneum or within the liver, the probability of malignancy increases, and further imaging evaluation by either CT or MR is usually necessary.

Nonmalignant GI abnormalities presenting as palpable abdominal masses in neonates, such as large duplication or choledochal cysts or a distended stomach or bowel segment, are commonly accompanied by bowel obstruction evident on conventional abdominal radiographs and can be further evaluated by the appropriate fluoroscopically monitored GI contrast examinations. Sonography and scintigraphy can also be helpful.

In infants beyond the neonatal period and in children, the likelihood that an intraabdominal mass reflects malignant rather than benign disease increases. Nevertheless, malignancy still accounts for less than one-half of the palpable abdominal masses in infants and children. Plain film radiography and ultrasound again should be the primary screening imaging modalities, with nuclear scintigraphy, CT, and MR imaging used for further evaluation as indicated. As in neonates, cystic or fluid-filled masses typically are benign; solid masses always have to be considered malignant until proved otherwise.

***Retroperitoneal Masses***

Most solid extracranial tumors in infants and children arise from the kidney or adrenal gland. Mesoblastic nephroma, a generally benign tumor, accounts for the majority of solid renal masses in children younger than 1 year of age, but the tumor is indistinguishable from Wilms' tumor on imaging examinations and requires biopsy for definitive diagnosis. For children older than the age of 1, nearly all solid tumors arising in the kidney are Wilms' tumors. The combination of ultrasound and CT typically provides sufficient information about the size and location of the mass, vascular invasion or compromise, and lymph node and hepatic metastases for surgical planning (Fig. 9-9). Some surgeons, however, have questioned the need for routine CT examinations of Wilms' tumor patients, and the accuracy of radiographic staging has been controversial. [97],[98] and [99]

Most nonrenal retroperitoneal solid tumors are neuroblastomas. [100] No current imaging modality can reliably differentiate neuroblastoma from ganglioneuroblastoma and ganglioneuroma. Although some teratomas are indistinguishable from neuroblastomas on imaging studies, most of them have sufficient evidence of multitissue origin on ultrasound and CT to enable a correct diagnosis to be suggested. Because most teratomas contain fat, MR is an excellent tool for making a precise diagnosis.

Wilms' tumors and neuroblastomas may be so large as to make accurate assessment of the organ of origin difficult by ultrasound, [101] but CT with intravenous contrast enhancement is usually quite accurate for this purpose. Several studies have suggested that MR may be superior to ultrasonography and CT in the diagnosis and staging of Wilms' tumor.[102] However, these studies were performed with small numbers of patients, and MR is performed routinely in such patients in only a limited number of institutions. The primary potential advantage of MR over CT is the ability of MR imaging to evaluate the renal vein, inferior vena cava, and other surrounding vascular structures without the need for intravenous contrast. A second advantage is the ability to directly visualize the tumor in the coronal and sagittal planes. This allows a more accurate evaluation of the liver and surrounding structures and can aid in differentiating hepatic, renal, and adrenal tumors ( Fig. 9-19). On MR, most Wilms' tumors are heterogeneous, with primarily low signal intensity on T1-weighted images and heterogeneous areas of intermediate and increased signal intensity on T2-weighted images. Much of the heterogeneity appreciated on the T2-weighted images is secondary to regions of necrosis and hemorrhage within the tumor.

**FIGURE 9-19.** Wilms' tumor. **A:** Ultrasound demonstrates a large mass (*arrow*) within the inferior vena cava (IVC), causing obstruction of hepatic veins. **B:** Computed tomography (CT) demonstrates a large, right renal mass with massive retroperitoneal adenopathy (*solid arrows*) surrounding an opacified aorta (*open arrow*). **C:** CT at a higher level demonstrates tumor thrombus in the IVC (*arrow*). **D:** CT at a still higher level demonstrates tumor thrombus in right atrium (*arrows*) and right pleural effusion. **E:** An axial magnetic resonance (MR) scan demonstrates tumor thrombus in the right atrium and a right pleural effusion (same level as **D**). **F:** Coronal MR scan demonstrates tumor from the right kidney extending into the IVC and right atrium (*arrow*).

Other retroperitoneal masses can be identified, but specific diagnoses may be difficult to make. Rhabdomyosarcoma, fibromatosis, fibrosarcoma, and other tumors do not have specific imaging characteristics, although precise evaluation of their location may suggest the correct diagnosis. Patients with lymphoreticular malignancies commonly have nonspecific retroperitoneal lymphadenopathy, but other manifestations of the disease usually lead to the proper diagnosis.

### *Intraperitoneal Masses*

Most intraperitoneal masses in infants and young children are either related to abnormal bowel and typically diagnosable by a combination of plain film and barium studies, or are cystic, likely benign, and diagnosable by ultrasound. Hepatic tumors and lymphoma account for the majority of intraperitoneal abdominal masses that are identified as solid by ultrasound. Lymphomas can appear relatively hypoechoic, mimicking fluid-filled masses, but careful ultrasonic examination usually can correctly determine the solid nature of the mass and should be followed by abdominal CT scanning for staging purposes.

MR cine angiography is increasingly used in the setting of hepatic neoplastic disease to evaluate the hepatic vasculature and intravascular extension of tumor ( Fig. 9-20). Several studies have compared MR with CT in the evaluation of hepatocellular carcinoma. [103,104] These studies showed that MR is superior to CT in the detection of a pseudocapsule, the evaluation of vascular involvement, and the identification of internal tumor architecture. MR also was shown to be superior to CT in identifying tumor recurrence. On MR, liver tumors usually demonstrate intermediate signal intensity on T1-weighted images and increased signal intensity on T2-weighted images. The internal architecture is variable and ranges from homogeneous to markedly heterogeneous. [105] Calcification is usually not well seen on MR examination. MR angiography commonly performed with intravenous bolus injection of gadolinium contrast agents permits imaging of the hepatic arterial supply, portal vein, and hepatic veins. The role of contrast-enhanced MR imaging of the substance of the tumor itself is not yet established. Preliminary results indicate that DEMRI may differentiate hypovascular from hypervascular lesions and be prognostically useful. [106]

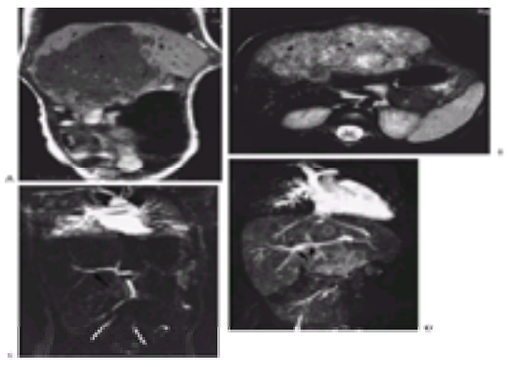

**FIGURE 9-20.** Hepatoblastoma. Coronal T1-weighted **(A)** and axial T2-weighted **(B)** magnetic resonance (MR) imaging shows a large intrahepatic tumor (*stars*). **C:** MR arteriogram demonstrates the hepatic artery (*arrow*). **D:** MR venogram demonstrates the central left and right portal veins (*closed arrows*) and laterally displaced left hepatic vein (*open arrow*). (Courtesy of Dr. Taylor Chung, Department of Diagnostic Imaging, Texas Children's Hospital, Houston, TX.)

### *Pelvic Tumors*

Rhabdomyosarcoma is the most common pelvic tumor in boys; ovarian tumors and rhabdomyosarcomas must be considered in girls. Although cystography and excretory urography have been widely used in the past for evaluation of rhabdomyosarcomas arising in or near the urinary bladder, MR and contrast-enhanced CT scanning allow evaluation of tumor masses in the intravesical and extravesical areas and supply information both about the primary tumor and about any intraabdominal metastases that might be present.

MR has some advantages over CT in the evaluation of pediatric pelvic tumors, and in some institutions MR is the examination of choice. The greatest advantage of MR over CT is its ability to directly image in the coronal, sagittal, and axial planes. This is particularly useful in delineating rhabdomyosarcoma, for which invasion of the posterior aspect of the bladder wall and the anterior aspect of the rectum is an important finding. The ability to evaluate the bladder and to assess the upper urinary tracts for obstruction without the use of intravenous contrast is another advantage. Both MR and CT can identify enlarged pelvic lymph nodes, an important capability critical to staging of intrapelvic neoplasms. As stated, the disadvantages of MR include its high cost, its limited availability, its susceptibility to motion, and the absence of a widely utilized bowel contrast agent.

Most ovarian tumors are cystic and benign and are identified as such by ultrasound. Teratomas may appear echogenic or echolucent but frequently have mixed characteristics and calcifications that may suggest the correct diagnosis. Although malignant ovarian tumors are uncommon in childhood, they appear solid on ultrasonographic examination or have mixed solid and cystic areas ( Fig. 9-21). If necessary, they can be more thoroughly evaluated by means of pelvic and abdominal MR or CT scanning.

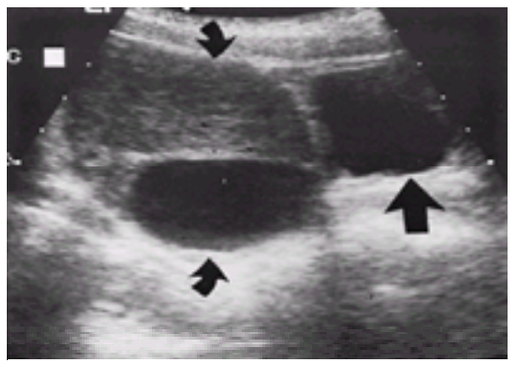

**FIGURE 9-21.** Ovarian dysgerminoma. Pelvic sonogram discloses a mixed solid and cystic tumor (*curved arrows*) superior to the bladder (*straight arrow*).

### *Miscellaneous Abdominal Masses*

Malignant disease involving the spleen characteristically is infiltrative in nature and causes splenomegaly rather than a discrete splenic mass. This is especially true of leukemia. Lymphomatous involvement of the spleen can be diffusely infiltrative in nature, can result in discrete tumor foci, or can cause a combination of both of these types of disease. Lymphoreticular malignancies isolated to the spleen are extraordinary, so the diagnosis is usually apparent on the basis of extrasplenic lesions. Splenic cysts are typically hypoechoic, and careful ultrasonography usually obviates the need for additional studies. Discrete hepatic and splenic metastases from solid tumors and lymphomas can be identified by CT if they measure at least 3 mm in diameter, and many smaller lesions are also detectable by this modality. MR has a similar sensitivity to CT in evaluating the liver and spleen, and ultrasound is only slightly less sensitive. Of note, because most patients with primary abdominal tumors have CT or MR scans and many have ultrasound studies as well, these examinations of the primary tumors are typically sufficient to evaluate for any accompanying hepatic and splenic metastases that might be present.

Although tumor-laden lymph nodes in the porta hepatis may cause biliary obstruction, most biliary tract pathology in children is cystic and benign and easily evaluated by ultrasound and nuclear medicine studies. Most pancreatic lesions in children are also cystic and benign. They are commonly evaluated by ultrasound but can also be studied by CT and MR. MR cholangiopancreatography has proven to be effective even in very young patients and in many institutions has largely replaced endoscopic retrograde cholangiopancreatography in the evaluation of the pancreaticobiliary tree. Rarely, solid masses in the pancreas can be found, and these typically represent metastatic disease, lymphoma, pancreaticoblastoma, or rare endocrine tumors. Unless the patient already has a known primary, the discovery of a solid pancreatic abnormality on ultrasound should prompt CT or MR scanning for further evaluation.

### *Extremities*

Osteogenic sarcoma and Ewing's sarcoma are the most common primary bone tumors of childhood, but when bone lysis is encountered, all members of the group of conditions known as the “small round cell tumors of childhood” must be considered in the differential diagnosis (see Chapter 8). These tumors include metastases, especially from neuroblastoma, rhabdomyosarcoma, Wilms' tumor, leukemia, and lymphoma, as well as Langerhans' cell histocytosis and osteomyelitis. An algorithmic approach based on numerous criteria may narrow the differential diagnosis, [107] but an exact diagnosis is not always possible. Most osteogenic sarcomas make tumoral bone and can be diagnosed on plain film radiography ( Fig. 9-5). However, not all osteogenic sarcomas manifest with obvious malignant bone formation, and it not always possible to make a definitive diagnosis, especially in the earliest stages of the disease (see Chapter 35). Patients presenting with pain and unusual fractures should have osteogenic sarcoma and other malignancies considered ( Fig. 9-22). Small destructive lesions of bone associated with soft tissue masses should also raise the possibility of early osteogenic sarcoma. When a combination of clinical information and radiographic appearance makes a primary bone tumor likely, an MR scan should be obtained, which typically very accurately demonstrates the extent of intramedullary disease and of associated extraosseous malignancy and edema and can do so in multiple planes.[108]

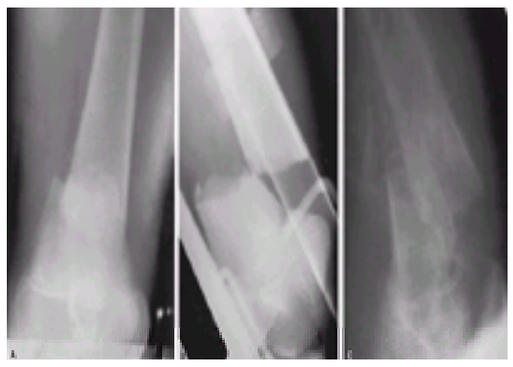

**FIGURE 9-22.** Osteosarcoma in a 13-year-old boy. Anteroposterior **(A)** and lateral **(B)** views of the distal femur show a transverse fracture after trauma. Transverse fractures are unusual after infancy and frequently indicate an underlying pathologic process. **C:** Follow-up examination 3 weeks later demonstrates irregular edges of the fracture and tumoral new bone, suggesting a malignant process.

## Staging

Imaging procedures are invaluable in the staging of most solid tumors and may come to play a role in the evaluation of acute leukemia ( Table 9-4). Although the staging procedures used depend on tumor type and location, the underlying principle is evaluation of local and distant extent of tumor. Local extent is usually evaluated by the primary diagnostic modalities discussed previously, and this section deals with the evaluation of common areas of metastatic disease.

| |
|---|
| Central nervous system |
| MR |
| Lungs and mediastinum |
| CT without contrast for lungs only and with and without contrast for mediastinum |
| Liver |
| Enhanced CT (or MR) for primary evaluation; ultrasound for ease of follow-up |
| Retroperitoneal and intraperitoneal lymph nodes |
| CT |
| Bones |
| Radioisotope bone scan with plain films of areas positive on bone scan |
| Exceptions: Langerhans' cell histiocytosis and neuroblastoma in which a combination of both plain film skeletal surveys and total body bone scintigrams may be appropriate. |

CT, computed tomography; MR, magnetic resonance.

**TABLE 9-4. RECOMMENDED IMAGING EVALUATION FOR METASTATIC DISEASE**

### *Central Nervous System Metastases*

Metastatic disease to the brain, the spinal cord, and the meninges can be evaluated by CT but is more typically studied by MR. Of note, a major advantage of MR for detection of metastatic lesions within the spinal canal is obviation of the need for intrathecal contrast material typically used in conjunction with CT scanning. Although there is a lack of signal from cortical bone on MR studies, metastatic involvement of adjacent cranial and vertebral structures can usually be identified on MR by changes in the marrow signal.

### *Pulmonary Metastases*

Although metastases to the lung can be seen on chest radiographs, CT is a far more sensitive imaging modality for this purpose. CT frequently identifies metastases 2 to 3 mm in diameter, which may not be seen on plain chest films (Fig. 9-23). CT also can identify metastatic lesions at the periphery of the lungs, a problem area for plain films. Spiral CT has been especially valuable for cooperative patients because of the lack of “skip areas” found with conventional CT. The major disadvantage of CT has been its inability to differentiate metastases from benign lesions, especially granulomas, which may appear in the lungs. However, children are far less likely to have granulomas than adults, and nodular lesions in the lungs of children with known malignant solid tumors, though they are often benign, should be considered metastases until proved otherwise. Although its ability to assess the lung parenchyma is superb, CT is somewhat less successful in differentiating subtle hilar masses and nodes from normal vascular structures, and when such lesions are potentially present, MR imaging can be helpful.

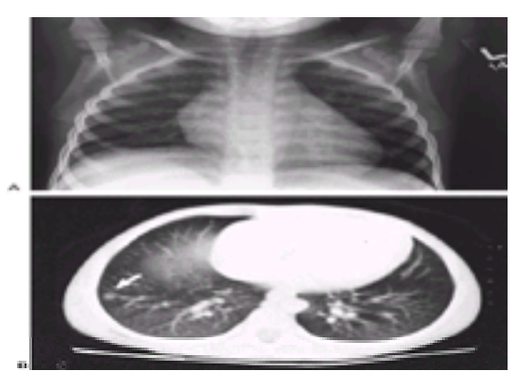

**FIGURE 9-23.** Wilms' tumor. **A:** Anteroposterior chest radiograph demonstrates a clear lung. **B:** Computed tomography of the lungs demonstrates a pulmonary nodule (*arrow*).

Patients with pleural metastases frequently have large effusions, which makes evaluation of the pleural surfaces and the lungs difficult by conventional chest radiography. CT has the advantage of often allowing visualization of underlying thoracic structures even in the presence of pleural effusion ( Fig. 9-24) and can facilitate percutaneous pleural biopsy when necessary. The imaging approach to mediastinal metastatic disease is the same as that for the primary intramediastinal tumors discussed previously.

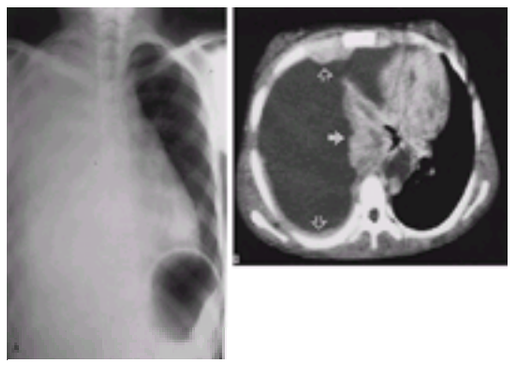

**FIGURE 9-24.** Non-Hodgkin's lymphoma in a 13-year-old boy. **A:** A chest radiograph shows a large right pleural effusion of unknown cause. **B:** A computed tomography scan demonstrates a collapsed lung (*closed arrow*) and pleural plaques of tumor (*open arrows*), one of which was biopsied for diagnosis.

### *Intraabdominal Metastases*

The liver represents the most common site of metastatic disease within the abdomen, and the organ is assessed reasonably well by ultrasound and even better by CT and MR. In many but not all of the studies performed comparing CT to MR in the detection of metastatic disease in adults, MR was found to be more sensitive than CT, even when the CT imaging was performed during the intraarterial infusion of iodinated contrast agent, so-called “CT angiography.” [109,110] Nonetheless, in most instances CT is entirely adequate to investigate possible metastatic disease. As most liver metastases arise from solid intraabdominal tumors, the CT and MR examinations invariably performed to assess the primary lesions suffices to evaluate for possible accompanying hepatic metastatic disease. These studies also evaluate the spleen, adrenal glands, pancreas, and kidneys for possible metastases. Although less sensitive than CT or MR, ultrasound can be a valuable adjunct in the evaluation of metastatic disease, including liver metastases, and is especially useful for short-term interval follow-up studies for which the time, the expense, and, in some cases, the necessity for sedation or anesthesia make CT or MR less feasible.

The retroperitoneal lymph nodes (Table 9-2) can be evaluated for metastases from nonlymphomatous tumors with 92% accuracy by lymphangiography and by CT scans with 84% accuracy.[111] However, CT scanning is not able to differentiate lymph nodes enlarged because of benign disease from those enlarged because of tumor infiltration. CT also suffers from an inability to identify normal-sized lymph nodes that may be infiltrated by tumor. Although reactive hyperplasia causes mild enlargement of lymph nodes, moderate to massive enlargement usually suggests infiltration by tumor. In such cases, CT may give sufficient diagnostic information. If more detailed information is required, lymphangiography can be performed. MR also can identify abnormally enlarged retroperitoneal lymph nodes, but its ability to identify enlarged lymph nodes is not greater than that of CT scanning and it too cannot diagnose tumor in normal-sized nodes nor distinguish between tumor and benign hyperplasia as the cause of enlargement of any particular node.

### *Skeletal Metastases*

Skeletal metastases may be found in patients with most solid tumors, and bony infiltration may be seen in patients with lymphoreticular malignancies, including Langerhans' cell histiocytosis. Radioisotope bone scans are generally more sensitive than plain film radiographs for the detection of metastatic disease and constitute the usual means for the initial diagnosis and the follow-up of bony metastases. [112] An exception to this rule is Langerhans' cell histiocytosis and neuroblastoma in which a combination of both plain film skeletal series and total body bone scintigraphy can be helpful to optimize lesion detection. [113,114 and 115]

In general, CT and MR imaging should be reserved for the evaluation of bony metastases when the patient presents with clinical symptoms (e.g., bone pain) but has negative plain film and scintigraphic results. MR is preferable to CT when evaluating these metastatic lesions because of its increased sensitivity to marrow disease and superior demonstration of associated extraosseous masses and edema, information that is critical if the lesion is to the irradiated or surgically resected. CT can demonstrate the cortical bone better than MR but is seldom necessary. In addition to assessing focal bony metastases, MR is also useful when evaluating for diffuse bone marrow infiltration by tumor, a condition that typically presents with abnormally decreased T1-weighted marrow signal ( Fig. 9-25).

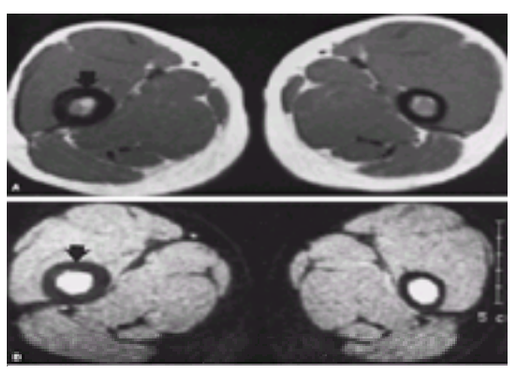

**FIGURE 9-25.** Axial **(A)** T1-weighted and short t inversion recovery (STIR) **(B)** magnetic resonance images through the femora of a child with diffuse bilateral femoral metastases from neuroblastoma. On the T1-weighted image, the marrow signal intensity is intermediate, and it is unclear on this image whether the marrow is abnormal. The cortex surrounding the femur, however, is abnormally thickened (*arrow*). On the STIR image, the bright signal intensity of the marrow belies the diffuse metastatic disease. Thickening of the right femoral cortex is again evident along with some minimal abnormally increased intracortical signal ( *arrow*).

## Guide to Therapy

Accurate assessment of tumor volume and local extent is particularly important when surgery, radiation therapy, or both, are used. Generally, the imaging studies recommended for primary tumors in previous sections of this chapter and in the disease-specific chapters of this book give adequate information for the surgeon or radiation therapist. Diagnostic arteriography is rarely indicated but, as noted, is occasionally performed for liver and musculoskeletal tumors, particularly before resective surgery.

## Evaluation of Therapy

Therapeutic responses can be evaluated with the same imaging modalities used in evaluation of the primary tumor. In most instances, CT or MR is the modality of choice. However, if ultrasound has been satisfactory in delineating the primary tumor, this method should be used for following the response to therapy because it is less costly and requires no sedation or anesthesia. Metastatic lesions are also best followed using the same modality that demonstrated them at the time of presentation and diagnosis.

There is at present considerable controversy regarding the most appropriate parameter to gauge changes in tumor size. Some investigators have advocated the reporting of one, two, or three maximal lengths in orthogonal planes. Others have suggested that the multiple of two maximal lengths in orthogonal planes be used and others that estimates of tumor volume be used.[116,117,118,119 and 120]

Physiologic assessments of therapeutic response by PET, MRS, and quantitative DEMRI may also play a significant role in tumor management in the future.

**Detection of Recurrences**

Recurrent disease can be defined as reappearance of tumor in its original location or as metastases in distant sites. The primary site is usually best followed with the imaging modality used for the initial tumor. Adequate evaluation for metastatic disease requires knowledge of the natural history of the tumor. Chest films, chest CT, craniospinal and extremity MR, bone scans, and abdominopelvic ultrasound, CT, and MR scans are all reasonably used depending on the site of the original tumor.

The vexing problem, which has yet to be resolved, is how often follow-up studies should be obtained. A study of recurrent Hodgkin's disease in children showed that 56% of patients who relapsed developed their recurrences within 2 years and 71% within 3 years of presentation. [121] However, an overall relapse rate of 48% in the years before 1970 has dropped to less than 10% since 1970. This reflects inadequate staging in the early years and improved therapy and better staging in recent years. Close-interval follow-up imaging procedures can detect recurrences, but the population at risk is quite small.

Studies of the value of CT in the follow-up of abdominal neuroblastoma [122] demonstrated patients with stage III or IV disease to be at high risk for recurrence during the first 18 months after presentation. These researchers recommend close-interval follow-ups, with CT scans every 12 weeks during this high-risk period. Patients with stage I and II disease were at low risk of recurrence, and a single CT scan 12 weeks after surgery was recommended. A more recently completed study, however, suggested that in patients with advanced-stage neuroblastoma history, physical examination and selective laboratory evaluation were more sensitive and cost-effective than radiographic imaging in detecting progressive and recurrent disease. [123]

Statistical analyses of recurrent disease are complex but feasible, and several have been performed and published. [121,124,125] One of these studies suggests that follow-up chest radiographs are obtained too frequently for pediatric patients with Hodgkin's disease, [121] and the authors suggested an optimal frequency of every 3 months after the onset of remission for 18 months and then every 6 months for another 3 years for patients with this disease. A study of patients with Ewing's sarcoma suggested that these patients are at risk for bone metastases for 3 years if they had truncal primaries and for 4 years if they had extremity primaries. [125] However, therapeutic results have improved dramatically since this study was done, modifying the natural history of treated Ewing's tumor. A study of bone metastases in patients with osteosarcoma demonstrated a linearly increasing risk for 5 to 29 months after diagnosis. [126]

Although these statistical analyses represent the best way to evaluate the required frequency of follow-up studies, the changing natural history of most treated children's tumors makes accurate assessment of optimal timing of follow-up studies difficult. Table 9-5 suggests a plan of follow-up that fits the current situation.

**TABLE 9-5. RECOMMENDED FOLLOW-UP IMAGING PROCEDURES**

**Complications of Antitumor Therapy**

All three primary modalities used in antitumor therapy (surgery, radiation therapy, and chemotherapy) may lead to complications that can be diagnosed by imaging procedures. Most complications of surgery, including infection, bleeding, scarring, and adhesion formation, are not unique to cancer patients and are not dealt with further in this chapter. Complications of radiation therapy and chemotherapy can be described as direct effects, such as radio-osteonecrosis and cardiomyopathy, or secondary effects, such as steroid-induced ulcers or infections consequent to immunosuppression.

From the viewpoint of the imaging specialist, much attention historically has been paid to the effects of radiation therapy. Children are more likely than adults to develop complications of radiation therapy because growing bone is more sensitive to irradiation than the more stable adult bone. Interference with normal bone growth may lead to shortening of a radiated bone or overall diminution in height from spinal irradiation. [127] In long bones, characteristic deformities similar to those seen in patients with trauma and rickets have been described. [128] Loss of spinal height is best determined clinically, but radiographs typically show failure of maturation of the vertebral bodies in irradiated fields. [129] Spinal irradiation may also lead to scoliosis with secondary loss of height, but the average angle of radiation-induced scoliosis is less than 10 degrees, infrequently leading to clinically apparent abnormalities. Other areas in which the impact of radiation on growth is seen include hypoplasia of the clavicles and the iliac bones when they are included in radiation fields.

Depending on dose-time relations, the impact of radiation on mineralization ranges from mild osteoporosis to frank radio-osteonecrosis. Because profound bone necrosis has a radiographic pattern simulating small-cell infiltration, the differentiation between radiation effect and recurrent or metastatic disease can be difficult on both conventional radiographs and CT. Radio-osteonecrosis does not cause rupture of the bony cortex and tends to be stable over successive examinations whereas infiltrative bone disease usually breaks through the cortex into the subperiosteal region and shows progression over fairly short intervals of time. MR can detect radionecrosis and can often distinguish it from tumor. On the MR scan, there is increased signal intensity for muscle, bone, and bone marrow, and deep fascial planes, which corresponds to the radiation port. Fluid also may be seen in the region. These changes represent the diffuse inflammation and edema associated with radiation necrosis. In the bone marrow, these changes appear feathery and ill defined and usually can be differentiated from focal metastatic lesions.

Radiation-induced tumors of bone are most commonly benign, with osteochondroma being the most frequently observed lesion. [130] These osteochondromas typically arise from growth plates in non-weightbearing bones. However, they can arise in virtually any bone in which the growth plate is irradiated. They have been described in patients receiving doses as small as 12 Gy. Many of these tumors have been removed surgically and have been found to be benign. If not removed, they should be followed carefully with periodic examination, because any osteochondroma has the potential to undergo malignant degeneration.

Radiation-induced malignant tumors are a well-known phenomenon. Osteosarcoma is the most common, although chondrosarcomas and fibrosarcomas are also seen. The latent period for sarcoma development is 4.5 to 27.0 years, with a median time of 11 years and a mean time of 12 years. [131]

Cartilage necrosis may occur when joints are included in the radiation field, and resultant calcification of articular cartilage may be identified on plain films. Similarly, conventional radiographs can demonstrate ischemic necrosis of the humeral heads and femoral heads, [132] although scintigraphy and MR are more sensitive in detecting such necrosis.[133,134] Muscle atrophy may be suggested on plain films but is easily evaluated on MR, manifesting as diminished muscle bulk and increased intramuscular signal on T1-weighted imaging reflecting fatty replacement of muscle tissue.

Radiation can also have significant deleterious effects on nonmusculoskeletal structures. Irradiation of the brain, usually in conjunction with intrathecal chemotherapy,

may lead to leukomalacia and, occasionally, calcification that can be identified on CT [135] and MR scans. Frank brain necrosis may occur with high doses.

The thyroid gland is particularly susceptible to radiation damage, and thyroid cancers may be identified by nuclear medicine studies, ultrasound, CT, or MR. Acute radiation reaction in the lungs is well demonstrated on chest films, appearing as air space and interstitial infiltrates within a well-defined anatomic area corresponding to the radiation field. Acute changes usually appear near the end of therapy or within a month of the completion of therapy and may last 2 to 9 months. If the dose is high enough, chronic interstitial fibrosis may develop that is well circumscribed within the radiation port. CT is more accurate than conventional chest radiographs in detecting the earliest changes of radiation fibrosis. [136] High-resolution CT is particularly sensitive for identifying even minimal pulmonary fibrosis. [33]

The GI mucosa is highly susceptible to radiation damage. Barium studies are the best way to evaluate esophagitis and enterocolitis, because they show mucosal changes and bowel tethering due to mesenteric disease most definitively. CT and ultrasound can, however, also be of help in demonstrating findings of radiation-induced GI tract disease. Neutropenic enteritis, which can occur with total body irradiation for bone marrow ablation, with aggressive chemotherapy, or with a combination of these two therapies, can be assessed by ultrasound or CT. [137,138]

The liver and kidneys can also be damaged by irradiation. Radiation hepatitis has been well defined on radioisotope liver scans as areas of diminished radionuclide uptake corresponding to the radiation portals. Isotope liver scans may be abnormal in both the acute and chronic phases of radiation hepatitis. Because such hepatitis may mimic metastatic disease on scintigraphy, further investigation of a suspicious finding on an isotope liver scan by ultrasound, MR, or CT scanning may be helpful. Irradiation of the immature kidney may result in a failure of normal growth. [139] Serial ultrasound examinations are excellent for determining and comparing renal size and, in such cases, can demonstrate a lack of growth of the irradiated kidney over a period of several years.

The adverse effects of chemotherapy can also be evaluated with imaging studies, depending on the organ involved. Leukomalacia after intrathecal chemotherapy, usually in association with radiotherapy, has been defined on CT and MR studies. Pulmonary toxicities that can be demonstrated by plain films and high-resolution CT include reversible processes such as bronchiolitis obliterans with organizing pneumonia ( Fig. 9-26) and irreversible fibrosis. [140] Radiographic abnormalities, however, often occur relatively late in the course of lung toxicities, and pulmonary function tests can be more sensitive than imaging studies for detecting early changes. Cardiomyopathy secondary to anthracycline therapy causes cardiomegaly and pulmonary edema in later stages. However, early changes can be evaluated by calculating left ventricular ejection fractions by echocardiography, radionuclide techniques, or MR imaging.

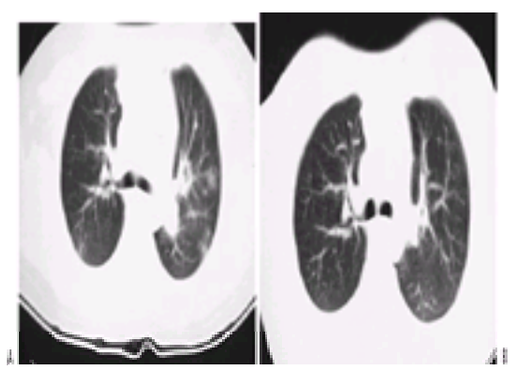

**FIGURE 9-26.** Bronchiolitis obliterans with organizing pneumonia in a patient who had undergone bone marrow transplantation for acute lymphocytic leukemia. **A:** An initial chest computed tomography scan shows scattered patchy pulmonary opacities. **B:** A follow-up study performed 9 months later after treatment with steroids shows resolution of the previously depicted pulmonary process.

The secondary effects of chemotherapy agents can also be diagnosed by imaging. The most common are infections secondary to immunosuppression. These are dealt with in Chapter 41. The other common group of secondary effects is related to steroids and include such radiographically demonstrable abnormalities as pseudotumor cerebri, retarded skeletal maturation, ischemic necrosis of the femoral heads, diffuse osteoporosis with compression fractures of vertebral bodies, abnormal fat deposition, and gastric and duodenal ulcers. The appropriate imaging study to identify the abnormality depends on the anatomic region involved.

## FUTURE CONSIDERATIONS

In the first edition of this book, we identified several areas for potential advancement in digital radiography, MR, CT, ultrasound, and nuclear medicine, including PET scanning. Great progress has been made in the technology for digital image acquisition and for the electronic archival, disbursal, and display of diagnostic images, technologies that are now available at many institutions throughout the world. The utility of MR has also continued to advance rapidly with the introduction of faster sequences and innovations that have increased the signal-to-noise ratio, improved spatial resolution, and decreased susceptibility of the modality to motion artifact. MR diffusion imaging has been introduced and MR vascular imaging refined. CT imaging speed has continued to increase as has the availability of advanced computer hardware and software necessary for the manipulation of CT data to facilitate multiplanar reconstruction, three-dimensional rendering, and CT angiography.

Advances in other areas have been more limited. The potential value of *in vivo* MRS continues to be exciting but speculative and controversial. Several major centers are investing heavily in MRS equipment and research, although at present the technique has yet to significantly impact the clinical care of children with neoplasia. Doppler ultrasound evaluation of blood flow within tumors has not proven helpful in distinguishing malignant from benign masses, or in facilitating prognostication or assessing tumor response in known malignancies. The introduction of innovative therapeutic radiopharmaceuticals, such as radio-labeled monoclonal antibodies, has not yet impacted the treatment of pediatric tumors, nor has PET scanning, to this point in time, been embraced as a critical modality for the assessment of childhood malignancies.

The medical economic climate has had a profound effect on medical imaging and clinical medicine. Managed care and per diem payments by third-party payers have changed radiology from a profit center to a cost center in many instances. Radiologists must carry out rigorous studies of efficacy and outcome to determine the best imaging approach to diagnostic problems and, more important, the proper follow-up of treated patients. The large cooperative study groups such as the Children's Oncology Group, provide an opportunity for us to conduct controlled trials with proper protocols, and radiologists are more involved in these studies than at any previous time.

# 10

# GENERAL PRINCIPLES OF CHEMOTHERAPY

FRANK M. BALIS
JOHN S. HOLCENBERG
SUSAN M. BLANEY

## INTRODUCTION

Since the introduction of chemotherapy for the treatment of childhood leukemia in the 1940s, [1] the prognosis of childhood cancer has improved dramatically ( Fig. 10-1). The 5-year survival rate for this group of diseases, many of which were uniformly fatal in the prechemotherapy era, was 75% for all forms of childhood cancer diagnosed between 1989 and 1995. [2] This striking improvement in survival is a direct result of the incorporation of anticancer drugs into treatment regimens that previously relied only on surgery or radiotherapy for the primary tumor. [3] The multimodality approach, which integrates surgery and radiotherapy to control local disease with chemotherapy to eradicate systemic (metastatic) disease, has become the standard approach to treating most childhood cancers.

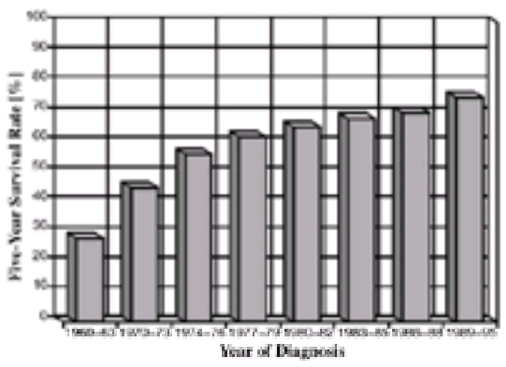

**FIGURE 10-1.** Five-year survival rate for all childhood cancers diagnosed between 1960 and 1995. (Data from Greenlee RT, Murray T, Bolden S, Wingo PA. Cancer statistics, 2000. CA Cancer J Clin 2000;50:7.)

## PRINCIPLES OF CANCER CHEMOTHERAPY

The ultimate goal of the multimodality treatment approach, in which anticancer drugs play a critical role, is to cure the patient of his or her cancer. The feasibility of achieving cures by the addition of anticancer drugs to surgery or radiation was first demonstrated in chemosensitive childhood cancers, such as Wilms' tumor. [4] However, curing the underlying disease is not the goal of most pharmacologic interventions. With the exception of antimicrobial and anticancer chemotherapy, the common classes of drugs (e.g., antihypertensives) are administered with the intent of controlling the disease or the symptoms caused by disease, rather than curing the underlying disease. The model for curing cancer is based on the successful model of curing bacterial infections. This strategy attempts to exploit differences between cancer and normal host cells and eradicate or kill all cancer cells in the body. This “killing paradigm” [5] has had a profound impact on the approach to anticancer drug discovery, drug development, and the design of treatment regimens that incorporate anticancer drugs.

The predominant strategy for anticancer drug discovery has been high-throughput screening to evaluate the antiproliferative or cancer cell killing effects of candidate drugs in tumor cell lines *in vitro*. [6] The precise mechanism of action of the candidate drugs was not critical to the selection process, and for many agents (e.g., doxorubicin) the mechanism of action was not defined until after the drugs were in widespread clinical use. This non-mechanistically based screening method

identified drugs that are cytotoxic and nonselective. As a result, most conventional anticancer drugs produce substantial clinical toxicity.

In clinical drug development, the initial dose-finding (phase I) clinical trials define the maximum tolerated dose, which is based on the severity of toxicity, as the optimal dose, rather than using a therapeutic endpoint to establish the optimal dose. This design is based on the premise that the highest tolerable dose will produce the maximum achievable cancer cell kill. In subsequent phase II trials, the maximum tolerated dose is evaluated in small cohorts of patients with different types of cancer to establish whether the drug has activity, which is defined as a greater than or equal to 50% decrease in the size of measurable tumors in at least 20% to 30% of patients with a specific type of cancer.[7]

Conventional front-line treatment regimens for most types of childhood cancer are composed of multiple anticancer drugs that are administered at their maximum tolerated dose intensity, even though these regimens typically produce substantial toxicity. Methods of rescuing or circumventing anticancer drug toxicity, such as the administration of hematopoietic growth factors and bone marrow or stem cell transplant to alleviate hematologic toxicity, have been incorporated into treatment regimens to allow for administration of higher doses of anticancer drugs.

The basic principles that guide the current use of cancer chemotherapy in pediatric and medical oncology are based on the goal of curing patients by eradicating all cancer cells and on empiric observations made in early clinical trials involving children with drug-sensitive cancers, such as acute lymphoblastic leukemia (ALL), Burkitt's lymphoma, and Wilms' tumor.[8] These principles include the use of multidrug combination regimens (i.e., combination chemotherapy), the administration of chemotherapy before the development of clinically evident metastatic disease (i.e., adjuvant chemotherapy), and the administration of drugs at the maximally tolerated dose rate (i.e., dose intensity).

**Combination Chemotherapy**

The importance of administering anticancer drugs in combination regimens was first appreciated in the treatment of ALL. Compared with single-agent therapy, the use of drug combinations significantly increased the percentage of patients achieving complete remission and prolonged the duration of their remissions.[9] At best, only 60% of patients treated with a single agent achieved complete remissions, but standard four- and five-drug combination induction regimens achieve complete remission rates that approximate or exceed 95%. Almost all patients on single-agent therapy experienced a relapse within 6 to 9 months, despite continuation of therapy with the same drug. Long-term remissions and cures were only attained after the institution of combination chemotherapy that incorporated the most active single agents.

The primary scientific rationale for the use of combination chemotherapy is to overcome drug resistance to individual agents, the incidence of which can often exceed 50% even in newly diagnosed cancers.[10,11] Because it is not feasible to predict whether a particular patient's tumor will respond to a given drug, administering anticancer drugs in combination ensures a greater chance of achieving a response (i.e., exposing the tumor to at least one active agent). In addition to providing a broader range of coverage against naturally resistant tumor cells, combination chemotherapy also may prevent or delay the development of acquired resistance in initially responsive tumors and provide additive or synergistic cytotoxic effects if agents with different mechanisms of action are selected.

A thorough knowledge of the clinical pharmacology of individual anticancer drugs is required to design effective combination chemotherapy regimens. Traditionally, combination chemotherapy regimens contain drugs with demonstrated single-agent activity against the type of tumor being treated, with a preference for agents that produced complete responses in patients with advanced or recurrent disease; drugs that are non–cross-resistant to overlap against drug-resistant subpopulations of tumor cells; drugs with non-antagonistic (i.e., additive or synergistic) mechanisms of action; and drugs with non-overlapping toxicity profiles, allowing each agent to be administered at its optimal dose and schedule.

**Adjuvant Chemotherapy**

Anticancer drugs are most effective when administered in the adjuvant setting to patients who are without evidence of residual disease after local therapy with surgery or radiation but who are at high risk to relapse at metastatic sites. Before the routine use of adjuvant chemotherapy, relapse at metastatic sites occurred in 60% to 95% of children with localized solid tumors after local therapy. The aim of adjuvant chemotherapy is to prevent metastatic recurrence by eliminating micrometastatic tumor deposits that are present at the time of diagnosis in the lungs, bone, bone marrow, lymph nodes, or other sites.[12] Adjuvant chemotherapy is efficacious for most of the common pediatric cancers, including Wilms' tumor, Ewing's sarcoma, lymphoma, rhabdomyosarcoma, astrocytoma, and osteosarcoma (Table 10-1).[13,14,15,16,17,18 and 19]

| Tumor | Adjuvant therapy | Survival (%) | |
|---|---|---|---|
| | | Without adjuvant chemotherapy | With adjuvant chemotherapy |
| Wilms' tumor | Vincristine, dactinomycin ± doxorubicin | 40 | 90 |
| Ewing's sarcoma | Vincristine, dactinomycin, cyclophosphamide | 5 | 50–60 |
| Lymphoma | CHOP, COMP, $CA_{1-5}$ | <10 | 50–90 |
| Rhabdomyosarcoma | Vincristine, dactinomycin, cyclophosphamide | 10–20 | 60 |
| Osteosarcoma | HDMTX, doxorubicin, cisplatin, BCD | 15 | 60 |
| Astrocytoma | Prednisone, vincristine, lomustine | 20 | 40 |

C, cyclophosphamide; H, doxorubicin; O, vincristine; M, methotrexate; P, prednisone; HDMTX, high-dose methotrexate; B, bleomycin; D, dactinomycin; $CA_{1-5}$, ten-drug regimen.

**TABLE 10-1. BENEFICIAL EFFECTS OF ADJUVANT CHEMOTHERAPY ON SURVIVAL OF PATIENTS WITH COMMON FORMS OF CHILDHOOD CANCER**

Theoretical considerations and experimental evidence support the use of adjuvant chemotherapy.[20,21 and 22] Microscopic foci of tumor should be more chemosensitive on a cell-kinetic basis, because a larger fraction of the cells are actively proliferating and potentially susceptible to the cytotoxic effects of the drugs. The smaller burden of tumor cells also implies a lower probability that drug-resistant cells are present. The mathematical modeling experiments of Goldie and Coldman, which assume that a curable tumor is one with no drug-resistant tumor cells and that the development of drug resistance is the result of a random genetic event, predict that the chance for cure is maximized if all available active drugs are given simultaneously in the adjuvant setting when there is minimal residual disease, and the probability that drug-resistant cells are present is low.[10,23]

Clinical experience has demonstrated a correlation between low tumor burden and the efficacy of chemotherapy.[22,23 and 24] Children presenting with extensive or disseminated tumors are less likely to be cured than children with the identical type of cancer but with a low tumor burden. For example, the event-free survival for patients with metastatic Ewing's sarcoma treated on the European Cooperative Ewing's Sarcoma Studies was 27% compared with 60% for patients presenting with localized disease.[25]

The selection of appropriate drugs and the optimal timing of drug therapy relative to the definitive local therapy are important considerations in the design of successful adjuvant chemotherapy regimens. Traditionally, drugs have been selected based on their activity in advanced disease. Animal models and clinical experience have shown that regimens producing the most dramatic responses in metastatic or recurrent disease have the greatest likelihood of being curative in the adjuvant setting.[24]

Adjuvant chemotherapy should begin as soon as possible after definitive local therapy. A delay to allow for recovery from surgery or radiation therapy may compromise the chance of curing the patient. One strategy to avoid delays caused by potential adverse interactions between chemotherapy and surgery or irradiation is the administration of the drug therapy before definitive local therapy. This approach, called *primary* or *neoadjuvant chemotherapy*, may also improve local control of the primary tumor by shrinking the primary and making it more amenable to surgical resection, in addition to providing earlier therapy for micrometastases.[26,27]

**Dose Intensity**

Most anticancer drugs have a steep dose-response curve, and a small increment in the dose can significantly enhance the therapeutic effect of a drug in preclinical studies. In animal tumor models, a twofold increase in the dose of cyclophosphamide can result in a tenfold increase in tumor cell killing. [28,29] Retrospective clinical studies have also demonstrated a relationship between dose intensity of anticancer drugs and disease outcome, but this relationship has not been consistently confirmed in randomized prospective trials.

In a meta-analysis (i.e., a compilation of data from multiple clinical trials) of chemotherapeutic regimens containing cyclophosphamide, methotrexate, and fluorouracil for metastatic breast cancer, Hryniuk and Bush observed a strong correlation between response rate and the relative dose intensity of the various regimens. [30] The relative dose intensity is calculated by normalizing the dose rate (mg per $m^2$ per week) for each agent to the dose rate in an arbitrarily selected standard regimen and then averaging the relative dose intensities for all agents in the regimen to derive the relative dose intensity for the regimen. Over a threefold range in relative dose intensity, the response rate in metastatic breast cancer ranged from 12% to 84%. Retrospective meta-analyses in stage II breast cancer, ovarian cancer, colorectal cancer, and lymphoma have also demonstrated a correlation between the dose intensity of the drug regimen and disease outcome. [31,32] However, prospective randomized trials have failed to demonstrate a survival advantage for more dose-intensive regimens, including high-dose chemotherapy with bone marrow or stem cell rescue, compared with standard dose regimens in breast, ovarian, and small cell lung cancers [33,34 and 35] and for more dose-intensive cisplatin in germ cell tumors.[36]

For children with ALL and osteosarcoma, relapse rates are significantly lower in patients receiving more dose-intense chemotherapy. [37,38,39,40 and 41] In a randomized trial, patients with ALL receiving standard doses of methotrexate and mercaptopurine had a median survival of 15 months compared with 6 months for the group randomized to a half-dose maintenance regimen.[37] In children with high-risk ALL, those who received less than 94% of the protocol-prescribed dose of vincristine, anthracycline, and L-asparaginase during intensification therapy were 5.5 times more likely to experience a subsequent adverse event than patients who received at least 99% of the prescribed dose of these agents.[38] Oral mercaptopurine dose intensity during maintenance therapy is also predictive of event-free survival in ALL. [39] However, in the latter study, lower mercaptopurine dose-intensity was primarily the result of missed doses rather than reductions of the daily dose, leading the authors to conclude that prescribing higher doses of mercaptopurine could be counterproductive if greater hematologic toxicity resulted in treatment delays.

Retrospective analyses of osteosarcoma trials demonstrated a twofold higher relapse rate in patients receiving less than 75% of their recommended dose of chemotherapy compared with patients receiving 75% or more in one study[40] and a threefold higher relapse rate in a second study using 80% of the protocol prescribed dose as a cutoff.[41]

Meta-analyses, such as those performed by Hryniuk and Bush, have also been performed for several pediatric tumors. [42,43] Analysis of 44 clinical trials involving 1,592 patients older than 1 year of age with stage IV neuroblastoma revealed a fivefold to tenfold range in the dose intensity of the individual agents studied. [42] The dose intensity of four drugs (i.e., teniposide, cisplatin, cyclophosphamide, and doxorubicin) significantly correlated with response and survival. Similarly, examination of the relation between individual drug dose intensities and disease outcome in osteosarcoma and Ewing's sarcoma suggests that doxorubicin dose intensity is an important determinant of response in osteosarcoma and disease-free survival of patients with Ewing's sarcoma.[43] The dose intensities of the other agents in the combination regimens used to treat these tumors did not appear to be as strongly correlated with disease outcome, suggesting that future combination regimens should be designed to optimize the dose intensity of doxorubicin.

Prospective randomized trials to assess the importance of dose intensity in childhood cancers have not been systematically performed for most tumor types. The administered dose intensity of dactinomycin and doxorubicin in pulse-intensive regimens for Wilms' tumor was significantly higher than for the standard treatment regimens, but there was no survival advantage associated with the enhanced dose intensity. [44,45] In a randomized trial of Filgrastim in children with high-risk ALL, the treatment interval was shorter with Filgrastim, resulting in a slight increase in dose intensity but no impact on event-free survival. [46]

Methods for maximizing dose intensity include greater patient and physician willingness to tolerate drug toxicities; more aggressive supportive care of patients experiencing these side effects; selective rescue of the patient from toxicity, such as with bone marrow or peripheral stem cell transplantation or the administration of colony-stimulating factors, such as granulocyte colony-stimulating factor (G-CSF) the use of regional chemotherapy (e.g., intra-arterial or intrathecal delivery) to achieve high drug concentrations at local tumor sites while minimizing systemic drug exposure; and the development of new treatment schedules, such as long-term continuous infusions that may allow more drug to be administered over a given period.

## CLINICAL PHARMACOLOGY OF ANTICANCER DRUGS

The primary role of the pediatric oncologist is to orchestrate the administration of complex combination chemotherapy regimens to children in the setting of multimodal (i.e., surgery, radiotherapy, and chemotherapy) therapy. Special care must be taken because the anticancer drugs used in these regimens have the lowest therapeutic index of any class of drugs and predictably produce significant, even life-threatening toxicity at therapeutic doses ( Fig. 10-2).[47] However, implementing significant dose reductions or delays in therapy to attenuate these toxicities may compromise the therapeutic effect and place the patient at an increased risk for disease recurrence, a uniformly fatal event with most childhood cancers. The cancer chemotherapist must carefully balance the risks of toxicities from therapy against the risk of tumor recurrence from inadequate treatment. The crucial adjustments in the dose and schedule of chemotherapy needed to achieve this balance often must be made empirically, however, because therapeutic drug monitoring for most agents is not available.

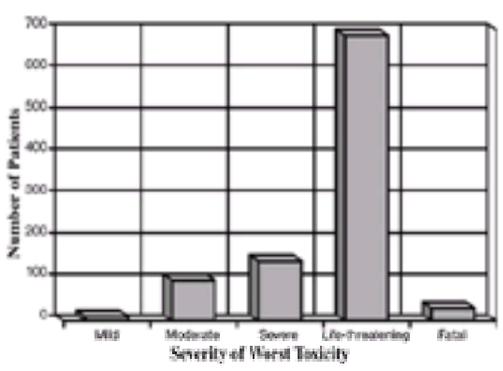

**FIGURE 10-2.** The worst degree of any toxicity experienced by patients (n = 1,062) treated on one of the eight treatment arms of the Intergroup Rhabdomyosarcoma Study III. Seventy-eight percent of patients had at least one severe or life-threatening toxicity, and there were 32 toxicity-related deaths. (Adapted from Table 6 in Crist W, Gehan EA, Ragab A, et al. The third Intergroup Rhabdomyosarcoma Study. J Clin Oncol 1995;13:610.)

To ensure that these drugs are used safely and effectively, the pediatric oncologist must have an in-depth knowledge of the clinical pharmacology of these agents, including the mechanisms of drug action, pharmacokinetics (e.g., absorption, distribution, metabolism, and elimination), spectrum of toxicities, potential drug interactions, and mechanisms of drug resistance.

### Mechanism of Action

Although advances in basic research have provided profound insights into the pathogenesis of many forms of childhood cancer and offer hope for the development of specific and selective new cancer treatments,[48,49,50,51,52 and 53] most current conventional anticancer drugs have nonselective mechanisms of action that target vital macromolecules (e.g., DNA) or metabolic pathways that are critical to both malignant and normal cells; and as a result they cause many undesirable and potentially severe toxic effects (Fig. 10-2).

Most anticancer drugs produce their cytotoxic effects by interfering at some stage with the synthesis or function of the vital nucleic acids, DNA and RNA ( Fig. 10-3). For example, the alkylating agents are chemically reactive compounds that damage DNA by covalently bonding to and crosslinking nucleobases within the DNA, [54] and

the antimetabolites block the synthesis of nucleotide precursors or are directly incorporated into DNA as fraudulent bases. The topoisomerases are also an important target of anticancer drugs. These nuclear enzymes maintain the three-dimensional structure of DNA and are critical for DNA replication, transcription, repair, and recombination. The topoisomerases work by cleaving and religating DNA, and agents such as the anthracyclines, epipodophyllotoxins, and camptothecins interfere with religation, resulting in protein-associated DNA strand breaks. [55,56,57] and [58]

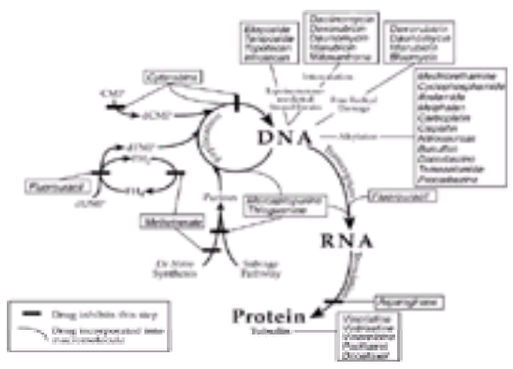

**FIGURE 10-3.** Site of action of the commonly used anticancer drugs. CMP, cytidine monophosphate; dCMP, deoxycytidine monophosphate; dTMP, deoxythymidine monophosphate; dUMP, deoxyuridine monophosphate; $FH_2$, dihydrofolate; $FH_4$, tetrahydrofolate.

Dysregulation of the cell cycle and programmed cell death (apoptosis) are common to all forms of cancer. [59,60] and [61] These cellular processes are genetically controlled, and mutations to genes involved in these highly complex and interrelated pathways can result in loss of control of DNA replication and cell division and suppression of the apoptotic response to receptor-linked or DNA damage-induced signals. In addition to their role in tumorigenesis, mutations in cell cycle regulatory genes and genes involved in apoptosis may modulate the sensitivity of cancer cells to anticancer drugs. [59,61,62] and [63] The cellular damage produced by most anticancer drugs appears to induce apoptosis in chemosensitive cancer cells. Overexpression of oncogenes that promote apoptosis, such as C- *myc* and N-*myc*, can enhance the chemosensitivity of tumor cells, whereas overexpression of Bcl-2, which blocks the apoptotic pathway, can attenuate drug-induced apoptosis and convey pleiotropic resistance to anticancer drugs. [64,65]

The cell cycle is regulated by negative feedback controls or checkpoints that block the cell from proceeding to the next cell cycle event until the prior event is completed and until needed repairs to DNA are performed. [66,67,68] and [69] Normal cells are arrested in $G_1$ phase in response to DNA damage caused by cytotoxic drugs, allowing for repair of the DNA damage. [70,71] If this DNA damage is not repaired, the complex process of DNA replication and cell division is disrupted. Mutations in cell cycle regulatory genes that have been implicated in tumorigenesis most frequently involve genes controlling the transition from the $G_1$ to S phases of the cell cycle, [59] and loss of checkpoint function (e.g., p21) can enhance chemo- and radiosensitivity. [59,72] The same mechanisms that play a role in the pathogenesis of cancer could also sensitize the cancer cell to DNA-damaging anticancer drugs.

p53 mutations and loss of p53 function, which occur in one-half of all human cancers, have been associated with enhanced or decreased sensitivity to anticancer drugs in preclinical studies. [73,74,75] and [76] The role of p53 as a dual-effect regulator that induces apoptosis in its activated state and regulates the cell cycle at the $G_1$/S and $G_2$/M checkpoints may be responsible for these seemingly contradictory results. Clinical studies correlating p53 mutational status to disease outcomes, such as response and survival, have also failed to consistently demonstrate a relationship. [76]

An understanding of the mechanism of drug action is useful in predicting which tumors may respond to the drug based on their biochemical and cytokinetic profiles and which drug combinations may produce additive or synergistic antitumor effects. Combining agents that together could enhance the inhibition of vital intracellular processes through sequential or concurrent blockade or lead to complementary inhibition of specific metabolic pathways has been a traditional strategy for the design of combination regimens. [77] A drug's schedule of administration may also be influenced by its mechanism of action. For example, the antimetabolites, which are inhibitory only during S phase in the cell cycle, tend to be more cytotoxic if administered by prolonged infusion. This approach ensures that a greater number of tumor cells are exposed to the drug as they pass through S phase.

## Pharmacokinetics

The discipline of pharmacokinetics deals with quantitative aspects of drug disposition in the body, including drug absorption, distribution, biotransformation (metabolism), and excretion (Table 10-2). Although the pharmacokinetic behavior of most of the commonly used anticancer drugs has been studied in adults, many of these agents have not been extensively evaluated in children. As the technology to measure the concentration of these drugs and their metabolites in biologic fluids has improved, a greater emphasis has been placed on studying anticancer drug pharmacokinetics.

| Term | Common abbreviation | Units | Definition |
|---|---|---|---|
| Clearance | Cl | Volume (mL/min) | Used to quantify the rate of drug elimination; expressed in terms of volume of plasma cleared of drug per unit of time. Total clearance is the sum of renal, metabolic, spontaneous chemical degradation, and biliary (fecal) elimination. |
| Half-life | $t_{1/2}$ | Time (h) | Time required to reduce the drug concentration by 50%. Plasma drug disappearance frequently has multiple phases with differing rates of disappearance (e.g., rapid distribution phase, terminal or elimination phase). Half-lives listed for drugs in this chapter are the postinfusion (terminal, elimination) half-lives, unless otherwise noted. |
| Area under the curve | AUC | Conc. × time (μM•h) | Quantitates total drug exposure; integral of drug concentration over time or the area under the plasma concentration-time curve; used in calculation of clearance and bioavailability. |
| Volume of distribution | Vd, $V_{ss}$ | Volume (L) | Relates plasma concentration to total amount of drug in the body (i.e., volume required to dissolve the total amount of drug to give the final concentration found in plasma); a property of the drug rather than a real volume or physiologic compartment. |
| Bioavailability | F | Fraction (%) | Rate and extent of absorption of a drug, frequently synonymous with the fraction of a dose absorbed when administered by some route other than intravenous. |
| Biotransformation | — | — | Enzymatic metabolism of a drug; may result in the activation of a prodrug, conversion to other biologically active intermediates, or inactivation of a drug. |

Conc., concentration.

**TABLE 10-2. PHARMACOKINETIC TERMS**

Pharmacokinetic studies have revealed substantial interpatient variability in drug disposition and systemic drug exposure with most anticancer drugs. [78,79] Administering a standard dose of etoposide, doxorubicin, or cyclophosphamide to a group of children results in a twofold to tenfold range in systemic drug exposure, as measured by the area under the plasma drug concentration-time curve (AUC), [80] and substantial variability in systemic drug exposure is also observed with orally administered agents such as methotrexate and mercaptopurine. [81] Assuming that drug effect is more closely related to systemic drug exposure than dose, these differences in drug disposition could account for the variability in toxicities and responses observed with most combination chemotherapy regimens using standardized doses of individual agents. [82] Variability in anticancer drug disposition in children may result from age-related developmental changes in body composition and excretory organ function, variation in rate of metabolism and excretion of drug by the kidneys or liver, variation in the extent of drug-protein binding, drug interactions, and pharmacogenetics. [78,83,84,85,86,87,88] and [89]

The most important determinant of variability in anticancer drug pharmacokinetics is the rate of drug metabolism. Enzymatically catalyzed biotransformation of lipophilic drugs and other xenobiotics usually yields more hydrophilic (water soluble) metabolites that have lost their pharmacologic activity and that are more readily excreted in urine or feces. [90] Drug metabolizing enzymes are divided into two groups based on the type of reaction that they catalyze. Phase I reactions (e.g., oxidation, hydrolysis, reduction, and demethylation) introduce or expose a functional group (e.g., hydroxyl group) on the drug. Phase I reactions usually diminish the drug's pharmacologic activity, but some prodrugs, such as cyclophosphamide, are converted to active metabolites by these enzymes. Phase II conjugation reactions covalently link a highly polar conjugate (e.g., glucuronic acid, sulfate, glutathione, amino acids, or acetate) to the functional group created by the phase I reaction. The

conjugated drugs are highly polar, usually devoid of pharmacologic activity, and rapidly excreted.

The cytochrome P450 (CYP) superfamily of enzymes catalyze oxidation and demethylation reactions for a wide spectrum of drugs and xenobiotics. These heme-containing proteins, which are membrane-bound and typically reside in the endoplasmic reticulum, have very broad and overlapping substrate specificity. [91] The CYP enzymes are categorized into families and subfamilies according to their amino acid sequence similarity. Sequences that are more than 40% identical belong to the same family (e.g., CYP1) and sequences that are more than 55% identical are in the same subfamily (e.g., CYP1A).[92] Subfamilies may contain multiple isoforms (e.g., CYP1A2). More than 1,000 CYP sequences have been identified across all species. Humans have at least 17 families and 39 subfamilies of CYP genes. The CYP1, CYP2, and CYP3 families are primarily responsible for hepatic drug and xenobiotic metabolism in humans, and CYP3A is the most important subfamily, accounting for the metabolism of half of all drugs.[92,93] CYP3A4 is the most abundant P450 enzyme in the liver, and it is known to metabolize more than 50 different drugs. Genetic, environmental, physiologic, and developmental factors contribute to individual differences in the rate of drug metabolism by the CYP enzymes. [90,94] A number of CYP genes are known to be genetically polymorphic, and, in some cases, these alterations can influence enzyme activity and drug metabolism phenotype.[95,96] Exposure to certain drugs or environmental chemicals can induce the expression of specific CYP enzymes or inhibit CYP enzyme activity. [91] For example, members of the CYP3A subfamily are induced by rifampin, barbiturates, phenytoin, and dexamethasone, and this enzyme induction can enhance the rate of metabolism of other drugs that are substrates for CYP3A enzymes. CYP3A enzymes are inhibited by macrolide antibiotics and azole antifungal drugs, which can block the metabolism of other CYP3A substrates.[93]

Pharmacogenetic variation in the level of expression of other non-P450 drug-metabolizing enzymes is an important determinant of toxicity for mercaptopurine (thiopurine methyl transferase),[97,98,99] and[100] fluorouracil [dihydropyrimidine dehydrogenase (DPD)],[101] and the investigational agent amonifide (acetylator status).[102]

The significant interpatient variation in systemic drug exposure with current dosing methods, the toxic nature of these agents, and the potential importance of dose intensity in cancer chemotherapy point to the need for more precise, individualized dosing methods for anticancer drugs,[79,85,86,103,104] such as the adaptive dosing techniques that have been successfully applied to individualize carboplatin dose [105] and therapeutic drug monitoring of methotrexate that plays a critical role in determining the duration of leucovorin rescue after high-dose methotrexate therapy.[79,98,104] A prerequisite for these individualized dosing methods is the establishment of the relation between a drug's pharmacokinetics and pharmacodynamics (toxicity or therapeutic effect). Systemic drug exposure (AUC) of anticancer drugs is usually the best correlate of the drug's toxic or therapeutic effects. However, this requires plasma sampling at multiple times over a prolonged period, which may not be practical for monitoring large numbers of patients. Through pharmacokinetic modeling, a limited number of sampling times that can reliably estimate the AUC can often be identified, providing a more practical pharmacokinetic monitoring schedule.[79,106,107] Parameters other than AUC, such as peak or trough concentration or average steady-state concentration, can also be evaluated for clinical correlations.

Even though therapeutic drug monitoring has yet to play a significant role in the day-to-day management of the patient with cancer, the pharmacokinetic parameters are important for determining the optimal dose, schedule, and route of administration of the drug. Knowledge of the route of elimination of a drug is also helpful in adjusting the dosage for patients with hepatic or renal dysfunction.[108,109] and[110]

Physiologic differences between children and adults can affect drug disposition and must be considered in determining the appropriate dose and schedule of the drug for children. Developmental differences in drug absorption, plasma protein or tissue binding, functional maturation of excretory organs, and distribution of drug in the various tissues of the body (Table 10-3) can result in differences in systemic drug exposure for children compared with adults treated with the same dose.[83,84] The most dramatic changes in excretory organ function and body composition occur during the first few days to months of life, but there are very limited data on the disposition of anticancer drugs in infants (younger than 1 year old).[111]

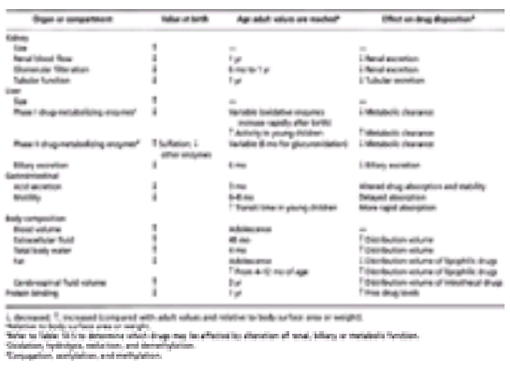

**TABLE 10-3. PHYSIOLOGIC DIFFERENCES IN CHILDREN THAT MAY INFLUENCE DRUG DISPOSITION**

## Toxicity

In therapeutic doses, actively dividing normal host cells, such as those in the bone marrow or the mucosal epithelium, are sensitive to the cytotoxic effects of anticancer drugs.[112] The nonselective mechanisms of action and resulting low therapeutic indices of these agents mean that a high incidence of potentially severe toxicities must be tolerated to administer effective doses.[113,114] and[115] Acute toxicities common to many of the anticancer drugs include myelosuppression, nausea and vomiting, alopecia, orointestinal mucositis, liver function abnormalities, allergic or cutaneous reactions, and local ulceration from subcutaneous drug extravasation. These acute toxicities occur over hours to weeks after a dose and are usually reversible. Many drugs also have unique toxicities affecting specific organs or tissues, such as cardiotoxicity associated with the anthracyclines; hemorrhagic cystitis associated with cyclophosphamide and ifosfamide; peripheral neuropathy from vincristine, cisplatin, and paclitaxel; nephrotoxicity from cisplatin and ifosfamide; ototoxicity from cisplatin; and coagulopathy from L-asparaginase. Many of these latter toxicities are cumulative (i.e., occur after multiple doses), and in some cases they are not completely reversible (e.g., anthracycline cardiotoxicity).

A significant portion of an oncologist's time is spent in providing supportive care for patients experiencing acute and long-term drug toxicities. [116] A number of therapeutic approaches have evolved to attenuate these toxicities, to make the therapy more tolerable, and to safely increase the dose intensity of regimens by circumventing dose-limiting toxicities.[112,117,118] and[119] Bone marrow or peripheral stem cell transplantation to rescue patients from myeloablative doses of anticancer drugs is an example of this rescue approach. Other widely used forms of rescue include the administration of leucovorin or carboxypeptidase-G $_2$[120] to counteract the toxicities of high-dose methotrexate, the use of antiemetics to block nausea and vomiting,[121,122] and[123] the use of mesna to prevent the hemorrhagic cystitis caused by the oxazaphosphorines,[124] the use of colony-stimulating factors (e.g., G-CSF or erythropoietin) to alleviate myelosuppression,[125,126,127] and[128] and the use of dexrazoxane (ICRF-187) to prevent anthracycline cardiotoxicity.[129,130]

Amifostine is a broad-spectrum cytoprotective agent that protects many normal tissues and organs, including bone marrow, kidney, lung, orointestinal mucosa, and peripheral nerves, against the toxic effects of radiation and a variety of anticancer drugs, such as the alkylating agents, the anthracyclines, and platinum compounds.[131,132,133,134,135,136,137] and[138] Amifostine is a prodrug that is converted by alkaline phosphatase to WR-1065, which is a free sulfhydryl compound that scavenges free radicals and binds to active metabolites of anticancer drugs.[134] Preferential conversion of amifostine to WR-1065 and uptake of WR-1065 in normal tissues compared to tumors account for the selective nature of the rescue.[135] Preliminary clinical trials of amifostine have been conducted in children,[139,140] but its role in treating childhood cancers has yet to be defined.

The toxicity of anticancer drugs has a major impact on the dosing of these agents. The endpoint of the phase I dose-finding studies for most anticancer drugs is the identification of the maximum-tolerated dose, which is considered the optimal dose. The dosing interval (every 21 to 28 days) for anticancer drugs is determined by the duration of acute toxicities, and dose modifications are usually based on the severity or duration of toxicities on the prior treatment cycle. The life-time cumulative dose of the anthracyclines and bleomycin is limited to prevent cardiotoxicity and pulmonary toxicity. This toxicity-based dosing approach for anticancer drugs reflects the lack of data on the relationship between dose and anticancer effect.

The severity, incidence, and time course of toxicities are important factors in designing optimal drug combinations or adjusting doses to avoid overlapping toxicities. For example, nonmyelosuppressive agents, such as vincristine, prednisone, L-asparaginase, and high-dose methotrexate with leucovorin rescue, often can be administered with traditional myelosuppressive drugs without compromising the dose of either agent. Some combinations have administered nonmyelosuppressive agents during the period of marrow suppression from myelotoxic drugs to ensure continuous exposure of the tumor to cytotoxic therapy. [141,142]

The long-term side effects of cancer chemotherapy are also of particular concern to the pediatric oncologist because of the high cure rates and the long life spans of successfully treated patients. The adverse late effects of chemotherapy on growth, development, and reproductive function; possible permanent cardiac, pulmonary, or renal damage; and possible carcinogenic and teratogenic effects are discussed in Chapter 49.

**Drug Interactions**

In addition to being administered in combination regimens, the anticancer drugs are also administered with antiemetics, antibiotics, analgesics, stool softeners, and other agents used to alleviate the side effects of chemotherapy or the underlying cancer. This degree of polypharmacy introduces a significant risk of drug interactions.[87,143,144 and 145] Clinicians must be aware of potential drug interactions, which can alter the disposition of anticancer drugs or alter their effects at the target site in tumor or normal tissues, to avoid unexpected or severe toxicities or antagonism that can diminish a drug's antitumor effect. [87,143] However, little information is available about drug interactions involving the anticancer drugs with one another or with other classes of drugs. To some extent, the already high incidence of toxicities and treatment failures and the continued reliance on empirical dosing methods that do not include routine therapeutic drug monitoring obscure the recognition of possible interactions.

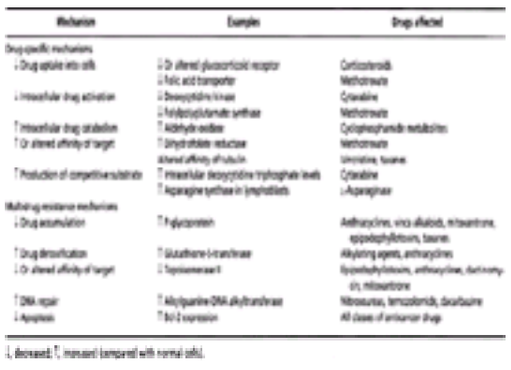
In some instances, drug interactions have been exploited to increase the antitumor effects of the anticancer agent being administered, such as with the combination of fluorouracil and leucovorin.

**Drug Resistance**

Although toxic effects of anticancer drugs are usually predictable, the response of any given tumor to individual agents is not. Clinical resistance to anticancer drugs is the primary reason for treatment failure in childhood cancers. Drug resistance can be present at the outset of treatment or can become clinically apparent under the selective pressure of drug exposure.[146] The magnitude of the problem of drug resistance was appreciated early in cancer chemotherapy for childhood cancers. Less than one-half of children with ALL who were treated with single-agent therapy achieved a complete remission, and almost all of the patients who did respond eventually relapsed despite continuation of the drug that produced the remission. [8,147]

The development of most forms of drug resistance has a genetic basis.[10,148] The inherent genetic instability of tumor cells results in the spontaneous generation of drug-resistant clones as a consequence of a mutation, deletion, gene amplification, translocation, or chromosomal rearrangement. [10,148] These genetic alterations are presumed to be random events, which may account for the variability in response observed in most clinical trials. This genetic basis for drug resistance means that resistance can be inherited by subsequent generations of tumor cells, and under the selective pressure of drug exposure, drug-resistant cancer cells become the predominant subpopulation. At a biochemical level, there are a variety of mechanisms by which tumors become drug resistant. In most cases, these alterations in cellular metabolism can be related to an increase, a decrease, or an alteration in some gene product, such as the gene amplification identified in methotrexate-resistant cells that results in overproduction of dihydrofolate reductase (DHFR), the target enzyme of methotrexate. [149]

Genetically-based molecular or biochemical alterations in cancer cells can produce anticancer drug resistance that is specific to a single agent or class of agents or provides protection from a broad range of anticancer drugs ( Table 10-4). In the latter form of resistance, termed *multidrug resistance*, a single cellular alteration conveys resistance simultaneously to multiple unrelated drugs, including drugs to which the cancer has not been exposed. [150,151 and 152] The best studied multidrug-resistant phenotype is associated with decreased intracellular drug accumulation and an increase in a plasma membrane, adenosine triphosphate–dependent drug efflux pumps, such as P-glycoprotein (P-gp), or the family of multidrug resistance proteins (MRPs). [151,153,154,155,156,157,158,159,160 and 161]



| Mechanism | Examples | Drugs affected |
|---|---|---|
| Drug-specific mechanisms | | |
| ↓ Drug uptake into cells | ↓ Or altered glucocorticoid receptor | Corticosteroids |
| | ↓ Folic acid transporter | Methotrexate |
| ↓ Intracellular drug activation | ↓ Deoxycytidine kinase | Cytarabine |
| | ↓ Polyglutamate synthase | Methotrexate |
| ↑ Intracellular drug catabolism | ↑ Aldehyde oxidase | Cyclophosphamide metabolites |
| ↑ Or altered affinity of target | ↑ Dihydrofolate reductase | Methotrexate |
| | Altered affinity of tubulin | Vincristine, taxanes |
| ↑ Production of competitive substrate | ↑ Intracellular deoxycytidine triphosphate levels | Cytarabine |
| | ↑ Asparagine synthase in lymphoblasts | L-Asparaginase |
| Multidrug resistance mechanisms | | |
| ↓ Drug accumulation | ↑ P-glycoprotein | Anthracyclines, vinca alkaloids, mitoxantrone, epipodophyllotoxins, taxanes |
| ↑ Drug detoxification | ↑ Glutathione S-transferase | Alkylating agents, anthracyclines |
| ↓ Or altered affinity of target | ↓ Topoisomerase II | Epipodophyllotoxins, anthracyclines, dactinomycin, mitoxantrone |
| ↑ DNA repair | ↑ Alkylguanine DNA alkyltransferase | Nitrosoureas, temozolomide, dacarbazine |
| ↓ Apoptosis | ↑ Bcl-2 expression | All classes of anticancer drugs |

↓, decreased; ↑, increased (compared with normal cells).

**TABLE 10-4. MECHANISMS OF ANTICANCER DRUG RESISTANCE**

P-gp and the *mdr-1* gene that encodes for it are expressed in human tumor specimens, including ALL, neuroblastoma, rhabdomyosarcoma, neuroepithelioma, Ewing's sarcoma, retinoblastoma, and osteosarcoma,[162,163,164,165,166 and 167] and in a variety of normal human tissues, such as the biliary canaliculi in the liver, the proximal tubules in the kidney, the mucosal lining of the jejunum and colon, the adrenal gland, hematopoietic progenitor cells, and the endothelial cells of blood vessels within the central nervous system (CNS) and testis.[168] P-gp appears to be responsible for excretion of toxic compounds from these normal cells. [162,168,169] Although the presence of P-gp in tumor specimens has been associated with a worse prognosis and a poor response to therapy in some studies, the clinical significance of P-gp expression in childhood cancers remains controversial, in part because of the lack of a universal standard for quantifying expression at an RNA or protein level.[150,151,166,170]

Chemosensitizers, which are capable of reversing multidrug resistance caused by P-gp *in vitro*, are undergoing clinical testing. The initial agents that were tested included drugs with other, unrelated pharmacologic actions, such as the calcium channel blocker, verapamil, and the immunosuppressant, cyclosporine; toxicity prevented achievement of adequate concentrations to block P-gp in patients. Newer chemosensitizing agents, such as valspodar, which are being developed specifically as P-gp inhibitors, are in the initial phases of clinical testing in childhood cancers. If these chemosensitizers are demonstrated to enhance the efficacy of anticancer drugs in well-designed prospective trials, this would support a role for P-gp as a clinically significant mechanism of drug resistance. However, because these chemosensitizers also inhibit P-gp excretory function in normal tissues, such as the liver and kidney, they can interfere with the elimination of the anticancer drug, leading to enhanced systemic exposure and increased toxicity. [171,172 and 173] The potential for marked alteration in the pharmacokinetics of the anticancer drug when administered in combination with a chemosensitizing agent must be taken into consideration in the design and interpretation of clinical trials testing the efficacy of chemosensitizers.

The less well-studied MRP family of drug transporters also appear to have a broad substrate specificity, which includes anionic drugs, neutral drugs that are conjugated to glutathione, glucuronate, or sulfate, nucleoside analogs, and cisplatin. [160,161] P-gp inhibitors, such as valspodar, do not effectively block drug transport by MRP1 and MRP2. The role of these transporters in clinical resistance to anticancer drugs is under study.

Other mechanisms for multidrug resistance include an enhanced capacity to repair DNA damage produced by alkylating agents [152,174,175]; the detoxification of chemically reactive forms of alkylating agents and anthracyclines by glutathione [176]; decreased levels of topoisomerase II, the target enzyme of the anthracyclines, epipodophyllotoxins, and dactinomycin[177]; and suppression of apoptotic pathways.[60,61,65] The loss of DNA mismatch repair activity results in multidrug resistance by

impairing the cancer cell's ability to detect DNA damage and activate apoptosis. [178]

The mechanism of drug resistance is an important consideration in selecting agents to be included in combination regimens or as second-line therapy in relapsed patients. Ideally, drug combinations should be composed of non–cross-resistant agents, and relapse treatment regimens should avoid the use of drugs that are cross-resistant with drugs used in the front-line regimen. With advances in the understanding of the mechanisms of drug resistance, specific treatment approaches may be devised to prevent the development of or overcome drug resistance in tumor cells.

In the remainder of this chapter, the pharmacologic characteristics of the anticancer drugs used to treat childhood cancers are reviewed. Tables summarize the general pharmacologic properties (Table 10-5) and pharmacokinetic parameters (Table 10-6) of the commonly used anticancer drugs.

**TABLE 10-5. PHARMACOLOGIC PROPERTIES OF THE COMMONLY USED ANTICANCER DRUGS**

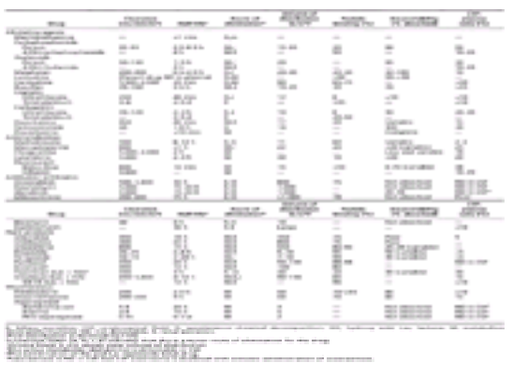


**TABLE 10-6. PHARMACOKINETIC PARAMETERS OF THE COMMONLY USED ANTICANCER DRUGS**

## ALKYLATING AGENTS

The alkylating agents have a broad range of clinical activity in childhood cancers. These drugs are chemically reactive compounds that exert their cytotoxic effect through the covalent bonding of an alkyl group to important cellular macromolecules ( Fig. 10-4).[54] Although a number of nucleophilic macromolecules and their precursors are potential targets for alkylation intracellularly, damage to the DNA template and the resulting induction of apoptosis appear to be the major determinants of cytotoxicity.[54,61,63,179,180] With the bifunctional alkylating agents that have two alkylating groups, this damage appears to result primarily from interstrand and intrastrand DNA-DNA and DNA-protein crosslinks.[179,181]

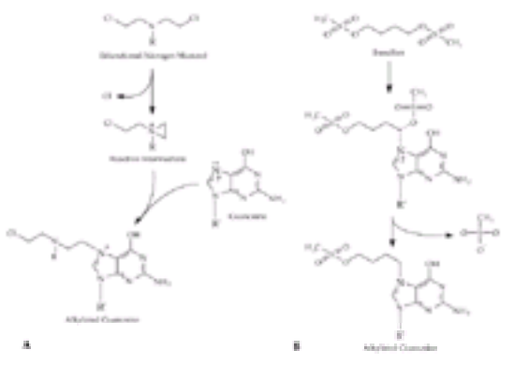

**FIGURE 10-4.** Mechanisms of alkylation of the nucleophilic $N^7$ position of guanosine. **A:** The bifunctional nitrogen mustard illustrates the $S_N1$ type of alkylation reaction, in which a reactive intermediate forms spontaneously and then rapidly reacts with the nucleophilic group. The rate-limiting step for $S_N1$ alkylation is the formation of the reactive intermediate, and thus the reaction exhibits first-order kinetics (i.e., independent of the target nucleophile concentration). If the second chloroethyl group also reacts with another nucleotide base, a crosslink is formed. **B:** Busulfan exemplifies an $S_N2$ reaction, characterized by a bimolecular nucleophilic displacement. In this case, the methylsulfonate group on either end of busulfan is displaced by the nucleophilic group on guanosine. The rate of $S_N2$ alkylation reactions depends on the concentration of the alkylating agent and the target nucleophile, and it therefore follows second-order kinetics.

Alkylating agents have steep dose-response curves in experimental model systems.[182] A log-linear relationship exists between tumor cell killing and the concentration of the alkylating agent, and this correlation is maintained through four to five orders of magnitude of cell killing. This steep dose-response relationship for alkylating agents provides a strong rationale for their use in high-dose therapy regimens. Because of the significant myelosuppressive effects of these drugs, high-dose alkylator therapy is generally administered in conjunction with bone marrow or peripheral stem cell transplantation to prevent permanent bone marrow aplasia. The use of melphalan and busulfan in childhood cancers is limited almost exclusively to high-dose transplantation preparative regimens, and other alkylating agents, such as cyclophosphamide and thiotepa, are also frequently incorporated into these regimens. [183,184 and 185]

Myelosuppression is the major dose-limiting toxicity for most of the commonly used alkylating agents. Other common acute toxic effects include nausea and vomiting, alopecia, allergic and cutaneous reactions, and gastrointestinal and neurologic toxicity at high doses. Of particular concern to the pediatric oncologist are the potential long-term effects of alkylator therapy. Alkylating agents can produce gonadal atrophy, permanently affecting reproductive function. The nitrogen mustards and the nitrosoureas have been linked to pulmonary fibrosis, and nephrotoxicity of the nitrosoureas, cisplatin, and ifosfamide can permanently impair renal function. [186,187] These agents are also highly carcinogenic, mutagenic, and teratogenic. [188,189]

The pharmacokinetics of the alkylating agents has been difficult to study, because the chemical reactivity and inherent chemical instability of the active alkylating species make their measurement in biologic fluids difficult. Spontaneous hydrolysis of alkylating agents or their active metabolites in solution can be a major route of

drug elimination. Most alkylating agents also undergo some degree of enzymatic metabolism, which can produce active and inactive metabolites. [190]

Several mechanisms for the development of resistance to alkylating agents have been described, including a decrease in drug uptake or transport by the cell; an increase in intracellular thiol compounds (glutathione) that are capable of detoxifying active alkylating species; enhancement of intracellular enzymatic catabolism to inactive metabolites; and an increase in the capability for repair of DNA damage produced by alkylation. [152,174,176,191,192,193,194,195,196] and [197] Loss of DNA mismatch repair capacity induces resistance to the methylating agents procarbazine and temozolomide, busulfan, and the platinum analogs. [178] *In vitro* studies indicate that resistance to alkylating agents is difficult to induce despite protracted exposure of cells to the drugs and that, after resistance has been induced, it often is not stable without drug in the medium to create continuous selection pressure. Cross-resistance to these drugs is not common in preclinical models. [198,199] and [200]

Of the various classes of alkylating agents, the nitrogen mustards and the nitrosoureas are most frequently used in the treatment of the childhood cancers. The chemical structures of the nitrogen mustards, the nitrosoureas, and several nonclassical alkylators are shown in Figure 10-5, Figure 10-7, Figure 10-9, and Figure 10-11).

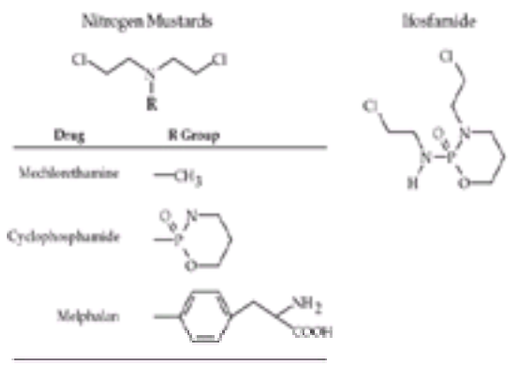

**FIGURE 10-5.** Chemical structures of the nitrogen mustard alkylating agents and the cyclophosphamide isomer, ifosfamide.

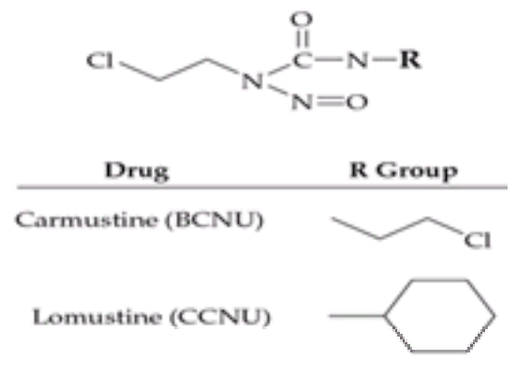

**FIGURE 10-7.** Chemical structures of the nitrosoureas, carmustine and lomustine.

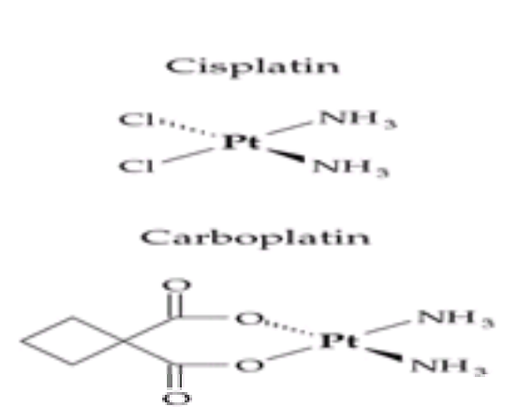

**FIGURE 10-9.** The chemical structures of platinum compounds, cisplatin and carboplatin, which platinate DNA in a manner analogous to alkylation by the nitrogen mustards. Reactive intermediates are formed after spontaneous elimination of chloride (cisplatin) or dicarboxylatecyclobutane (carboplatin).

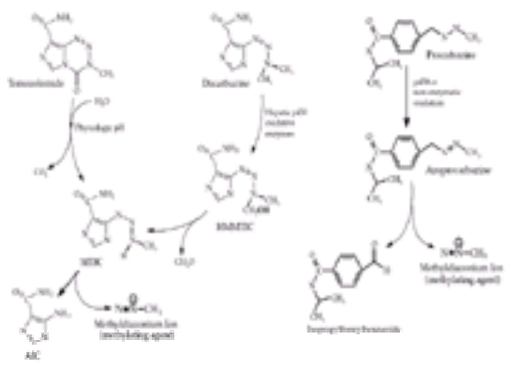

**FIGURE 10-11.** Chemical structures and activation pathways of the methylating agents, dacarbazine, temozolomide, and procarbazine, which are prodrugs. Dacarbazine requires enzymatically catalyzed activation, and temozolomide undergoes spontaneous chemical conversion in solution at physiologic pH to the active metabolite, methyltriazenyl-imidazole carboxamide (MTIC). The metabolic pathway for procarbazine is highly complex and incompletely shown. In addition to the methyldiazonium ion, free radicals can also be generated from azoprocarbazine. AIC, amino-imidazole carboxamide; HMMTIC, hydroxymethyl-MTIC.

## Nitrogen Mustards

The nitrogen mustards were the first class of alkylating agent used to treat cancer and remain the most widely used for childhood cancers. Mechlorethamine (nitrogen mustard), introduced into clinical trials in 1942, was the first drug demonstrated to be effective in the treatment of human cancers. A large number of synthetic nitrogen mustard analogs have since been screened for antitumor activity, and several with greater chemical stability and other pharmacologic advantages have largely supplanted mechlorethamine in clinical practice. Cyclophosphamide and its isomer ifosfamide and melphalan (phenylalanine mustard) are the most widely used in pediatric oncology (Fig. 10-5).

### *Mechlorethamine*

Although the role of mechlorethamine in the treatment of cancer has declined, it is still a model for the chemical reactions of bifunctional alkylators ( Fig. 10-4). The spontaneously formed alkylating intermediate is highly chemically reactive, and it rapidly undergoes hydrolysis, leading to inactivation, or it alkylates a wide variety of molecules, with a propensity to react with the $N^7$ position on guanosine.[179,190,201] Because of this inherent instability, even in aqueous solutions, mechlorethamine must be administered intravenously immediately after preparation to avoid significant loss of activity. Those administering the drug must take precautions, because direct contact with this reactive compound can irritate skin or mucous membranes.

Mechlorethamine has been used primarily in combination with vincristine, prednisone, and procarbazine (MOPP) for the treatment of Hodgkin's disease, but the MOPP regimen is being supplanted as standard therapy for this disease. [202] Topical mechlorethamine has been effective in treating the cutaneous lesions of histiocytosis.[203,204] The use of mechlorethamine as a sclerosing agent in the intracavitary therapy of pleural and pericardial effusions has declined with the advent of less toxic agents such as tetracycline.

The pharmacokinetics of mechlorethamine in humans has not been well delineated. In animals, the drug disappears from plasma in seconds. [190,205] In addition to its rapid spontaneous hydrolysis, mechlorethamine is rapidly metabolized (N-demethylated) in the liver. [205] As a result of this rapid degradation, renal excretion is not likely to play a role in drug clearance.

In addition to its major clinical toxicities of myelosuppression, nausea, and vomiting, mechlorethamine has an anticholinergic effect, leading to diaphoresis, lacrimation, and diarrhea. It is a potent vesicant, producing a sclerosing thrombophlebitis above the site of administration and severe local tissue damage if extravasated. If extravasation occurs, sodium thiosulfate should be injected into the area as rapidly as possible to neutralize the drug. [206] Neurotoxicity in the form of an acute or delayed encephalopathy has been reported with the use of high doses of mechlorethamine. [207]

### *Oxazaphosphorines*

The oxazaphosphorines, cyclophosphamide and ifosfamide, are inactive prodrugs that require biotransformation by hepatic microsomal oxidative enzymes before expressing alkylating activity.[208,209] Cyclophosphamide is a true nitrogen mustard derivative with a bifunctional bischloroethylamine side chain. Ifosfamide is also bifunctional but has one chloroethyl group shifted to a ring nitrogen ( Fig. 10-5). Cyclophosphamide is one of the most widely used anticancer drugs, with a broad range of clinical activity that includes the acute leukemias and a variety of solid tumors ( Table 10-5). It is also used in preparative regimens before bone marrow or peripheral stem cell transplantation and as an immunosuppressant in nonmalignant disorders. Ifosfamide appears to have a similar spectrum of antitumor activity and is undergoing intensive clinical evaluation in the treatment of a variety of childhood cancers. Phase II trials have demonstrated the activity of ifosfamide alone or in combination with etoposide in sarcomas (e.g., Ewing's sarcoma, rhabdomyosarcoma, and osteosarcoma), lymphoma, germ cell tumors, Wilms' tumor, and neuroblastoma.[210,211 and 212]

Cyclophosphamide is usually administered as a single-dose bolus or in fractionated doses over 2 to 3 days. Ifosfamide is administered on a fractionated schedule over 5 days, because in the initial trials, the single-dose schedule produced intolerable nephrotoxicity, cystitis, and neurotoxicity. Ifosfamide has also been administered as a continuous 5-day infusion. The maximally tolerated total dose of ifosfamide is approximately threefold to fourfold higher than an equitoxic dose of cyclophosphamide.[213]

#### Biotransformation

The metabolic pathways of cyclophosphamide and ifosfamide are shown in Figure 10-6. The steps in the biotransformation of these two drugs are qualitatively identical. Hydroxylation of the 4-carbon position on the ring by hepatic microsomal mixed-function oxidases yields the primary 4-hydroxy metabolites, which are in spontaneous equilibrium with the open-ring aldehydes. Hydroxylation of cyclophosphamide is catalyzed primarily by CYP2B6 P450 enzyme with minor contributions from CYP3A4 and CYP2C9, and ifosfamide hydroxylation is catalyzed primarily by CYP3A4 with a minor contribution from CYP2A6.[214] Although not chemically reactive, the 4-hydroxy metabolites are cytotoxic *in vitro* and are thought to be the transport forms of the active alkylating species, phosphoramide mustard and isophosphoramide mustard, which are formed by spontaneous elimination of acrolein from the open-ring aldehydes. Quantitatively, the rate of activation of cyclophosphamide is greater than that of ifosfamide, and this difference in the rate of activation accounts for the difference in clinical pharmacokinetics and maximum tolerated dose of the two isomers.[209,215,216,217,218,219 and 220]

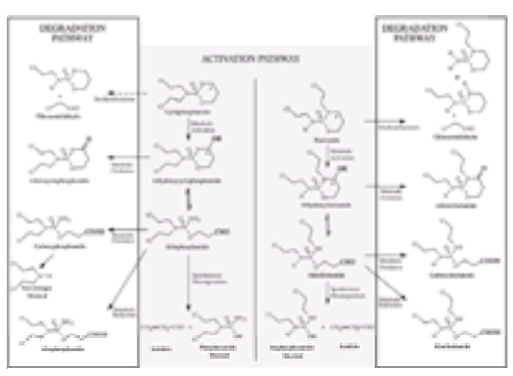

**FIGURE 10-6.** Metabolic pathways for the oxazaphosphorines, cyclophosphamide and ifosfamide. Both compounds must undergo hydroxylation at the 4 position before expressing alkylating activity; this reaction is catalyzed by hepatic microsomal enzymes. The 4-hydroxy metabolites are in spontaneous equilibrium with the open-ring aldehydes (aldophosphamide or aldoifosfamide), which can release acrolein and form the active alkylating mustards (phosphoramide mustard or isophosphoramide mustard). Further oxidation at the 4 position of the primary metabolites leads to the formation of inactive metabolites (ketocyclophosphamide and carboxyphosphamide or ketoifosfamide and carboxyifosfamide), which are excreted in the urine. The open-ring aldehyde metabolites can be chemically reduced to an alcohol (alcophosphamide or alcoifosfamide). Inactivation by dechlorethylation leads to formation of the potentially toxic by-product chloracetaldehyde. This is a minor pathway for cyclophosphamide but is more active with ifosfamide.

Further oxidation of the hydroxyl group at the 4-carbon position on primary metabolites by aldehyde dehydrogenase leads to inactivation. 4-Ketocyclophosphamide and carboxyphosphamide are the principal urinary metabolites of cyclophosphamide. Aldehyde dehydrogenase is found in a wide variety of tissues and in cancer cells.[215,220] The chloroethyl side chain can also be enzymatically cleaved by CYP3A4. Less than 10% of the administered dose of cyclophosphamide is metabolized via this pathway, but up to 50% of the ifosfamide is dechlorethylated, resulting in a greater rate of production of the potentially toxic byproduct chloracetaldehyde compared with cyclophosphamide.[215,216,218,221]

#### Pharmacokinetics

The complexity of oxazaphosphorine metabolism (Fig. 10-6) and the instability of their active metabolites have hampered the study of cyclophosphamide and ifosfamide pharmacokinetics. Methods used to measure plasma drug concentrations have included measurement of total or fractionated radioactivity after administration of radiolabeled cyclophosphamide, total plasma alkylating activity after chemical derivatization, and inactive parent drug or specific metabolites after chromatographic separation.[190,216] The first two assays are nonspecific, because the radioassay cannot differentiate between parent drug and the active and inactive metabolites and because chemical reactivity in the second assay may not correlate with cytotoxicity. Gas chromatographic and high-pressure liquid chromatographic methods are used to measure the concentrations of parent prodrugs and inactive stable metabolites, but these compounds are less relevant because they do not represent the active alkylating species. Chromatographic techniques have also been developed to quantify the active but unstable intermediate metabolites. These

methods use immediate chemical derivatization to prevent breakdown of the metabolites.[209,216,218,220]

The pharmacokinetic behavior of unchanged cyclophosphamide and ifosfamide has been well described. When administrated orally in low doses, 75% to 95% of the cyclophosphamide is absorbed.[209,222,223,224 and 225] The minimal first-pass metabolism after oral administration indicates that the hepatic extraction ratio for cyclophosphamide is low. Plasma concentrations of the active metabolites, 4-hydroxycyclophosphamide and phosphoramide mustard, after oral administration are equivalent to those achieved with intravenous administration.[225] The oral bioavailability of ifosfamide is greater than 95%.[226,227 and 228] Peak concentrations of 4-hydroxy-ifosfamide and chloracetaldehyde were twofold higher than those achieved with the same dose administered intravenously.[209,229]

Cyclophosphamide and ifosfamide are eliminated primarily by hepatic biotransformation to active and inactive metabolites, which are excreted mainly in the urine. Less than 20% of the dose is excreted as unchanged drug in the urine, and biliary excretion of unchanged drug is minimal.[209,223,224,230,231,232,233 and 234] The total body clearance in adults is 30 to 35 mL per minute per $m^2$ and 60 to 80 mL per minute per $m^2$ for cyclophosphamide and ifosfamide, respectively.[219,223,235,236] Total clearance of cyclophosphamide in children (40 to 50 mL per minute per $m^2$) appears to be higher than in adults.[237,238 and 239] The plasma half-life in children (3 to 4 hours) is also reported to be shorter than that in adults (6 to 8 hours).[223,224,230,236,237,238,239 and 240] Ifosfamide clearance in children ranges from 50 to 130 mL per minute per $m^2$, similar to that reported in adults, and the half-life of ifosfamide in children is 1 to 5 hours.[241,242 and 243] Considerable interpatient variability in the disposition and metabolism of the oxazaphosphorines has been observed.[237,241,242,244,245,246 and 247]

Cyclophosphamide and ifosfamide can rapidly induce their own metabolism. With infusional or fractionated dosing, there is a decrease in the plasma half-life and an increase in clearance of the parent prodrugs and an increase in metabolite concentrations.[224,226,240,243,248,249,250,251 and 252] Cyclophosphamide exposure induces the expression of CYP2C9 and CYP3A4 enzyme levels in human hepatocytes.[253] The increase in the rate of metabolism occurs within 12 to 24 hours of the first dose, and a new steady state is achieved by 48 to 72 hours. Over a 5-day course of ifosfamide, the parent drug half-life decreases and the clearance increases by 30% to 50%.[249,251] Conversely, the AUC of the active 4-hydroxy-metabolite increases by 50%,[251,254] which may account for enhanced efficacy of the fractionated dosing schedules.

The oxazaphosphorines are chiral and are administered as a racemic mixture of two optical isomers (i.e., enantiomers) that can be recognized by drug-metabolizing enzymes as being different. Stereochemistry does not appear to have a significant impact on the pharmacokinetics, antitumor activity, or toxicity of cyclophosphamide.[255] However, the clearance of the S-optical isomer of ifosfamide was 1.4-fold more rapid than the clearance of the R-isomer in children, and the half-life of S-ifosfamide was shorter.[243] The clinical significance of this difference in the rate of metabolism of the enantiomers is uncertain.

The fraction of the cyclophosphamide dose that is converted to active metabolites appears to be constant (60% to 70% of the dose), and there is no evidence of saturation of the activating enzymes over a broad dosage range of 100 to 3,000 mg per $m^2$.[230,246] However, at doses of 4,000 mg per $m^2$ used in autologous bone marrow preparative regimens, saturation of drug-activating enzymes becomes apparent.[256,257] Saturation (nonlinearity) of ifosfamide metabolism has also been described at doses exceeding 2,500 mg per $m^2$. The half-life was prolonged to 15 hours, a higher percentage of the drug is excreted in the urine unchanged, and the AUC of ifosfamide metabolites do not increase in proportion to the dose.[218,233,258]

The activated metabolites of cyclophosphamide and ifosfamide appear in plasma rapidly, reach a peak by 2 hours after the dose, and have a half-life of approximately 4 hours.[190,225,259] At equivalent doses, the plasma concentrations of alkylating metabolites of ifosfamide are approximately one-third that generated from cyclophosphamide, presumably because of a difference in the rate of enzymatic activation.[209,215,216,218] Plasma concentrations of the active metabolites are considerably lower than those of the parent prodrug, because of the chemical instability and reactivity of the active 4-hydroxy-metabolites. The plasma concentration of the active 4-hydroxy-metabolites is approximately 1% to 3% of that of the parent drug.[218,254,259,260]

Patients with severe renal function impairment (i.e., creatinine clearance less than 20 mL per minute) have significantly higher plasma alkylating activity as measured by a nonspecific assay.[230,236,261] However, in a single anuric patient, Wagner and associates found no change in the disposition of cyclophosphamide and its activated metabolite,[235] and ifosfamide disposition did not appear to be altered in an anuric child.[262] The degree of cyclophosphamide-related hematologic toxicity does not correlate with the severity of renal insufficiency.[209,263] There is no strong evidence to support dosage modifications of cyclophosphamide in patients with renal dysfunction; however, ifosfamide dosage adjustment may be indicated because of the increased risk of neurotoxicity in patients with renal dysfunction.[109,262] Cyclophosphamide and ifosfamide can be efficiently removed from blood by dialysis.[262,264] The hemodialysis extraction efficiency for 4-hydroxyifosfamide is lower than for the parent drug.[262] Hepatic dysfunction may alter the rate of drug activation and the rate of elimination. With hepatic parenchymal damage, the half-life of cyclophosphamide is prolonged, and peak levels of alkylating activity in plasma are lower.[230]

**Toxicity**

Myelosuppression is the major dose-limiting toxicity of the oxazaphosphorines, but unlike the lipid-soluble alkylating agents, such as the nitrosoureas, it rarely causes cumulative marrow damage. Nausea, vomiting, and alopecia occur in most patients.[54,208]

Hemorrhagic cystitis is a toxicity that is unique to the oxazaphosphorines. It may range from mild dysuria and frequency to severe hemorrhage from bladder epithelial damage. The reported incidence of this complication ranges from 5% to 10% for cyclophosphamide and 20% to 40% for ifosfamide.[54,219] This toxic effect is dose-related and appears to be caused by the activated metabolites and by the biologically active by-products such as acrolein ( Fig. 10-6). The incidence and severity of chemical cystitis can be lessened by aggressive hydration and frequent emptying of the bladder, by bladder irrigation, or by the concurrent administration of mesna (2-mercaptoethane sulfonate). After administration, mesna is rapidly oxidized in plasma to a chemically stable and pharmacologically inert disulfide that is then rapidly excreted by the kidneys and converted back to its chemically reduced active form during tubular transport. It is therefore only active in urine and does not interfere with the antitumor effects of cyclophosphamide or ifosfamide.[117,124,265] Although the dose and schedule of mesna varies, it is commonly administered at a dosage equal to 60% of the total ifosfamide dose, divided into three doses and administered at 0, 4, and 8 hours after ifosfamide.[124] Mesna can be administered orally or intravenously. Mesna also reduces the incidence of oxazaphosphorine-induced bladder cancers in rats, a complication that also has been reported in humans.[219,266]

The oxazaphosphorines are also nephrotoxic. Cyclophosphamide can have a direct renal tubular effect that can result in water retention.[267,268] Ifosfamide produces proximal tubular damage resembling Fanconi's syndrome, with glucosuria, amino aciduria, and phosphaturia. Rickets has been observed in younger children.[269,270,271,272,273,274 and 275] Decreased glomerular filteration rate (GFR) and distal tubular damage manifested by concentrating defects and renal tubular acidosis also have been reported.[276,277] Comprehensive follow-up evaluation of glomerular and tubular function in children previously treated with ifosfamide revealed dysfunction in 78%, including 28% with moderate or severe nephrotoxicity.[278] Cumulative doses exceeding 70 to 80 g per $m^2$ appear to be the primary risk factor.[278,279] Young children are at higher risk for proximal renal tubular damage from ifosfamide.[269]

Other toxic effects of ifosfamide include reversible neurotoxicity characterized by somnolence, disorientation, and lethargy in approximately 20% of patients and, more rarely, hallucinations, coma, and seizures.[280,281] The incidence of neurotoxicity was 50% with oral administration, presumably the result of first-pass metabolism of ifosfamide to neurotoxic metabolites.[218] The neurotoxicity has been attributed to the metabolite chloracetaldehyde ( Fig. 10-6), which results from dechlorethylation of ifosfamide.[282] The dechlorethylation pathway accounts for 50% of ifosfamide metabolism but less than 10% for cyclophosphamide. The incidence of neurotoxicity also appears to be greater in children who previously received high cumulative doses of cisplatin. Cisplatin-induced renal damage might have diminished the rate of elimination of neurotoxic metabolites of ifosfamide in these patients.[283] Neurotoxicity may be reversible or preventable with methylene blue.[284,285] Transient hepatic dysfunction has also been reported with ifosfamide.[219] Cardiac toxicity has been observed in patients treated with high doses (greater than or equal to 100 to 200 mg per kg) of cyclophosphamide. Ifosfamide has also been implicated as a cause of cardiomyopathy and arrhythmias at doses of 10 to 18 g per $m^2$ in a transplant setting.[286]

Although pulmonary toxicity is not commonly associated with the oxazaphosphorines, cases of early- and late-onset interstitial pneumonitis from cyclophosphamide and ifosfamide have been reported.[287,288,289 and 290] Clinical features of drug-induced lung injury typically include fever, cough, dyspnea on exertion, diffuse interstitial infilterates on chest radiographs, and bilateral pleural thickening usually presenting within weeks to months of drug exposure. Factors that appear to augment oxazaphosphorine lung damage include administration of cyclophosphamide in combination with other cytotoxic drugs and the concurrent use of cyclophosphamide and irradiation. Inspired oxygen has also been shown to enhance lung injury in animals.[290] Oxazaphosphorine-induced lung injury appears to be unresponsive to

corticosteroid therapy, and the prognosis is poor.

### Resistance

Mechanisms of resistance to cyclophosphamide involve intracellular inactivation of the activated metabolites and enhanced repair of DNA adducts. [179,208,291] Elevated levels of glutathione resulting from increased activity of the enzyme glutathione-S-transferase, can detoxify the biologically active metabolites of the oxazaphosphorines.[291,292,293,294 and 295] Sensitivity to cyclophosphamide is also inversely correlated with intracellular levels of the enzyme aldehyde dehydrogenase, which oxidizes activated cyclophosphamide metabolites to inactive forms.[195] Intracellular levels of this enzyme can be estimated in tissue or tumor specimens by histochemical staining. Enhanced DNA repair by nucleotide excision repair enzymes or $O^6$-alkylguanine-DNA alkyltransferase may also contribute to resistance. [291]

### Drug Interactions

Compounds known to alter the activity of P450 microsomal enzymes can affect the rate of activation and elimination of the oxazaphosphorines. Phenobarbital pretreatment enhances the rate of metabolism of cyclophosphamide and its activated metabolites in animals and in humans but does not affect the total quantity of alkylating metabolites formed in humans.[143] Cimetidine, which can interfere with the metabolic clearance of many compounds, increases concentrations of alkylating metabolites and prolongs the survival of tumor-bearing mice treated with cyclophosphamide. [296,297] This potential interaction has not been delineated in humans, but the oncologist should be cautious in combining these agents because of the possibility of exaggerated toxicities. Concurrent allopurinol appears to enhance the myelotoxicity of cyclophosphamide.[298] Busulfan, which is administered with cyclophosphamide in transplant preparatory regimens, can block the conversion of cyclophosphamide to its active metabolite, when cyclophosphamide is administered less than 24 hours after a dose of busulfan. [299] Concurrent fluconazole, which can inhibit the metabolism of drugs that are substrates of CYP2C9 and CYP3A4, can also block the activation of cyclophosphamide, whereas dexamethasone and chlorpromazine appear to induce the metabolism of cyclophosphamide.[237]

#### *Melphalan*

Melphalan (L-phenylalanine mustard, Fig. 10-5) is a rationally designed anticancer drug that has the bischloroethylamine moiety attached to the amino acid phenylalanine, with the intention that it would be taken up preferentially by melanin-producing cancers. Although this agent has a broad range of clinical activity in adult cancers (e.g., multiple myeloma, melanoma, breast and ovarian cancers, lymphoma), its use has been limited in the treatment of childhood cancers. At standard doses (35 mg per $m^2$), melphalan appears to be active against rhabdomyosarcoma.[300] The administration of bone marrow ablative doses (140 to 220 mg per $m^2$) of melphalan followed by rescue with autologous bone marrow transplant has resulted in high response rates in children with neuroblastoma, Ewing's sarcoma, and acute leukemia.[185,301,302,303 and 304] Melphalan has also been administered intra-arterially by isolated perfusion for cancers localized to an extremity or the liver. [305,306]

Like other chemically reactive compounds, melphalan is rapidly cleared from the body. It is inactivated after spontaneous hydrolysis or alkylation reactions with plasma or tissue proteins. Melphalan does not appear to undergo any appreciable enzymatic degradation. [54,201,307] The absorption of melphalan after oral administration has been reported to be incomplete and highly variable. [201,307,308,309 and 310] The fraction of a dose absorbed usually ranges from 32% to 100%, but patients with no detectable drug in plasma and urine after an oral dose have been reported. [308,309 and 310] Melphalan bioavailability is higher and less variable when the drug is administered in the fasting state.[311] The incidence of myelosuppression is lower with oral than with intravenous melphalan, and poor therapeutic response may be attributable in part to poor absorption in some patients receiving oral melphalan. [308,312] The disposition of melphalan after intravenous administration in children and adults is similar.[313] With standard parenteral doses, the terminal half-life ranges from 60 to 120 minutes, with a total clearance exceeding 200 mL per minute per $m^2$.[309,310,314,315 and 316] Drug disposition in children and adults is not dose-dependent. Pharmacokinetic parameters in patients receiving high-dose therapy (up to 220 mg per $m^2$) are similar to those found at standard doses.[313,317,318,319,320,321 and 322] Wide interindividual variation in melphalan AUC and clearance has been observed in most studies and has led to the development of pharmacokinetically guided dosing strategies for melphalan. [190]

Renal excretion is a minor route of elimination, accounting for 20% to 30% of total drug clearance. [109,314,323] However, patients with renal dysfunction have a higher incidence of hematologic toxicity, and in nephrectomized animals, the half-life of intravenous melphalan is prolonged, and enhanced myelosuppression is observed.[324,325] In a group of patients with a wide range of renal function, drug clearance after high-dose melphalan was correlated with creatinine clearance, but the decrease in melphalan clearance in patients with renal dysfunction was insignificant compared with the high degree of interindividual variation in drug disposition. [326] In another study of high-dose melphalan, the clearance of melphalan in patients with renal dysfunction (27.5 L per hour) was similar to that in patients with normal renal function (23.6 L per hour).[327]

At standard doses (5 to 35 mg per $m^2$), myelosuppression is the primary toxicity, and cumulative marrow damage has been observed with repeated doses. [54,201] Pulmonary fibrosis and secondary leukemia are late effects associated with the chronic administration of melphalan. [201] At high doses with autologous bone marrow or stem cell reinfusion, gastrointestinal toxicity (e.g., mucositis, esophagitis, or diarrhea) becomes dose limiting. [185,302,321]

### Nitrosoureas

The nitrosoureas are a group of lipid-soluble alkylating agents ( Fig. 10-7) that are highly active in experimental tumor models, including intracranially implanted tumors. The 2-chloroethyl derivatives, carmustine (BCNU) and lomustine (CCNU), are the nitrosoureas most widely used in pediatric oncology. [328,329] Rapid spontaneous chemical decomposition of these compounds in solution generates an alkylating intermediate (chloroethyldiazohydroxide) and an isocyanate moiety that can carbamoylate amine groups on proteins. Alkylation, including crosslinking of DNA by the monofunctional lomustine and the bifunctional carmustine, is generally accepted as the primary mechanism of action of the nitrosoureas.[330,331 and 332] However, the isocyanates can inhibit DNA repair of alkylator damage and may contribute to the antitumor activity and the toxicity of the nitrosoureas.[328,329] The nitrosoureas alkylate the $N^3$ position on cytidine and the $N^7$ and $O^6$ positions on guanosine,[179] but the primary factor determining tumor cell resistance to the nitrosoureas is the capacity to enzymatically repair $O^6$-alkyl-guanosine.[333,334] $O^6$-benzylguanine, an inhibitor of the DNA repair protein, $O^6$-alkylguanine-DNA-alkyltransferase, is being clinically tested in combination with carmustine. [335]

The nitrosoureas have been used primarily to treat patients with brain tumors or lymphomas, and high-dose carmustine has been incorporated into transplant preparative regimens. Delayed and cumulative myelosuppression and other serious long-term cumulative renal and pulmonary toxic effects, which are particularly concerning in children, limit the clinical utility of these agents in combination regimens. [336,337] Carmustine has been incorporated into biodegradable polymer wafers that can be implanted into the tumor cavity after surgical resection for brain tumors. Drug is released slowly from the polymer wafer over 2 weeks, providing prolonged sustained exposure to high concentrations of carmustine locally with a lower risk of systemic toxicity. [338,339 and 340]

#### *Biotransformation and Pharmacokinetics*

In addition to their rapid spontaneous decomposition, nitrosoureas undergo significant hepatic metabolism. [328,341] The cyclohexyl ring of lomustine is hydroxylated at the 4-position to yield two isomeric derivatives that are more soluble and have greater alkylating activity than the parent drug. [328,329] Carmustine is inactivated by denitrosation through the action of microsomal enzymes and glutathione conjugation.[328] As a result of this rapid spontaneous and enzymatic degradation, the clearance of nitrosoureas from plasma is extremely rapid. In early studies of carmustine and lomustine, parent drug could not be detected in plasma after intravenous or oral administration.[342,343] With high-dose carmustine administered by intravenous infusion, the half-life was 22 minutes, and clearance exceeded 2,000 mL per minute per $m^2$.[344] Similar results have been reported with standard doses of the drug (half-life, 22 minutes; clearance, 1,700 mL per minute per $m^2$).[345] The half-life of the active 4-hydroxylated metabolites of lomustine is 3 hours.[346] When administered orally, the nitrosoureas are well absorbed, and lomustine is extensively converted to hydroxylated metabolites presystemically during its first pass through the liver. [347] These results confirm that the metabolites of lomustine are primarily responsible for the drug's antitumor activity. Although carmustine is also well absorbed, severe vomiting after oral administration frequently precludes adequate absorption. [348]

The lipid-soluble nitrosoureas are widely distributed and readily penetrate into the CNS. After equilibration, drug concentrations in the cerebrospinal fluid (CSF) approximate those in plasma, which accounts for the activity of this group of drugs in treating brain tumors. [343,349] Implantation of carmustine-containing polymer wafers into the tumor bed for brain tumors bypasses the blood–brain barrier and provides local drug concentrations that are higher than those achieved with systemic administration. However, the depth of penetration into the brain parenchyma from the wafer is very limited (5 mm at 30 hours) due to the rapid diffusion of drug into

capillaries.[350,351]

### *Toxicity*

Gastrointestinal toxicity (i.e., nausea and vomiting) and cumulative delayed myelosuppression are the most consistent side effects of the nitrosoureas. The nadir of blood counts occurs 4 to 5 weeks after administration, and the platelet count tends to be the most affected. With repeated dosing, chronic marrow hypoplasia develops.[329] With cumulative doses of more than 1,500 mg per $m^2$, progressive renal atrophy has been reported.[352,353] Although in children this complication has been primarily associated with sesmustine (methyl-CCNU), it has also been reported after high cumulative doses of lomustine. Mitchell and Schein recommend that if nitrosourea therapy continues for more than 15 months or if cumulative doses of greater than 1,000 mg per $m^2$ are reached, patients should be evaluated for nephrotoxicity and therapy discontinued if renal size or GFR is significantly decreased.[329] Similar cumulative doses (greater than or equal to 1,500 mg per $m^2$) of carmustine are associated with progressive and frequently fatal pulmonary toxicity characterized by cough, dyspnea, tachypnea, and a restrictive-type ventilatory defect.[290,336,354,355] Carmustine-induced pulmonary toxicity can vary substantially in time to onset, manifestations, outcome, and histopathologic appearance.[336] Long-term follow-up of 17 children with brain tumors treated with carmustine revealed that 6 (35%) had died of pulmonary fibrosis and that all of the surviving patients studied had radiographic abnormalities or restrictive defects on spirometry.[337] Four of the six patients who died presented with pulmonary symptoms 8 to 13 years after treatment. Females appear to be more susceptible to the complication than males.[336,356] Pulmonary fibrosis appears less frequently with lomustine, but cases have been reported.[290] CNS toxicity has been reported rarely.[329] High-dose carmustine (300 to 750 mg per $m^2$) can produce hypotension, tachycardia, flushing, and confusion.[345]

### *Drug Interactions*

In animals, phenobarbital enhances the microsomal metabolism of the nitrosoureas and significantly reduces the antitumor activity of carmustine and, to a lesser extent, that of lomustine.[357] This potential interaction has not been studied in humans. Carmustine, an inhibitor of glutathione reductase, potentiates the hepatotoxicity of high doses of acetaminophen in animals. Liver damage results from the depletion of intrahepatocyte glutathione by a minor but reactive quinone metabolite of acetaminophen.[358]

## Busulfan

The bifunctional alkylating agent, busulfan, is an alkyl alkane sulfonate ( Fig. 10-4). The busulfan alkylation reaction occurs by nucleophilic displacement of the methylsulfonate group on either end of the molecule (Fig. 10-4). Busulfan has a greater propensity to alkylate thiol groups on amino acids and proteins than the nitrogen mustards, but it also can alkylate the $N^7$ position on guanosine.[54]

Busulfan is not water soluble and is commercially available as an oral formulation (2 and 25 mg tablets). An investigational dimethyl sulfoxide (DMSO)-based intravenous solution has been used in pharmacokinetic studies,[359,360] and a microcrystalline suspension (Spartaject Busulfan) is under clinical development for intravenous and intrathecal administration. Busulfan has been used in conventional doses (1.8 mg per $m^2$ per day) as palliative therapy for chronic myelogenous leukemia (CML), and high-dose busulfan (16 mg per kg or 600 mg per $m^2$, in 16 divided doses every 6 hours) has also become an important component of bone marrow transplant preparative regimens, usually in combination with cyclophosphamide.[184]

The pharmacokinetics of busulfan is highly variable and age-dependent.[361,362] Oral busulfan is rapidly absorbed, peaking 1 to 2 hours after the dose; and the bioavailability of oral busulfan in adults and children is 70% (range, 40% to greater than 90%).[359,360,363] Busulfan is a small lipophilic compound and penetrates well across the blood–brain barrier. CSF concentrations at steady state are equivalent to those in plasma.[364,365] The primary route of elimination of busulfan appears to be glutathione conjugation, which is catalyzed by an isoform of glutathione- *S*-transferase (GSTA1-1).[361,366] Busulfan has a short half-life of 2.5 hours and a clearance in children of 80 mL per minute per $m^2$.[359,367] These pharmacokinetic parameters appear to be linear over the wide dosage range used. Compared with adults, busulfan apparent clearance (Cl/F) is more rapid in children, especially children who are 5 years of age or younger[359,368,369]; and the higher apparent clearance in young children is the result of more rapid glutathione conjugation rather than lower bioavailability.[369]

The variability in the disposition of busulfan after oral dosing can result in up to a 20-fold range in systemic drug exposure among patients treated with a fixed dose (16 mg per kg).[361,370] Factors contributing to this variability include the age-dependent clearance, variable bioavailability, hepatic dysfunction, drug interactions, and circadian rhythmicity.[370] The busulfan AUC in young children treated with 1 mg per kg is less than one-half the AUC in adults receiving the same dose ( Fig. 10-8).[361,365,371] On the every-6-hour oral dosing schedule, busulfan trough plasma concentrations exhibited a marked circadian rhythm, with the highest troughs occurring at 6:00 a.m.[362,372]

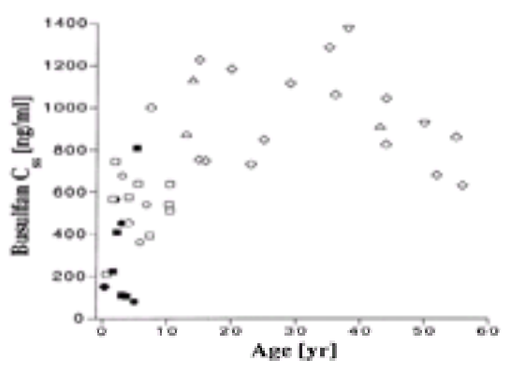

**FIGURE 10-8.** Plasma busulfan steady state concentrations ($C_{ss}$) as a function of age. $C_{ss}$ is derived by dividing the area under the curve by the dosing interval (6 hours). Patients were treated with 16 to 30 mg per kg of busulfan in combination with cyclophosphamide before bone marrow transplant. Closed symbols represent patients who rejected their graft or had a mixed chimera. Patients who experienced grade 0 treatment-related toxicity are designated by the circles, grade 1 toxicity by the squares, grade 2 toxicity by the diamonds, grade 3 toxicity by the upright triangles, and grade 4 toxicity by the inverted triangles. Young children had substantially lower $C_{ss}$, less toxicity, and were at greater risk for graft rejection. (From data presented in Table 1, Table 2, and Table 3 in Slattery JT, Sanders JE, Buckner CD, et al. Graft-rejection and toxicity following bone marrow transplantation in relation to busulfan pharmacokinetics. Bone Marrow Transplant 1995;16:31.)

In the transplant setting, busulfan plasma levels (AUC or steady state level, which is derived from AUC and dosing interval) appear to be predictive of hepatic toxicity and graft rejection.[361] In adults, the risk of developing severe hepatic veno-occlusive disease (VOD) is higher when the busulfan AUC exceeds 1,500 µM • minute ($C_{ss}$ of 1,000 ng per mL),[368,373,374] but this toxic level has not been confirmed in children.[375,376] With a busulfan and cyclophosphamide preparative regimen, graft rejection is more common in children (Fig. 10-8) and adults with a busulfan $C_{ss}$ less than 600 ng per mL.[361,368,376] The busulfan AUC or $C_{ss}$ associated with VOD or graft rejection are probably dependent on the preparative regimen administered and the underlying disease.[361] The busulfan dose can be pharmacokinetically adjusted to achieve a $C_{ss}$ or AUC in a safe and effective range by monitoring patients after the first dose.[361,377]

Myelosuppression is the primary toxicity from busulfan. Gastrointestinal toxicity, which is only observed at high doses, includes nausea, vomiting, and mucositis. Busulfan can rarely produce pulmonary toxicity (busulfan lung), which is characterized by diffuse interstitial fibrosis and bronchopulmonary dysplasia. Busulfan lung presents with cough, fever, rales, and dyspnea and usually progresses to respiratory failure.[290,367] Hepatic VOD is observed in up to 40% of patients who are treated with high-dose busulfan without pharmacokinetically guided dosing, and the VOD is severe in 10% of patients.[370,375,378,379] Seizures have also been reported with high-dose therapy, but they are preventable with prophylactic anticonvulsants.[367,380] Girls who receive high-dose busulfan (600 mg per $m^2$) have a high incidence of

severe and persistent ovarian failure. [381]

**Nonclassical Alkylating Agents**

***Platinum Compounds***

Cisplatin and carboplatin are heavy metal coordination complexes (Fig. 10-9) that exert their cytotoxic effects by platination of DNA, a mechanism of action that is analogous to alkylation. Reactive aquated intermediates are formed in solution in a manner similar to the nitrogen mustards (Fig. 10-4). Chloride is the leaving group that is replaced by a water molecule in cisplatin, and dicarboxycyclobutane is the leaving group in carboplatin. These reactive intermediates covalently bind to DNA ($N^7$-position of adenine and guanine) and form intrastrand and interstrand DNA crosslinks. [382,383,384,385 and 386] The rate of reaction of these platinum analogs with water to form reactive intermediates is an important determinant of the stability of the compounds in solution and influences the drugs' pharmacokinetics. [384,387,388] Cisplatin is more reactive than carboplatin and is less stable in aqueous solution. Chloride-containing solutions, such as 0.9% NaCl, are required to stabilize cisplatin before administration.

Cisplatin is an effective agent for the treatment of testicular tumors and has demonstrated activity against osteosarcoma, neuroblastoma, Wilms' tumor, other germ cell tumors, and brain tumors. [389,390,391 and 392] The drug is administered intravenously on a variety of schedules, including a single dose, infused over 4 to 6 hours; divided doses, usually daily for 5 days; and by continuous infusion for up to 5 days. The divided dose and continuous-infusion schedules may lessen the gastrointestinal and renal toxicities. [389] Other strategies used to overcome cisplatin's dose-limiting nephrotoxicity include fluid hydration, mannitol diuresis, the use of hypertonic sodium chloride solutions to promote chloruresis, and the coadministration of sodium thiosulfate or amifostine. [132,393,394 and 395] Cisplatin has been administered regionally in a number of trials, including intraperitoneally for ovarian cancer, intravesicularly for bladder cancer, intrapleurally for the malignant pleural effusions, and intra-arterially for brain tumors and for sarcomas of the extremity, including osteosarcoma. [384,388,396]

Compared with cisplatin in adult trials, carboplatin has a similar spectrum of antitumor activity, but may be less efficacious than cisplatin in several solid tumors, including testicular cancer. [386,397] The pharmacokinetic and toxicity profiles of the two platinum analogs are quite different (Table 10-5 and Table 10-6). [387,398] In children, carboplatin is administered as a bolus dose of 400 to 600 mg per $m^2$ or in divided doses of 400 mg per $m^2$ on 2 consecutive days or 160 mg per $m^2$ daily for 5 days, every 4 weeks. Adaptive dosing formulas, which individualize carboplatin dose based on the GFR, have also been developed for children and are described in Pharmacokinetics below. Carboplatin is active against brain tumors, neuroblastoma, sarcomas, and germ cell tumors. [399,400 and 401]

***Pharmacokinetics***

The chemical stability (reactivity) of the platinum analogs is a critical determinant of their pharmacokinetics. The reactive intermediates of cisplatin and carboplatin are rapidly and covalently bound to plasma protein and tissue. [384,388,402] After binding with plasma or tissue proteins, the reactive platinum intermediates are inactivated. Only the free (unbound) platinum species (including the parent drug) are cytotoxic. [403,404] This interaction of platinum compounds with protein is a time-dependent reaction. For cisplatin, more than 90% of total platinum in plasma is protein bound and inactivated within 2 to 4 hours, [388,405] and this represents the major route of drug elimination. Carboplatin is more chemically stable, and only 20% to 40% of total platinum is protein bound at 2 hours, and this slowly increases to 50% over 24 hours. [406,407 and 408] Tissue-bound platinum may be retained in the body for a prolonged time and is still measurable in plasma for 10 to 20 years after treatment. [409]

Techniques used to assay plasma concentrations of platinum analogs include measurement of total platinum (protein-bound plus unbound forms) by flameless atomic absorption spectrometry or separation of unbound platinum species by ultrafilteration before flameless atomic absorption spectrometry or high-pressure liquid chromatography to separately quantify the parent drug and other unbound (aquated) platinum species.

The pharmacokinetic behavior of bound and unbound, active forms of platinum differ appreciably. For cisplatin, after an initial rapid decay, total platinum (greater than or equal to 95% protein-bound) persists in plasma and can be detected in urine for many days. The terminal half-life of total platinum ranges from 1 to 5 days. [403,405,410] In contrast, the unbound, active platinum species have a much more rapid decline, with a half-life of less than 1 hour, which is primarily a reflection of the chemical reactivity of cisplatin and the avid binding of the reactive intermediates to tissue and plasma protein. [403,411] In children receiving cisplatin, the half-lives of total and ultrafilterable (unbound) platinum are 44 hours and 40 minutes to 1.5 hours, respectively. [392,412,413]

Approximately 50% of the platinum administered as cisplatin is excreted in the urine over 4 to 5 days, most in an inactive form. [405,414,415] Initially, total platinum clearance equals or exceeds creatinine clearance, reflecting excretion of unbound platinum species, but as protein binding becomes extensive, renal clearance of total platinum drops to only a small fraction of creatinine clearance. [403] The renal clearance of the unbound, ultrafilterable species of platinum can actually exceed creatinine clearance, suggesting tubular secretion. [412,416,417] In children, the clearance of cisplatin was not related to the GFR. [412] Approximately 25% of unbound platinum species is excreted in the urine, and the degree of renal excretion is schedule dependent (i.e., greater with short infusions). [418] In patients with impaired renal function, the peak level of active, unbound platinum was elevated, but the terminal half-life was not prolonged, presumably because of the rapid reaction of these active species with plasma and tissue protein leading to inactivation. [414,419] However, dosage reductions in patients with renal dysfunction may be indicated because of the drug's nephrotoxic effects, which could further impair renal function. [108,388]

The disposition of carboplatin is characterized by a lower rate and degree of protein binding than for cisplatin. As a result, the terminal half-life of unbound carboplatin is longer (2 to 3 hours), and renal excretion is the primary route of elimination. [386,387 and 388,406,408,413,415,420] By 24 hours, as much as 70% of the total platinum from carboplatin is excreted in the urine, most as parent drug. Carboplatin is dialyzable in patients with severe renal insufficiency. [421,422]

Pharmacokinetic parameters for carboplatin in children are similar to those in adults. The total clearance in children with a normal creatinine clearance is approximately 70 mL per minute per $m^2$, and the half-life is 2 to 3 hours. [413,423,424 and 425] In children younger than 5 years of age, carboplatin clearance was 120 mL per minute per $m^2$, but in children younger than 1 year of age, the clearance was 75 mL per minute per $m^2$. [426] These age-related differences in carboplatin clearance appear to be related to differences in the GFR. The variability in carboplatin clearance supports the use of the adaptive dosing formulas based on GFR described subsequently.

The total clearance of ultrafilterable carboplatin is highly correlated with GFR (Fig. 10-10), [105,387,406,408,425,426 and 427] and patients with renal dysfunction and higher carboplatin AUCs have a greater probability of experiencing dose-limiting hematologic toxicity. These associations allowed the development of adaptive dosing formulas for individualizing carboplatin dose based on GFR in adults and children (Table 10-7). [105,423,425,427,428,429 and 430] The use of these formulas to calculate an individualized dose decreases the variability in systemic drug exposure (AUC) and reduces the incidence of severe thrombocytopenia. [406,431,432] When administered as a single dose in combination with ifosfamide and etoposide, a targeted carboplatin AUC of up to 10 mg • minute per mL was tolerable. [431] In ovarian and testicular cancers in adults, a carboplatin AUC of 5 to 7 mg • minute per mL was associated with a higher response rate and a lower risk of disease recurrence. [427,432]

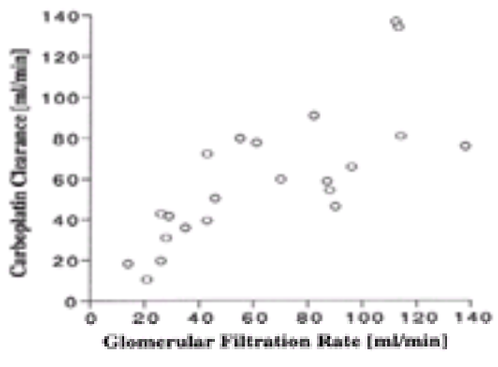

**FIGURE 10-10.** Relation between carboplatin clearance and glomerular filteration rate as measured by $^{51}$Cr-EDTA clearance in 22 children. (Adapted from Newell

DR, Pearson ADJ, Balmanno K, et al. Carboplatin pharmacokinetics in children: the development of a pediatric dosing formula. J Clin Oncol 1993;11:2314.)

| Population | Formula[a] |
|---|---|
| Adults[418] | $D\ [mg/m^2] = 0.015 \times CL_{cr}[mL/min/m^2] \times \left(\frac{prePlt - trgtPlt}{prePlt} \times 100 - priorRx\right) + 86$ |
| Adults[419] | $D\ [mg] = trgtAUC\ [mg \cdot min/mL] \times (GFR\ [mL/min] + 25)$ |
| Children[419] | $D\ [mg/m^2] = trgtAUC\ [mg \cdot min/mL] \times (0.93 \times GFR\ [mL/min/m^2] + 15)$ |
| Children[419] | $D\ [mg] = trgtAUC\ [mg \cdot min/mL] \times GFR\ [mL/min] + (0.36 \times BW\ [kg])$ |

BW, body weight; $CL_{cr}$, creatinine clearance; D, dose; GFR, glomerular filteration rate estimated by radioisotopic method; prePlt, pretreatment platelet count; priorRx, 0 for previously untreated and 17 for previously treated; trgtAUC, target systemic drug exposure (AUC); trgtPlt, target nadir platelet count.
[a]Units for each parameter are listed in the brackets.

**TABLE 10-7. ADAPTIVE DOSING FORMULAS FOR TARGETING CARBOPLATIN DOSE TO ACHIEVE A DESIRED NADIR PLATELET COUNT OR AREA UNDER THE CURVE (AUC), WITH THE TARGET AUC RANGING FROM 7 TO 10 MG•MINUTE PER ML**

***Toxicity***

The toxicity profiles of these two platinum analogs are strikingly different. Cisplatin is associated with only mild myelosuppression but produces significant and potentially irreversible nephrotoxicity, ototoxicity, and neurotoxicity; the dose-limiting toxicity of carboplatin is hematologic toxicity, primarily thrombocytopenia, and the nonhematologic toxicities observed with cisplatin are only seen at doses of carboplatin exceeding 800 mg per $m^2$.[384,387,398,433]

Nephrotoxicity, manifested as azotemia and electrolyte disturbances (especially hypomagnesemia requiring oral supplementation), was the dose-limiting toxicity in the initial clinical trials with cisplatin.[433,434 and 435] The exact mechanism of cisplatin nephrotoxicity is not defined, but patients experience a reduction in renal blood flow and GFR and a loss of tubular function. Pathologic changes are seen primarily in the renal proximal and distal tubule epithelium and collecting ducts.[394,433,436,437] Renal damage from cisplatin is cumulative.

Although pretreatment hydration, diuresis, chloruresis, and less-toxic dose schedules have reduced the incidence and severity of cisplatin-induced nephrotoxicity, moderate and permanent reductions in the GFR of patients receiving cisplatin have been documented.[438,439 and 440] However, in a long-term follow-up study of 40 children who received a median of 500 mg per $m^2$ of cisplatin, 22 of the 24 patients with abnormally low end-therapy GFRs partially recovered, with a median increase in GFR of 13 mL per minute per $m^2$.[441] The long-term nephrotoxic effects of cisplatin in infants are similar to those reported in older children.[442]

Pretreatment with amifostine lessens the severity of renal damage by cisplatin without altering the antitumor effect of the drug in adults.[132,443] The proportion of patients who experienced a greater than or equal to 40% reduction in creatinine clearance after at least four courses of cisplatin was 32% with cisplatin alone and 10% when amifostine was administered before cisplatin.[444] Amifostine also lowered the incidence and severity of neurotoxicity and ototoxicity in adults.[443]

As a result of its nephrotoxic effects, cisplatin can alter its own elimination rate and that of other drugs, such as methotrexate, that rely on renal excretion.[445] In one series, the renal clearance of ultrafilterable platinum fell from almost 500 mL per minute with the first course to 150 mL per minute by the fourth course in patients receiving repeated doses, probably as a result of decreased renal tubular secretion of the drug.[446] Higher renal cortical concentrations of platinum were found at autopsy in patients who had clinical renal toxicity than in patients without evidence of renal toxicity.[447]

As methods to prevent nephrotoxicity have allowed the administration of higher single and cumulative doses of the drug, ototoxicity and peripheral neuropathy have become more prominent.[433] Cisplatin causes a reversible sensory peripheral neuropathy (i.e., numbness, tingling, and paresthesias) at cumulative doses of 300 to 600 mg per $m^2$.[281,433] Lhermitte's sign (an electric shock sensation when the neck is flexed) is common at high cumulative doses of cisplatin.[448] Symptoms may progress after discontinuation of cisplatin and persist for months to years. Seizures and encephalopathy have also been reported in children receiving intensive cisplatin therapy.[449] The irreversible hearing loss is in the high-frequency range and appears to be related to a cumulative dose of cisplatin of greater than 400 mg per $m^2$.[401,450,451 and 452] Other toxic effects include prominent nausea and vomiting, mild myelosuppression, Raynaud's phenomenon, and hypersensitivity reactions.[389]

Carboplatin's myelosuppressive effects are delayed, with platelet nadirs typically seen up to 3 weeks after the dose and milder granulocyte nadirs at 3 to 4 weeks, which determines the frequency with which the drug can be administered. Some patients require 5 to 6 weeks to recover completely.[453] Not only are the nephrotoxicity, ototoxicity, and peripheral neuropathy from carboplatin milder than cisplatin, but the nausea and vomiting, which can be dose-limiting with cisplatin, are also less severe.[387,453,454] High cumulative doses of carboplatin are associated with a small drop in GFR and serum magnesium, but these changes are usually not clinically significant.[455] Hypersensitivity reactions to carboplatin are relatively common, and the risk increases after multiple cycles of therapy.[456,457]

***Resistance***

Studies in preclinical tumor models have implicated several possible mechanisms of resistance to platinum compounds.[382,458,459] Decreased drug accumulation may be related to altered drug uptake or the presence of a membrane efflux pump. Increased intracellular levels of thiol-containing compounds, such as glutathione and metallothionein, can react with and inactivate the active aquated forms of cisplatin and carboplatin. The enhanced repair of platinum-DNA adducts by the nucleotide excision repair pathway removes the cytotoxic lesion produced by the platinum analogs. Platinum-induced DNA damage activates apoptosis and expression of cellular proteins that suppress the apoptotic response to this damage or loss of mismatch repair activity may alter sensitivity to the platinum analogs.[178,460]

**Dacarbazine**

Although dacarbazine (Fig. 10-11) was originally developed as an inhibitor of purine biosynthesis, it does not exert its antitumor effects as an antimetabolite.[461] Dacarbazine is a prodrug that undergoes hepatic microsomal metabolic activation (N-demethylation), which is catalyzed primarily by CYP1A2, to the active metabolite, methyltriazenyl-imidazole carboxamide (MTIC).[462] MTIC then spontaneously decomposes into a reactive methylating species (methyldiazonium ion) and the primary circulating metabolite aminoimidazole carboxamide (AIC).[461,463,464] The methyldiazonium ion can methylate nucleophilic sites, including the $O^6$ and $N^7$ positions on guanosine, but it cannot form crosslinks.

Dacarbazine is generally administered intravenously (150 to 250 mg per $m^2$) on a divided once-daily dosage schedule for 5 days. It is used primarily in the treatment of sarcomas, neuroblastoma, and Hodgkin's disease. Absorption after oral administration is slow, incomplete, and variable.[465] After intravenous administration, the drug is rapidly cleared from the plasma, with a terminal half-life of 40 minutes and a total clearance of 450 mL per minute per $m^2$. One-half of the dose is excreted unchanged in the urine, and renal clearance exceeds the GFR, suggesting the drug is also eliminated by renal tubular secretion.[466] The remainder of the dose presumably undergoes biotransformation. The half-life and renal clearance of the metabolite AIC are similar to that of the parent drug.[466] Methylated DNA adducts in white blood cells of patients treated with dacarbazine (250 to 800 mg per $m^2$) increase rapidly during the first hour after treatment but then decline with a more prolonged half-life (72 hours) than the parent drug.[467]

When dacarbazine was administered as a 1,000 mg per $m^2$ infusion over 24 hours, the steady-state plasma concentration was 8.6 mg per mL.[468] Other pharmacokinetic parameters derived from the study of this schedule included a total clearance of 110 mL per minute per $m^2$, a volume of distribution at steady state of 23 L per $m^2$, and a terminal half-life after infusion of 3 hours.

Gastrointestinal toxicity, consisting of moderate to severe nausea and vomiting, is the primary toxicity and is frequently dose-limiting. Tolerance usually develops over the 5-day course of administration. At standard doses, myelosuppression is mild. Other side effects include a flu-like syndrome with malaise, fever, and myalgias; mild hepatic dysfunction; and local pain at the site of intravenous injection. Rare cases of liver failure and death from VOD and hepatic vein thrombosis (Budd-Chiari syndrome) have been associated with the use of this drug.[469]

**Temozolomide**

The methylating agent temozolomide is structurally and mechanistically related to dacarbazine. Like dacarbazine, temozolomide is a prodrug, but temozolomide does not require enzymatic activation in the liver. In solution at physiologic pH, temozolomide spontaneously decomposes to MTIC, the same active metabolite that is derived by enzymatic N-demethylation of dacarbazine (Fig. 10-11).[470,471]

Temozolomide is only available in capsules (5, 20, 100, and 250 mg sizes) for oral administration. It is insoluble in aqueous solution, and this has precluded the development of an intravenous formulation. Based on preclinical studies [470,472] that demonstrated divided dosing schedules had greater antitumor effect than a single bolus dose and on the initial phase I clinical trial, [473] in which responses were only observed on the divided dose schedule, temozolomide is administered as a single daily dose for 5 consecutive days. The recommended dose for children is 200 mg per $m^2$ per day (1,000 mg per $m^2$ per course).[474,475] A continuous daily dosing schedule is also being investigated, and a dose of 75 mg per $m^2$ per day appears to be tolerable for 6 to 7 weeks in adults.[476] Temozolomide is used in children exclusively for the treatment of recurrent brain tumors, but it also has activity against sarcomas in preclinical models.[470]

Absorption of temozolomide from the gastrointestinal tract is rapid and complete.[473,477] The peak concentration of temozolomide is achieved in plasma within 1.5 hours of the dose.[475] When administered with food, the bioavailability is slightly lower but remains greater than 90%.[478] Temolozomide is also rapidly eliminated. Its half-life (1.8 hours) is similar to the drug's half-life in a pH 7.4 phosphate buffer solution *in vitro*,[471] suggesting that decomposition to the active metabolite, MTIC, is the primary route of elimination for temozolomide. A pharmacokinetic study of radiolabeled temozolomide confirmed that AIC, which is the end-product of temozolomide decomposition to MTIC, is the primary urinary metabolite.[479] In children, 5% to 15% of the dose of temozolomide was recovered in urine as unchanged drug.[475] The clearance of temozolomide is 100 mL per minute per $m^2$. The active metabolite, MTIC, is much less stable and has an estimated half-life of 2.5 minutes and clearance exceeding 5,000 mL per minute per $m^2$.[479,480] Temozolomide is widely distributed in tissues and penetrates well across the blood–brain barrier,[477] and could therefore be considered the transport form for MTIC.

Myelosuppression is the dose-limiting toxicity of temozolomide. Nadir neutrophil and platelet counts typically occur 21 days after the start of therapy, and recovery of blood counts may take 7 to 10 days.[471,474,475] This delayed myelosuppression necessitates administering temozolomide on a 28-day schedule. The myelosuppression from temozolomide does not appear to be cumulative.[473] Nonhematologic toxicities are mild and include nausea and vomiting, which can be controlled by pretreatment with standard antiemetics, headache, fatigue, constipation, and serum transaminase elevations.[477]

The DNA repair protein $O^6$-alkylguanine-DNA alkyltransferase removes the methyl adduct from the $O^6$-position of guanine. Although this adduct accounts for only 5% of DNA adducts formed by temozolomide,[470] it is thought to be the primary cytotoxic lesion. Tumor cell lines with high levels of this repair protein are resistant to the cytotoxic effect of temozolomide.[470,471,481] Depletion of $O^6$-alkylguanine-DNA alkyltransferase with the modulating agent $O^6$-benzylguanine, markedly enhances the cytotoxic effects of temozolomide.[482] Loss of DNA mismatch repair capacity enhances to resistance to temozolomide.

**Procarbazine**

Procarbazine is a methylhydrazine analog that was originally synthesized as monoamine oxidase inhibitor but was discovered to have antitumor activity in animals. Procarbazine is currently used as part of the MOPP chemotherapy regimen for the treatment of Hodgkin's disease[483] and is also active against brain tumors.[484] Procarbazine is a prodrug that requires metabolic activation *in vivo* to express its antitumor activity.[461] This activation yields methylating and free radical intermediates, which appear to produce the drug's antitumor effect.

The spontaneous chemical decomposition and biotransformation of procarbazine is complex and beyond the scope of this chapter, but it has been reviewed elsewhere.[461,464,485] Metabolic activation probably occurs in the liver and is catalyzed by the cytochrome P-450 enzyme complex ( Fig. 10-11).[486] In liver perfusion studies, procarbazine is extensively converted to its active azo-metabolite.[487]

The disposition of procarbazine and its active intermediates has not been well characterized in humans. The drug is rapidly and completely absorbed from the gastrointestinal tract,[488] and it undergoes complete first-pass conversion to cytotoxic metabolites, which probably accounts for the activity of the drug when administered orally. After intravenous administration, procarbazine is rapidly metabolized and has a half-life of less than 10 minutes.[489] The metabolites of procarbazine are excreted primarily in the urine. Procarbazine or unidentified metabolites enter the CSF readily.[489] Drugs such as phenobarbital and phenytoin that are capable of inducing hepatic microsomal enzymes can increase the rate of procarbazine activation.[461] Procarbazine can inhibit the biotransformation of the barbiturates, phenothiazines, and other sedatives, resulting in potentiation of their sedative effects. The inhibition of monoamine oxidase by procarbazine can put patients at risk for hypertensive reactions from foods high in tyramine (e.g., bananas, wine, and cheese). Procarbazine also appears to alter its own metabolism over a 14-day course of therapy. The plasma concentrations of procarbazine metabolites differ markedly between day 1 and 14 of treatment.[490]

The primary toxicities of procarbazine include nausea, vomiting, and myelosuppression. Some patients develop evidence of neurotoxicity consisting of paresthesias, somnolence, depression, or agitation. Neurotoxicity is prominent with high-dose intravenous administration.[491] Patients are also at risk for the long-term toxicities, including azoospermia, ovarian failure, and teratogenic and carcinogenic effects.[461]

## ANTIMETABOLITES

The antimetabolites are structural analogs of vital cofactors or intermediates in the biosynthetic pathways of DNA and RNA. By acting as fraudulent substrates for the enzymes in these pathways, antimetabolites inhibit synthesis of the nucleic acids and their building blocks or are incorporated into the DNA or RNA, resulting in a defective product. Antimetabolites that are used in the treatment of childhood cancers include the folate analog methotrexate, the purine analogs mercaptopurine and thioguanine, and the pyrimidine analogs cytarabine and fluorouracil. The structures of these antimetabolites and their naturally occurring counterparts are shown in Figure 10-12.

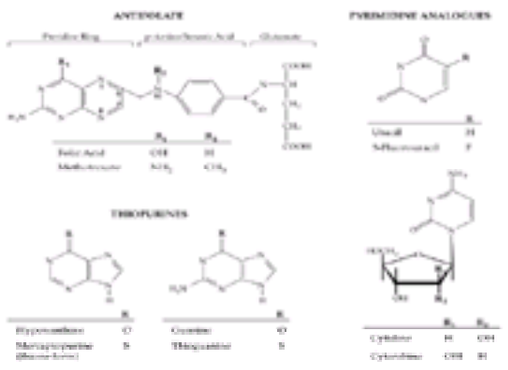

**FIGURE 10-12.** Chemical structures of commonly used antimetabolites compared with the structures of corresponding endogenous compounds of which they are analogs.

In general, the clinical pharmacology of these agents is similar to that of the endogenous compounds that they structurally resemble. The absorptive, metabolic, and excretory pathways are frequently shared by the endogenous compound and the antimetabolite. The rate of elimination of the antimetabolites is usually rapid. Most of the antimetabolites are prodrugs that require metabolic activation within the target cell to express their cytotoxic effects. The purine and pyrimidine analogs, for example, require intracellular conversion to phosphorylated nucleotides, which are the active forms of these drugs. Because most antimetabolites interfere directly with DNA synthesis, they are cell-cycle and S-phase specific; the maximum cytotoxic effect occurs in cells that are synthesizing DNA. This partially explains the schedule dependence of this class of anticancer drugs. More prolonged drug exposure that results from administering these agents by continuous infusion or by chronic daily dosing increases the chance of exposing a higher proportion of the tumor cell population to the drugs during active DNA replication.

**Methotrexate**

Methotrexate is the most widely used antimetabolite in childhood cancers. It is effective in the treatment of ALL, non-Hodgkin's lymphoma, the histiocytoses, and osteosarcoma. Methotrexate is administered on an intermittent schedule by variety of routes, including oral, intramuscular, subcutaneous, intrathecal, and intravenous. Chronic oral or intramuscular therapy is administered weekly at a dose of 20 mg per $m^2$. With intravenous therapy, an extraordinarily wide range of doses has been used, ranging from a 10 mg bolus to 33,000 mg per $m^2$ as a 24-hour infusion. Doses above 100 to 300 mg per $m^2$, which are usually administered by continuous infusion, must be followed by a course of the rescue agent leucovorin (5-formyl-tetrahydrofolate) to prevent the development of severe toxicities.

The loading and infusion doses required to achieve a desired steady-state plasma concentration ($\{MTX\}_{plasma}$) can be estimated from the following formulas[492]:

Loading dose (mg per $m^2$) = 15 • $\{MTX\}_{plasma}$ (μM)

Infusion dose (mg per $m^2$ per hour) = 3 • $\{MTX\}_{plasma}$ (μM)

For example, to achieve a steady state plasma concentration of 10 μM, the loading dose would be 150 mg per $m^2$, followed by an infusion of 30 mg per $m^2$ per hour. Infusion durations of up to 42 hours are tolerable when followed by leucovorin rescue. In clinical practice, infusion durations range from 4 to 36 hours depending on the type of cancer being treated. Patients who are treated with a high-dose methotrexate infusion must be adequately hydrated and alkalinized to prevent precipitation of methotrexate in acidic urine, and routine monitoring of serum creatinine and plasma methotrexate concentrations is mandatory to determine the duration of leucovorin rescue. For most infusion regimens, 12 to 15 mg per $m^2$ of leucovorin should be continued every 6 hours until plasma methotrexate concentration falls to 0.05 to 0.10 μM.

***Mechanism of Action***

Methotrexate is a structural analog of folic acid, a required cofactor for the synthesis of purines and thymidine. As a result of the substitution of an amino group for the hydroxyl group at the 4-position on the pteridine ring of folic acid ( Fig. 10-12), methotrexate is a tight-binding inhibitor of DHFR, the enzyme responsible for converting folates to their active, chemically reduced (tetrahydrofolate) form.[493,494] 10-Formyltetrahydrofolate acts as the single carbon donor in the de novo purine synthetic pathway, and 5,10-methylenetetrahydrofolate donates its single-carbon group and is oxidized to dihydrofolate in the conversion of deoxyuridylate (dUMP) to thymidylate by thymidylate synthase. In the presence of an excess of methotrexate, intracellular tetrahydrofolate pools are depleted, leading to depletion of purines and thymidylate and inhibition of DNA synthesis. Accumulation of partially oxidized dihydrofolic acid, resulting from the inhibition of DHFR, appears to contribute to the inhibition of de novo purine synthesis.[494,495] and [496] A critical determinant of methotrexate cytotoxicity is the rate of thymidylate synthesis, because the synthesis of thymidylate from uridylate is the only reaction that oxidizes the tetrahydrofolate cofactor to the inactive dihydrofolate form. Another determinant is achieving an intracellular methotrexate concentration that is in excess of DHFR binding sites, because intracellular levels of this target enzyme are 20-fold to 30-fold higher than required to maintain tetrahydrofolate pools.[493,497,498]

Methotrexate shares membrane transport processes and intracellular metabolic pathways with the naturally occurring folates. It competes with the tetrahydrofolates for an energy-dependent transport system for cell entry. On entry, methotrexate is rapidly and tightly bound to DHFR, and uptake into the target cell is essentially unidirectional until the enzyme binding sites are saturated, allowing for even greater intracellular accumulation of drug.[493]

With the accumulation of free intracellular drug in excess of DHFR binding sites, methotrexate, like the naturally occurring folates, is metabolized intracellularly to polyglutamated derivatives, which cannot readily efflux from the cell. Methotrexate polyglutamate formation enhances the cytotoxicity of the drug by allowing greater accumulation of free intracellular drug and retention of the drug within the cell, even after extracellular drug is cleared. Methotrexate polyglutamates are also more potent inhibitors of DHFR and are capable of directly inhibiting other enzymes in the synthetic pathways for thymidine (thymidylate synthase) and purines.[494,497,499,500] Methotrexate polyglutamate formation is optimal *in vitro* when cells are exposed to high concentrations for prolonged periods, and children with ALL randomized to receive high-dose methotrexate as initial induction therapy had higher methotrexate polyglutamate levels in their lymphoblasts than patients randomized to low-dose methotrexate.[501,502] The lymphoblasts from children with ALL and good prognostic features, such as B-lineage immunophenotype, hyperdiploidy, young age, low presenting white blood cell count, and female sex, tend to accumulate methotrexate polyglutamates more efficiently than blasts from higher risk patients, suggesting that ALL in lower risk patients may be more sensitive to the antileukemic effects of methotrexate.[502,503,504] and [505]

***Pharmacokinetics***

At standard oral doses of 7.5 to 20.0 mg per $m^2$, the rate and extent of absorption of methotrexate is highly variable ( Fig. 10-13).[81,506,507,508] and [509] Peak plasma concentrations can occur from 0.5 to 5.0 hours after oral administration, and the percentage of the dose that is absorbed ranges from 5% to 97%.[506] The AUC of oral methotrexate ranged from 0.63 to 12 μM • hour at a dose of 18 to 22 mg per $m^2$, and over a broader dosage range, the AUC correlated poorly with the dose ( Fig. 10-13).[81] In patients who are studied after multiple doses, there was also considerable intrapatient variation in the AUC.[81] Absorption of methotrexate is saturable, and as the dose is increased, the fraction of the dose that is absorbed diminishes.[510,511,512] and [513] Simply increasing the dose in patients who have low plasma concentrations after standard oral doses may not overcome poor bioavailability. The bioavailability of oral methotrexate can also be significantly reduced when administered with food.[514] Despite this variability with oral dosing, there was no relation between the relapse rate and methotrexate pharmacokinetic parameters, such as peak concentration, AUC, and erythrocyte methotrexate levels.[81,515,516] When administered intramuscularly or subcutaneously, methotrexate is completely absorbed.[512,513,517,518]

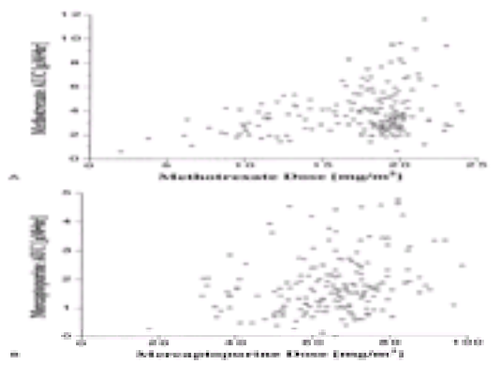

**FIGURE 10-13.** Area under the plasma concentration-time curve (AUC) as a function of dose in children with acute lymphoblastic leukemia that is treated with weekly oral methotrexate **(A)** and daily oral mercaptopurine **(B)**. Drug exposure was highly variable and did not correlate with the dose for both agents. (From Balis FM, Holcenberg JL, Poplack DG, et al. Pharmacokinetics and pharmacodynamics of oral methotrexate and mercaptopurine in children with lower risk acute lymphoblastic leukemia: a joint Children's Cancer Group and Pediatric Oncology Branch study. Blood 1998;92:3569.)

The disposition of methotrexate in children differs from that in adults.[519,520,521 and 522] In one study, children had lower plasma concentrations of methotrexate and excreted the drug in the urine more rapidly after a 6-hour infusion than did adults.[523] The volume of distribution was also greater in children. Within the pediatric age group, the clearance of methotrexate (normalized to body surface area) is also age-dependent.[524] Children younger than 10 years of age (n = 94) had a clearance of 160 mL per minute per $m^2$, compared with 110 mL per minute per $m^2$ in those older than 10 (n = 21). Infants (younger than 1 year old) may have a slightly lower (15%) clearance rate than children, but dose adjustments do not appear to be necessary, because the degree of toxicity is similar and 42-hour methotrexate plasma concentrations after high-dose infusions, are similar to those in older children.[111]

The plasma disappearance of methotrexate is multiphasic, with a terminal half-life of 8 to 12 hours.[492,494,525] Retention of the drug in large extravascular fluid collections, such as ascites or pleural fluid, is associated with prolongation of the half-life as a result of slow release of retained drug into the circulation.[494,525] This prolonged exposure to the drug can increase the risk for toxicity. Patients who have large extravascular fluid collections and are receiving methotrexate should have their methotrexate levels monitored closely.

Methotrexate is eliminated primarily by renal excretion, undergoing glomerular filteration and renal tubular reabsorption and secretion.[526,527] Approximately 70% to 90% of a dose is excreted unchanged in the urine, most within the first 6 hours. The renal clearance of methotrexate can exceed the rate of creatinine clearance. In patients with significant renal dysfunction, methotrexate clearance is delayed, resulting in prolonged drug exposure and a greater risk of severe toxicities. High-dose methotrexate should not be given to patients with a creatinine clearance of less than 50% to 75% of normal. Low-dose therapy should be withheld in patients with a serum creatinine level greater than 2 mg per dL. Any patient who is suspected of having renal dysfunction and who receives methotrexate should have the plasma levels closely monitored and receive leucovorin if drug clearance is delayed.[528]

Methotrexate is also metabolized in the liver to 7-hydroxy-methotrexate.[529] Although this is a minor route of elimination, plasma concentrations of 7-hydroxy-methotrexate can be equivalent to or exceed those of methotrexate after high-dose infusions, because of the slower clearance of the metabolite.[525,530,531 and 532] 7-Hydroxy-methotrexate may compromise the cytotoxicity of methotrexate by competing for membrane transport and polyglutamation. Once polyglutamated, however, 7-hydroxy-methotrexate appears to be able to bind to and inhibit DHFR.[493] Methotrexate clearance is not significantly altered with hepatic dysfunction, but modification of the methotrexate dose in patients with abnormal liver function tests may be indicated to avoid additional hepatic damage.

Total renal and metabolic methotrexate clearance is approximately 100 mL per minute per $m^2$, but it may vary widely among patients.[494,532,533] In patients with normal creatinine clearance, there is not a good correlation between methotrexate clearance and creatinine clearance.[533] Renal tubular dysfunction, which is not measured by creatinine clearance, may account for this disparity. A small test dose of methotrexate can accurately predict the kinetics and steady-state concentration of a high-dose infusion.[534] Optimal management dictates that each course of high-dose methotrexate be closely monitored by following renal function and plasma methotrexate concentration to determine the dose and duration of leucovorin rescue.

Penetration of systemically administered methotrexate into CSF is only 3% in patients without meningeal tumor spread,[535,536] but is 20% in patients with leptomeningeal carcinomatosis.[536] At infusion rates exceeding 3,500 mg per $m^2$ over 24 hours, the CSF methotrexate concentration is typically greater than 1 µM[536]; and high-dose methotrexate infusion regimens are effective for treating and preventing leptomeningeal leukemia.[537]

***Toxicity***

The primary toxic effects of methotrexate are myelosuppression and orointestinal mucositis, which occur 5 to 14 days after the dose. The development of toxic reactions is related to the concentration of drug and the duration of exposure.[492,494,525] In patients receiving a 6-hour infusion of methotrexate, a 48-hour methotrexate concentration above 1 µM was associated with the development of significant toxicity.[525] These toxicities can be prevented by administration of leucovorin. With the use of therapeutic drug monitoring and continuation of leucovorin rescue until plasma methotrexate concentration has fallen below 0.05 to 0.10 µM, the toxicity of high-dose methotrexate can be avoided in most patients.[492,494]

Nephrotoxicity observed with high-dose methotrexate can delay methotrexate clearance and markedly intensify the drug's other toxic effects.[538,539] The renal damage may be related to precipitation of methotrexate or 7-hydroxy-methotrexate in acidic urine or to direct toxic effects on the renal tubule.[494,539] Drug precipitation can be prevented by vigorous intravenous hydration and alkalinization of the urine. In one study, aggressive hydration and alkalinization resulted in enhanced excretion of methotrexate (lower plasma drug concentrations) and a decreased incidence of severe methotrexate toxicity.[540]

The development of renal dysfunction during high-dose methotrexate is a medical emergency. Patients must be closely monitored and the leucovorin dose increased in proportion to the plasma methotrexate concentration (see the recommendations by Bleyer[541]). Hemodialysis and charcoal hemoperfusion have not proved useful for drug removal in patients with renal dysfunction[542,543 and 544] unless they are used repeatedly.[545] The recombinant bacterial enzyme, carboxypeptidase-$G_2$, catabolizes methotrexate to the inactive metabolite, 4-amino-4-deoxy-$N^{10}$-methylpteroic acid (DAMPA), and provides a novel and useful approach to rescuing patients who develop methotrexate nephrotoxicity by providing an alternative route of elimination.[120,546] Carboxypeptidase-$G_2$ is well tolerated and results in a 95.6% to 99.6% reduction in plasma methotrexate concentrations within minutes. Unlike dialysis, there is no rebound of plasma drug levels after carboxypeptidase-$G_2$.

Hepatic toxicity consisting of transient elevations of serum transaminase and, less commonly, hyperbilirubinemia has been associated with standard and high doses of methotrexate but is more common and more severe with high-dose therapy. Hepatic fibrosis has been observed primarily in patients receiving chronic low-dose methotrexate.[520,547] Other side effects include a dermatitis characterized by erythema and desquamation, allergic reactions, and acute pneumonitis.[547,548 and 549] Methotrexate osteopathy is a cumulative toxicity that causes bone pain, osteoporosis, and an increased risk for fractures. Neurotoxicity from high-dose methotrexate includes an acute, stroke-like encephalopathy, seizures, and chronic leukoencephalopathy, particularly in association with cranial irradiation.[281,550,551,552 and 553]

***Resistance***

Mechanisms of resistance to methotrexate identified experimentally include decreased membrane transport, increased levels of the target enzyme DHFR, altered affinity of DHFR for methotrexate, decreased polyglutamation of methotrexate, and decreased thymidylate synthase activity.[494,497,554] Increases in target enzyme levels have been associated with amplification of gene encoding for DHFR, a phenomenon that has also been documented in lymphoblasts from patients whose disease was clinically resistant to methotrexate.[494,555,556] Flow cytometric analysis of lymphoblasts from 29 children with newly diagnosed and relapsed ALL demonstrated heterogeneous expression of elevated DHFR in 11 of 29 specimens and impaired methotrexate transport in 3 of 29 specimens.[557] Newly diagnosed patients whose marrow specimens contained DHFR overproducing subpopulations of lymphoblasts had shorter remission durations than comparable patients whose lymphoblasts only expressed lower DHFR levels. Impaired methotrexate uptake and decreased expression of the reduced folate carrier, which is the membrane transport protein involved in cellular uptake of methotrexate, have been observed in tumor specimens from patients with ALL and osteosarcoma.[558,559 and 560]

***Drug Interactions***

Several drugs have been associated with increased toxicity when coadministered with methotrexate.[87,143,144] The most significant interactions involve agents that interfere with methotrexate excretion, primarily by competing for renal tubular secretion. These drugs include probenecid, salicylates, sulfisoxazole, penicillins, and the nonsteroidal antiinflammatories indomethacin, ketoprofen, and ibuprofen.[87,143,561,562 and 563] Nephrotoxic drugs, such as the aminoglycosides and cisplatin, may also alter the clearance of methotrexate.[143] Pharmacodynamic interactions resulting in synergistic cytotoxic effects have been reported with methotrexate and fluorouracil, methotrexate and cytarabine, and methotrexate and asparaginase.[564]

**Thiopurines**

Mercaptopurine and thioguanine are thiol-substituted derivatives of the naturally occurring purine bases hypoxanthine and guanine ( Fig. 10-12). Mercaptopurine has been used in the treatment of ALL for five decades, primarily for the maintenance of remission. It is also used in the treatment of CML, histiocytosis, and inflammatory bowel disease. In standard maintenance regimens, mercaptopurine is administered orally at a dose of 75 to 100 mg per $m^2$ per day with upward or downward dose

adjustments based on the degree of myelosuppression. Ensuring that patients are receiving their maximum tolerated dose of mercaptopurine appears to be an important factor in the outcome for children with ALL.[516] In a retrospective analysis, when the actual dose of mercaptopurine received increased by 22% as a result of more aggressive prescribing guidelines, the relapse-free survival improved by 18%. [565] High-dose intravenous infusions of mercaptopurine (1,000 mg per $m^2$ over 6 to 24 hours) have also been evaluated as an approach to circumvent the pharmacokinetic limitations of oral dosing. [566,567,568 and 569] Thioguanine is used in the treatment of acute nonlymphocytic leukemia and is administered orally in doses of 75 to 100 mg per $m^2$ daily for 5 to 7 days or in doses of 40 to 60 mg per $m^2$ daily for more prolonged courses. Thioguanine is also currently being studied as a maintenance agent for ALL, [570] and thioguanine infusional therapy has been investigated. [571,572]

The thiopurines are prodrugs that must be converted intracellularly to thioguanine nucleotides to exert a cytotoxic effect. The metabolic pathways for activation of mercaptopurine and thioguanine are outlined in Figure 10-14. The active intracellular metabolites are phosphorylated thiopurine nucleotides, which inhibit de novo purine synthesis and purine interconversion and are incorporated into DNA. [573,574 and 575] Incorporation of thioguanosine into DNA appears to be the critical determinant of thiopurine cytotoxicity.[576] Thioguanine is tenfold more potent and less schedule dependent than mercaptopurine against lymphoblastic leukemia cell lines and lymphoblasts from patients with ALL *in vitro*.[577]

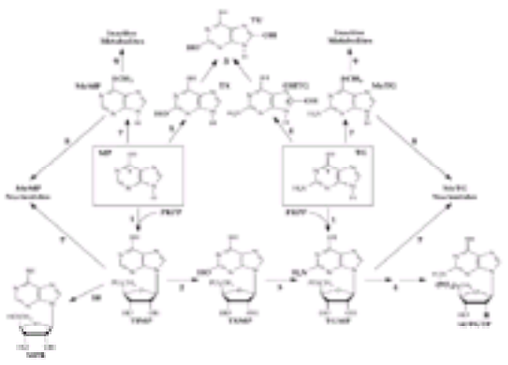

**FIGURE 10-14.** Metabolic pathways of mercaptopurine (MP) and thioguanine (TG). Intracellular activation of these prodrugs involves conversion to thioguanine nucleotides. For MP, this is a three-step process, starting with conversion to thioinosine monophosphate (TIMP), catalyzed by the enzyme hypoxanthine-guanine phosphoribosyl transferase (HGPRT) (1). Phosphoribosylpyrophosphate (PRPP) is a required cofactor in this reaction. TIMP is converted to thioxanthosine monophosphate (TXMP) by inosine monophosphate dehydrogenase (2) and then to thioguanine monophosphate (TGMP) by guanosine monophosphate synthetase (3). Thioguanine is converted directly to TGMP by HGPRT. TGMP is phosphorylated by kinases to TGTP (R = OH) and converted to the deoxyribonucleotide dTGTP (R = H) by ribonucleotide reductase (4). dTGTP can then be incorporated into DNA (not shown). There are competing catabolic pathways for the thiopurines, including oxidation to the inactive metabolite, thiouric acid (TU). For MP, this is catalyzed in a two-step reaction by xanthine oxidase (5). The initial oxidation step from TG to 8-hydroxy-thioguanine (OHTG) is catalyzed by aldehyde oxidase (6). The thiopurines also undergo S-methylation, catalyzed by thiopurine methyltransferase (TPMT) (7). Methylmercaptopurine (MeMP) and methylthioguanine (MeTG) can be converted to methylated thionucleotides along the same pathways as the parent drug (8). TPMT can also convert TIMP and TGMP to methylated thionucleotides. MeMP and MeTG can also be oxidized or desulfurated to inactivate metabolites (9). Dephosphorylation of TIMP to mercaptopurine riboside (MPR) is another inactivating step that is catalyzed by several intracellular enzymes (10).

The common toxic effects of mercaptopurine include myelosuppression, hepatic dysfunction (e.g., elevated transaminases and cholestatic jaundice), and mucositis. Myelosuppression is also the primary toxic effect of thioguanine, but chronic administration of oral thioguanine is associated with the development of hepatic VOD. [578]

***Biotransformation***

The thiopurines are extensively metabolized *in vivo* to active and inactive metabolites (Fig. 10-14).[576,579,580,581 and 582] The activation pathway for thioguanine, which is converted to the nucleotide thioguanosine monophosphate in a single step, is more direct than that for mercaptopurine, which undergoes a three-step conversion to the thioguanine nucleotide. The primary degradative pathway for mercaptopurine is conversion to the inactive metabolite thiouric acid by the enzyme xanthine oxidase. The oxidation of thioguanine to thiouric acid follows a different metabolic pathway. Thioguanine is initially converted by aldehyde oxidase to 8-hydroxy-thioguanine, which is the primary circulating metabolite of thioguanine. [573,582]

The thiopurines are also subject to S-methylation by the enzyme thiopurine methyltransferase (TPMT). [583] The level of intracellular TPMT activity is an important determinant of the availability of thiopurines for conversion to active thioguanine nucleotides, and, as a result, TPMT regulates the cytotoxic effect of these thiopurines.[97] The activity of this enzyme is controlled by a common genetic polymorphism, resulting in a trimodal distribution of intracellular enzyme levels ( Fig. 10-15).[97,576] One in 300 patients is deficient of TPMT activity and extremely sensitive to the cytotoxic effects of mercaptopurine, thioguanine, and azathioprine. Even a short course of therapy can result in profound myelosuppression, and erythrocyte thioguanine nucleotide levels in these TPMT-deficient patients are markedly elevated (Fig. 10-15).[584,585 and 586] Very low doses of mercaptopurine (5% to 10% of the standard dose) are tolerable in TPMT-deficient patients, but these doses yield erythrocyte thioguanine nucleotide levels higher than those typically found in patients with normal TPMT levels receiving standard doses of mercaptopurine. [585,586,587 and 588] The 10% of patients who are heterozygous at the TPMT locus and have intermediate enzyme activity levels require more mercaptopurine dose reductions for toxicity than homozygous patients with full enzyme activity.[589] TMPT activity is also inversely related to the erythrocyte thioguanine nucleotide level and the severity of neutropenia, suggesting that TPMT modulates the cytotoxic effect of mercaptopurine.[590] Consideration should be given to measuring erythrocyte TPMT levels in patients who are exquisitely sensitive to the toxic effects of thiopurines.

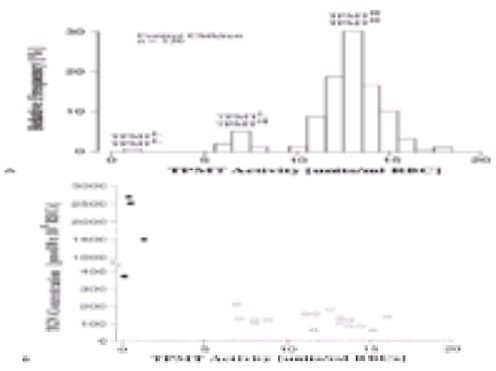

**FIGURE 10-15. A:** Frequency distribution histogram of erythrocyte thiopurine methyltransferase (TPMT) activity in 130 unrelated control children, demonstrating a trimodal distribution resulting from a genetic polymorphism (i.e., a low activity allele, $TPMT^L$, and a high activity allele, $TPMT^H$, at a single genetic locus). One in 300 subjects are TPMT-deficient ($TPMT^L/TPMT^L$ genotype), 11% have intermediate activity ($TPMT^H/TPMT^L$ genotype), and 89% have high activity ($TPMT^H/TPMT^H$ genotype). Within the predominant high-activity population, there is a wide range of TPMT activity. (From Lennard L, Lilleyman JS, Van Loon J, Weinshilboum RM. Genetic variation in response to 6-mercaptopurine for childhood acute lymphoblastic leukaemia. Lancet 1990;336:225.) **B:** Erythrocyte (RBC) thioguanine nucleotide (TGN) levels relative to erythrocyte TPMT activity in four TPMT-deficient patients ( *closed circles*) and 16 control patients (*open circles*) receiving azathioprine. Azathioprine is spontaneously converted to mercaptopurine *in vivo*. The four patients with very low or undetectable TPMT activity experienced severe myelosuppression and had elevated RBC TGN levels compared with controls treated with the same dose. (From Lennard L, Van Loon JA, Weinshilboum RM. Pharmacogenetics of acute azathioprine toxicity: relationship to thiopurine methyltransferase genetic polymorphism. Clin Pharmacol Ther 1989;46:149.)

### *Pharmacokinetics*

The bioavailability of oral mercaptopurine is less than 20%, and the resulting plasma drug concentrations are highly variable ( Fig. 10-13).[81,591] Only one-third of patients achieve plasma concentrations of mercaptopurine above the minimal *in vitro* cytotoxic concentration of 1 µM.[591] Substantial interpatient variability after oral dosing has been confirmed by other investigators.[81,592,593] The median peak plasma concentration was 0.59 µM (range, 0.13 to 2.30 µM) and the median AUC was 1.8 µM • hour (range, 0.39 to 4.80 µM • hour) at oral doses ranging from 65 to 85 mg per $m^2$.[81] Plasma mercaptopurine AUC is not predictive of erythrocyte thioguanine nucleotide levels.[81] Significant intrapatient variability has also been observed in patients monitored after multiple doses over the course of maintenance therapy.[81] The bioavailability of mercaptopurine is limited by the extensive first-pass metabolism of the drug by xanthine oxidase in the liver and intestinal mucosa. When mercaptopurine is coadministered with the xanthine oxidase inhibitor allopurinol, the fraction of the dose absorbed increases fivefold.[594]

The bioavailability of oral thioguanine is also poor, and plasma concentrations are variable, with a 30- to 50-fold range in peak plasma concentration and AUC.[595,596] and[597] The mean (± SD) peak plasma concentration was 0.46 ± 0.68 µM, and the AUC ranged from 0.18 µM • hour to 9.5 µM • hour.[597] These plasma concentrations were within the range required *in vitro* to produce cytotoxicity.[577] The bioavailability was diminished further in non-fasting patients and patients experiencing nausea and vomiting.[596] Plasma thioguanine AUC after an oral does did not correlate with erythrocyte thioguanine nucleotide levels. to produce cytotoxicity.[597]

Mercaptopurine is eliminated primarily by biotransformation. However, renal excretion of unchanged drug does become quantitatively significant (20% to 40%) with high intravenous doses.[567,598] Elimination is rapid, with a total clearance rate of 800 mL per minute per $m^2$ and a half-life of less than 1 hour.[591,594] The intravenous infusion of 50 mg per $m^2$ per hour achieves steady-state plasma drug concentrations in excess of 5 µM and CSF concentrations greater than 1 µM, above concentrations of the drug known to be cytotoxic *in vitro*.

Intravenous administration of thioguanine has been evaluated on single-dose, daily-for-5-days, and continuous infusion schedules.[571,597,599,600] With standard doses (less than or equal to 100 mg per $m^2$), the drug is cleared rapidly. Total clearance is greater than 2,000 mL per minute per $m^2$, and the terminal half-life is 20 minutes.[599] However, a reduced clearance rate (320 mL per minute per $m^2$) and a longer terminal half-life (2 to 6 hours) at doses exceeding 700 mg per $m^2$ indicate that the pharmacokinetics of this drug are dose dependent.[599,600] Similarly, on the continuous infusion regimen, thioguanine clearance declined from 1,370 to 575 mL per minute per $m^2$ and the half-life increased from 2.2 to 5.1 hours when infusion rate was escalated from 10 to 20 mg per $m^2$ per hour.[571] Thioguanine is cleared primarily by biotransformation, with only small amounts of the drug excreted unchanged in the urine.[601] The primary circulating metabolite is 8-hydroxy-thioguanine.[582] Saturation of the degradative enzymes at high doses probably accounts for the dose-dependent pharmacokinetics. Thioguanine penetration into the CSF during the continuous intravenous infusion was 18%.[597]

Erythrocyte levels of thiopurine-derived thioguanine nucleotides have been monitored in children receiving oral therapy. As with plasma concentrations of the parent drug, the erythrocyte metabolite levels are highly variable.[81] Erythrocyte thioguanine nucleotide levels have been correlated with the degree of myelosuppression and the risk of relapse.[602,603] and[604] Children with ALL whose erythrocyte thioguanine nucleotide levels were below the median value of 284 pmol per 8 • $10^8$ erythrocytes had a twofold higher relapse rate than patients with values above the median.[603,604] However, the differences in erythrocyte thioguanine nucleotide levels in the remission and relapse patients were small, and the range of values overlapped completely (100 to 1,300 pmol per 8 • $10^8$ erythrocytes in remission patients and 100 to 800 pmol per 8 • $10^8$ erythrocytes in relapsed patients).[603,604] In other studies, no relationship was found between thioguanine nucleotide levels and outcome.[81,516] Erythrocyte thioguanine nucleotide levels in patients receiving daily oral thioguanine are fivefold higher than nucleotide metabolite levels from mercaptopurine therapy.[570,597,605,606]

### *Drug Interactions*

The classic example of a drug interaction in cancer chemotherapy is the effect of the xanthine oxidase inhibitor allopurinol on the catabolism of mercaptopurine to thiouric acid. When these two agents are administered concurrently, the hematologic toxicity of mercaptopurine is significantly enhanced.[607] Allopurinol pretreatment results in a fivefold increase in bioavailability of the oral dose of mercaptopurine.[594] However, the disposition of intravenously administered mercaptopurine is not affected by the coadministration of allopurinol.[567,594,598] This differential effect results from inhibition of first-pass metabolism of orally-administered mercaptopurine by allopurinol.[594] The dose of oral mercaptopurine should be reduced by 75% when administered to patients receiving allopurinol, but intravenous mercaptopurine doses need not be modified unless the patient has renal dysfunction. The renal excretion of unchanged mercaptopurine increases from 20% to more than 40% of the dose in patients who receive the drug by intravenous infusion in combination with allopurinol.[567] Although allopurinol enhances the bioavailability of mercaptopurine, it has not been shown to augment the antileukemic effect of the drug and may antagonize the antitumor effects on a pharmacodynamic level.[143,594] Because the first step in the oxidation of thioguanine is catalyzed by aldehyde oxidase rather than xanthine oxidase, the coadministration of allopurinol and thioguanine does not require a dose modification. Methotrexate and folates also inhibit xanthine oxidase, and methotrexate can minimally enhance mercaptopurine bioavailability.[608,609]

## Pyrimidine Analogs

### *Cytarabine*

Cytarabine (cytosine arabinoside, ara-C) is an arabinose nucleoside analog of deoxycytidine ( Fig. 10-12) that is active in the treatment of the acute leukemias and lymphoma. After intracellular metabolic activation, cytarabine interferes with DNA replication and repair through inhibition of DNA polymerase a and through incorporation into DNA.[610,611,612] and[613] Depending on the dose and schedule of cytarabine used, incorporation into DNA is thought to inhibit chain elongation, result in chain termination or reinitiation at sites of previously replicated segments, or cause DNA strand breaks.[610,611] and[612] Inhibition of DNA synthesis or incorporation into DNA by cytosine arabinoside triphosphate (ara-CTP) can only occur during the DNA synthesis phase (S phase) of the cell cycle, and more prolonged exposure to cytarabine allows the drug to be incorporated into a larger fraction of the cells as they pass through S phase. Cytarabine incorporation into DNA may also be enhanced by timed retreatment with cytarabine after recruitment of leukemic cells into an active phase of DNA synthesis after the first treatment cycle and the simultaneous administration of cytarabine and colony-stimulating factors, which stimulate leukemic cells into S phase.[614,615,616] and[617]

A wide range of doses and schedules for cytarabine have been used. The standard dose is 100 to 200 mg per $m^2$ as a bolus injection every 12 hours or by continuous infusion, and it is usually administered daily for 5 to 7 days. High-dose regimens (3 g per $m^2$ every 12 hours for four to 12 doses or as a continuous infusion) have also been used with the intention of overcoming resistance mechanisms.[618,619] Low-dose cytarabine regimens (5 to 20 mg per $m^2$ per day over several weeks) are used for the treatment of myelodysplastic syndromes.[620]

#### Biotransformation

After entering cells by the carrier-mediated nucleoside transport system, cytarabine is converted to the active nucleotide, ara-CTP, by three sequential phosphorylations catalyzed by intracellular kinases.[610,621] Ara-CTP then competes with the natural substrate deoxycytidine triphosphate for DNA replicative and repair enzymes. Cytarabine and ara-cytidine monophosphate can also be catabolized to the inactive by-products uridine arabinoside (ara-U) and ara-uridine monophosphate (ara-UMP) by deaminases that are present in high concentrations within cells.[622,623] Cytidine deaminase is a ubiquitous enzyme, and the catabolism of cytarabine to ara-U is the primary route of elimination for the drug. Alterations in these uptake and metabolic pathways within the cancer cell can result in drug resistance, such as a decrease in membrane transport, a decrease in activation by deoxycytidine kinase, an increase in degradation by cytidine deaminase, and an increase in the competing natural substrate, deoxycytidine triphosphate.[610,611,618]

#### Pharmacokinetics

The pharmacokinetic behavior of cytarabine is directly related to the activity of the major degradative enzyme, cytidine deaminase. The bioavailability of oral cytarabine is less than 20% because of extensive presystemic metabolism by high levels of this enzyme in gastrointestinal epithelium and liver.[624] The hepatic extraction ratio for cytarabine is estimated to be as high as 80%.[625] Subcutaneously injected cytarabine is completely absorbed.[624]

Drug elimination is rapid with intravenous dosing. Total clearance is 1,000 mL per minute per $m^2$ or greater, and the postdistributive half-life is 2 to 3 hours.[619,623,624,626,627] Metabolism to ara-U accounts for 80% to 90% of total cytarabine clearance, and renal clearance accounts for less than 10% of total clearance. The ara-U formed is excreted in the urine. Because of the ubiquity of cytidine deaminase (e.g., liver, gastrointestinal tract, plasma, leukocytes), hepatic dysfunction does not significantly alter the rate of elimination of cytarabine. With high-dose prolonged intravenous infusions, the mean steady-state plasma concentration of cytarabine was 5 µM at a dose of 2 g per $m^2$ per day, and the steady-state concentration of ara-U was tenfold higher (60 µM). [619] In these patients, plasma clearance appeared to decrease with increasing dose, suggesting saturation of deaminases at the higher dose levels. [619,628] In children receiving an infusion of 5 g per $m^2$ per day, total clearance was 555 mL per minute per $m^2$,[628] and at steady state, ara-U plasma concentrations are more than tenfold higher than steady-state cytarabine concentrations in children.[629]

The pharmacokinetics of cellular ara-CTP, the active intracellular metabolite of cytarabine, have been characterized in the leukemic blasts from patients receiving high-dose cytarabine. After a 3 g per $m^2$ dose administered as a short infusion, there was considerable interpatient variability in the amount of ara-CTP accumulated in these blasts. There was no correlation between the pharmacokinetics of the parent drug in plasma and the cellular concentrations of ara-CTP in leukemic blasts.[630,631] Patients responding to the drug had a significantly slower rate of elimination of ara-CTP. The half-life of ara-CTP was 5.6 hours in responding patients and 3.2 hours in resistant patients. Responding patients also had significantly higher trough concentrations (196 µM versus 23 µM). [630] This is consistent with earlier studies demonstrating greater *in vitro* ara-CTP formation in the leukemic blasts from patients achieving a complete remission on cytarabine therapy compared with nonresponders.[632] The pharmacokinetics of the active intracellular metabolite appear to be more predictive of outcome than plasma concentrations of the parent drug. The cellular retention of ara-CTP in leukemic blasts was shorter in blasts from patients with T-cell ALL and acute nonlymphoblastic leukemia compared to non–T-cell ALL.[633]

**Toxicity**

The primary toxicities of cytarabine are myelosuppression, nausea and vomiting, and gastrointestinal mucosal damage, including life-threatening bowel necrosis.[610,634,635 and 636] A syndrome of high fever, malaise, myalgias, joint or bone pain, rash, conjunctivitis, and chest pain has also been reported in children receiving cytarabine in standard doses.[637] Coadministration of corticosteroids appears to relieve these symptoms. Neurotoxicity from cytarabine has been primarily associated with high-dose therapy.[281,638,639,640 and 641] The most common manifestation of neurotoxicity is an acute cerebellar syndrome manifesting 3 to 8 days after initiation of therapy, but seizures and encephalopathy have also been reported. [281,640] Nystagmus, ataxia, dysarthria, dysmetria, and dysdiadochokinesia are the classic cerebellar manifestations. In most cases, these neurologic symptoms resolve within a week, but as many as 30% of patients do not regain full cerebellar function.[281,640] Neuropathologic findings include loss of Purkinje's cells and a reactive gliosis in the cerebellum. In addition to dose, other risk factors for the development of neurotoxicity include advanced age and hepatic or renal dysfunction. [640,642,643 and 644] Lowering the dose of cytarabine from 3,000 to 2,000 mg per $m^2$ and administering the drug daily instead of every 12 hours is recommended for patients with renal dysfunction. [644] The drug should be immediately withdrawn if nystagmus or ataxia occurs. Skin and ocular toxic effects have also been observed on high-dose regimens. [636]

***Fluorouracil***

The fluorinated pyrimidine fluorouracil ( Fig. 10-12) is one of the few rationally designed anticancer drugs. It has been widely used in the treatment of carcinomas of the gastrointestinal tract, breast, ovary, and head and neck but it is not used for the treatment of the common childhood cancers. Fluorouracil is administered intravenously as a bolus injection (500 mg per $m^2$), usually on a daily-for-5-days schedule, or as a continuous infusion (800 to 1,200 mg per $m^2$ over 24 hours). Protracted low-dose infusional fluorouracil is also effective and well tolerated. [645,646]

Fluorouracil is a prodrug and must be converted intracellularly to nucleotides before expressing cytotoxicity. [647,648 and 649] There are several possible pathways for the anabolism of fluorouracil to active intracellular metabolites, and the relative importance of each pathway is tissue- and tumor-dependent. [650] The deoxyribonucleotide 5-fluorodeoxyuridine monophosphate (5-FdUMP) is a potent inhibitor of thymidylate synthase, leading to depletion of the DNA precursor, thymidine; and the ribonucleotide fluorouridine triphosphate is incorporated into RNA. Inhibition of thymidylate synthase by FdUMP is thought to be the primary mechanism of action in most tumors.[651] Mechanisms of resistance to fluorouracil in preclinical models include an increase in intracellular catabolism by DPD, a decrease in the activity of activating enzymes, and an increase in levels of the target enzyme thymidylate synthase. [652,653 and 654] A mutant thymidylate synthase with decreased affinity for FdUMP has also been described.[655]

**Pharmacokinetics**

Bioavailability of oral fluorouracil is highly variable, in part because of a saturable first-pass elimination process. [656,657] In one study of 13 patients, two had undetectable plasma drug levels after an oral dose of 750 mg, and the fraction of the dose absorbed ranged from 0% to 74%. [657] Because of this erratic absorption, fluorouracil should not be administered by the oral route, unless it is administered with agents, such as eniluracil, [658] which blocks the presystemic catabolism of fluorouracil and enhances its bioavailability. Bioavailable fluorouracil prodrugs, such as capecitabine and tegafur-uracil, have been also developed for oral administration. These agents are converted to fluorouracil after absorption and provide more prolonged drug exposure, similar to a prolonged intravenous infusion.[659,660,661 and 662] Subcutaneously administered fluorouracil is well tolerated and has nearly complete bioavailability. [663]

Fluorouracil is eliminated primarily by biotransformation. The degradative pathway is the same as that for the naturally occurring pyrimidines uracil and thymine. [648,658] Less than 10% of the drug is excreted unchanged in the urine. With standard bolus dosing, the elimination of fluorouracil is rapid. The half-life is 6 to 20 minutes, and total clearance is greater than 1,000 mL per minute.[649,658,664,665] With a continuous infusion schedule, the pharmacokinetics differ significantly, with clearance values as high as 5,000 mL per minute. In children treated with 80 mg per $m^2$ per hour for 12 hours, the mean steady-state concentration of fluorouracil was 6.7 µM, and the clearance was 2,500 mL per minute per $m^2$.[666] This schedule-dependent clearance is consistent with a dose-dependent or saturable clearance process. [649,664,667,668] Although the liver is thought to be the principal site of drug catabolism, the high clearance values with infusions exceed the rate of hepatic blood flow, indicating that biotransformation must also be taking place in other organs.[664]

Circadian dependency of fluorouracil toxicity appears to be related to rhythmic threefold to 25-fold fluctuations in plasma drug concentrations over the course of the day.[647,669,670,671 and 672] During a continuous intravenous infusion, the plasma fluorouracil concentrations were highest in the late morning and lowest shortly before midnight; and plasma concentrations of fluorouracil were inversely related to the activity of the catabolic enzyme, DPD, in peripheral blood mononuclear cells. [670,671] Adjustments in the dose or rate of fluorouracil infusion may be indicated based on the time of day the drug is being administered. [672,673]

**Toxicity**

The incidence and severity of clinical toxicities of fluorouracil depend on the dosing schedule. With intravenous bolus dosing, myelosuppression is the primary toxicity, but if the drug is given as a continuous infusion at doses up to 14,000 mg over 24 hours, myelosuppression is less prominent and stomatitis and diarrhea become dose-limiting.[674] Protracted low-dose infusions can produce palmar-plantar dysesthesia (hand-foot syndrome). Reversible neurologic toxicity characterized by somnolence, cerebellar ataxia, and headache; ocular toxicity consisting of conjunctivitis and ectropion; dermatitis; and, rarely, cardiotoxicity, which can include chest pain, arrhythmias, and ischemic changes on electrocardiogram, are also reported. [647] Inherited partial deficiency of the catabolic enzyme DPD in 1% to 3% of the population is associated with severe fluorouracil toxicity. [101,654,675,676] Fluorouracil half-life is markedly prolonged, and there is no evidence of catabolism in DPD-deficient patients.[675]

**Drug Interactions**

Folates are required for the stable binding of 5-FdUMP to its target enzyme, thymidylate synthase, and the combination of leucovorin and fluorouracil is synergistic in experimental systems.[677] This combination has been studied in a large number of clinical trials, primarily in adults with gastrointestinal tumors. In randomized clinical trials, the combination results in higher response rates than fluorouracil alone. [677] Pediatric trials of fluorouracil and leucovorin have failed to demonstrate substantial

activity against sarcomas.[666,678] Other modulators of the fluorouracil anticancer effect include the interferons, cisplatin, zidovudine, and antifolates. [646,677,679,680 and 681]

## ANTITUMOR ANTIBIOTICS

Most of the current antitumor antibiotics (Fig. 10-16) are natural products that were originally isolated from the microbial broth of a variety of species of the group of soil microorganisms, *Streptomyces*. The agents from this class of anticancer drugs that are used in the treatment of childhood cancers include the anthracyclines, mitoxantrone, dactinomycin, and bleomycin.

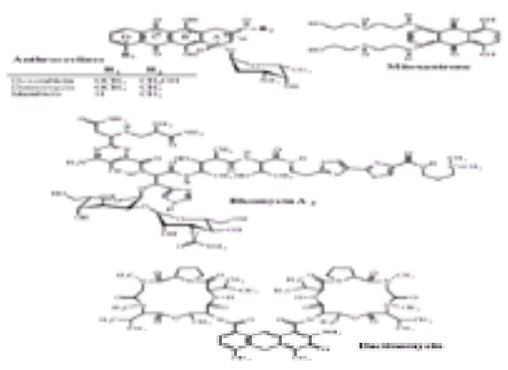

**FIGURE 10-16.** Chemical structures of the antitumor antibiotics commonly used in the treatment of childhood cancers: the anthracyclines, doxorubicin, daunomycin, and idarubicin; mitoxantrone; bleomycin $A_2$; and dactinomycin. Doxorubicin and daunomycin differ only in the presence or absence of a hydroxyl group on the carbonyl side chain at ring position 9. The structure of idarubicin (4-demethoxydaunomycin) is identical to daunomycin except for the absence of a methoxy group at ring position 4. Mitoxantrone differs from the anthracyclines by virtue of its three-ring nucleus, its symmetric aminoalkyl side chains, and its lack of a glycosidic substituent, which is important for water solubility of the anthracyclines.

The antitumor antibiotics avidly bind to DNA by a process called *intercalation*, in which a planar, multiring portion of the drug inserts between base pairs of the DNA double helix. The anthracyclines mitoxantrone and dactinomycin interfere with the topoisomerases, nuclear enzymes that regulate the three-dimensional shape of DNA by cleaving and religating DNA during replication, transcription, repair, and recombination. Intercalators like the anthracyclines produce protein-associated DNA strand breaks, apparently by interfering with this cleavage-religating process. [55,56 and 57] Alterations in the activity or function of the topoisomerases may be one mechanism of multidrug resistance.[682,683]

### Anthracyclines

The anthracyclines doxorubicin, daunomycin (daunorubicin), and idarubicin are highly pigmented compounds composed of a planar tetracyclic anthraquinone nucleus linked to the amino sugar daunosamine (Fig. 10-16). Doxorubicin has a wide range of clinical activity against pediatric cancers, including the acute leukemias, lymphomas, sarcomas of soft tissue and bone, Wilms' tumor, neuroblastoma, and hepatoblastoma. The use of daunomycin and idarubicin is currently limited to the acute leukemias.

The mechanism of anthracycline antitumor activity may be multifactorial. [682,684,685,686,687,688 and 689] These agents intercalate into DNA and induce topoisomerase II–mediated single- and double-strand breaks in DNA. Topoisomerase II–mediated DNA cleavage may occur by nonintercalative mechanisms. [684] In addition, anthracyclines block helicase-catalyzed dissociation of duplex DNA into single strands and oxidize DNA bases. [684] The anthracyclines can undergo chemical reduction through several enzymatically catalyzed pathways or by interaction with oxymyoglobin in the heart, yielding reactive free radical intermediates ( Fig. 10-17).[684] Transfer of an electron from these unstable radicals to molecular oxygen yields superoxide radicals that can generate hydrogen peroxide and hydroxyl radicals, compounds that can cause oxidative damage to cellular macromolecules. The interaction of anthracyclines with iron plays a role in free radical formation. Anthracyclines may also exert cytotoxic effects through a direct interaction with the cell membrane.[684] Experimental evidence indicates that topoisomerase-mediated DNA damage is the most important mechanism. Resistance to these agents is associated with increased expression of a family of membrane-bound drag transporters which includes P-gp, MRP, breast cancer resistance protein and lung resistance–related protein. [690] Idarubicin appears to be less susceptible to this form of drug resistance than daunomycin *in vitro*, possibly because it is more lipophilic. [691,692] Altered levels or affinity of the target enzyme, topoisomerase II, also confers resistance to the anthracyclines.[684]

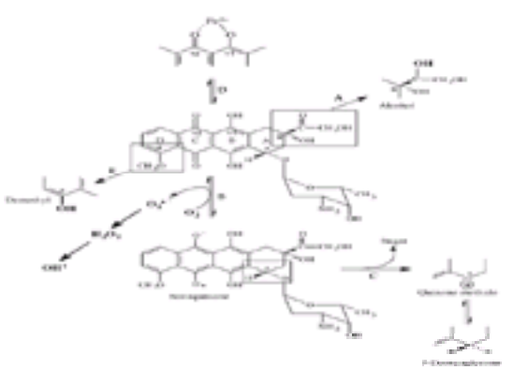

**FIGURE 10-17.** Doxorubicin chemistry. Reduction of the carbonyl group at the 9 position leads to the formation of the alcohol, doxorubicinol (A). The alcohol metabolites of daunomycin and idarubicin are also prominent metabolites of these agents. The alcohol metabolites of doxorubicin and daunomycin retain some cytotoxic activity but are considerably less active than the parent drug, whereas the cytotoxicity of idarubicinol is equivalent to that of the parent drug. Reduction of the C ring, catalyzed by one of several flavoproteins, reductases, or oxymyoglobin, leads to the formation of the semiquinone free radical (B). In the presence of oxygen, the unpaired electron is donated to oxygen to form the highly reactive superoxide radical, and the anthracycline returns to its parent form (i.e., redox-cycling). Superoxide ($O_2^{\bullet -}$) is converted to hydrogen peroxide ($H_2O_2$) by superoxide dismutase, and $H_2O_2$ is reductively cleaved in the presence of iron or doxorubicin semiquinone to hydroxyl radicals ($^{\bullet}OH$), which is destructive to tissues. Under hypoxic conditions, molecular rearrangement leads to the loss of the sugar and formation of an intermediate free radical (not shown) that can react with cellular macromolecules or become further reduced to the inactive 7-deoxyaglycone metabolite, the tautomer of which is quinone methide, an alkylating species (C). This is thought of as a minor pathway that leads to inactivation. Oxygens at ring positions 11 and 12 chelate iron, which is subsequently reduced by cellular reducing systems such as cytochrome P-450 reductase or by auto-oxidation of the hydroquinone (B ring) or, with doxorubicin, oxidation of the ring position 9 side chain (D). Demethylation of the methoxy group at ring position 4 of doxorubicin or daunomycin (E). This hydroxyl group may subsequently be conjugated with glucuronide or sulfate, which detoxifies the drugs.

The anthracyclines are administered by a wide range of schedules, including bolus injection daily, weekly, or every 3 to 4 weeks, short infusions of up to 6 hours; continuous infusion over 24 to 96 hours; and long-term, low-dose infusions over weeks to months. The antitumor effect does not appear to be influenced by these variations in the schedule of administration.[684,693,694] However, schedule can significantly influence toxicity. Administering doxorubicin weekly or by infusion appears to reduce cardiotoxicity and nausea and vomiting but enhances mucositis. [693,695,696 and 697] Doxorubicin has also been administered intraarterially. [698]

#### *Biotransformation*

The principal metabolites of the anthracyclines ( Fig. 10-17) are the corresponding alcohols (13-dihydroderivative), doxorubicinol, daunomycinol, and idarubicinol, formed by the action of aldoketoreductase.[684,699] Doxorubicinol and daunomycinol retain cytotoxic activity but are considerably less active than the parent drugs, but idarubicinol is as potent as idarubicin.[700] Anthracycline free-radical species can be generated by several reactions. One electron reduction to the semiquinone free radical is catalyzed by flavin-based oxidoreductases, including NADPH cytochrome P-450 reductase, NADH dehydrogenase, and xanthine oxidase.[686] If the extra electron in the semiquinone is donated to molecular oxygen, the parent drug is regenerated (redox cycling). Under hypoxic conditions, the semiquinone is converted to a 7-deoxyaglycone metabolite. Although reactive intermediates are formed after elimination of the sugar, this reaction appears to inactivate the drug.[684,685] Deoxyaglycones are minor metabolites of the anthracyclines.[699] Anthracyclines avidly chelate iron; the resulting drug-iron complex can undergo reduction to yield free radicals by cellular reducing systems (e.g., glutathione, NADH cytochrome P-450 reductase) or by auto-oxidation of the anthracycline molecule.[686] Anthracyclines may be inactivated by conjugation with sulfate or glucuronide after demethylation (i.e., doxorubicin and daunomycin) of the methoxy group at the 4 position on the ring ( Fig. 10-17).

***Pharmacokinetics***

Instability of doxorubicin and daunomycin in an acid environment prevents their oral administration. Idarubicin can be administered orally and has a bioavailability of 20% to 30%.[699,701,702 and 703] The severe vesicant properties of the anthracyclines prohibit intramuscular or subcutaneous administration.

After an intravenous injection, there is an initial rapid decline in plasma concentration, which is generally attributed to the rapid and avid binding of these drugs by tissues; the distributive half-life is approximately 10 minutes.[699,704,705,706 and 707] This extensive binding also accounts for the very large volumes of distribution (greater than 500 L per $m^2$). Tissue anthracycline levels can be up to 100-fold higher than plasma drug concentrations, and tissue levels persist longer.[694,708,709] The distributive phase is followed by a long terminal elimination phase, with half-lives of 30 hours for doxorubicin and 15 to 20 hours for daunomycin and idarubicin.[704,707,710,711] Despite the fact that drug concentrations at the start of the terminal phase are 1/50 the peak concentrations, 66% to 80% of the total drug exposure occurs during this terminal phase.[705,706] With prolonged continuous infusion of 4 mg per $m^2$ per day, doxorubicin plasma concentration averaged 6.0 ng per mL, and the plasma concentration was strongly correlated with the degree of leukopenia.[695]

The anthracyclines are eliminated by biotransformation (primarily hepatic) and biliary excretion. Renal excretion accounts for only 5% to 15% of total drug clearance.[707,710,711] The total clearance exceeds 500 mL per minute per $m^2$, and in children, clearance corrected for body surface area is independent of age.[698,705,707,711] The pharmacokinetic parameters appear to be linear over a wide range of dosage schedules.[712,713]

Dosage modifications are usually not required for doxorubicin and daunomycin in patients with renal dysfunction, although doxorubicin clearance is delayed in patients on hemodialysis.[714] Idarubicin clearance is correlated with creatinine clearance and appears to be reduced with renal impairment.[715] Delayed clearance of doxorubicin associated with an increase in myelosuppression and mucositis has been reported in adults and children with hepatic dysfunction.[707,716,717 and 718] However, abnormal liver function test results do not correlate well with doxorubicin clearance.[110,719,720] The best recommendation is that dose reduction be reserved for patients with multiple liver function test abnormalities or direct bilirubin elevations greater than 2.0 mg per dL, although this guideline may significantly underdose some patients.[110,686,721] Modification of anthracycline dose may also be indicated in obese patients (greater than 130% of ideal body weight), because they appear to eliminate doxorubicin slower and therefore have a twofold higher drug exposure (i.e., AUC) than nonobese patients receiving the same dose.[722]

The alcohol metabolites of the anthracyclines are also detectable in plasma. Exposure to doxorubicinol as measured by the AUC is approximately one-half that of doxorubicin.[699,706,723] In contrast, aldoketoreductase has a higher affinity for daunomycin and idarubicin, and the terminal half-lives of daunomycinol (20 to 40 hours) and idarubicinol (50 to 80 hours) are longer than those of their respective parent drugs. As a result, exposure to daunomycinol and idarubicinol is twofold and fivefold higher than to daunomycin and idarubicin, respectively.[698,699,705,711,712,724] There is accumulation of idarubicinol with daily administration (oral or intravenous) of idarubicin.

***Toxicity***

The acute toxicities of the anthracyclines include myelosuppression, mucositis (less prominent with daunomycin), nausea, vomiting, diarrhea, and alopecia.[725] Extravasation of these agents leads to severe local tissue damage and deep ulcerations, which heal very slowly and are difficult to skin graft. Extravasation has traditionally been managed with ice packs and local injection of corticosteroids and sodium bicarbonate, but these measures have only marginal benefit. In a prospective clinical trial of topical DMSO (99% solution), no ulcerations occurred in 20 patients with suspected anthracycline extravasation when DMSO was applied twice and allowed to air dry, six times per day for 14 days.[726] In severe cases, consideration should be given to early surgical excision of the affected tissues followed by full-thickness skin graft or skin flap coverage.[727]

Anthracyclines can also potentiate radiation reactions in many tissues, including skin, liver, esophagus, lungs, and heart, and the concurrent use of these two modalities should be avoided. A radiation recall phenomenon can be observed if an anthracycline is administered in the postirradiation period.[725]

Anthracyclines can cause acute and chronic cardiac toxicity.[728,729] The acute form is characterized by arrhythmias and conduction abnormalities, but there can also be an acute drop in left ventricular function, reaching a nadir at 24 hours, followed by variable recovery.[730] Rarely, this acute toxicity is manifested as the myocarditis-pericarditis syndrome, which in its severest form is characterized by the rapid onset of congestive failure associated with pericarditis.[731] In general, the acute asymptomatic cardiac changes are transient and do not prevent further use of anthracyclines.[684]

Chronic cardiomyopathy can be separated into an early form, which occurs during treatment or within 1 year of completing anthracyclines, and a late form, which occurs more than a year after completing anthracyclines.[728,732] The early form of cardiomyopathy is related to the cumulative dose of anthracyclines. The incidence of clinically apparent congestive heart failure starts increasing after cumulative doses exceed 450 mg per $m^2$ for doxorubicin and 700 mg per $m^2$ for daunomycin.[733,734] A maximum lifetime safe cumulative dose has not been defined for idarubicin, but cumulative doses of up to 150 mg per $m^2$ appear to be well tolerated.[735] Other factors that are reported to increase the risk for the development of a cardiomyopathy include a high dose rate (bolus or short infusion) of doxorubicin administration, prior or concurrent mediastinal irradiation, and preexisting cardiac disease. Children appear to be at higher risk for cardiac toxicity, and those younger than 5 years are at higher risk than older children.[725,736,737] Girls have a significantly higher incidence of abnormal cardiac findings at any given cumulative dose of doxorubicin than boys.[735,737,738] Lowering peak concentrations of anthracycline by administering the drugs on a lower-dose weekly schedule or by 6- to 96-hour continuous infusions appears to reduce the cardiotoxic effects without compromising the antitumor effect.[694,697,739,740 and 741] A daily divided dosing schedule of doxorubicin was as cardiotoxic as a single bolus dose.[742]

Late cardiotoxicity appears to be more common in children[743,744,745 and 746] than in adults and is characterized by a progressive decrease in fractional shortening, left ventricular mass and wall thickness relative to body size, and an increase in left ventricular afterload.[732,743] The probability of abnormal cardiac function is associated with young age at diagnosis, female sex, dose rates of greater than or equal to 50 mg per $m^2$, and cumulative doses greater than or equal to 550 mg per $m^2$. The heart appears unable to grow in proportion to the child, leading to a small, poorly compliant left ventricle. Prolonged infusions of anthracyclines may not protect children from late cardiotoxicity.[732] Although late anthracycline cardiotoxicity was initially thought to occur primarily in children who received a cumulative doxorubicin dose greater than or equal to 300 mg per $m^2$,[747] sporadic cases with lower cumulative doses were reported,[737,744,745 and 746] and a recent long-term follow-up study in children who were 7 to 14 years out from treatment confirmed that cardiac abnormalities occur at lower total doses.[748] Sudden late decline in cardiac function has also been attributed to intercurrent viral infections in patients with diminished cardiac reserve resulting from prior anthracycline therapy.[749]

Late-onset congestive heart failure and late-effects studies showing a high incidence of subclinical cardiac damage and dysrhythmias in children who were previously treated with presumably safe cumulative doses of anthracyclines suggest that children are more sensitive to the cardiotoxic effects of these agents. Maximum, lifetime cumulative dose levels defined in adults may not be applicable to children, especially very young children. In one study, the risk of late cardiotoxicity in children was low if the cumulative anthracycline dose was less than 350 mg per $m^2$ and the echocardiogram at 1 year off therapy was normal.[750] These data indicate that long-term monitoring of cardiac function should be performed in children who were previously treated with anthracyclines.

Serial echocardiography and radionuclide cineangiography can detect subclinical decline in left ventricular function at cumulative anthracycline doses below the maximum lifetime limit, and endomyocardial biopsies show a steady increase in damage to myocytes with increasing cumulative dose. [729] The primary pathologic change in the myocardium is the destruction and loss of myofibrils and sarcoplasmic vacuolation. [751] Myocardial damage appears to result from the generation of free radicals of the drug (Fig. 10-17) or secondary oxygen-free radicals. These highly reactive species can damage lipid biomembranes and cellular organelles. [684] Myocardium has limited ability to withstand this oxidative stress, because of its low levels of catalase, which detoxifies peroxides. In an experimental model, the alcohol metabolites were more cardiotoxic than the parent anthracyclines and have been shown to accumulate in the heart. [708,709,752,753] Cardiac doxorubicin and doxorubicinol concentrations in human autopsy hearts were significantly higher than concentrations in skeletal muscle and smooth muscle organs (i.e., bladder and uterus).[753]

Endomyocardial biopsy is the most sensitive and direct method of assessing the degree of anthracycline-induced cardiomyopathy. [751] The results correlate well with cardiac function measured at cardiac catheterization, but the technique is invasive, expensive, and technically demanding. Conventional noninvasive functional studies, however, such as the electrocardiogram, echocardiogram, and radionuclide cineangiography, may not demonstrate abnormalities until a critical degree of myocardial injury has occurred, and these studies do not appear to be predictive for the late cardiac effects of anthracyclines. [732,753] Cardiac troponin T serum levels and myocardial uptake of radiolabeled antimyosin antibody, which are sensitive and specific measures of myocardial cell injury, are elevated in children treated with anthracyclines and may be predictive for functional outcome after treatment. [754,755,756 and 757]

Children receiving anthracycline therapy should have their cardiac function closely monitored. Echocardiograms or radionuclide cineangiography are generally recommended before starting therapy and then periodically before courses of anthracyclines. A decline in the shortening fraction to less than 28% by echocardiogram or a 15-percentage point decline in left ventricular ejection fraction (LVEF) or an LVEF less than 45% by cineangiography are indications to discontinue anthracycline therapy. However, the optimal method of screening and the use of screening results to determine anthracycline dose modifications remain controversial. [732,758,759 and 760]

Current approaches to the prevention of anthracycline cardiac toxicity include altering the schedule of drug administration to lower peak concentrations, coadministration of agents that protect the myocardium from the toxic effects of anthracyclines, and the development of less cardiotoxic anthracycline analogs, such as idarubicin and epirubicin, the new morpholino anthracycline derivatives, and liposomal formulation of doxorubicin. [729,761,762]

The most promising cardioprotective drug is a chelating agent, dexrazoxane. This drug undergoes hydrolysis intracellularly to a compound that is similar in structure to EDTA and tightly binds iron, a cofactor in anthracycline free-radical reactions. [684,686] Preclinical studies demonstrated the ability of dexrazoxane to block the cardiotoxicity of anthracyclines[763] and led to several clinical trials of this drug in patients who were receiving doxorubicin-containing chemotherapy regimens. [763,764 and 765] The dexrazoxane dose is determined from the doxorubicin dose as a ratio of 10 mg of dexrazoxane for each 1 mg of doxorubicin. Clinical and subclinical cardiac toxicity, as measured by incidence of congestive heart failure, decline in LVEF on radionuclide cineangiography, and endomyocardial biopsy, was significantly reduced in patients receiving dexrazoxane.[130,766,767] The cardioprotective effect of dexrazoxane has also been demonstrated in a randomized trial in children. [765] In most trials, dexrazoxane had no effect on the antitumor activity of doxorubicin.

### *Drug Interactions*

Doxorubicin elimination half-life may be prolonged when coadministered with cyclophosphamide or nitrosoureas, and doxorubicin clearance appears to be enhanced by coadministration with etoposide.[699] The cardioprotectant, dexrazoxane, does not modify doxorubicin pharmacokinetics. [768] Chemosensitizers used to modulate multidrug resistance mediated by P-gp can substantially alter the disposition of the anthracyclines. [171] For example, cyclosporine and its analog valspodar increases the systemic drug exposure (i.e., AUC) of doxorubicin by 50% and doxorubicinol by three- to fourfold. Doxorubicin-related toxicity is also significantly enhanced when the drug was administered in combination with cyclosporine.[769,770 and 771] The mechanism of this interaction is likely to be related in part to inhibition of P-gp in the biliary tract and decreased excretion of doxorubicin and doxorubicinol into the bile.

## Mitoxantrone

Mitoxantrone is a synthetic anthracenedione that has a planar tricyclic nucleus with two symmetric paraaminoalkyl side chains, but no glycosidic substituent ( Fig. 10-16).[684] Mitoxantrone induces topoisomerase II–mediated DNA strand breaks similar to the anthracyclines,[772,773] but it has a diminished capacity to undergo redox reactions compared to the anthracyclines. As a result, it does not appear to induce significant free-radical tissue injury, which is believed to be the mechanism of anthracycline cardiomyopathy.[684] Mitoxantrone is currently used in salvage regimens for the acute leukemias and lymphomas.[774,775 and 776] It is usually administered on a daily for 3 to 5 days, weekly, or every 3-week schedule.[777,778]

The plasma concentration-time profile of mitoxantrone resembles that of the anthracyclines, with an initial rapid decline ($t_{1/2}$, 10 minutes) and a prolonged terminal elimination phase ($t_{1/2}$, greater than 24 hours).[773] Mitoxantrone is metabolized by oxidation of the terminal hydroxyl groups on the side chains to the inactive mono- and dicarboxylic acids.[779] Biliary excretion appears to be a major route of elimination for mitoxantrone, but renal excretion of parent drug accounts for less than 10% of the administered dose.[773] Mitoxantrone is avidly tissue bound. It has a volume of distribution of 500 to greater than 3,000 L per $m^2$ and can be detected in tissues for weeks after a dose.[773,780] Mitoxantrone clearance is variable and ranges from 100 to 500 mL per minute per $m^2$.[773]

The acute toxicities of mitoxantrone include myelosuppression, mucositis, mild nausea and vomiting, diarrhea, and alopecia. Patients may also notice a bluish discoloration of the sclera, fingernails, and urine. Tissue damage from extravasation of mitoxantrone is uncommon. Mitoxantrone is less cardiotoxic than anthracyclines at equivalent myelosuppressive doses in animal models and in some clinical trials, but the long-term cardiac effects in children have not been studied.[781,782 and 783]

## Bleomycin

Bleomycin is a unique antibiotic that is a mixture of 11 low-molecular-weight (1,500 d), water-soluble glycopeptides. The major species is bleomycin $A_2$ (Fig. 10-16), which accounts for 65% of the commercial preparation. Bleomycin chelates divalent redox-active transition metal ions, such as iron, cobalt, zinc, nickel, or copper, but it is only active in the ferrous form.[784,785,786 and 787] The bleomycin-iron complex binds tightly to DNA, with partial intercalation between guanosine-cytosine base pairs. After binding to DNA, the bleomycin-iron complex produces single- and double-strand DNA breaks by a $Fe^{2+}$-$O_2$-catalyzed free radical reaction.[788] The bleomycin • Fe coordination complex oxygenates the C4' hydrogen of deoxyribose, and cuts DNA in the minor groove, predominately at the CpT and GpC sequences in actively transcribed chromatin domains.[784,789]

The primary determinants of bleomycin cytotoxicity are cellular uptake, DNA repair activity, concurrent medications that alter DNA conformation (e.g., intercalating agents), and the level of activity of bleomycin hydrolase. The latter is a cysteine proteinase that is found in normal tissues and tumor cells and that hydrolyzes a terminal carboxamide group to form an inactive metabolite.[784,789,790] Lung and skin, the tissues with the greatest susceptibility to bleomycin damage, have the lowest levels of this enzyme. In contrast, liver, spleen, intestine, and bone marrow, sites that are less susceptible to bleomycin toxicity, have high levels of this enzyme. [785,791] Bleomycin-resistant cells lines have an increased capacity to hydrolyze bleomycin and an enhanced capacity to repair DNA damage. [792,793]

### *Dosage and Toxicity*

Bleomycin can be administered intravenously by bolus or infusion, intramuscularly, or subcutaneously at doses of 10 to 20 U per $m^2$. A unit is a measure of the drug's cytotoxic activity in bacteria and is equivalent to approximately 1.2 to 1.7 mg of peptide. [791] The drug is active against Hodgkin's disease, lymphomas, and testicular cancer and other germ cell tumors. Bleomycin also has been administered regionally into the pleural space for malignant pleural effusions and intravesicularly for bladder tumors.[794,795]

Unlike most other anticancer drugs, bleomycin is not myelosuppressive. The dose-limiting toxicity is an interstitial pneumonitis that can lead to pulmonary fibrosis. Below a total cumulative dose of 450 U, sporadic cases of pulmonary toxicity are reported, with an incidence of 3% to 5%. At cumulative doses above 450 U, the

incidence increases with the dose.[796,797] Patients with this toxicity present with a persistent dry cough and exertional dyspnea that can progress to tachypnea, hypoxia, and death.[796,797] The chest x-ray typically shows reticulonodular infilterates at the base. A decline in the single breath diffusing capacity for carbon monoxide is the most sensitive measure of subclinical damage, but it may not delineate those patients who are at highest risk to develop clinically symptomatic toxicity. [796,797] and [798] Pulmonary irradiation and the use of supplemental oxygen may enhance the risk of pulmonary toxicity in patients receiving bleomycin, [785,797,799] but others have found that serum creatinine and age older than 30 years may be more important predictors of pulmonary toxicity than the dose or exposure to supplemental oxygen. [800,801] and [802] Concurrent use of G-CSF does not appear to enhance bleomycin pulmonary toxicity.[803] The pathologic changes in the lung include edema and cellular infilteration in the perivascular interstitial space, followed by damage to alveolar lining cells and formation of hyaline membranes and fibrosis. [804] These changes may progress even after the drug is stopped. Pulmonary function should be closely monitored in patients receiving bleomycin, and the drug should be discontinued at the first sign of lung damage. High-dose corticosteroids may be of value in decreasing fibroblast activity, although this recommendation is based only on anecdotal experience. [797]

Dermatologic toxicity from bleomycin is common. Linear hyperpigmentation of the skin is the most common finding, but other mucocutaneous reactions include erythema, induration, desquamation, and sclerosis of the skin; alopecia; nail hyperpigmentation and deformities; and mucositis. [805] Other side effects include nausea and vomiting, fever, hypersensitivity reactions, and Raynaud's phenomenon.

***Pharmacokinetics***

Bleomycin is not administered orally as it would probably be enzymatically degraded in the intestinal tract. Absorption after intramuscular and subcutaneous injection is almost complete, and plasma concentrations with a continuous subcutaneous infusion closely simulate those after an intravenous infusion. [785,791,806,807] With intravenous bolus dosing in children, the drug has a biphasic plasma disappearance curve with a terminal half-life of approximately 3 hours. Total clearance was 41 mL per minute per $m^2$, and renal clearance accounted for 65% of total drug clearance. [808] Patients with renal failure have prolonged terminal drug half-lives, higher plasma concentrations, and delayed clearance.[785,791,809,810] Bleomycin clearance is diminished in children previously treated with cisplatin, including those in whom the serum creatinine and blood urea nitrogen levels were not increased. [785,808] Concurrent use of other nephrotoxic drugs may also impair bleomycin elimination and augment its toxicity. A 45% to 65% dosage reduction has been recommended for patients with a creatinine clearance of less than 30 mL per minute per $m^2$.[785] In patients undergoing hemodialysis, bleomycin was not detected in the dialysate. [811]

**Dactinomycin**

Dactinomycin (actinomycin D) was one of the first drugs demonstrated to have significant antitumor activity in humans, and it has been in clinical use for almost 40 years. It continues to have a role in the treatment of Wilms' tumor and rhabdomyosarcoma, but it has been supplanted by the anthracyclines in many treatment regimens. Dactinomycin is composed of a planar tricyclic ring chromophore (phenoxazone) to which two identical cyclic polypeptides are attached ( Fig. 10-16).[812] The drug intercalates between DNA bases, preferentially binding to the base sequence d(ATGCAT). [813] Dactinomycin binding to DNA causes topoisomerase-mediated single- and double-strand breaks in DNA.[682,814] It also blocks the replication and transcription of the DNA template. [812]

There is limited information on the clinical pharmacology of dactinomycin. The drug is administered intravenously, traditionally on a daily-for-5-days schedule at a dose of 15 µg per kg per day. A single bolus dose of 45 to 60 µg per kg is also used for Wilms' tumor, because it is more convenient, it is no more toxic than the daily-for-5-days regimen, and it is equally effective. [44] A daily for 3 days schedule on weeks 1, 2, 4, and 5 was more hepatotoxic.[815]

After an intravenous bolus injection, dactinomycin has an initial rapid disappearance as a result of its avid tissue binding. [816,817] This distributive phase is followed by a prolonged elimination phase with a half-life of approximately 36 hours. [816] The drug is eliminated by renal and biliary excretion, although only 30% of the administered dose is recovered in the urine and stool over the week after a dose. Only a small fraction of the dose appears to be metabolized. [816]

The primary toxicities of dactinomycin are myelosuppression, orointestinal mucositis, and severe nausea and vomiting. Extravasation of this drug can result in severe local tissue damage and ulceration. Hepatic VOD is a potentially fatal toxicity of dactinomycin in patients with Wilms' tumor. VOD usually occurs during the first 10 weeks of treatment and is characterized by fever, hepatomegaly, ascites, weight gain, jaundice, elevated serum transaminases, and thrombocytopenia. [818] The risk of VOD is similar, with 60 µg per kg for 1 day and 15 µg per kg per day for 5 days schedules. [44] The incidence of VOD in Wilms' tumor is approximately 5%, and risk factors include low body mass, young age, and concomitant radiation.[815,818,819] Dactinomycin is a radiation sensitizer that can enhance the local toxicity of radiation therapy if administered concurrently. Potentiation of radiation pneumonitis is especially problematic. [820] It can also cause a radiation recall effect if administered up to 2 years after irradiation.[821]

## PLANT PRODUCTS

Plant products have been used to treat a variety of diseases for hundreds of years and are still an important source of medically useful and illicit drugs. [822] It has been estimated that in recorded history more than 3,000 species of plants have been used as some form of cancer treatment. Despite extensive screening in the modern era of cancer treatment, however, only a few clinically active anticancer drugs have been derived from the higher plants. [823,824] The only plant products with indications for the treatment of childhood cancers are the vinca alkaloids, which were derived from leaf extracts of the periwinkle plant, and the epipodophyllotoxins, which are semisynthetic derivatives of podophyllotoxin, which was extracted from the roots and rhizomes of the mandrake. The taxanes, which were derived from the yew tree, and the analogs of camptothecin, which was derived from the Chinese tree, *Camptotheca acuminata,* have clinical activity against a variety of adult cancers, but the role of these new agents in treating childhood cancers is still under investigation. As with other natural products, these anticancer drugs have novel and complex chemical structures (Fig. 10-18) and potent biologic properties. [58,824,825,826] and [827] The biotransformation of these drugs is also complex, and the metabolic pathways have only been partially defined.[57,828]

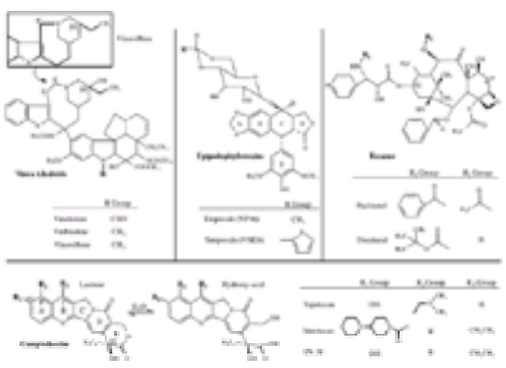

**FIGURE 10-18.** Chemical structures of the plant alkaloids commonly used in the treatment of childhood cancers: the vinca alkaloids, vincristine, vinblastine, and vinorelbine extracted from the periwinkle plant; the epipodophyllotoxins, etoposide and teniposide, synthetic derivatives of the natural product podophyllotoxin, which is derived from the mandrake plant (May apple); the taxanes, paclitaxel and docetaxel, derived from the yew tree; and the camptothecins, topotecan and irinotecan, derived from the stem wood of *Camptotheca acuminata*. Vincristine and vinblastine are identical except for the substituent at the R position, whereas the catharanthine ring of vinorelbine is modified. The asterisks on the taxane structure are hydroxylation sites. The hydroxyl group on the 10-position of SN-38 is the site of glucuronidation.

**Vinca Alkaloids**

The vinca alkaloids, vincristine, vinblastine, and vinorelbine, are structurally similar alkaloids composed of two multiring subunits, vindoline and catharanthine ( Fig. 10-18). Despite their structural similarity, these agents, which act as mitotic inhibitors, have differing clinical and toxicologic properties. The vinca alkaloids exert their cytotoxic effect by binding to tubulin, a dimeric protein that polymerizes to form microtubules. [828,829] The resulting disruption of the intracellular microtubular system

interferes with a number of vital cell functions, including mitosis; maintenance of the cytostructure; movement and transport of solutes, such as neurotransmitters in neuronal axons and hormones and proteins in secretory cells; membrane trafficking and transmission of receptor signals; and transport of p53 to the nucleus. [830,831] The cytotoxic effect of these agents is primarily related to their ability to inhibit mitotic spindle formation, causing metaphase arrest during mitosis. The vinca alkaloids are subject to multidrug resistance, and alterations in the a-and b-tubulin subunits also confer resistance. [830]

Vincristine has a wide spectrum of clinical activity and is currently used in the treatment of ALL, Hodgkin's and non-Hodgkin's lymphomas, rhabdomyosarcoma and other soft tissue sarcomas, Ewing's sarcoma, Wilms' tumor, brain tumors, and neuroblastoma. Vinblastine has been used in the treatment of histiocytosis, testicular cancer, and Hodgkin's disease. Vinorelbine is currently being evaluated in childhood cancers.

***Dosage and Pharmacokinetics***

Vincristine and vinblastine are poorly absorbed if administered orally and are therefore administered intravenously as a bolus injection. Oral vinorelbine is bioavailable, but the resulting plasma concentrations are variable. [832,833] The standard dose for vincristine is 1.0 to 2.0 mg per $m^2$, administered every 1 to 3 weeks. For infants 1 year of age or younger vincristine dose is scaled to body weight (0.03 to 0.05 mg per kg). Many regimens limit the total single dose of vincristine to 2 mg based on reports of increased neurotoxicity at doses above 2 mg, especially on the weekly schedule. However, this practice of capping the dose may underdose some patients, because there is substantial interpatient variation in the plasma pharmacokinetics of vincristine, with a greater than tenfold variation in the AUC.[721,834,835] Escalation of the dose beyond the 2-mg maximum may be well tolerated by some patients. Vinblastine doses range from 3.5 to 6.0 mg per $m^2$, administered in 1- to 3-week cycles. Vinorelbine is administered as a 10-minute infusion at a dose of 30 mg per $m^2$ weekly for up to 6 weeks.

After bolus administration, the vinca alkaloids manifest a rapid initial decline in plasma concentration (initial half-life of 5 to 10 minutes), followed by a prolonged terminal elimination phase with half-life of approximately 12 to 40 hours. [826,828,836,837,838,839,840,841] and [842] The long terminal half-life and the large steady-state volume of distribution (Table 10-6) are consistent with avid and extensive tissue binding that is characteristic of these drugs. Vincristine and vinorelbine clearance is more rapid in children than adults, and adults have a more than twofold longer terminal half-life. [833,836,837] Vincristine disposition in children is highly variable, resulting in a wide interpatient range in drug exposure at a standard dose of 1.5 mg per $m^2$.[836,837,843] Vincristine enters the CSF after intravenous administration, although the CSF concentrations are only 3% to 5% of the corresponding plasma concentrations. [844,845]

Hepatic metabolism and biliary excretion are the principal routes for elimination of the vinca alkaloids. From 70% to 75% of the radioactivity from a radiolabeled dose of vincristine appears in the feces by 72 hours, and slightly more than 10% of the radioactivity is excreted in the urine. [840,846,847] One-half of the radiolabeled material in urine and feces represents metabolites. CYP3A is involved in the metabolism of the vinca alkaloids, [848,849] and [850] and drugs that induce CYP3A4, such as anticonvulsants, and drugs that inhibit CYP3A4, such as azole antifungal agents, can alter the disposition of the vinca alkaloids. [837,851,852,853] and [854] The structures of the various metabolites of the vinca alkaloids are not fully known, but a desacetyl-metabolite of vincristine, vinblastine, and vinorelbine has been identified. [826]

Dosage modifications of the vinca alkaloids are generally recommended in infants and in patients with delayed biliary excretion as evidenced by an elevated direct bilirubin. Infants appear to manifest increased toxicity with standard doses of vincristine based on body surface area. Infants and younger children have a relatively larger ratio of body surface area to weight, and in a randomized crossover study in infants comparing dosing of vincristine based on body surface area (1.5 mg per $m^2$) to dosing by body weight (0.05 mg per kg), the dose calculated from body surface area resulted in greater systemic drug exposure (AUC). [855] Vincristine clearance normalized to body surface area is lower in infants than children, but this difference is not apparent if clearance is normalized to body weight ( Fig. 10-19).[837]

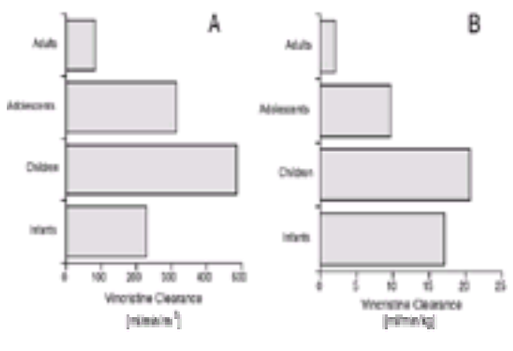

**FIGURE 10-19.** Clearance of vincristine normalized to body surface area **(A)** and body weight **(B) i**n infants (n = 2), children (younger than 10 years, n = 43) and adolescents (n = 9). (Adapted from Crom WR, de Graaf SSN, Synold T, et al. Pharmacokinetics of vincristine in children and adolescents with acute lymphocytic leukemia. J Pediatr 1994; 125:642).

***Toxicity***

Neurotoxicity is the dose-limiting toxicity of vincristine. It is related to the cumulative dose and occurs more commonly on a weekly schedule. Manifestations of the peripheral sensory and motor neuropathy include loss of deep tendon reflexes, neuritic pain (muscular cramping, jaw pain), paresthesias, and wrist and foot drop. Cranial motor nerves may be affected, and autonomic nerve involvement may be responsible for constipation, paralytic ileus, and urinary retention. In most cases, these symptoms are reversible on withdrawal of the drug. Vincristine neurotoxicity can be markedly accentuated in children with Charcot-Marie-Tooth disease. [856] Accidental intrathecal administration of vincristine has been reported and is usually fatal. Other toxicities associated with vincristine include alopecia, inappropriate antidiuretic hormone syndrome, seizures, and orthostatic hypotension. Nausea and vomiting and myelosuppression are rarely encountered. Vincristine can increase the platelet count.

Myelosuppression is the dose-limiting toxic effect of vinblastine and vinorelbine. Vinblastine also frequently causes mucositis. Neurotoxicity with vinblastine is minimal and is less prominent with vinorelbine than vincristine. [830] Vinorelbine causes constipation in 30% of patients. Vinca alkaloids are vesicants; extreme care must be taken to avoid extravasation during their administration. Ulcerations from vinca alkaloid extravasation were prevented in experimental animal model systems with the local injection of hyaluronidase (150 turbidity reducing units) and the application of local warming. [206] Hydrocortisone injection and local cooling increased ulcerations in these studies.

**Epipodophyllotoxins**

Etoposide (VP-16) and teniposide (VM-26) are semisynthetic analogs of the natural product, podophyllotoxin, an antimitotic agent that binds to tubulin. However, the epipodophyllotoxins do not act as microtubule inhibitors. [857,858] Instead, these glycosidic derivatives of podophyllotoxin ( Fig. 10-18) exert their antitumor effect through stabilization of the normally transient covalent intermediates formed between the DNA substrate and topoisomerase II, leading to single- and double-strand DNA breaks.[56,859,860,861,862] and [863] Resistance to epipodophyllotoxins can result from increased activity of the P-gp and related membrane efflux pump responsible for multidrug resistance, resulting in decreased intracellular drug accumulation, and from altered topoisomerase II activity (lower enzyme levels, phosphorylation of the enzyme, or mutations leading to decreased affinity for the drug), leading to a reduction in the formation of drug-induced cleavable complexes. [857]

There are no major differences in the antitumor spectra of these two drugs. Activity has been observed against the acute leukemias, Hodgkin's and non-Hodgkin's lymphomas, neuroblastoma, rhabdomyosarcoma and other soft tissue sarcomas, Ewing's sarcoma, germ cell tumors, and brain tumors.[864,865,866] and [867]

***Dosage and Toxicity***

Because the solubility of the epipodophyllotoxins in water is poor, both are supplied in nonaqueous formulations. Etoposide is formulated in polysorbate 80,

polyethylene glycol, and alcohol, and teniposide is formulated in Cremaphor EL, alcohol, and dimethylacetamide. Before intravenous administration, these agents are diluted in 5.0% dextrose in water or 0.9% saline to a concentration of less than 0.4 mg per mL and infused over 30 to 60 minutes to avoid the hypotension associated with rapid injections. Etoposide phosphate is a water-soluble prodrug of etoposide that overcomes the formulation difficulties of the parent drug. [868] Etoposide phosphate is rapidly converted to etoposide *in vivo* by plasma phosphatases and has a toxicity profile, maximum tolerated dose, and pharmacokinetic profile similar to that of etoposide.[869,870]

Etoposide is usually administered on a daily schedule for 3 to 5 days at a dose of 60 to 120 mg per $m^2$ per day. Teniposide is administered at a dose of 70 to 180 mg per $m^2$ daily for 3 days. Both agents have also been administered on a single high-dose schedule (up to 800 mg per $m^2$ of etoposide and up to 1,000 mg per $m^2$ of teniposide), and etoposide (2,400 mg per $m^2$) has been incorporated into bone marrow transplant preparative regimens. A chronic oral low-dose (50 mg per $m^2$ per day) schedule of etoposide has also being studied. [871,872]

Etoposide antitumor activity is dose- and schedule-dependent.[871,873,874] In adults with small cell lung cancers, the response rate in patients treated on a daily-for-5-days schedule is significantly higher than in patients treated with same total dose infused over 24 hours. [875] The chronic oral dosing schedule is also highly active in a variety of adult cancers.[876,877] However, a comparative trial of cisplatin in combination with either 21 days of oral etoposide at 50 mg per $m^2$ per day or 3 days of intravenous etoposide at 130 mg per $m^2$ per day in adults with lung cancer failed to demonstrate a survival advantage for this 21-day oral dosing schedule. [878]

The primary dose-limiting toxicity of the epipodophyllotoxins is myelosuppression. Other toxicities include alopecia, nausea, vomiting, phlebitis, mild peripheral neuropathy, hepatocellular enzyme elevations, and mucositis. Arrhythmias are relatively rare. Diarrhea was the dose-limiting toxicity in children treated with etoposide on the chronic oral dosing schedule, but myelosuppression and mucositis were also prominent toxicities. [879] Non–dose-limiting hypersensitivity reactions, which are characterized by urticaria, flushing, rash, and angioedema, are common and related to the cumulative dose of etoposide or teniposide. [880] Severe hypersensitivity reactions, such as bronchospasm and anaphylaxis, are less common and occur less frequently with etoposide than with teniposide. [881] A severe skin rash has also been reported with high-dose teniposide. [882]

A distinctive form of secondary acute leukemia, characterized by a short latency period (median time to presentation, 30 months), chromosomal translocations involving chromosome band 11q23, and M4 or M5 FAB morphologic subtype (monocytic or myelomonocytic), has been reported with alarming frequency in epipodophyllotoxin-treated patients.[883,884,885 and 886] The cumulative risk of developing this form of secondary leukemia has been estimated to be 5% to 12% in children with ALL treated with high cumulative doses of epipodophyllotoxins on a weekly or twice-weekly schedule. [886] In contrast, the incidence of this form of secondary acute nonlymphoblastic leukemia in survivors of germ cell cancers who were treated with etoposide is less than 1%. The 6-year cumulative incidence of secondary leukemia and myelodysplastic syndrome in patients who were treated on 12 pediatric cooperative group clinical trials was 3.3%, 0.7%, and 2.2% for cumulative etoposide doses of less than 1.5 g per $m^2$, 1.50 to 2.99 g per $m^2$, and greater than or equal to 3 g per $m^2$, respectively. Thus, epipodophyllotoxin cumulative dose does not appear to be a risk factor for development of secondary leukemia. [887]

***Pharmacokinetics and Drug Interactions***

The disposition of the epipodophyllotoxins is characterized by a significant degree of intrapatient and interpatient variability. [888,889] The bioavailability of oral etoposide is approximately 50% at doses of 200 mg per $m^2$ or less, but it ranges from 10% to 80%,[890,891] and there is considerable dose-to-dose variation within each patient.[892,893] Bioavailability is also nonlinear. At higher doses (greater than 200 mg per $m^2$), the fraction of the dose absorbed decreases.[894,895] Because oral absorption is erratic and dose-dependent and this route of administration has been associated with increased toxicity, the clinical usefulness of oral administration of standard doses of etoposide has been limited. However, the more efficient absorption of lower doses of etoposide (bioavailability, 70%) suggests that the chronic oral low-dose schedule may circumvent some of these limitations.[896,897] The mean bioavailability of etoposide from oral etoposide phosphate is 76% (range, 37% to 144%),[898] and the mean bioavailability of teniposide is 40% (range, 20% to 70%). [899] The absorption of teniposide also appears to decrease as the dose is increased.

The epipodophyllotoxins are extensively metabolized, although specific details of the metabolic pathways have not been fully elucidated. Some of these metabolites retain cytotoxic activity.[888,900] Metabolites identified in urine include the hydroxy acid derivatives [901] and glucuronide and sulfate conjugates.[888,902] The epipodophyllotoxins also undergo CYP3A4 mediated O-demethylation to the active catechol form, which can be oxidized to a reactive quinone. [903] Renal clearance accounts for 30% to 40% of the total systemic clearance of etoposide, but less than 10% of teniposide clearance. [892,899,904,905,906 and 907] This difference probably reflects the difference in the degree of protein binding of the two drugs (Table 10-6). Biliary excretion is not a major route of elimination for etoposide, accounting for less than 10% of total drug elimination in most studies. [902] Penetration of the epipodophyllotoxins into the CSF is limited, [865,905,908] but the concentrations achieved may be cytotoxic.[909]

The clearance of the epipodophyllotoxins is highly variable. For etoposide, the median clearance in children is 26 mL per minute per $m^2$, and the range is 14 to 54 mL per minute per $m^2$.[908] For teniposide, the median clearance is 13 mL per minute per $m^2$, and the range is 4 to 22 mL per minute per $m^2$.[910] The pharmacokinetic parameters are independent of the dose for doses up to 3,000 mg per $m^2$.[905,908,911] The clearance of etoposide is also age independent. In infants 3 to 12 months of age, the median clearance was 19 mL per minute per $m^2$, and in children older than 1 year of age, the median clearance was 18 mL per minute per $m^2$.[912] Therefore, no special dosing guidelines are required for treating infants, and all patients should receive a dose calculated from body surface area.

The pharmacokinetics of etoposide have been evaluated in patients with hepatic and renal dysfunction. [908,913,914,915 and 916] Etoposide clearance was significantly delayed and the terminal half-life prolonged in patients with renal insufficiency, putting them at higher risk for toxic reactions. Overall, correlation was good between creatinine clearance and etoposide clearance in these studies, suggesting that etoposide dose modifications should be based on the creatinine clearance. Etoposide clearance was not delayed in patients with abnormal hepatic function, indicating that dose adjustments are not necessary in these patients. The protein binding of etoposide is highly variable in cancer patients (range, 76% to 97%), and the degree of binding is correlated with the serum albumin level. [917,918] Patients with low serum albumin experience more severe hematologic toxicity from etoposide, presumably because of higher free-drug concentrations. [916,919] A 30% to 40% dosage reduction may be indicated in these patients. The fraction of etoposide bound to protein is higher in pediatric cancer patients than in adults with cancer. [920]

The wide interpatient variation in plasma concentrations of etoposide and teniposide has prompted investigators to evaluate the relation between plasma drug levels and measures of toxicity and response and to develop dosing methods that incorporate dose adjustments based on the plasma drug concentration. [921,922,923 and 924] In children treated with escalating doses of teniposide by continuous infusion, there was a fivefold variation in steady-state plasma teniposide concentration at a given dose, and the plasma drug concentration was a better predictor of response than the dose. [923] This led to trials in which the dose rate of teniposide was individually adjusted to normalize the plasma teniposide steady-state concentration to 15 μM for the 72-hour infusion schedule [922] or the total AUC to 1,500 μM • hour for the daily-for-3-days schedule. [910] Eliminating the wide variation in drug exposure by adjusting the dose to achieve a target plasma concentration allows increased dose intensity without increasing the risk of acute toxicity. [910] Dose adjustment based on the AUC after the first dose of etoposide is precise in achieving a target AUC for subsequent doses in children.[924] Attempts to apply therapeutic drug monitoring to low-dose oral etoposide regimens have had limited success, because of the marked intrapatient variability in drug absorption and disposition. Because of the variability in the extent of protein binding of etoposide, dosage adjustments based on the nonprotein-bound (free) fraction of etoposide may prove more successful than total drug concentration. [925,926]

Cyclosporine, a modulator of the P-gp, diminishes the renal and nonrenal elimination of etoposide and teniposide, resulting in an increase in plasma exposure (AUC) to the drugs and an increase in clinical toxicity. [927,928 and 929] The concomitant administration of anticonvulsants with etoposide and teniposide in children results in a two- to threefold increase in clearance and a proportional decrease in systemic drug exposure, which could reduce the drugs' efficacy. [930,931] The enhanced clearance is presumably the result of induction of hepatic metabolism.

**Taxanes**

The taxanes, paclitaxel and docetaxel, are complex diterpenes (Fig. 10-18) that exert their cytotoxic effect by interfering with microtubule function. However, unlike the vinca alkaloids, the taxanes increase microtubule stability by preventing microtubule depolymerization, which results in tubulin bundling. [932,933 and 934] Taxane-induced cytoskeletal changes lead to cell cycle arrest in the $G_2$ (premitotic) and M (mitotic) phases and cell death by apoptosis. Because paclitaxel arrests cells in the $G_2$/M phase, the most radiosensitive phase of the cell cycle, it is also a potent radiosensitizer. [933,934] Resistance to taxanes *in vitro* has been ascribed to the development of

altered tubulin subunits with impaired ability to polymerize, to the presence of the P-gp drug-efflux pump responsible for multidrug resistance, and to elevated levels of Raf-1 kinase, which can suppress paclitaxel-induced apoptosis.[932,935,936]

Although paclitaxel and docetaxel have a broad spectrum of antitumor activity in adult cancers, paclitaxel does not appear to be active against common childhood cancers as a single agent.[937] Docetaxel is still under evaluation. Paclitaxel is insoluble in water and is formulated in Cremophor EL and ethanol. This vehicle has been implicated in the hypersensitivity reactions from paclitaxel. Because this formulation of paclitaxel leaches plasticizers (phthalate) from polyvinylchloride intravenous infusion bags, it must be mixed and stored in glass, polypropylene, or polyolefin containers and administered through polyethylene-lined infusion sets. Docetaxel is formulated in polysorbate 80 and ethanol.

Paclitaxel has been administered as a 1-, 3-, 24-, or 96-hour intravenous infusion. The standard adult dose of paclitaxel is 135 or 175 mg per $m^2$ infused over 3 hours, although doses of up to 250 mg per $m^2$ are tolerable. Longer infusions appear to be more myelosuppressive.[938,939] The recommended dose of paclitaxel administered as a 24-hour infusion in children is 350 mg per $m^2$.[940] Docetaxel is administered as 1-hour infusion every 3 weeks at a dose of 100 to 125 mg per $m^2$, but higher doses may be tolerable with Filgrastim support.[941,942]

Paclitaxel pharmacokinetics are dose dependent and probably schedule dependent, and complex pharmacokinetic models incorporating capacity-limited elimination and capacity-limited distribution have been devised to describe the disposition of the drug.[943,944] Paclitaxel is extensively tissue bound, accounting for its large volume of distribution. Hepatic metabolism (hydroxylation) by CYP2C8 at the C-6 position on the ring and by CYP3A4 on the C-13 side chain ( Fig. 10-18) followed by biliary excretion are the primary routes of paclitaxel elimination (80% of the dose is recovered as parent drug or metabolites in feces).[945,946,947 and 948] Docetaxel also undergoes hepatic metabolism by CY3A4 and biliary excretion.[949,950] Drugs or xenobiotics that induce CYP450 enzymes, such as the anticonvulsants, enhance paclitaxel clearance,[951,952] and CYP3A4 inhibitors, such as the imidazole antifungal agents, reduce paclitaxel clearance.[945] Patients with hepatic tumor involvement or biochemical evidence of liver dysfunction (e.g., elevated bilirubin or transaminases) are at increased risk for paclitaxel toxicity, presumably because of delayed paclitaxel clearance.[953,954] Dosage reductions are recommended for these patients.[953] Renal excretion accounts for only 5% of total drug clearance.[945,955]

Myelosuppression is the primary dose-limiting toxicity of paclitaxel.[830,956] Neurotoxicity is also prominent in children and is characterized by a stocking-glove peripheral neuropathy (paresthesias, diffuse myalgias, and loss of fine motor control) and seizures.[940] Acute encephalopathy and irreversible coma are also associated with paclitaxel.[957,958] Ethanol in the formulation can cause toxicity if high doses of paclitaxel are infused over a short period.[959,960] The incidence of acute hypersensitivity reactions (hypotension, urticaria, and bronchospasm) occurring within minutes of the start of the infusion[961] has been reduced by administering paclitaxel as a more prolonged infusion and by premedicating patients with corticosteroids and antihistamines (e.g., Benadryl and ranitidine). Cardiac arrhythmias (e.g., bradycardia and atrioventricular conduction disturbances), alopecia, mucositis, radiation-recall dermatitis, pneumonitis, and phlebitis at the injection site are also caused by paclitaxel.[830,934,962]

Docetaxel produces neutropenia without significant thrombocytopenia. Other toxicities include malaise, myalgias, skin rashes (including palmar-plantar erythrodysesthesia), nausea and vomiting, mucositis, diarrhea, alopecia, interstitial pneumonitis, and transient elevations of serum transaminases.[941,942,963] Neurotoxicity is less prominent with docetaxel, but fluid retention associated with weight gain, edema, and in some cases scleroderma-like skin changes, is a cumulative toxicity that occurs in 20% of patients.[941,964,965] Hypersensitivity reactions, rashes, and fluid retention may be ameliorated by premedication with an antihistamine and corticosteroid.

### Camptothecins

Topotecan and irinotecan are semisynthetic, water-soluble camptothecin analogs ( Fig. 10-18) that produce DNA strand breaks by forming a ternary complex with DNA and topoisomerase I.[58,825,827] In aqueous solutions, the camptothecins exist in an equilibrium between the active lactone form and the relatively inactive hydroxy-acid form, which results from reversible hydrolysis of the E-ring. The inactive form predominates at physiologic pH, although the ratio of lactone:hydroxy acid varies for topotecan (10%), irinotecan (25% to 30%) and its active metabolite SN-38 (50% to 65%).[825,827,966] Decreased intracellular levels of topoisomerase I, alterations in the affinity of topoisomerase I for the camptothecin analogs, and expression of membrane-associated drug efflux pumps (P-gp) are mechanisms of resistance to topotecan and irinotecan.[967,968,969,970,971,972,973 and 974] However, the camptothecin analogs are poor substrates for the P-gp.[975]

#### *Topotecan*

Topotecan appears to be active against neuroblastoma and rhabdomyosarcoma,[976] but its role in treating these and other childhood cancers is still being defined. It is usually administered daily for 5 days at a dose of 1.4 mg per $m^2$ per day or 2.0 mg per $m^2$ per day with filgrastim.[977] Continuous infusion schedules of 1 to 21 days' duration have also been studied. Topotecan dose must be substantially reduced when administered in combination with cisplatin or cyclophosphamide because of enhanced hematologic toxicity.[978,979] Myelosuppression is the most common topotecan toxicity. Diarrhea becomes dose limiting with more protracted schedules or with oral dosing.[980] Other toxicities associated with topotecan include nausea and vomiting, alopecia, mucositis, elevated hepatic transaminases, and rash.[977,981,982]

The bioavailability of oral topotecan in children is approximately 30%, but there is marked interpatient variability in absorption.[983] With intravenous administration, the clearance of the lactone form of topotecan is also highly variable.[981,984] The terminal half-life of topotecan is 3 to 5 hours, and renal excretion is the primary route of elimination (60% to 70% of total dose).[981,985,986] Impaired renal function decreases topotecan clearance, necessitating a dosage reduction.[987] N-demethylation is a minor metabolic pathway,[988] and mild to moderate hepatic dysfunction does not appear to impact on drug disposition.[989] Topotecan penetrates into the CSF better than other topoisomerase I inhibitors.[990,991]

#### *Irinotecan*

Irinotecan is a prodrug that is converted by carboxylesterase in the liver and intestinal tract to the active metabolite, 7-ethyl-10-hydroxy camptothecin (SN-38), which is 100- to 1,000-fold more potent than irinotecan. In adults, irinotecan is administered as a 90-minute intravenous infusion weekly for 4 weeks at a dose of 125 mg per $m^2$ per day. Several dosing schedules are being evaluated for childhood cancers.[992,993 and 994] Myelosuppression and diarrhea are the most common toxicities in children and adults. Diarrhea, diaphoresis, and abdominal cramping that are associated with the drug infusion[995] are responsive to atropine, and delayed diarrhea is responsive to loperamide.[996] Other irinotecan toxicities include nausea and vomiting, transient elevations of hepatic transaminases, asthenia, alopecia, malaise, and electrolyte abnormalities.[993,994,997]

Oral irinotecan is rapidly absorbed and more efficiently converted to SN-38 due to first-pass metabolism, but plasma drug and metabolite concentrations are highly variable.[998] With intravenous administration, conversion of irinotecan to SN-38 is inefficient (less than 10% of the dose).[966,999] Oxidation of the dipiperidine side-chain by CYP3A subfamily enzymes also yields two minor metabolites (7-ethyl-10-[4-N-(5-aminopentanoic acid)-1-piperidino]carbonyloxycamptothecin [APC] and 7-ethyl-10-(4-amino-1-piperidino)carbonyloxycamptothecin [NPC]).[1000] Induction of these CYP3A catabolic pathways by anticonvulsants can enhances the clearance of irinotecan and reduce the production of SN-38.[1001,1002] Irinotecan and its metabolites are eliminated primarily by biliary excretion.[1000] Renal excretion of the parent drug accounts for 15% to 25% of the dose.[966]

SN-38 is conjugated to SN-38 glucuronide (SN-38G) by hepatic uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1), the enzyme responsible for bilirubin conjugation.[1003] Patients who have partial UGT1A1 deficiency (Gilbert's or Crigler-Najjar syndromes) or who are receiving drugs that inhibit UGTA1A, such as valproic acid, are at risk for increased drug-related toxicity.[1004,1005] SN-38G is secreted into the bile and deconjugated to SN-38 by beta-glucuronidase in the gut. This intraluminal formation of SN-38 may be responsible for the delayed diarrhea from irinotecan.[1005] The product of the irinotecan AUC and the ratio of SN-38 and SN-38G AUCs (biliary index) is higher in patients with more severe diarrhea.[1006]

## MISCELLANEOUS AGENTS

### Corticosteroids

Although they are not generally thought of as anticancer drugs because of the diversity of their other clinical uses, the corticosteroids (prednisone, prednisolone, and dexamethasone) play a significant role in the treatment of ALL, lymphoma, and Hodgkin's disease and have been incorporated into treatment regimens for the histiocytoses and brain tumors. They are also useful in managing some of the complications of cancer, including hypercalcemia, increased intracranial pressure, anorexia, and chemotherapy-induced nausea and vomiting.

Glucocorticoids induce apoptosis by binding to intracellular glucocorticoid receptors. [1007] The receptor-glucocorticoid complex translocates to the nucleus, dimerizes, and binds to specific DNA response elements. This causes modulation of expression of many genes. Continuous saturation of the receptor by the steroid for many hours to days is needed to induce apoptosis in sensitive cell lines, and in children with ALL, thrice daily administration is more effective than intermittent schedules.[1007] Glucocorticoid receptor content on leukemic blasts and the duration of receptor occupancy appear to be the critical determinants of response to corticosteroid therapy *in vitro* and *in vivo*. Loss of or defect in the glucocorticoid receptor can lead to drug resistance *in vitro*.[1008],[1009] and [1010] Children with ALL and low levels of glucocorticoid receptor on their lymphoblasts have a poor prognosis when treated on corticosteroid-based regimens.

The chemical structures of the most commonly used synthetic analogs of cortisol, prednisone, prednisolone, and dexamethasone, are shown in Figure 10-20. The addition of the 1,2-double bond in prednisolone and dexamethasone increases the glucocorticoid and antiinflammatory potency fourfold and decreases mineralocorticoid activity. Further addition of the fluorine at position 9 in dexamethasone enhances the activity another fivefold. Prednisone is an inactive prodrug analogous to cortisone and requires chemical reduction of the ketone group at position 11 to a hydroxyl group, yielding prednisolone. This activation occurs in the liver.[1011],[1012] Prednisolone and dexamethasone are eliminated by the catabolic enzymes that inactivate cortisol by reduction of the 4,5-double bond (hepatic and extrahepatic), hydroxylation at the 6-position (hepatic), or reduction of the 3-ketone to a hydroxyl group followed by conjugation with a sulfate or glucuronide (hepatic).[1012]

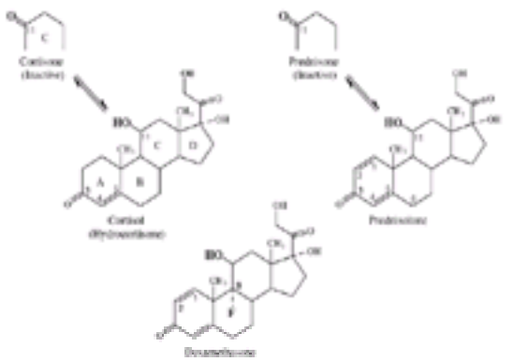

**FIGURE 10-20.** Chemical structures of the naturally occurring and synthetic corticosteroids commonly used in treating childhood cancers. Reduction of the keto group (cortisone and prednisone) to a hydroxyl group (cortisol and prednisolone) at the 11 position is necessary for activity. Addition of the 1,2-double bond (prednisolone and dexamethasone) and the fluorine group at the 9 position (dexamethasone) increases glucocorticoid activity.

### *Pharmacokinetics*

The absorption of orally administered prednisone, prednisolone, and dexamethasone is almost complete (greater than 80%). [1011],[1012] and [1013] Prednisone is rapidly converted to prednisolone, which is the predominant form in plasma after an oral dose of prednisone. [1011],[1012] In children, variable absorption of prednisone and prednisolone has been reported.[1013],[1014] The elimination half-lives are 2.5 hours for prednisolone and 4 hours for dexamethasone, reflecting differences in the rate of catabolism.[1014],[1015],[1016],[1017] and [1018] Hepatic metabolism is the primary route of elimination; renal clearance accounts for 10% or less of total clearance. [1019],[1020] The clearance of prednisolone is dose dependent and increases with increasing dose, because of concentration-dependent binding of prednisolone to plasma proteins.[1012],[1020],[1021] At low concentrations, prednisolone, like cortisol, is more than 95% bound to transcortin, but this specific carrier protein is saturated at higher prednisolone concentrations, so that the relative amount of free drug available for metabolic degradation increases.

Dexamethasone is not bound to transcortin, and the degree of protein binding is concentration independent. [1022] The lower rate of meningeal relapse in children treated with dexamethasone compared with prednisone may be explained by this difference in protein binding. [1023],[1024] and [1025] The concentration of prednisolone and dexamethasone in the CSF is equivalent to the free-drug concentration in plasma, and because prednisolone, unlike dexamethasone, is tightly and extensively bound to transcortin at low concentrations, its free plasma and CSF concentrations are lower at equipotent doses. Diurnal variation in plasma concentrations of prednisolone has also been observed with oral dosing. The drug concentrations are higher in the morning than in the evening after equal doses. [1021]

The capacity to activate prednisone to prednisolone is not impaired in patients with severe hepatic dysfunction, and prednisolone levels are elevated in this group, because of delayed catabolism. Unbound prednisolone concentration is also elevated in patients with severe renal dysfunction. [1012]

### *Toxicity*

The corticosteroids have some effect on almost every organ and tissue in the body, and the side effects of these agents are protean. Significant common toxicities include increased appetite, centripetal obesity, immunosuppression, myopathy, osteoporosis, avascular necrosis of the hip, peptic ulceration, pancreatitis, psychiatric disorders, cataracts, hypertension, precipitation of diabetes, growth failure, amenorrhea, impaired wound healing, and atrophy of subcutaneous tissue. [1008],[1022] Osteonecrosis of weightbearing joints occurs in children with high-risk ALL, and risk factors included age older than 10 years, female gender, and treatment with two rather than one 21-day course of dexamethasone.[1026]

### *Drug Interactions*

Ketoconazole interferes with the elimination of non–protein-bound prednisolone by inhibiting the catabolic enzyme, 6-b-hydroxylase, leading to a 50% increase in the AUC of unbound prednisolone in patients taking concurrent oral ketoconazole. [1027] Estrogen-containing oral contraceptives increase transcortin and lower free prednisolone concentrations.[1012] Drugs such as phenytoin, rifampicin, carbamazepam and barbiturates induce hepatic microsomal enzymes that catabolize prednisolone and result in enhanced prednisolone clearance. [1012]

## Asparaginase

Asparaginase is a bacterial enzyme that provides specific nutritional therapy for ALL and lymphomas. This enzyme rapidly depletes the circulating pool of asparagine by catalyzing the conversion of this amino acid to aspartic acid and ammonia. In most tissues, asparagine is synthesized from aspartic acid and glutamine by the enzyme asparagine synthase, and normal tissues can respond to asparagine depletion by up-regulation of this enzyme. In contrast, sensitive lymphoid cancers do not up-regulate asparagine synthase and, therefore, depend on exogenous circulating asparagine for protein synthesis. [1028] Asparaginase-resistant lymphoid tumor cells often have high levels of asparagine synthase, rendering them capable of synthesizing their own asparagine. [1028] Thus, asparaginase has a selective antileukemic effect.[1028],[1029]

The native (unmodified) forms of asparaginase are derived from *Escherichia coli* or *Erwinia carotovora* and are administered intravenously or intramuscularly at doses of 6,000 to 25,000 IU per $m^2$ on an intermittent schedule (usually three times each week). The intramuscular route is more commonly used in children in the United States, because of a lower risk of severe allergic reactions. [1030] Conjugation of polyethylene glycol to *E. coli* asparaginase (PEG-asparaginase) lowers the immunogenicity of this foreign protein and prolongs the drug's half-life, allowing for less frequent administration (2,500 IU per $m^2$ every 2 to 4 weeks).[1031] The $k_m$ of *E. coli* asparaginase for asparagine is 10 µM, which is approximately tenfold higher than the minimal concentration of the amino acid required *in vitro* to support cell

growth.[1028] The continual production and release of asparagine by normal tissues into the blood stream requires plasma asparaginase activity exceeding 0.1 IU per mL to suppress the concentration of asparagine below the critical level of 1 to 3 μM. [1032,1033] Doses of *E. coli* asparaginase at 2,500 IU per $m^2$ appear to be sufficient to deplete serum asparagine,[1034] whereas higher doses and more frequent administration of *Erwinia* asparaginase may be required.[1035]

In a randomized trial in standard-risk ALL, asparaginase plasma levels were more prolonged with a single dose of PEG-asparaginase than with nine to 12 doses of native *E. coli* asparaginase.[1036] Toxicity of the native and pegylated enzymes was similar, and the incidence of allergic reactions and silent antibodies was very low with both preparation. More prolonged asparaginase treatment regimens improve disease outcome but are associated with a higher incidence of allergic reactions.[1037,1038]

***Pharmacokinetics***

Parenteral administration of asparaginase is required because of denaturation and peptidase digestion within the intestinal tract. Peak plasma concentrations of the enzyme are dose related. Daily administration results in significant accumulation of asparaginase. [1039] Peak concentrations with intramuscular injection are approximately one-half those achieved with intravenous dosing. The time to peak concentration (rate of absorption) after intramuscular injection is 24 to 48 hours for *E. coli* asparaginase, less than 24 hours for *Erwinia* asparaginase, and 72 to 96 hours for PEG-asparaginase.[1040] The volume of distribution for asparaginase approximates plasma volume, and the rate of elimination is slow. The half-lives for *E. coli* asparaginase, *Erwinia* asparaginase, and PEG-asparaginase are 24 to 36 hours, 10 to 15 hours, and 5 to 7 days, respectively (Fig. 10-21).[1040]

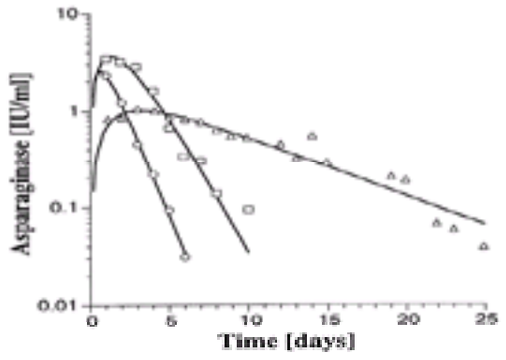

**FIGURE 10-21.** Disposition of serum asparaginase activity in ten patients treated intramuscularly with 25,000 IU per $m^2$ of native *Escherichia coli* asparaginase (*open squares*), ten patients treated intramuscularly with 25,000 IU per $m^2$ of native *Erwinia* asparaginase (○), and ten patients treated intramuscularly with 2,500 IU per $m^2$ of polyethylene glycol polyethylene glycol-asparaginase ( △). Points represent the mean. (Adapted from Asselin BL, Whitin JC, Coppola DJ, et al. Comparative pharmacokinetic studies of three asparaginase preparations. J Clin Oncol 1993;11:1780).

Plasma concentrations of asparagine fall to undetectable levels within 24 hours of a dose of asparaginase. The duration of depletion of circulating asparagine is related to the rate of asparaginase elimination; consequently it is shorter with *Erwinia* asparaginase than with native *E. coli* asparaginase.[1034] PEG-asparaginase depletes serum asparagine for at least 14 days.[1041,1042] Even though asparaginase distributes primarily within the intravascular space, its effects are more wide reaching. For example, asparaginase cannot be detected in the CSF after systemic administration, but CSF levels of asparagine are depleted for long periods. [1043,1044] and [1045]

Patients who develop antibodies to asparaginase have a rapid fall in the plasma concentrations of the native enzyme, indicating that the antibody interferes with the therapeutic effects of asparaginase. [1029,1046] PEG-asparaginase elimination is more rapid in one-third of patients who have previously experienced hypersensitivity reactions to native *E. coli* asparaginase.[1040,1047] Consequently, weekly dosing of PEG-asparaginase is recommended in children previously treated with native asparaginase.[1040,1048] In children with relapsed ALL, weekly administration of PEG-asparaginase resulted in a higher remission induction rate than biweekly dosing. [1048]

***Toxicity***

The principal side effects of asparaginase are related to sensitization to a bacterial protein or decreased protein synthesis. [1029,1033] Allergic reactions range from local erythema and swelling at the injection site to urticaria, laryngeal edema, bronchospasm, or anaphylaxis. Diphenhydramine, epinephrine, and other resuscitative measures must be available when administering this agent, even for the initial dose. The overall incidence of hypersensitivity reactions in children is 16% to 33% with native *E. coli* asparaginase.[1029] PEG-asparaginase is less immunogenic than the native forms, but acute allergic reactions can occur with repeated administration. The incidence of hypersensitivity reactions is lower (10%) in patients receiving combination chemotherapy than in those receiving *E. coli* asparaginase as a single agent (40%), presumably because of the immunosuppressive effects of the other drugs in the regimen. [1049] *E. coli* and *Erwinia* asparaginase are minimally cross-reactive, so those patients experiencing hypersensitivity reactions to one can be safely be switched to the other. [1050] PEG-asparaginase has also been administered safely to patients who were hypersensitive to the native *E. coli* enzyme.[1031,1048]

Coagulopathies resulting from deficiencies or imbalances in coagulation factors (fibrinogen, II, V, VII, VIII-X, antithrombin III, and protein C) can lead to clotting and hemorrhagic complications, including stroke. The thromboembolic events reflect a decreased capacity to inhibit thrombin, resulting from the acquired antithrombin III deficiency.[1051] Decreased serum albumin, insulin, and lipoproteins are also associated with asparaginase therapy. Other toxicities include an encephalopathy characterized by somnolence, disorientation, seizures, and coma, which have been related to hyperammonemia in some patients; acute pancreatitis, which can progress to hemorrhagic pancreatitis; and hepatotoxicity characterized by hyperbilirubinemia and elevated serum transaminases. [1029,1033] Myelosuppression and gastrointestinal toxicity (with the exception of nausea and vomiting) are usually not observed.

***Drug Interactions***

Asparaginase can rescue patients from the toxic effects of methotrexate and cytarabine. The sequential combinations of methotrexate or cytarabine followed by asparaginase have proven effective in consolidation therapy of ALL and in the treatment of children with relapsed leukemia. [1029,1033] The rescue effect is usually attributed to a decrease in protein synthesis in normal tissue. Antagonism has been observed if asparaginase is administered before these antimetabolites. [1052]

**Protein Kinase Inhibitors**

Protein kinases play a key regulatory role in cellular growth, differentiation, and apoptosis. The genes encoding these enzymes are aberrantly activated by a variety of mechanisms, such as translocations and point mutations, in human cancers. Although transforming mutations to tyrosine kinase genes are rare in childhood cancers, the *BCR-ABL* fusion protein expressed by the Philadelphia chromosome (Ph) in CML and 3% to 5% of children with ALL is clinically significant, because it confers a poor prognosis. A number of small molecule inhibitors of these protein kinases are in clinical development. [1053] STI-571 is a 2-phenylpyrimidine derivative that selectively inhibits the *BCR-ABL* fusion protein and selectively induces apoptosis in Ph-positive ($Ph^+$) CML cells by blocking *BCR-ABL*-initiated signaling pathways.[1054] ABL-initiated signaling pathways have recently been approved by the FDA. Daily oral dosing of STI-571 is very well tolerated and has produced hematologic remissions in most patients with $Ph^+$ CML. Disappearance of $Ph^+$ cells from the bone marrow has been observed in a few patients after treatment with this agent.[1055]

## CENTRAL NERVOUS SYSTEM PHARMACOLOGY OF ANTICANCER DRUGS

The penetration of the anticancer drugs into the CNS is relevant to the treatment of childhood cancers, because primary and metastatic tumors of the brain or meninges are common in children and because anticancer drugs are associated with acute and chronic neurotoxicity. The degree of drug penetration across the

blood–brain barrier is determined by the physicochemical properties of the drug, such as lipophilicity, molecular size, and degree of ionization, and the free (non–protein-bound) drug concentration in plasma. [1056,1057] and [1058] Most anticancer drugs penetrate poorly into the CSF, which is also used as a surrogate for blood–brain barrier penetration ( Table 10-6). The inability to achieve adequate antileukemic drug concentrations in the CSF probably accounts for the high rate of leptomeningeal relapse in children with ALL after the introduction of effective systemic therapy. Strategies used to circumvent limited penetration into the CNS are listed in Table 10-8. Regional drug administration, such as intrathecal, intraarterial, and interstitial implants, is the most commonly used approach. [1056]

| Strategy | Examples |
|---|---|
| High-dose systemic chemotherapy | High-dose methotrexate, cytarabine |
| Identifying drugs that penetrate the blood-brain barrier (cross into cerebrospinal fluid) | Thiotepa, topotecan |
| Disruption of the blood–brain barrier | Osmotic disruption with mannitol |
| Regional drug administration | |
| Intrathecal injection | Methotrexate, cytarabine |
| Intraarterial injection | Cisplatin |
| Interstitial therapy | Gliadel |

**TABLE 10-8. TREATMENT STRATEGIES TO CIRCUMVENT THE BLOOD–BRAIN BARRIER**

### Intrathecal Chemotherapy

Poor penetration of systemically administered anticancer drugs into the CSF can be circumvented by direct injection of the agents into the CSF. Intrathecally injected chemotherapy (e.g., methotrexate and cytarabine) is highly effective as primary or preventive therapy for meningeal leukemia and lymphoma. As a form of regional chemotherapy, intrathecal administration has the advantage of delivering very high drug concentrations to the CSF and meninges with low doses and therefore with minimal systemic toxicity.[1056,1059] However, there are disadvantages to intralumbar administration. Repeated lumbar punctures are painful, inconvenient, and technically challenging. In 10% of intralumbar injections, the drug is not delivered into the subarachnoid space but is instead injected or leaks into the subdural or epidural space.[1060] Because of the slow circulation of the CSF, distribution of drugs within the subarachnoid space, specifically to the ventricles, is not uniform. Ventricular methotrexate concentrations after an intralumbar dose are highly variable and are less than 10% of ventricular concentrations after direct intraventricular injection.[1061] The depth of penetration of effective drug concentrations into the brain parenchyma is limited to a few millimeters for the commonly used intrathecal agents because of the rapid diffusion of drug into capillaries within the highly vascular brain tissue. As a result, intrathecal therapy is not likely to be effective for parenchymal brain tumors.[1062] Intrathecal therapy is also associated with unique toxicities, such as chemical arachnoiditis.

The distribution of drug from the lumbar sac to the ventricles can be significantly improved by positioning the patient prone for 60 minutes after intralumbar injection. In animals, ventricular methotrexate concentrations after intralumbar drug administration were more than 20-fold higher when they were placed in the prone position compared to keeping them upright.[1063] Many of the problems associated with intralumbar injection can also be overcome with direct intraventricular administration. This approach entails the surgical placement of a catheter into the lateral ventricle. The catheter is then attached to a subcutaneously implanted reservoir for access.[1064] Administration of drugs directly into the ventricle via this reservoir is more convenient and less painful and allows for more frequent injections. Intraventricular therapy ensures that the drug is delivered to the subarachnoid space and results in better drug distribution throughout the CSF. [1061] Better drug distribution may account for the improved therapeutic results from intraventricular therapy compared with intralumbar administration in the treatment of overt meningeal leukemia.[1065] However, even when methotrexate was infused continuously into the ventricle for prolonged periods in animals, steady-state drug concentrations in the lumbar space were lower than simultaneous ventricular concentrations, presumably because the rate of CSF flow into the lumbar sac is slower than the rate of diffusion or excretion of methotrexate from the CSF. [1066]

Ventricular access devices, which are reserved for patients with overt leptomeningeal disease, allow for more flexible drug administration schedules, such as the C•T schedule (daily for 3 consecutive days). C•T methotrexate and cytarabine proved to be effective for inducing and maintaining CSF remission in patients with multiply recurrent leptomeningeal leukemia. [1067]

There are a limited number of agents that are routinely administered intrathecally. The most commonly used agents are the antimetabolites methotrexate and cytarabine and the alkylating agent thiotepa. Phase I clinical trials of intrathecal delivery of the preactivated cyclophosphamide analog mafosfamide, a sustained-release formulation of cytarabine (DepoCyt), and a microcrystalline formulation of busulfan, as well as a phase II trial of intrathecal topotecan, are ongoing.

#### *Methotrexate*

Intrathecal methotrexate has been in clinical use for more than 30 years, primarily for the treatment of the meningeal spread of cancer, especially leukemia and lymphoma. It is also administered adjuvantly to patients with newly diagnosed ALL to prevent meningeal relapse. Acute and delayed neurotoxic reactions to intrathecal methotrexate have been reported. An acute chemical arachnoiditis characterized by headache, nuchal rigidity, vomiting, fever, and CSF pleocytosis can present several hours to days after a dose. A subacute encephalopathy, which may be irreversible in some patients, presents with extremity paresis and cranial nerve palsies, ataxia, visual impairment, seizures, and coma. This syndrome is associated with elevated CSF drug concentrations. [1068] An ascending radiculopathy with loss of primarily motor function resembling Guillain-Barré syndrome is also associated with intrathecal methotrexate, as well as cytarabine, and occurs days to weeks after a course of therapy.[1069] A chronic, progressive demyelinating encephalopathy (i.e., leukoencephalopathy) that appears months to years after intrathecal methotrexate leads to dementia, spastic paralysis, seizures, and coma in more advanced cases. Severe, often fatal reactions can result from the inadvertent administration of excessive doses of methotrexate or the administration of the wrong agent (e.g., vincristine) intrathecally. Great care must be taken by clinicians administering drugs by this route.[1070] Intrathecal methotrexate overdose should be treated immediately with CSF drainage or ventriculolumbar perfusion. Intrathecal instillation of carboxypeptidase-$G_2$ was also effective in animals and is now available for human use on an investigational basis. [1071]

Methotrexate elimination from the CSF after intrathecal injection is biphasic, with a terminal half-life of 14 hours. [1072] Methotrexate is eliminated by passive diffusion out of the CSF, bulk resorption of CSF, and a nonspecific active transport system. [1066] Conditions associated with delayed clearance of methotrexate from the CSF include meningeal leukemia, communicating hydrocephalus, or the lumbar puncture syndrome. [1072]

When methotrexate is administered intrathecally, the volume of the CSF is the initial volume in which the drug is distributed. In young children, CSF volume increases much more rapidly than the body surface area, reaching 80% of the adult volume by the age of 3 years. [1073] An intrathecal dose based on body surface area would underdose young children and overdose adolescents. Bleyer and colleagues recommended an intrathecal dosage schedule for methotrexate based on age instead of body surface area (Table 10-9).[1073] This regimen has been less neurotoxic, and since this dosing scheme was incorporated into front-line leukemia protocols, the CNS relapse rate has declined from 12% to 7%.[1074] The greatest decline was observed in the youngest patients, the group in whom the intrathecal methotrexate dosage was increased with the new adaptive dosing regimen.

| Age (yr) | Dose (mg) |
|---|---|
| <1 | 6 |
| 1 | 8 |
| 2 | 10 |
| ≥3 | 12 |

### *Cytarabine*

Intrathecally administered cytarabine is also of value in the treatment and prevention of meningeal leukemia. The clinical pharmacology of intrathecal cytarabine is quite different from that seen with systemic administration of this agent. With an intraventricular dose of 30 mg, peak concentrations exceed 2 mM and remain above 1 µM (a cytotoxic concentration *in vitro*) for 24 hours.[623,1075] Levels of cytidine deaminase, the enzyme that metabolizes cytarabine to ara-U, are low in brain and CSF, and metabolism to ara-U is therefore only a minor pathway of elimination.[1076] The ratio of ara-U to cytarabine in the CSF is only 0.08. The terminal half-life of cytarabine is 3.5 hours, and the clearance is 0.42 mL per minute, similar to the CSF bulk flow rate.[1075] Plasma concentrations of cytarabine after an intrathecal 30 mg dose are less than 1 µM. Leukemic cells in the CSF were found to accumulate significant levels of intracellular ara-CTP after intrathecal cytarabine, and this active metabolite was retained in cells longer (half-life of 8 to 36 hours) than in peripheral lymphoblasts.[1077] Neurotoxicity from intrathecal cytarabine includes arachnoiditis, radiculopathy, seizures, encephalopathy, or myelopathy.[1058,1078]

DepoCyt, which is a liposome-encapsulated formulation of cytarabine, was specifically developed for intrathecal use. Sustained release of cytarabine from the liposomes markedly prolongs the cytarabine half-life (141 hours) and the duration of exposure to cytotoxic concentrations (9 days) in CSF.[1079] The recommended dosage in adult patients is 50 mg, and a phase I clinical trial in children is ongoing. When given with concomitant oral dexamethasone, the toxicity profile of DepoCyt is similar to that of unencapsulated cytarabine. Acute toxicities include fever, headache, back pain, nausea, and encephalopathy.[1079,1080]

### *Thiotepa*

The alkylating agent thiotepa can be safely administered intrathecally at a dose of 10 mg and is a second-line agent for childhood meningeal cancers. Thiotepa toxicity is similar to that of intrathecal methotrexate.[1081] However, thiotepa is highly lipophilic and diffuses rapidly out of the CSF, leading to limited drug distribution within the subarachnoid space. After intraventricular administration, thiotepa is rapidly cleared from the CSF at a rate tenfold higher than CSF bulk flow, and exposure in the lumbar CSF is less than 10% of that achieved in the ventricle.[1082]

### High-Dose Systemic Therapy for Meningeal and Central Nervous System Tumors

Limited CNS penetration of some anticancer agents can be overcome by administering high doses of the drugs systemically. This approach has been successfully applied with methotrexate and cytarabine. The advantages of the systemic approach over intrathecal therapy include sustained CSF drug concentrations with prolonged intravenous infusions and better drug penetration into the deep perivascular spaces and brain parenchyma. However, methotrexate concentrations are not uniform throughout the subarachnoid space at steady state during a continuous intravenous infusion of methotrexate. The lumbar CSF concentrations are higher than ventricular CSF concentrations.[1066] The other disadvantage of this approach is the potential for severe systemic toxicity.[1056]

Very high systemic methotrexate doses can be safely delivered with leucovorin rescue, and therapeutic concentrations of methotrexate can be achieved in the CSF. A dose of 33,600 mg per $m^2$ administered over 24 hours as a loading dose (6,000 mg per $m^2$) followed by a continuous infusion (1,200 mg per $m^2$ per hour for 23 hours) results in CSF methotrexate concentrations of 30 to 40 µM.[537] The remission induction rate in patients with overt meningeal leukemia with this regimen is 80%. This regimen has also been successful as preventive therapy for meningeal leukemia in patients with ALL.[1083]

The CSF penetration of cytarabine is more favorable than methotrexate but is dose dependent. The ratio in one study decreased from 33% to 18%, with an increase in the dose from 4,000 to 18,000 mg per $m^2$ administered as a 72-hour infusion.[619] The standard high-dose (3,000 mg per $m^2$) regimen given every 12 hours results in persistent cytotoxic concentrations of cytarabine in the CSF, in part because the elimination half-life of cytarabine in CSF is eightfold longer than in plasma because of the low levels of cytidine deaminase in brain and CSF.[1084] High-dose intravenous cytarabine appears to be effective for treating CNS leukemia and lymphoma but is associated with significant systemic toxicity.[1085,1086 and 1087]

Other agents for which the systemic approach may be applicable include cyclophosphamide and thiotepa. Cyclophosphamide in high doses (80 mg per kg per day for 2 days) appears to be active against brain tumors.[1088] The systemic approach may also be more appropriate for thiotepa. After intravenous administration, plasma and CSF drug concentrations are equivalent, and significant amounts of the active metabolite, TEPA, also penetrate into the CNS.[1082]

## PERSPECTIVES

Although a high proportion of children with certain types of cancer are being cured, there are still too many who fail to respond or who relapse and eventually succumb to their cancer after a good initial response. Failure of multimodality therapy to cure individual patients may result from de novo or acquired resistance to the anticancer drugs that are used in the regimen or inadequate drug delivery to the cancer. The latter pharmacologic limitations of therapy can result from interpatient variability in drug disposition with poor absorption or more rapid drug clearance in a subgroup of patients, limiting drug exposure or dose modifications necessitated by acute and chronic toxicity.

In clinical practice, selection of chemotherapeutic combination regimens to treat individual patients is based only on tumor histology and the extent of disease. Despite the known heterogeneity in the responsiveness of tumors to single-agent therapy, a phenomenon that suggests a high incidence of de novo drug resistance, the drug sensitivity profile of individual tumors is not a determinant in the drug selection process. As a result, many patients probably receive one or more drugs that are inactive against their tumors and that produce toxicities that limit the use of other, more effective agents. Culturing tumor samples *ex vivo* and quantifying drug sensitivity, similar to the sensitivity testing routinely performed with bacterial isolates, has not proven to be practical, because sufficient tumor specimens are not readily accessible, and adequate *in vitro* growth is achieved in only a small proportion of specimens (28% of a series of pediatric tumors).[1089] Measurement of biochemical or genetic markers of drug resistance in tumor specimens is a promising potential means of quantifying drug sensitivity, but the clinical applicability of this approach must still be demonstrated.

Identifying the mechanisms of drug resistance at a molecular level may lead to the development of chemosensitizing agents, such as P-gp inhibitors. In addition, alterations that result in resistance to one agent may enhance sensitivity to the effects of a second drug that effects the same pathway.

Anticancer drug dosing is toxicity based. The optimum dose of most anticancer drugs is the maximum tolerated dose, and after this fixed dose is administered, dose modifications are based on the severity of ensuing toxicity. A more rational approach would be to individualize drug dose and schedule based on specific patient characteristics (adaptive dosing) and on plasma drug concentration (therapeutic drug monitoring). These strategies have been successfully applied to adapting carboplatin dose for renal function and to basing leucovorin rescue on methotrexate plasma concentration after high-dose methotrexate therapy. Although therapeutic and toxic drug concentrations are not known for most anticancer drugs, simply defining the average plasma concentration after a standard drug dose might help to identify outliers and produce rational dose modifications for patients with organ dysfunction.

Those patients who are cured are at risk for significant and often life-threatening acute and long-term toxic effects of the treatment. The severity of the toxicity of the anticancer drugs reflects their nonselective mechanisms of action and the emphasis on dose intensity to maximize tumor cell kill. Methods to circumvent or ameliorate chemotherapy-induced toxicity have improved the tolerability of chemotherapy. Examples of rescuing patients from dose-limiting toxicities include the use of hematopoietic growth factors, such as Filgrastim and interleukin-11, to limit the duration of granulocytopenia and thrombocytopenia after myelosuppressive therapy, the administration of mesna to block the urotoxicity of the oxazaphosphorines, leucovorin rescue from high-dose methotrexate, and the prevention of anthracycline cardiotoxicity with dexrazoxane.

The search for more selective and less toxic anticancer drugs and for more effective drug combinations must continue. Our rapidly expanding knowledge of the molecular pathogenesis of malignant transformation and tumor progression is leading to the development of more selective drugs that are designed to interfere with the critical steps in these processes. Identification and development of molecularly targeted anticancer drugs has become the primary focus of anticancer drug development.

To meet these challenges, a greater effort must be made to incorporate the advances made in the basic science of oncology and pharmacology into the design and use of chemotherapeutic treatment regimens.

## INTRODUCTION

The early development of agents for the treatment of oncologic diseases has focused, for most of the last 30 years, on empirical screening of new compounds, followed by dose, schedule, and toxicity profile determination. The clarification of mechanism of action as well as activity often occurs after the agent is in clinical trials and antitumor activity has been determined. None of the current drug screening panels is predictive of disease-specific tumor chemotherapy selection with the exception of chemotherapy-sensitive diseases such as leukemia and lymphoma. However, these panels are useful in identifying agents that are mechanistically similar.

The emergence of molecular-targeted therapy through rational drug design is more recent. As the molecular phenotypes of specific malignancies have been elucidated, targets for therapy have been more clearly defined. The characterization of pathways that define malignant transformation and phenotype as well as progression, invasion, and metastasis have focused new agent development on key pathways involved in angiogenesis, apoptosis, cell cycle regulation, receptor signaling, cellular proliferation, and differentiation that may be perturbed in malignant tissues compared to their normal counterparts. Alterations in tumor biologic processes mediated by oncogene activation and loss of suppressor gene function affect these pathways. Blocking oncogene function or restoring suppressor gene activity may lead to the development of tumor-specific therapy.

With the emergence of molecular-targeted therapies, preclinical assay development and validation will be critically important for agent development. Advances in molecular biology and combinatorial chemistry, using the emerging technologies of microarray, proteomics, and combinatorial libraries, have led to the identification of a variety of new agents, including small molecule inhibitors, antibodies, peptides, genes, and antisense oligonucleotides. The drug development community has used these emerging technologies to push molecular-targeted therapies ahead more rapidly. The integration of these new treatment modalities into clinical practice represents both a tremendous opportunity and a challenge for the pediatric oncologist. New clinical trial designs as well as tumor biology investigations will be required to gain an understanding of the role of these agents.

The primary objectives of this chapter are to provide information about specific classes of molecular-targeted therapies that are in clinical development and to provide an overview of issues relating to the development of targeted agents for childhood cancers. A central concept is that the ultimate benefit of molecular-targeted therapies for pediatric tumors depends on how modulation of specific targets alters the balance between tumor cell survival-signaling pathways and tumor cell death-signaling pathways in comparison to the effect of target modulation on noncancerous cells.

## CENTRAL ROLE OF THE APOPTOTIC PATHWAY

Given the goal of achieving higher levels of tumor cell kill, the application of molecular-targeted therapies for specific childhood cancers needs to be based on an understanding of the primary survival and cell death pathways for specific cancers. Extraordinary advances in cancer biology over the past decade have elucidated multiple intracellular signaling pathways that promote cancer cell survival as well as pathways that control cancer cell death. [1,2 and 3] There are two primary intracellular pathways leading to cell death (Fig. 11-1).[1] The death receptor (DR) pathway is initiated by the binding of a member of the tumor necrosis factor (TNF) receptor superfamily [e.g., CD95 (Fas), TNF receptor 1, and the TNF-related apoptosis-inducing ligand (TRAIL) receptors DR4/TRAIL-R1 and DR5/TRAIL-R2] with its ligand, leading to activation of caspase-8 and to eventual apoptosis. The mitochondrial death pathway is activated by various types of stimuli or cellular injury, leading to changes at the mitochondrial membrane causing release of cytochrome C in a multistep process. Cytochrome C binds to apoptotic protease activating factor-1 (Apaf-1) in the cytoplasm, leading to caspase-9 activation.[4] In both pathways, activation of upstream caspases, such as caspases-8 and -9, is amplified by a cascade

mechanism leading to widespread activation of downstream caspases, for example, caspase-3.

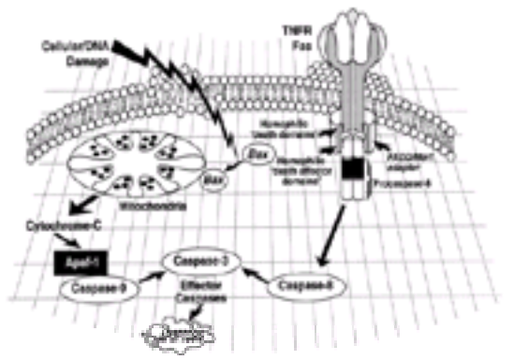

**FIGURE 11-1.** The two primary apoptotic pathways. The death receptor (DR) pathway (*right*) is initiated by ligation and clustering of members of the DR superfamily [tumor necrosis factor receptor (TNFR) I, CD95, and the TNF-related apoptosis-inducing ligand (TRAIL) receptors DR4 and DR5]. Receptor clustering leads to formation of death-inducing signal complexes by the recruitment of adapter proteins, such as Fas-activated death domain (FADD), which contain both “death domains” for interacting with the DRs and “death-affector domains” for interacting with procaspase-8. The procaspase-8 that is recruited to the complex is activated by proteolytic cleavage to active caspase-8. The mitochondrial pathway ( *left*) is responsive to internal toxic stimuli such as DNA damage. These stimuli activate pro-apoptotic members of the bcl-2 family, including Bax, Bad, Bim, and Bid, which are then attracted to the mitochondria. Their interaction with the mitochondria results in the release of cytochrome C from the mitochondria into the cytoplasm, leading to its association with apoptotic protease-activating factor 1 (Apaf-1) and subsequently procaspase-9 to form a complex, the “apoptosome,” resulting in formation of active caspase-9. In both the DR and the mitochondrial pathways, the final common pathway is activation of downstream caspases such as caspase-3.

Other pathways leading to cancer cell death are primarily extrinsic to the cancer cell. These extrinsic pathways to cell death also offer therapeutic targets. For example, cancer cells may be killed by nutrient deprivation through inhibition of angiogenesis. In pediatric tumor preclinical models, some anti-angiogenic agents have produced tumor regression, with particularly impressive activity when these agents are combined with agents targeting the tumor cell population. [5,6]

Counterbalancing the signaling pathways leading to cell death are multiple factors and signaling pathways that favor cell survival ( Fig. 11-2), including: (a) anti-apoptotic members of the bcl-2 family that inhibit mitochondrial release of cytochrome C and other apoptogenic factors [7]; (b) anti-apoptotic members of the immunosuppressive acidic protein family that inhibit activated caspases; (c) survival signals that are initiated at the cell membrane by activation of growth factor receptors and that are mediated intracellularly by phosphoinositide-3-kinase (PI3'K) activation, resulting in activation of the serine/threonine kinase Akt [8]; and (d) activation of nuclear factor-kB (NF-kB).[9,10] and [11]

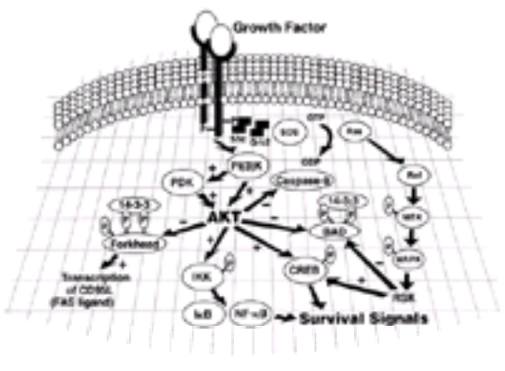

**FIGURE 11-2.** Survival signaling pathways. Growth factors and other stimuli produce signals that promote cell survival over apoptosis. The phosphoinositide 3-kinase (PI3'K) pathway plays a central role in survival signaling through activation of the Akt serine-threonine kinase. Activated Akt phosphorylates a number of proteins involved in either survival or apoptotic pathways: the pro-apoptotic protein Bad, leading to its inactivation and cytoplasmic sequestration by association with 14-3-3 proteins; caspase-9, leading to its inactivation and to suppression of caspase-9–induced cell death; members of the forkhead family of transcription factors, leading to their interaction with 14-3-3 proteins and their cytoplasmic sequestration, resulting in reduced transcription of death genes such as Fas ligand; IKK, leading to enhanced degradation of the IkBs and to nuclear factor-kB (NF-kB) activation and transcription of survival-promoting genes; the cAMP response element binding protein (CREB) transcription factor, leading to increased transcription of bcl-2. Survival is also promoted through the mitogen-activated protein kinase (MAPK) pathway, which is activated by growth factors in a pathway involving Ras. Survival signals through the MAPK pathway are provided in part through activation of pp90 ribosomal S6 kinase (Rsk) family members. Similar to Akt, Rsk family members can phosphorylate and activate CREB and can phosphorylate Bad, leading to its inactivation. GDP, guanosine diphosphate; GTP, guanosine triphosphate; P, phosphate.

## G3139: Bcl-2-Targeted Therapy

### *Background*

Bcl-2 inhibits apoptosis and is an important contributor to chemoresistance for some cancers. For these cancers, blocking the anti-apoptotic activity of bcl-2 may increase the efficacy of cytotoxic therapy. G3139 is an 18mer phosphorothioate oligonucleotide that was designed to bind to the first six codons of the human bcl-2 messenger RNA (mRNA). G3139 down-regulates bcl-2 mRNA leading to reduced bcl-2 protein levels *in vitro*.[12] Bcl-2 antisense oligonucleotides have been shown to sensitize acute myelogenous leukemia (AML) cells and lymphoma cells to conventional cytotoxic agents such as cytarabine (Ara-C) and methotrexate. [13,14] In tumor xenograft models, G3139 was active as a single agent against follicular non-Hodgkin's lymphoma (NHL), [12] Merkel cell carcinoma,[15] and Epstein-Barr virus–associated lymphoproliferative disease.[16] G3139 enhanced the therapeutic efficacy of cyclophosphamide in a severe combined immunodeficiency disease mouse model of human NHL[17] and also chemosensitized human melanoma in severe combined immunodeficiency disease (SCID) mice.[18]

### *Clinical Experience*

Initial clinical trials of G3139 in adults used outpatient subcutaneous 21-day infusions. [19] The maximum tolerated dose (MTD) was 147.2 mg/m$^2$/day (approximately 5 mg/kg/day), with dose-limiting toxicities of thrombocytopenia, hypotension, fever, and asthenia. Plasma levels of G3139 equivalent to the efficacious plasma concentration (1.0 µg/mL) determined in *in vivo* models were achieved. Bcl-2 protein expression was reduced in tumor cells derived from lymph nodes in two patients and peripheral blood or bone marrow mononuclear cell populations from five patients.

A rational use of G3139 based on its mechanism of action is to combine it with chemotherapy to overcome bcl-2–associated resistance to chemotherapy. G3139 has been studied in phase I trials with several chemotherapy agents, including mitoxantrone, [20] docetaxel,[21] and paclitaxel.[22] G3139 has also been combined with fludarabine and high-dose Ara-C for the treatment of refractory/recurrent AML, [23] with G3139 given by continuous infusion on days 1 to 10 and with fludarabine and Ara-C given on days 6 to 10. Complete responses were observed in three of the first ten patients, and toxicities were not substantially different from those anticipated for a high-dose Ara-C regimen.

### *Pediatric Applications*

Pediatric tumors for which bcl-2–directed therapy may be warranted include neuroblastoma and AML. Immunopositivity for bcl-2 expression has been demonstrated for primary and metastatic sites of neuroblastoma tumors and in pre- and postchemotherapy tumor samples.[24] An association of higher bcl-2 expression with unfavorable histology and N-*myc* gene amplification has been reported in some studies, suggesting an association with poor prognosis.[25,26 and 27] For AML, bcl-2 overexpression has been found in 61% of adults at diagnosis and 74% of patients at relapse.[28] High expression of bcl-2 was associated with a poorer response to chemotherapy and shorter survival.[29,30,31 and 32] A complicating factor in assessing the role of bcl-2 in resistance to chemotherapy is that after chemotherapy, bcl-2 expression levels in tumor cells may increase, possibly as a result of preferential killing of cells with low bcl-2 expression.[33] For patients with AML, high levels of bcl-2 have been demonstrated in residual leukemia cells from patients in clinical remission.[33] These findings suggest that correlations between bcl-2 measurements and clinical outcomes may be limited by the ability to accurately measure bcl-2 at diagnosis in subpopulations of cancer cells that could lead to relapse.

### Rituximab: A Signaling Monoclonal Antibody That Induces Apoptosis

#### *Background*

Rituximab is a highly specific mouse/human chimeric antibody engineered by grafting the variable regions targeting the CD20 antigen from murine antibody genes onto the constant regions of human immunoglobulin (Ig) G genes. The CD20 antigen is a 35,000-d phosphoprotein present exclusively on B cells (pre-B and mature B lymphocytes) and present on most B-cell lymphomas.[34,35] Rituximab can kill cells by triggering antibody-dependent cellular toxicity, by activating the complement cascade,[36] and by triggering intracellular signaling pathways leading to apoptosis.[37,38] The latter activity may contribute to rituximab's ability to enhance the activity of chemotherapy agents.[39,40]

#### *Clinical Experience*

The initial trials of rituximab targeted adults with recurrent low-grade lymphomas and used a weekly schedule of administration. High levels of activity were observed, particularly for patients with follicular center cell lymphoma.[41] Rituximab was also shown to be active against diffuse large B-cell lymphoma (DLCL).[42] Rituximab has been safely combined with standard CHOP [cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), prednisone] chemotherapy for patients with low-grade or follicular B-cell NHL.[43] A very high overall response rate was observed (55% complete remission and 40% partial remission), with seven of eight bcl-2–positive patients converting to PCR negativity in blood and marrow (molecular complete remissions).[43] Patients with previously untreated intermediate- and high-grade NHL were treated with rituximab given on day 1 and CHOP chemotherapy given on day 3.[44] A promising overall response rate of 97% was observed, with no appreciable increase in toxicity compared to CHOP alone. Building on these promising results, a randomized trial in elderly adults with DLCL comparing CHOP to CHOP plus rituximab demonstrated significantly higher event-free survival and survival rates for patients receiving rituximab plus chemotherapy.[45]

Toxicities attributed to rituximab include infusional or allergic reactions, B-cell depletion, neutropenia, and thrombocytopenia. Tumor lysis syndrome has also occurred in patients with large tumor burden or high circulating lymphocyte counts.[46,47 and 48] Most of these side effects are mild or manageable, but rarely, life-threatening or fatal infusional reactions, tumor lysis syndromes, and skin reactions have been reported.

#### *Pediatric Applications*

The primary cancer diagnoses for which rituximab may be relevant are the B-immunophenotype NHLs, particularly diffuse large B-cell NHL (DLCL) and Burkitt's lymphoma. Both Burkitt's lymphoma cells and DLCL cells express high levels of CD20.[49,50,51,52,53 and 54] Rituximab induces apoptosis in Burkitt's cell lines,[55] apparently via signal transduction pathways that involve influx of $Ca^{2+}$, Src family kinase activation, phospholipase C gamma 2 (PLCg2) phosphorylation, activation of the mitogen-activated protein kinase (MAPK) family members p44 (ERK1) and p42 (ERK2), up-regulation of the pro-apoptotic protein Bax, and activation of caspase-3.[37,38] Anti-CD20 monoclonal antibodies are active against Burkitt's lymphoma in a xenograft nude mouse model.[56]

Pediatric clinical experience with rituximab in children with Burkitt's lymphoma is restricted to anecdotal reports of responses in patients who progressed after intensive chemotherapy.[57] Rituximab has been used to treat children with posttransplant lymphoproliferative disease with a high rate of complete responses.[58,59 and 60] This experience suggests that rituximab can be given safely to children at the standard doses used for adult patients and that unanticipated toxicities have not yet been observed in children. Evaluation of rituximab in combination with standard chemotherapy agents is planned for children with Burkitt's lymphoma and DLCL.

## GROWTH FACTOR RECEPTOR TYROSINE KINASE INHIBITORS

Receptor tyrosine kinases (RTKs) include the cell surface receptors for growth factors such as platelet-derived growth factor (PDGF), epidermal growth factor (EGF), transforming growth factor-a (TGF-a), and insulin-like growth factor-1 (IGF-1).[61] The RTKs are glycoproteins with an extracellular ligand-binding domain, one membrane-spanning domain and a conserved cytoplasmic domain containing a site with tyrosine kinase activity ( Fig. 11-3). Binding of ligand to RTKs leads to receptor dimerization, which triggers phosphorylation or auto-phosphorylation of tyrosine residues in the cytoplasmic domains ( Fig. 11-3). These phosphorylated residues become attachment sites for a variety of adaptor molecules, leading to activation of signal transduction pathways that modulate cell growth, differentiation, and survival. Relatively specific inhibitors of these pathways have entered clinical evaluation, including small molecule inhibitors and monoclonal antibodies directed against the cell surface receptors (Table 11-1 and Table 11-2 list agents under evaluation). An example from each class is discussed in the following sections.

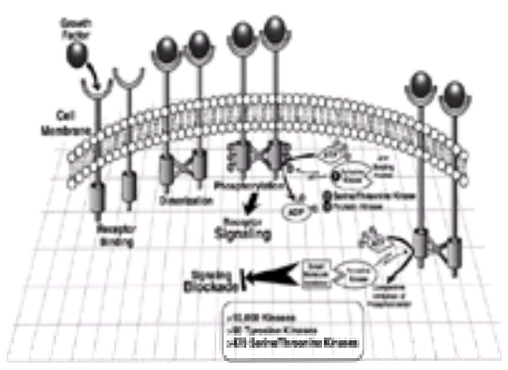

**FIGURE 11-3.** The protein, tyrosine, and serine/threonine kinases are effectors of signal transduction activated by phosphorylation. Growth factors bind to the extracellular portion of the receptor. Subsequent to receptor binding, dimerization occurs. The receptor autophosphorylates the conserved intracellular receptor domain. The RTK intracellular domain is enlarged to demonstrate its intrinsic kinase activity and ATP binding pocket. After autophosphorylation, signal transduction occurs. Most small molecule kinase inhibitors compete for binding in the ATP-binding pocket of the receptor. Inhibition may be reversible or irreversible. Signal transduction may be blocked by receptor tyrosine kinase inhibitors. ADP, adenosine diphosphate; P, phosphate.

**Trastuzumab: ErbB-2 Signaling Inhibitor**

***Background***

Trastuzumab (Herceptin) is a humanized monoclonal antibody that selectively binds with high affinity to the extracellular domain of ErbB-2. ErbB-2 (Her2 or *neu*) is a member of the EGF receptor (EGFR) family of type-1 RTKs. Although a high-affinity ligand for ErbB-2 has not been identified, [62] ErbB-2 can serve as a heterodimerization partner for other members of the EGFR family including EGFR, ErbB-3, and ErbB-4. [63] By serving as an essential component of these receptor complexes, ErbB-2 plays a central role in controlling cell growth, differentiation, and apoptosis. [63,64]

ErbB-2 is overexpressed in many adult cancers, including breast, ovarian, gastric, lung, and prostate cancers. ErbB-2 provides a survival signal in cancer cells in which it is overexpressed.[65] It appears to mediate resistance to the cytotoxic effects of TNF,[66] chemotherapy,[67] radiation therapy,[68,69] and hormonal therapy.[70] Overexpression of ErbB-2 in women with breast cancer, which is usually a result of amplification of the ErbB-2 gene on chromosome 17, is associated with poor outcome.[71]

Trastuzumab appears to act primarily as an anti-proliferative agent when used to treat ErbB-2 overexpressing cancer cells *in vitro* or *in vivo*.[64] Trastuzumab-mediated growth inhibition may be due to interference with the interaction of ErbB-2 with other EGFR family members [72] or may be caused by acceleration of ErbB-2 degradation.[73] Trastuzumab is also capable of activating complement and can trigger antibody-dependent cell-mediated cytotoxicity. [64] Trastuzumab enhances the antitumor activity of a variety of chemotherapy agents both *in vitro* and *in vivo*.[74,75 and 76]

***Clinical Experience***

Trastuzumab has been tested primarily in patients with breast cancer. The agent has generally been given on a weekly schedule. [77] Trastuzumab induced objective responses in approximately 15% of women with metastatic breast cancer whose tumors overexpressed ErbB-2.[77] In a randomized phase III study of cyclophosphamide and doxorubicin or paclitaxel administered in the presence or absence of trastuzumab, the addition of trastuzumab to chemotherapy increased response rate, time to progression, and survival in breast cancer. [78,79]

The primary toxicity associated with trastuzumab as a single agent was infusion-associated fever or chills that usually occurred only during the first infusion. [77] When given with chemotherapy, trastuzumab was generally well tolerated except for cardiac dysfunction, which was more common for patients receiving concurrent doxorubicin (19%) than for patients receiving concurrent paclitaxel (4%). [79] This exacerbation of chemotherapy-induced cardiac toxicity by trastuzumab is likely related to its interference with the role of ErbB-2 in mediating the activation of important cardiac survival pathways. [80] ErbB-2 and other members of the EGFR family are expressed on cardiac cells, both during development and postnatally. [81] They play essential roles in heart development [82,83] and cardiac myocyte survival and protection from apoptosis.[81]

***Pediatric Applications***

The primary pediatric tumors for which ErbB-2 may play a substantial role in tumor cell growth and survival are osteosarcoma [84,85] and medulloblastoma.[86,87] Because of the limited penetration of monoclonal antibodies into the cerebrospinal fluid, evaluation of systemically administered trastuzumab for medulloblastoma is not planned. ErbB-2 is expressed on approximately 40% of osteosarcoma tumor specimens,[84,85] with expression being more frequent in tumors of patients with metastatic disease at presentation.[84] For patients with nonmetastatic disease, ErbB-2 expression was associated with higher risk of treatment failure. [84] Pediatric development plans for trastuzumab include a phase II study in patients with recurrent osteosarcoma and a pilot study in combination with chemotherapy for patients with newly diagnosed metastatic osteosarcoma.

**ZD1839: Epidermal Growth Factor Receptor Small Molecule Inhibitor**

***Background***

EGFR (ErbB-1) and its ligands, EGF and TGF-a, are important in tumor cell proliferation and survival, and are also involved in motility, adhesion, invasion, and angiogenesis.[88] EGFR is overexpressed in a variety of epithelial malignancies, including glioma, non–small cell lung cancer (NSCLC), breast, head and neck, bladder, and ovarian carcinomas.[89] Overexpression is often associated with poorer prognosis.[88,89]

Inhibition of EGFR signaling can lead to cell cycle arrest and to apoptosis in cells that express EGFR. [88,90] Growth inhibition by EGFR inhibitors is associated with up-regulation of the cyclin-dependent kinase (cdk) inhibitor p27. [90,91] Inhibitors of EGFR can induce growth delay and, less commonly, regressions in tumor xenograft models.[92,93] EGFR expression may not be as important for antitumor effect as the tumor cell's reliance on this pathway for cellular proliferation and survival. [61,92,94] EGFR inhibitors potentiate the cytotoxic activity of chemotherapy [92,93,95] and radiation therapy,[96,97] a characteristic with important clinical ramifications.

The EGFR inhibitors with the most clinical data are the small molecule inhibitor ZD1839 [98] and the monoclonal antibody C225,[99] an IgG antibody that binds to the ligand-binding domain of the EGFR and competes for receptor binding. Other EGFR inhibitors under development are listed in Table 11-1.

***Clinical Experience***

ZD 1839 is a potent and specific inhibitor of EGFR tyrosine kinase activity that inhibits EGFR auto-phosphorylation and signaling at submicromolar concentrations. [99] Based on the observation from preclinical xenograft models that tumor regrowth occurs rapidly when ZD1839 is discontinued, chronic administration schedules are being evaluated. ZD1839 was evaluated in the phase I setting using both an intermittent schedule (14 days on, 14 days off) [100] and a continuous dosing schedule.[101] ZD1839 was generally well tolerated with few grade 3 to 4 adverse events observed. The most common grade 1 to 2 adverse events were diarrhea and a

characteristic acne-like skin rash. Grade 3 diarrhea developed at the 700 mg/day dose after 1 week of treatment in two of nine patients treated on the intermittent schedule, but it rapidly resolved with drug cessation. [100] The mean maximal drug concentration ($C_{max}$) after 14 days of therapy ranged from 113 to 2,255 ng/mL (0.5 to 5.0 µM) for patients receiving 50 to 700 mg/day and was proportional across the entire dose range. [100] The mean elimination half-life was 34 to 46 hours, supporting a once-daily administration schedule. Steady state levels were reached by day 7. At the dose of 400 mg/day, all patients had trough plasma concentrations greater than the *in vitro* 90% inhibitory concentration in an EGF-stimulated KB human oral squamous carcinoma growth assay. Objective responses were observed in patients with NSCLC at doses as low as 150 mg/day.[100,101] Phase III trials of ZD1839 as a single agent in adults are using the continuous daily schedule, and regimens combining ZD1839 with chemotherapy and with radiation therapy are being developed. [98]

### *Pediatric Applications*

Potential target tumors for agents such as ZD1839 that inhibit EGFR signaling include neuroblastoma, [102] rhabdomyosarcoma,[102] and high-grade gliomas.[103] Inhibition of EGFR signaling by ZD1839 or by antisense oligonucleotides repressed the growth of rhabdomyosarcoma cell lines. [102,104] Pediatric high-grade gliomas rarely show the EGFR gene amplification observed in adult gliomas,[103,105] but overexpression of the receptor was observed in 80% of pediatric high-grade gliomas. [103] The eventual utility of agents such as ZD1839 for pediatric tumors expressing EGFR will likely be in combination with chemotherapy and radiation therapy, because agents that inhibit EGFR signaling can potentiate the cytotoxic activity of these modalities. [93,106,107]

## STI571: Targeting the Bcr-Abl Fusion Protein and Other Tyrosine Kinases

### *Background*

STI571 is a small molecule tyrosine kinase inhibitor developed to target the tyrosine kinase activity of the p210 $^{Bcr\text{-}Abl}$ and p190$^{Bcr\text{-}Abl}$ fusion proteins associated with chronic myeloid leukemia (CML) and Philadelphia chromosome–positive ($Ph^+$) acute lymphoblastic leukemia (ALL).[108,109] The fusion proteins esult in constitutive tyrosine kinase activity, which appears to be a crucial event in neoplastic transformation. [110,111] STI571 also inhibits the tyrosine kinase activity of the PDGF receptor and c-kit at submicromolar concentrations. [112] STI571 inhibits the growth of cells expressing the Bcr-Abl fusion protein [108] and induces apoptosis of Bcr-Abl–positive cells,[108] showing activity both *in vitro*[108,113,114] and *in vivo*.[115]

Of particular relevance to the pediatric setting and the treatment of $Ph^+$ ALL in children, STI571 selectively inhibits proliferation and Bcr-Abl phosphorylation in ALL cells expressing the p190$^{Bcr\text{-}Abl}$ protein.[109] Bcr-Abl expression exerts protection against apoptosis induced by cytotoxic agents, [116,117 and 118] and this Bcr-Abl–driven chemoresistance may contribute to the poor outcome of patients with $Ph^+$ leukemia treated with conventional chemotherapy agents. STI571 potentiates the activity of cytotoxic agents against Bcr-Abl–expressing cells, [119,120] thereby providing the strategy for combining STI571 with chemotherapy agents for Bcr-Abl–expressing leukemias. STI571 also shows antitumor activity in preclinical models of tumors in which the PDGF receptor plays a central role, including high-grade gliomas [121] and dermatofibrosarcoma protuberans.[122]

### *Clinical Experience*

In the initial phase I trial of STI571 the agent was administered orally once per day and included patients with interferon-refractory chronic phase CML. [123] STI571 was rapidly absorbed, with a terminal half-life of 10 to 23 hours and with an increase in mean plasma area under the curve (AUC) values that were proportional to the administered dose up to a dose of 750 mg.[124] The $C_{max}$ and trough levels exceeded levels associated with activity in preclinical models. No dose-limiting toxicity (DLT) has been reported with the agent. Myelosuppression, neutropenia, and thrombocytopenia occurred occasionally at doses greater than or equal to 300 mg. [124,125] For patients with chronic phase CML, complete hematologic responses occurred in 100% and complete and major cytogenetic responses occurred in 35% of those treated with doses of STI571 of 300 mg or greater.[124,125] STI571 has been less effective in CML blast crisis and in $Ph^+$ ALL, with lower remission rates and shorter response durations observed.[124,126] Ongoing evaluations of STI571 in combination with cytotoxic agents will determine whether the synergistic increase in activity for STI571 with chemotherapy agents observed in preclinical models can be translated into the clinical setting.

### *Pediatric Applications*

STI571 warrants evaluation in children with $Ph^+$ (Bcr-abl–expressing) leukemias for multiple reasons, including its unique mechanism of action, its high level of activity with minimal associated toxicity in adults with CML, and its synergistic activity in combination with chemotherapy agents. Pediatric development plans for STI571 for these leukemias include single-agent evaluation for patients with chronic phase CML and evaluations in combination with standard chemotherapy agents for patients with $Ph^+$ ALL or with CML in blast crisis.

STI571 may also have a role for pediatric tumors in which PDGF signaling may play a role in tumor cell survival and growth. Tumors for which PDGF signaling may be important include high-grade gliomas, [121,127] neuroblastoma,[128,129] desmoplastic small round cell tumors,[130,131] alveolar rhabdomyosarcoma,[132] and osteosarcoma.[133,134] Pediatric tumors that have c-kit/stem cell factor–signaling pathways are a third group of cancers that may be targets for STI571 evaluation. A substantial percentage of pediatric AML cases express c-kit.[135] Ewing's sarcoma and peripheral neuroectodermal tumor cell lines express c-kit and stem cell factor, and c-kit expression protects tumor cells against apoptosis.[136] Rhabdomyosarcoma cell lines express c-kit and stem cell factor, but blocking stem cell factor signaling did not alter growth of the cell lines.[137] Neuroblastoma cells also expressed c-kit, [138] and stem cell factor appears to provide a survival signal for these cells. Pediatric studies with STI571 are planned for children with recurrent Ewing/PNET, neuroblastoma, osteogenic sarcoma, and desmoplastic round cell tumors as well as a study of children with high-grade glioma.[139]

## FARNESYL TRANSFERASE INHIBITORS AND THE FUNCTIONAL INHIBITION OF RAS SIGNALING

The role of Ras activation in many cancers has been an impetus to develop therapeutic strategies for Ras inhibition. [140,141] Activating Ras mutations occur in approximately 30% of human cancers, being especially prevalent in pancreatic adenocarcinomas and also occurring commonly in colorectal carcinomas, thyroid carcinoma, and acute myeloid leukemia.[142] Ras may also be persistently activated by upstream growth factors or oncogenic proteins. Ras function can be inhibited by blocking mitogenic signal transduction, by affecting Ras protein farnesylation, or by inhibiting the downstream regulatory factor molecules or effectors of Ras ( Fig. 11-4).

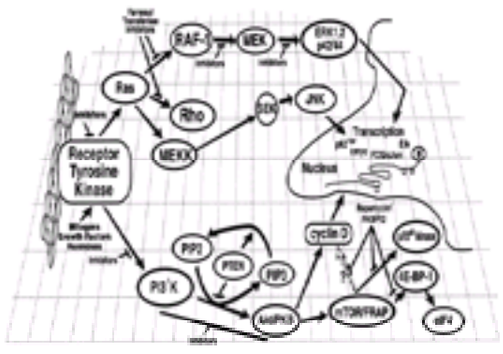

**FIGURE 11-4.** Sites at which molecularly targeted new agents inhibit the Ras and PI3'K signal transduction pathways to modulate transcription and translation are indicated by blunt-ended arrows. Blockade of receptor signaling at multiple steps in these pathways diminishes or blocks transcription activation, disrupting cellular genetic activity.

Ras, like many proteins, is farnesylated by the same farnesyl transferase (FTase) as other cellular proteins. FTase inhibitors (FTIs) are not exclusively Ras-specific. The development of FTIs was initially driven by the premise that their primary mechanism of action was inhibition of Ras isoprenylation, thereby inhibiting Ras signaling. More recent evidence suggests that the activity of FTIs may be related to alterations in RhoB, an endosomal protein that functions in receptor trafficking. [143] Treatment of cancer cells with FTIs leads to diminished levels of farnesylated RhoB and increased levels of geranylated RhoB. [144] The latter is able to inhibit survival signaling pathways in some cell types[145] and in some fibroblast models appear necessary for the apoptotic and antineoplastic responses to FTIs. [146] Activation of the PI3'K-Akt pathway may block the apoptotic effects of FTIs.[147] These observations complicate efforts to identify molecular characteristics of tumors cells that are predictive for response to FTIs.

Agents that inhibit the farnesylation reaction of FTase may be divided into three broad categories: the farnesyl diphosphate (FDP) analogs that compete with the substrate FDP for FTase, the peptidomimetics that compete with the CAAX portion of Ras for FTase, and the bi-substrate inhibitors that combine the properties of FDP analogs and peptidomimetics in a single molecule (Table 11-3).[140,142] Agents in each of these classes show *in vitro* activity against a range of tumor cell lines, including cell lines with wild-type Ras.[142] Tumor cells with mutant H-Ras appear to be more sensitive than cells with mutant K-Ras or N-Ras, perhaps reflecting differences in protein synthesis among the Ras isoforms, affecting the ability of the latter to more readily undergo geranylation when farnesylation is blocked. [148] *In vivo* antitumor activity (including regressions for some tumors) has been observed for different classes of FTIs, including the non-peptide CAAX peptidomimetics SCH66336,[149] R115777,[150] BMS-214662,[151,152] and the CAAX peptidomimetic L-744,832.[153,154]

| Agent | Target |
|---|---|
| Bi-substrate inhibitors | Combine the features of both the FDP analog and the peptidomimetics |
| FDP analogs | Compete with the substrate FDP for FTase |
| Inhibitors of farnesyl protein transferase | |
| R115777 | Tricyclic FTase |
| SCH66336 | FTase inhibitor, pyridoben zocycloheptine |
| Peptidomimetics (CAAX Mimetics) | |
| Downstream of RAS | |
| ISIS 5732/CGP69846A | c-raf kinase antisense oligonucleotide |
| PD 184352 | MEK |
| 98059 | MEK |
| U-0126 | MEK |
| ISIS 3521 | PKC, oligonucleotide |
| Bryostatin-1 | PKC |
| Other | |
| ISIS-2503 | H-Ras-antisense oligonucleotide |

FDP, farnesyl diphosphate; PKC, protein kinase C.

**TABLE 11-3. PROTEIN FARNESYL TRANSFERASE (FTase) INHIBITORS IN PRECLINICAL AND CLINICAL DEVELOPMENT**

### R115777 and SCH66336: Farnesyl Transferase Inhibitors

#### *Background*

A challenge in studying the FTIs in the clinic is defining the relationship between agent dose, serum levels, and agent effect on the target enzyme. This has been accomplished by direct measurements of FTase activity[155] and by developing assays for unprocessed forms of farnesylated proteins. [156] Drug-induced increases in the unfarnesylated species of the chaperone protein HDJ-2 and the intranuclear intermediate filament protein lamin A can be detected after treatment *in vitro* with FTIs.[156] Immunohistochemical detection of prelamin A in buccal mucosa cells of patients treated with FTIs has been used to confirm inhibition of protein farnesylation *in vivo*.[157] Because only two FTIs, R115777 and SCH66336, are currently under clinical evaluation in children, the description of clinical experience with FTIs is restricted to these two agents.

#### *Clinical Experience*

R115777 is an orally administered FTI that is competitive for the CAAX peptide substrate. [147] The agent has been studied in phase I trials on several different schedules, including twice daily × 5 days repeated every 14 days, [158] twice daily × 21 days repeated every 28 days,[159,160] and chronic twice-daily dosing.[161] These studies have demonstrated acceptable gastrointestinal absorption, an approximately 5-hour plasma half-life, and biologically relevant steady state plasma levels as predicted preclinically.[158,159] The primary toxicities for the 5-day treatment regimen were nausea, vomiting, headache, fatigue, anemia, hypotension, and reversible nephrotoxicity; only one case of DLT (peripheral neuropathy) was observed at doses up to 1,300 mg (approximately 750 mg/m $^2$).[158] By contrast, more prolonged dosing produced dose-limiting myelosuppression at a dose of 300 mg/m $^2$.[159] Complete responses were observed in the adult phase I leukemia study of R115777.[160]

SCH66336 is a potent inhibitor of farnesylation. Phase I studies in adults have used a twice-daily [157,162] or daily[163] dosing schedule. Administration of SCH66336 twice daily for 7 days resulted in dose-limiting gastrointestinal toxicity (nausea, vomiting, and diarrhea) and fatigue at a dose of 400 mg, and a dose of 350 mg was considered the recommended phase II dose.[157] Continuous daily oral administration of SCH66336 was studied in patients with miscellaneous solid tumors. [162] Doses of 300 mg or greater were not tolerated because of myelosuppression and neurotoxicity (confusion and disorientation). The recommended phase II dose was 200 mg twice daily. This dose caused mild toxicities, including diarrhea, anorexia, fatigue, and asymptomatic bradycardia. Similar results were obtained using a 14-day treatment schedule followed by 14 days of rest.[164] Using the presence of prelamin A in buccal mucosa cells as a marker for physiologically relevant FTase inhibition, *in vivo* inhibition of protein farnesylation was demonstrated at doses from 200 mg to 400 mg.[157] A partial response was observed in a patient with NSCLC.[157]

#### *Pediatric Applications*

As noted above, the activity of the FTIs may not be tightly associated with their effect on Ras isoprenylation and on Ras activation. However, FTIs have been considered for evaluation historically in pediatric tumors that have aberrant activation of the Ras pathway, either through changes in intracellular components of the Ras pathway or through inappropriate Ras activation initiated by growth factor receptors. For juvenile myelomonocytic leukemia (JMML), aberrant regulation of the Ras pathway occurs in some cases, either by Ras-activating mutations[165] or by inactivating mutations of neurofibromin,[166] a GTPase-activating protein that inhibits Ras activity. JMML cells show greater sensitivity to FTI-mediated growth inhibition than do normal myeloid precursor cells. [167] A phase II evaluation of R115777 for children with JMML is planned. Evaluations are also planned for R115777 in childhood acute leukemias, based in part on the activity observed for R115777 in adults with acute leukemia.[160]

FTIs have shown significant anti-proliferative effects in human malignant glioma cells *in vitro* at low micromolar concentrations.[168] *In vivo* antitumor activity for FTIs against human glioma cells has been demonstrated in xenograft models.[169] Of additional significance to the treatment of brain tumors, oncogenic Ras appears to contribute to radiation resistance in human tumors, and inhibition of oncogenic Ras activity by FTIs enhances the radiation sensitivity of these cells. [170,171] Given these observations, a pediatric evaluation of SCH66336 is planned for children with brain tumors.

FTIs are also of interest for patients with neurofibromatosis 1 because mutations in neurofibromin lead to increased Ras signaling. [172,173] Potential applications of FTIs for this patient population include treatment of plexiform neurofibromas[174] and treatment of neurofibromatosis 1–associated malignancies.[175]

## CELL CYCLE: CHECKPOINT CONTROL, REGULATION, AND MODULATION

### Cell Cycle

The first gap phase of the cell cycle ($G_1$) is defined by the commitment of the cell to enter the cell cycle and molecular preparation for the rigorous duplication of genomic DNA encoded on the chromosomes (Fig. 11-5). Mitogenic stimulation initiates $G_1$ progression, which can in turn be inhibited by cytokine blockade.[176,177] and [178] $G_1$ is followed by the synthetic phase of the cell cycle (S) in which the DNA (the genome) is duplicated. S phase is followed by the second gap phase of the cycle ($G_2$) during which the cell prepares to enter the mitotic phase (M), also known as *cell division*. M phase is the time during which the duplicated chromatids segregate into

the daughter cells. Mitosis may be followed by $G_0$, a phase in which DNA replication is quiescent and the cell is not committed to cycle. [179]

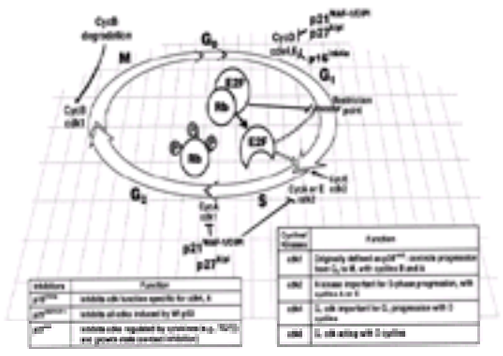

**FIGURE 11-5.** Cell cycle regulation by cyclin-dependent kinases and cyclins. The modulation of cell cycle transition is tightly controlled by E2F release from Rb and Rb phosphorylation. The p53 effector proteins p21 $^{WAF-1/CIP1}$, p27$^{Kip1}$, and p16$^{INK4a}$ inhibit the cyclins and cyclin-dependent kinases critical for cell cycle phase and restriction point transition.

### Checkpoint Control

Loss of checkpoint control, which defines the boundaries of the phases of the cell cycle ( Fig. 11-5), is common during malignant transformation. Progression through the cell cycle is tightly regulated by cyclin-dependent kinases (cdks), and their inhibitors p16 $^{INK4a}$, p21$^{WAF/CIP-1}$, and p27$^{KIP1}$ (Fig. 11-5). Controlled progression through the cell cycle is modulated by checkpoint control. [179] The transition through the phases of the cell cycle is controlled by the orderly phosphorylation and proteolysis of these cell cycle regulatory proteins. [180] The cdks are catalytic subunits that complex with cyclins to form holoenzymes that are activated by phosphorylation. [181] These kinases control cell cycle progression through protein phosphorylation events. The cyclins are proteins that are necessary for activation of cdks. During malignant transformation, progressive loss of cdk inhibitors and overexpression of cyclins leads to a growth and proliferation advantage for the malignant cell. The D cyclins (cycD), the retinoblastoma (Rb) protein, and p53 protein are often mutated in malignancy and regulate $G_1$/S progression. [178,182] Blocking of cell cycle progression with cdk inhibitors should lead to growth arrest or may result in apoptosis ( Fig. 11-5). [183,184 and 185]

To move from $G_1$ to S the tumor cell must pass the restriction point in $G_1$, the $G_1$ checkpoint. To traverse the checkpoint requires the phosphorylation of the Rb protein by cdks and the disassociation of the E2F transcription factor from the Rb protein complex. With the release of phosphorylated Rb, E2F facilitates progression by initiating the transcription of the genes important for progression through $G_1$ to S phases. [186,187 and 188]

### $G_1$ Phase and $G_1$/S Transition

CycDs associate with cdks 4 and 6 to traverse $G_1$. CycDs are synthesized in response to mitogenic activation. CycD and cdks 4 and 6 associate to form a complex that promotes the $G_1$/S transition facilitated by cdk2. [189,190] The CIP/KIP protein family inhibits cdks 4 and 6 activity (Fig. 11-5). The cycD/cdk complex phosphorylates Rb and relieves the repression of transcription by the Rb/E2F complex and the sequestration of the CIP/KIP proteins leading to activation of cycE/cdk2. CycE and cdk2 form a complex and facilitate the transition from late $G_1$ to S. Rb phosphorylation also allows E2F to activate transcription of S phase entry genes. When cycD is released and the CIP/KIP family of proteins is redistributed to cdk2, $G_1$ arrest occurs. [189]

Disruption of the $G_1$ checkpoint through loss of Rb or p16 or overexpression of cycD is universally present in human malignancies [191]; thus, restoration of the $G_1$ checkpoint is a rational therapeutic strategy. A number of investigational agents appear to act on Rb phosphorylation by cdk4. [180] Down-regulation of cycD reduces cdk4-mediated Rb phosphorylation. Agents that lead to cycD down-regulation include the retinoids, rapamycin and its ester analog CCI-779, flavopiridol, and the antiestrogens. 17-Allylamino-geldanamycin destabilizes cdk4. [180] Rb phosphorylation mediated by cdk4 is blocked by the inhibitory protein, p16 $^{INK4a}$. Hypomethylating or demethylating agents or histone deacetylase (HDAC) inhibitors that are discussed later can reactivate p16 $^{INK4a}$. [192] An alternative to reactivation of p16$^{INK4a}$ is the replacement of this cdk4 inhibitor with p16$^{INK4a}$ synthetic peptides [193] or p16$^{INK4a}$-expressing recombinant adenovirus technology. [194]

The specific cdk inhibitors currently under investigation all competitively inhibit the adenosine triphosphate (ATP)-binding pocket of the kinase. These agents are small molecules that are structurally dissimilar. The cdk inhibitors are reviewed and classified in several extensive reviews [181,195,196 and 197] Novel classes of cdk inhibitors have been generated using combinatorial libraries and structure-based design. [180] The direct inhibitors include purines, purine-like analogs, natural products, synthetics, and peptides [180,181,195,197] such as olomoucine and UCN-01 (Table 11-4). The indirect inhibitors include agents that decrease cycD levels, increase endogenous cdk inhibitors, and alter checkpoint control and other agents, such as rapamycin analog (CCI779), butyrates, and UCN-01. Analogs of flavopiridol and olomoucine cause cell cycle arrest in $G_1$ and $G_2$ as well as inhibit tumor cell growth *in vitro*. [198]

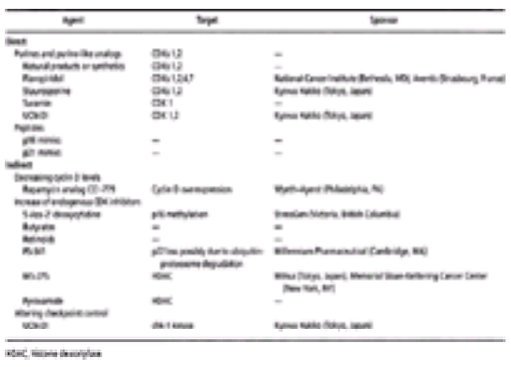

**TABLE 11-4. CYCLIN-DEPENDENT KINASE (CDK) AND CELL CYCLE MODULATORS**

### *Flavopiridol: A Cyclin-Dependent Kinase Inhibitor*

#### Background

Flavopiridol, another cdk inhibitor, is a nonchlorinated flavonoid derived from a plant alkaloid. Flavopiridol inhibits all cdks examined to date at concentrations of 100 to 300 nM. [212,213,214 and 215] In addition to inhibiting cdks, flavopiridol also decreases levels of cycD1, [216] which could contribute to $G_1$ arrest. *In vitro* testing revealed growth inhibition with $G_1$ or $G_2$ arrest in a range of cell types, [212,215] with differentiation being observed in some cases. [217] Flavopiridol induces apoptosis in some cell lines, including breast cancer, [218] chronic lymphocytic leukemia, [219] and prostate cancer. [220] Hypoxia-induced vascular endothelial growth factor (VEGF) mRNA and protein expression can be blocked by flavopiridol, and flavopiridol can induce apoptosis in endothelial cells, suggesting the potential for antiangiogenic activity. [221,222 and 223] EGFR tyrosine kinase [224] and protein kinase A (PKA) inhibition [181,224] were also noted with flavopiridol treatment.

Flavopiridol demonstrates sequence-dependent, additive, or synergistic activity with a number of chemotherapy agents, with greatest activity when the chemotherapy

agents are administered before flavopiridol.[225,226] *In vivo* studies using schedules that approximate continuous exposure demonstrated growth inhibition against several cancer cell lines.[224] The use of intermittent bolus schedules led to tumor regressions using head and neck,[227] prostate,[228] and lymphoid malignancy cell lines.[229]

### Clinical Experience

Human clinical trials of flavopiridol in adults have explored a 72-hour continuous infusion, given every 2 weeks.[230,231] Concentrations of flavopiridol that inhibit cdk activity, 300 to 500 nM, were attained. The recommended phase II dose on this schedule was 50 mg/m$^2$/day for 72 hours. In these studies the DLT was secretory diarrhea, treatable with cholestyramine and loperamide, which allowed further dose-escalation safely. The DLTs at this dose level were reversible hypotension, a proinflammatory syndrome with fever, fatigue, tumor pain, and modulation of acute phase reactants.[231] Patients with gastric cancer and renal cancer sustained a complete response and and a partial response, respectively. Minor responses were seen in NHL, colon cancer, and renal cancer. Most of the responses reported on this clinical trial were consistent with prolonged stable disease for 6 months to 1 year, suggestive of cytostatic activity.

Other schedules of flavopiridol administration have also been evaluated. Based on preclinical studies showing regressions in NHL human xenografts with bolus flavopiridol,[229] 1-hour daily infusion schedules were studied in an effort to achieve the micromolar concentrations associated with tumor regression preclinically. The MTDs on 1-, 3-, and 5-day every 21 day schedules were 37.5, 50.0, and 62.5 mg/m$^2$/day, respectively.[230] Micromolar concentrations were achieved at the highest doses, but only for brief periods. Other schedules and combinations of flavopiridol with cytotoxic chemotherapy are currently being evaluated in phase I clinical settings in both adults and children. Phase II studies are being performed in chronic lymphocytic leukemia, NSCLC, NHL, and colon, prostate, gastric, head and neck, and renal cancer. Further studies will address the pharmacodynamic parameters to best evaluate cdk inhibition and clinical trial design related to the evaluation of stable disease.

### Pediatric Applications

Flavopiridol is of potential interest in pediatric cancers primarily based on the ability of bolus schedules achieving higher plasma levels to induce apoptosis in leukemia and lymphoma xenograft models.[229] A pediatric phase I trial of flavopiridol using a daily × 3 infusion schedule is planned.

UCN-01 is of potential interest for T-ALL, based on results showing that T-ALL cells with p16 inactivation are especially sensitive to UCN-01.[232] Whereas T-ALL cells with intact p16 have an inhibitory concentration ($IC_{50}$) of more than 200 nM, cells with inactivated p16 have $IC_{50}$ values less than 50 nM. UCN-01 may also have applicability in potentiating the activity of standard chemotherapy regimens by its abrogation of $G_2$/M and S phase checkpoints.

## Translation of Proteins Required for Cell Cycle Progression and Proliferation

### *Rapamycin (Sirolimus) and CCI-779: Inhibitors of $G_1$/S Phase Transition and Protein Synthesis*

### Background

The Mammalian Target of Rapamycin (mToR) (sirolimus) and CCI-779, an ester of rapamycin (Table 11-4), act through inhibition of the mammalian target of rapamycin (mTOR) kinase, which results in diminished translation of proteins essential for proliferation.[233] Rapamycin also induces increased turnover of cycD1 mRNA and protein, which could contribute to its antiproliferative activity.[234,235] Rapamycin inhibits mTOR after first binding to the FK506 binding protein 12 (FKBP12) (Fig. 11-4). mTOR is a downstream component of the PI3'K/Akt signaling pathway that is activated by mitogenic growth factors, and mTOR is phosphorylated and activated by Akt.[236] Activation of mTOR leads to increased activity for two proteins that control the translation of mRNAs for proteins necessary for cell proliferation: (a) p70 S6 kinase ($p70^{s6k}$), which controls translation of a set of mRNAs encoding ribosomal proteins and translation elongation factors[237]; and (b) eukaryotic initiation factor (eIF)-4E, which is needed for translation of mRNAs for a set of transcription factors and other proteins involved in cell proliferation.[238] Activation of eIF-4E by mitogenic stimuli requires mTOR-mediated phosphorylation of eIF-4E binding protein (4EBP-1),[239,240] which leads to its dissociation from eIF-4E and to activation of eIF-4E.

### Clinical Experience

Rapamycin has been studied for its immunosuppressive effects in the allograft transplant setting.[241] In a randomized clinical trial for patients with renal allografts receiving cyclosporine and prednisone, those patients also receiving rapamycin (2 or 5 mg /day by mouth) had decreased occurrence and severity of biopsy-confirmed acute rejection episodes compared to patients receiving azathioprine.[242] Toxicities associated with rapamycin treatment included hyperlipidemia, arthralgias, anemia, and thrombocytopenia.[242] Trough concentrations of rapamycin greater than approximately 15 nM appear to be associated with greater risk for both thrombocytopenia and hyperlipidemia.[243] These concentrations exceed those required to inhibit $p70^{s6k}$ phosphorylation in cancer cells *in vitro*.[235,244,245] SDZ RAD, an orally administered rapamycin analog, is also under clinical evaluation as an immunosuppressive agent for organ transplant patients.[246,247]

Clinical trials of CCI-779 investigating a once-weekly and a daily × 5 schedule have studied dose ranges of 7.5 to 220 mg/m$^2$/week or 0.75 to 19.1 mg/m$^2$/day, respectively.[248,249] Toxicity has been generally mild, with skin and mucosal reactions such as dryness, urticaria, eczema-like lesions, aseptic folliculitis, and mucositis.[248,249] Hypertriglyceridemia has also been observed, and heavily pretreated patients have required dose reduction because of grade 3 thrombocytopenia.[248] Partial responses occurred in a patient with NSCLC on the daily × 5 schedule and in patients with renal cell carcinoma, breast cancer, and a neuroendocrine tumor on the weekly schedule. This antitumor activity occurred over a range of doses on both schedules. These findings suggest that a biologically active dose of CCI-779 (e.g., as determined by *in vivo* inhibition of $p70^{s6k}$)[250] below a dose with significant toxicity may be sufficient for maximum antitumor activity.

### Pediatric Applications

Interest in rapamycin and CCI-779 for pediatric cancers derives from preclinical studies showing activity of rapamycin against pediatric tumors such as rhabdomyosarcoma,[245,251,252] osteosarcoma,[253] medulloblastoma,[254] and high-grade glioma.[255,256] In addition, the rapamycin analog SDZ RAD inhibited growth of posttransplant lymphoproliferative disorder–like B-lymphoblastoid cell lines both *in vitro* and *in vivo*.[257] In contrast to results obtained in most adult cancers, rapamycin induces apoptosis in some rhabdomyosarcoma, medulloblastoma, and posttransplant lymphoproliferative disorder–like B-lymphoblastoid cell lines.[252,258] Exogenous IGF-1 can protect rhabdomyosarcoma cells against apoptosis.[245] Because GLI-transformed cells are sensitive to rapamycin,[259] pediatric tumors with an activated Hedgehog signaling pathway (in which GLI is a downstream mediator) may be appropriate targets for rapamycin evaluation. The Hedgehog pathway is activated in some cases of medulloblastoma and rhabdomyosarcoma.[259,260] In terms of combining CCI-779 with chemotherapy agents, some studies have shown a potentiating effect for rapamycin when combined with chemotherapy agents,[261,262] whereas other studies have shown either no effect or mild antagonism.[263,264] Thus, it is difficult to predict the eventual utility of combining these agents with chemotherapy.

### S Phase Events and Progression

Alterations in the Rb pathway are common in malignancy and result in persistent E2F activation and decreased cycA-cdk2 phosphorylation events that may not affect normal cells and may result in tumor cells susceptible to agents that inhibit cycA-cdk2. The end result of cycA-cdk2 inhibition may be tumor cell apoptosis. E2F has a critical role in cell cycle progression past the $G_1$ restriction point and then into S phase. E2F forms heterodimers with the DP family of proteins following Rb phosphorylation and subsequent release of E2F. The E2F-DP heterodimers transcriptionally activate the genes that encode S phase proteins transiently. CycA-cdk2 deactivates E2F to properly modulate S phase progression. The E2F-cycA-cdk2 complexes exhibit the kinase activity leading to E2F-1-DP-1 phosphorylation.[265] E2F-1 binding to DNA is suppressed by phosphorylated E2F-1-DP-1, thus modulating the expression of S phase regulatory proteins. If E2F is not deactivated by cdcA-cdk2, S phase arrest occurs and apoptosis follows.[265] Theoretically, the combination of a cdk inhibitor, flavopiridol, with S phase–specific chemotherapeutic agents would enhance the activity of this cytostatic agent. Activity should be additive or synergistic when flavopiridol is combined with cytotoxics such as cisplatinum, topoisomerase I and II inhibitors, and alkylators.[225,226,266]

### $G_2$ Checkpoint and $G_2$/M Transition

$G_2$ checkpoint inhibition plays a central role in sensitization to radiation and chemotherapy. Because the checkpoint continues to be regulated by cdc25C in the face of p53 deficiency, developing agents that modulate cdc2 phosphorylation through this bispecific phosphatase may be an effective strategy for tumor sensitization. DNA damage induces a series of events aimed at maintaining cdc2 in a phosphorylated state to block replication of the genome before mitosis by maintaining $G_2$ arrest. This cellular response provides sufficient time for both repairing DNA as well as preventing cellular replication of damaged cells that may lead to apoptosis. The investigational agent UCN-01 abrogates the $G_2$ arrest after treatment with either radiation or chemotherapy, particularly in p53-deficient cells. Other activities of UCN-01 include inhibition of cdc25C phosphorylation by chk-1, [267] cell cycle arrest in tumors expressing wild-type Rb, [180] and abrogation of the $G_2$ checkpoint after treatment with cisplatin or camptothecin. [267]

#### *UCN-01: A Serine/Threonine Kinase Inhibitor*

#### Background

UCN-01 is a 7-hydroxy staurosporine analog that inhibits serine/threonine kinases in a concentration-dependent manner. [181] Although UCN-01 is a potent protein kinase C -a, -b, and -g inhibitor, this is not the mechanism of its antitumor effect [199]; nor is UCN-01 a highly specific cdk inhibitor. UCN-01 arrests tumor cells in $G_1$ and blocks $G_2$/M checkpoint function through the Chk-1 kinase. [200,201] Inhibition of Chk-1 kinase by UCN-01 leads to inappropriate activation of Cdc2 and progression into mitosis. UCN-01 also induces $p21^{WAF/CIP-1}$ and $p27^{KIP1}$ cdk inhibitory proteins [202] that cause $G_1$ arrest by dephosphorylated Rb accumulation and decreased expression of cycA. UCN-01 also abrogates the S phase and $G_2$/M checkpoints that normally allow time for DNA repair before either DNA synthesis or mitosis, respectively. [203,204] and [205] Abrogation of S and $G_2$/M phase checkpoints enhance the cytotoxicity of DNA-damaging agents such as cisplatin. Cells with excessively damaged DNA proceed prematurely into S phase or mitosis and subsequently undergo apoptosis. UCN-01 induces DNA damage that results in the activation of caspase and serine protease(s) pathways. UCN-01 synergizes with a variety of chemotherapeutic agents with DNA-damaging effects, including cisplatin, [206] topoisomerase inhibitors, [204] Ara-C, [207] and mitomycin C, possibly by abrogating $G_2$ checkpoint function, preventing DNA repair. [208]

#### Clinical Experience

The pharmacokinetic data, from phase I studies of UCN-01 using a 72-hour continuous intravenous (i.v.) infusion every 2 weeks in the United States or a 3-hour schedule every 3 weeks in Japan, demonstrated that UCN-01 had a prolonged half-life of several weeks. The volume of distribution was very small at steady state and the systemic clearance was prolonged. [209] The delayed clearance and subsequent prolonged exposure to UCN-01 was the result of the tight binding of UCN-01 to human a-1 acid glycoproteins. [210] The U.S. study was modified so that the treatment interval was increased from 2 to 4 weeks to accommodate the prolonged half-life. The infusion time for UCN-01 was decreased to 36 hours for cycle two and all subsequent cycles to diminish agent accumulation. The highest dose administered was 53 mg/m$^2$/24 hours for 72 hours in cycle one and 36 hours every 4 weeks using the modified schedule. Using salivary concentration of UCN-01 as a surrogate for free plasma concentrations, free concentrations of UCN-01 in the salivary gland were 45 nM (range, 29 to 182 nM); these levels were sufficient to abrogate the $G_2$ checkpoint. DLTs included hyperglycemia, lactic acidosis, nausea and vomiting, and transient hypoxia with minimal or no symptoms and self-limited elevations in hepatic transaminases. Asymptomatic and transient hypotension, headache, anemia, fatigue, myalgia, anorexia, and fever were also observed. [209]

The pharmacokinetic data fit a two-compartment model. The median volume of the central compartment was 2.6 L (range, 0.1 to 9.1 L). The clearance and terminal half-life were 0.01406 L/hour (range, 0.001 to 0.04 L/hour) and 574 hours (range, 199 to 4,099 hours), respectively.

In the phase I trial of UCN-01, one patient with metastatic melanoma sustained a partial remission and several patients had prolonged stable disease of 6 months' duration or longer. [211] After disease progression on UCN-01, one patient received standard chemotherapy while UCN-01 plasma levels were still elevated; the patient achieved a complete response after this initial course of therapy. These findings suggest UCN-01 may potentiate the effects of standard chemotherapy. Combination studies with this agent will proceed based on preclinical studies that indicate the activity of UCN-01 is potentiated with S phase or DNA-damaging specific drugs such as cisplatin, Ara-C, fludarabine, and 5-fluorouracil (5-FU). [211]

## INHIBITION OF PROTEASOME-MEDIATED PROTEIN DEGRADATION

The primary route for endogenous nuclear and cytoplasmic protein degradation in eukaryotic cells is the ubiquitin-proteasome pathway. [268] Proteins are targeted for degradation by covalent linkage with multiple molecules of the small protein ubiquitin. Once targeted, proteins are rapidly degraded by proteasomes. Specificity in protein degradation resides in the enzymes involved in coupling ubiquitin to proteins. [268] Proteasome-regulated processes include cell cycle progression, transcription factor activation, apoptosis, angiogenesis, and the regulation of proliferation. [268,269] and [270]

The 26S proteasome [271,272] is critical for proteolysis of ubiquitinated proteins. The 20S proteasome core is a cylinderlike complex with four stacked rings with seven related subunits. [273] The proteolytically active sites are found on the inner surface. [274] The alpha subunits may regulate access to the inner core that is active in proteolysis. The 20S proteosome has less proteolytic activity *in vitro* than does the full 26S proteosome complex. The 26S proteosome includes the 19S regulators. Some of the 19S regulators contain adenosine triphosphatases that facilitate degradation of substrate proteins by proteosome-mediated protein identification, unfolding, and transportation into the 20S complex. [274] The energy-dependent degradation of proteins by the proteasome results in small peptides ranging in size from 4 to 25 amino acid residues. The beta subunit of the proteasome has chymotrypsin- and trypsin-type activity, as well as peptidylglutamyl peptide hydrolytic activity. Naturally occurring and synthetic inhibitors of the proteasome have been identified, [275] including the *Streptomyces* metabolite lactacystin [276] and peptide aldehydes such as MG-132. [277]

#### PS-341: An Inhibitor of Proteasome-Mediated Protein Degradation

#### *Background*

PS-341 is a dipeptidyl (L-phenylalanine-L-leucine) boronic acid derivative (Table 11-4) that is a potent (Ki approximately 0.6 nM) and selective proteasome inhibitor. [278,279] The inhibitor selectively targets the chymotryptic activity of the proteasome and has minimal activity against other serine and cysteine proteases. As determined by the National Cancer Institute *in vitro* screen, PS-341 has substantial cytotoxicity against a broad range of human tumor cells and has a unique pattern of activity suggesting a distinctive mechanism of action. [279] PS-341 induces apoptosis at nanomolar concentrations against some leukemia cell lines, an effect that does not require p53. [280] It also induces apoptosis in multiple myeloma cells *in vitro*. [281] PS-341 slowed tumor growth in prostate cancer, lung cancer, and murine mammary carcinoma *in vivo* models. [279,282] PS-341 and other proteasome inhibitors have been tested *in vitro* and *in vivo* in combination with cytotoxic agents, [282,283] and [284] in combination with radiation, [282,285] and in combination with signal transduction pathway modulators. [286] The combinations have generally been additive; however, sequencing and dose issues were not fully addressed in these experiments. The basis for the antitumor activity of PS-341 and other proteasome inhibitors is not well understood. The anticancer activity of PS-341 could result from a number of biological sequelae of proteasome inhibition, including inhibition of NF-kB activation; p53, $p21^{WAF/CIP-1}$, and $p27^{KIP1}$ stabilization; and inhibition of angiogenesis. [280,287,288] and [289]

Apoptosis, angiogenesis inhibition, cellular adhesion molecule expression, and signal transduction modulation are linked to the antineoplastic effects of PS-341. PS-341 treatment stabilizes p53 and modulates its downstream effectors, p21 and mdm2, in addition to the effectors Rb, bcl-2, and stress kinases. Increases in p21 create a basis for cdk inhibition and cell cycle arrest. Prolonged (12-hour) exposure to PS-341 results in S phase and $G_2$/M blockade. [290] After PS-341 treatment, prostate and pancreatic tumors orthotopically implanted in nude mice demonstrated a decrease in tumor cell proliferation and viability associated with decreased VEGF expression and microvessel density. [291] PS-341 inhibits activation of the NF-kB signaling pathway by interfering with IkB proteolysis. [292,293] Activation of the NF-kB pathway enhances cellular survival signals. NF-kB signaling regulates the expression of VEGF and cellular adhesion molecules. Cytotoxic agents induce NF-kB, which may result in drug resistance through control of cell survival pathways. [294] The role these target molecules play in the antitumor effects of PS-341 is unknown.

### *Clinical Experience*

The first phase I trial of PS-341 evaluated weekly i.v. bolus administration for 4 weeks over a 6-week period. [295] A preliminary report described no significant toxicity for patients treated at doses from 0.13 to 1.60 mg/m$^2$. Other phase I studies have evaluated PS-341 given twice weekly every other week for 2 weeks of a 3-week cycle[296,297] or twice weekly for 4 weeks of a 6-week schedule.[298,299] Patients on these studies received PS-341 at doses ranging from 0.13 to 1.90 mg/m$^2$. At these doses adverse events were primarily mild gastrointestinal toxicities, occasional thrombocytopenia, and sensory neuropathy. [297,298] Because excessive toxicity was observed in preclinical models when the proteasome inhibition exceeded 80%, phase I trials were designed to escalate to a PS-341 dose that achieved this level of proteasome inhibition in peripheral blood 1 hour after administration. [300] In peripheral blood of patients in the phase I studies, 20S proteasome was inhibited in a dose-dependent fashion, with up to 60% proteasome inhibition observed at PS-341 doses of 0.9 to 1.2 mg/m $^2$.[296,297] In terms of antitumor activity, one patient with prostate cancer achieved a partial response that lasted for 8 months, [295] and clinical activity has been observed for multiple myeloma. [299]

Because PS-341 is cleared so rapidly in plasma, routine pharmacokinetic analysis has not been helpful. The phase I studies described investigated 20S proteasome inhibition in the first cycle before treatment and 1 hour after treatment in the peripheral blood specimens. [300] Using this assay for proteasome inhibition, the maximum tolerated level of biologic inhibition is predicted to be approximately 80%. Biologic inhibition of proteasome activity will be used to determine the PS-341 dose.

### *Pediatric Applications*

In considering what clinical pathways to pursue after the pediatric phase I evaluation of PS-341, the effect of proteasome inhibition on several *in vitro* pediatric tumor models provides leads for possible pediatric clinical applications of the agent. Diminished ubiquitin-proteasome degradation of p27 $^{KIP1}$ during retinoic acid treatment of LAN-5 human neuroblastoma cell line was associated with a more than tenfold accumulation of p27 $^{KIP1}$ protein and with growth arrest.[301] Differentiation of a murine neuroblastoma cell line (Neu 2A) was induced on exposure to the proteasome inhibitor lactacystin. [302] Additionally, lactacystin blocked cell cycle progression beyond $G_1$ phase for synchronized Neu 2A cells and MG-63 human osteosarcoma cells *in vitro*.[302] Incomplete differentiation occurred with lactacystin treatment of human RD embryonal rhabdomyosarcoma cells.[303] Proteasome inhibition by lactacystin led to cellular apoptosis associated with the accumulation of ubiquitinated protein and activation of bcl-2–sensitive apoptotic pathways in the Ewing's sarcoma cell line A4573. [304] Peptidyl aldehyde proteasome inhibitor given in a single dose induced early tumor regression and a significant delay in tumor progression in a murine model of human Burkitt's lymphoma. [305]

Given the ability of NF-kB to stimulate proliferation and confer resistance to apoptosis, and given the ability of PS-341 to interfere with NF-kB signaling, pediatric tumors with activated NF-kB are also potential targets for PS-341 evaluation. Constitutive NF-kB activation is a common characteristic of childhood ALL [306] and is frequently observed in Reed-Sternberg cells from cases of Hodgkin's disease. [307] Treatment of Hodgkin's cells with the proteasome inhibitor MG-132 induced apoptosis and sensitized them to ionizing radiation. [285]

A pediatric phase I study of single-agent PS-341 has been opened. Given preclinical data suggesting a favorable interaction with other treatment approaches, including cytotoxic agents,[283,284] radiation,[282,285] and signal transduction pathway modulators,[286] the eventual utility of PS-341 in the treatment of pediatric cancers will most likely be in combination with other anticancer treatments. Preclinical data using pediatric tumor models may provide useful information for prioritizing possible combination studies.

## HEAT SHOCK PROTEIN AND INHIBITION OF CHAPERONE FUNCTION

### 17-Allylamino-17-Demethyoxygeldanamycin: An Inhibitor of Chaperone Function

### *Background*

Geldanamycin appears to exert its biologic activities primarily through interaction with heat shock protein 90 (hsp90). [308] Hsp90 is a member of the chaperone family of proteins that act in multimeric complexes to achieve and maintain appropriate folding and activation of client proteins. [309] Hsp90 contains a nucleotide-binding domain within its amino terminal. ATP binding and hydrolysis are essential for the function of hsp90. [310,311 and 312] Geldanamycin binds hsp90 at the ATP binding site and inhibits ATP binding and hydrolysis.[311,312] Geldanamycin compounds bind to hsp90 and the homologous chaperone protein Grp94, thereby disrupting the interaction between these chaperone proteins and many kinases and other molecules involved in proliferation and cell cycle control. [313,314,315,316,317,318 and 319] The physiologic consequence of geldanamycin binding to hsp90 is destabilization of hsp90 client proteins and their degradation through the ubiquitin-proteasome pathway. [320] The cell signaling pathways affected by geldanamycin include the following [309]: glucocorticoid-induced gene expression, [321] ErbB-2 signaling,[322] signal transduction pathways involving Raf,[317] signaling through Src family protein kinases,[323] p210$^{bcr-ab}$ signaling,[324] focal adhesion kinase signaling, [325] hypoxia-induced gene expression,[326,327] and T-cell activation and survival. [328] The variety of signal transduction pathways affected by geldanamycin [329,330 and 331] suggests obvious anticancer applications for the agent.

Although geldanamycin was broadly cytotoxic in the National Cancer Institute cell line screen, it was not developed further due to unacceptable preclinical toxicity and poor solubility. The first semisynthetic derivative inhibitor of the chaperone function of hsp90 is 17-allylamino-17-demethyoxygeldanamycin (17-AAG). Although this derivative does not bind as tightly to the ATP/adenosine diphosphate binding pocket, 17-AAG exhibits anti-proliferative effects similar to those of geldanamycin in human breast cancer cell lines and also decreases expression of p185 $^{erbB-2}$, Raf-1, and p53 at similar concentrations.[316] Sequence-dependent synergy was observed with paclitaxel.[332]

### *Clinical Experience*

17-AAG is being studied in phase I clinical trials that examine a daily schedule for 5 days every 3 weeks and a weekly schedule. The clinical trials are in early implementation stages and only limited pharmacokinetic data are available. Peak plasma concentrations range from 0.53 to 1.30 µM at dose levels 10, 14, and 20 mg/m$^2$ daily for 5 days every 3 weeks. The alpha– and beta–half-lives were 0.10 to 0.19 hours and 1.8 to 3.7 hours, respectively. The volume of distribution ranged from 11 to 182 L at steady state concentrations. No agent accumulation was observed during the 5 days of administration. [333]

### *Pediatric Applications*

Because of the diverse range of signaling pathways inhibited by geldanamycin, a number of pediatric tumors could be sensitive to the cytotoxic effects of the agent. An early report on geldanamycin demonstrated its activity against primitive neuroectodermal tumor cell lines, [334] suggesting potential applicability against the Ewing's family of tumors. The ability of geldanamycin to down-regulate ErbB-2 suggests potential applicability for medulloblastoma and osteosarcoma, two tumors known to express ErbB-2.[335,336 and 337] With further testing of geldanamycin in pediatric preclinical models, other tumors may be identified as potential targets for clinical evaluation of 17-AAG or other agents that inhibit hsp90 function.

## ANGIOGENESIS, MALIGNANT TRANSFORMATION, INVASION, AND METASTASIS

The search for molecular solutions targeted to cancer has intensified the study of malignant transformation, tumor invasion, and metastasis. Neoplastic transformation involves molecular and cellular processes that are intimately related to the formation of new capillary blood vessels, or angiogenesis. The earliest steps in the development of malignancy involve tumor initiation, promotion and transformation from a normal cell to a carcinoma *in situ* (Fig. 11-6). The next step in this sequence involves the angiogenic switch during which avascular tumors recruit their blood supply. [338,339] This sequence of events is followed by the recruitment of circulating endothelial cells to the tumor focus of angiogenesis. [340,341 and 342] Some tumors will stimulate fibroblasts in the tumor microenvironment to express VEGF, thus contributing to the change to an angiogenic phenotype. [343] Finally, as the tumor cells extravasate from blood vessels they induce endothelial cell proliferation and promote neovascularization. In addition, once tumors have established an angiogenic phenotype, the integrity of the basement membrane is compromised following increased expression of matrix metalloproteinase 2 (MMP-2; Gelatinase A), MMP-9 (Gelatinase B), collagenase IV, and membrane-type metalloproteinase 14 (MT1-MMP).[344] Tumor cells then reenter the circulation through intravasation of blood vessels and lymphatics via the extracellular matrix (ECM), extravasate distally,

and establish growth in a new microenvironment.[345]

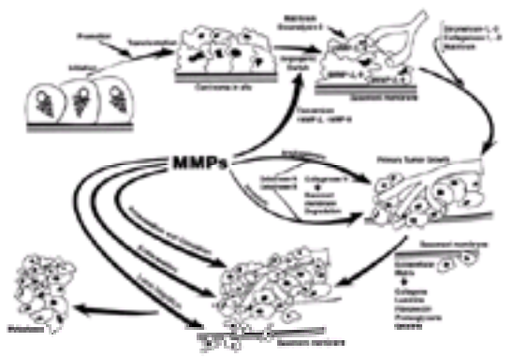

**FIGURE 11-6.** The role of matrix metalloproteinase (MMP) in tumor progression and metastases. The MMPs play a pivotal role in the angiogenic switch, angiogenesis, invasion, intravasation, and extravasation of tumor cells, local migration, and tumor metastasis, thereby making them suitable targets for control of tumor progression and metastases.

### Blockade of Matrix Breakdown as a Target: Matrix Metalloproteinase Inhibitors

The MMPs and their endogenous inhibitors, the tissue-localized tissue inhibitors of metalloproteinases (TIMPs), [346] modulate tumor cell invasion and metastasis through their interactions with the ECM, a metabolically active tissue.[345] ECM is composed of type IV collagen, laminin, entactin, proteoglycans, and glycosaminoglycans.[347] The MMPs are members of a family of enzymes that are regulated by growth factors, cytokines, and oncogenes.[348] The membrane-type MMPs require cleavage by other MMPs or proteases to release the active enzyme from the membrane.[349] In response to tumor cell invasion, host connective tissue cells, such as fibroblasts and inflammatory cells, induce the expression of MMPs.[350],[351] and [352] MMPs are expressed in a vast array of human tumors, making them unique targets for cancer therapy.[353] Because MMPs facilitate the processes of invasion, angiogenesis, and metastasis, MMP inhibitors may require chronic administration in a minimal disease setting to be most effective.

#### *BMS-275291: A Membrane-Type Metalloproteinase 14*

BMS-275291 (D2163) is an MMPI with $IC_{50}$ values in the range of 10–25 nM against MMP –1, -2, -8, and –9 and as well has activity against MMP-14 (MT-1 MMP). MT-1 MMP is involved in the activation of MMP-2. This relatively selective MMPI is only active in a micromolar range against TNF-a converting enzyme (TACE) and may not be associated with dose-limiting joint problems (see discussion under marimastat below). In metastatic models, progression is slowed by 60% to 90%. A phase I clinical trial is evaluating the potential biologic activity of BMS-275291 using the skin biopsy healing assay at doses ranging from 600 to 2,400 mg. [354]

#### *COL-3: An Enhancer of Matrix Metalloproteinase Degradation*

**Background**

COL-3 is a tetracycline analog, 4-dedimethylamino sancycline. By formulating OL-3 without the dimethyl amino group at the C4 position, its antimicrobial activity is abolished. COL-3 has anti-MMP activity via decreased expression of MMP-2 and MMP-9. Diminished MMP-2 expression may inhibit tumor growth and metastases. Inhibition of MMP-2 is not achievable *in vivo* (Ki 148 µM).[355] On matrigel invasion assays,[356],[357] COL-3 demonstrated 60% to 90% inhibition of tumor cell invasion. Inhibition of MMP expression has been demonstrated *in vitro* using human colon cancer and breast cancer cell lines also.

**Clinical Experience**

A phase I study of COL-3 demonstrated acceptable toxicity using doses ranging from 36 to 98 $mg/m^2$ in adults with advanced cancer. Toxicities included photosensitivity (grade 2 or 3), anemia (grades 3 to 4), fatigue (grades 2 to 3), and minimal nausea or vomiting (grades 1 to 2). The $C_{max}$ ranged from 1.0 to 2.6 µg/mL, even at doses ranging from 70 to 98 $mg/m^2$. The elimination half-life and renal clearance were 58 hours (range 24 to 140 hours) and 10 mL/minute, respectively. Plasma VEGF level did not change with COL-3 treatment; MMP-2 levels decreased slightly in the study subjects.

#### Marimastat: Matrix Metalloproteinase Inhibitor of Matrix Metalloproteinases 1, 2, 3, 7, 9, and 12

Marimastat inhibits MMP-1, -2, -3, -7, -9, and -12. Marimastat is an orally administered agent. Pharmacokinetic evaluation of this agent demonstrated trough plasma concentrations ranging from 30 ng/mL [5 mg twice daily (b.i.d.)] to 400 ng/mL (75 mg b.i.d.).[358] The elimination half-life is 8 to 12 hours [358] in healthy volunteers. Cancer patients have a shorter elimination half-life (4 to 5 hours). [359] The agent is excreted renally (40%) and is metabolized (60%). [358] Phase I trials determined that extended administration is feasible, but unusual joint problems limited chronic administration of marimastat at the upper dose levels. Musculoskeletal problems developed in 30% of patients at doses of 10 mg bid twice a day administered over 3 to 5 months [358] and are associated with prolonged administration of other hydroxamic acid–type MMPIs. The musculoskeletal problems include tendonitis that manifests as joint stiffness and pain in the hands, arms, and shoulder that resolve with interruption of therapy and dose modification. Half of the patients (6 of 12) in a study of patients with advanced gastric cancer had either a frozen shoulder or Dupuytren's-like disease.[360],[364]

Marimastat has completed phase II trials in lung, pancreas, colon, ovarian, prostate, [361],[362] and gastric cancer.[363] There were no objective responses in these studies. Some patients with pancreatic and colorectal cancer had their disease status monitored by the serum markers CA19-9 and CEA, [361],[362] respectively. Some of these patients did show a decreased *rate of increase* of these serum markers, pretreatment versus on-study rate of increase, but this may only represent regression toward the mean.

Marimastat has also been studied in phase III trials for advanced gastric cancer using 10 mg b.i.d., versus placebo, and for pancreatic cancer studying marimastat, 10 mg b.i.d., versus gemcitabine. Neither study showed a survival advantage for marimastat as a single agent. [358] Phase III studies with marimastat are proceeding in advanced breast cancer, small cell carcinoma of the lung, NSCLC, and glioblastoma. Marimastat has been combined with doxorubicin and cyclophosphamide, [365] carboplatin,[366] carboplatin and paclitaxel,[367] and gemcitabine or 5-FU.[368],[369]

#### *AG-3340 (Prinomastat): Inhibitor of Matrix Metalloproteinases 2, 3, 9, and 13*

**Background**

Prinomastat was rationally designed using protein structure based–modeling of human MMP active sites. Prinomastat inhibits MMP-2, -3, -9, and -13 but not MMP-1. Prinomastat is an orally bioavailable MMPI with an $IC_{50}$ of 8.3 µM.[370] Its half-life is short, 3 hours; it is 70% protein bound. Dose and schedule were predicted on preclinical models of growth inhibition that predicted that the maintenance of plasma concentrations above 1 ng/mL rather than total daily dose would be clinically effective.[371] Prinomastat given to nude mice with human colon tumors (COLO-320DM) every 6 hours at a dose of 6.25 mg/kg resulted in a maximal growth inhibition of 74% ($p$ <.05). When Prinomastat was administered every 12 (12.5 mg b.i.d.) or 24 (25 mg daily) hours, there was no growth inhibition in the COLO-320DM nude mouse model.

Combination of Prinomastat with other agents was evaluated preclinically. Prinomastat combined with carboplatin increased survival in an orthotopic nude rat model of primary and metastatic human lung cancer.[372],[373] An oral dose of 100 mg/kg/dose of Prinomastat was compared to an intraperitoneal dose of 10 or 20 mg/kg/dose of

carboplatin; neither agent improved overall survival in the orthotopic nude rat model. Prolongation of overall survival ( $p$ <.03) was observed when prinomastat combined with carboplatin was compared to carboplatin alone, 41.6 ± 2.5 days versus 35.7 ± 2.7 days.

### Clinical Experience

Prinomastat was studied at doses between 5 and 100 mg twice daily.[374] Minor regressions were reported in 3 of 47 patients and stable disease lasting from 4 to 10 months was reported in 12 of 47 patients. Interruption of therapy and dose modification were used to manage the musculoskeletal adverse events. Prinomastat was combined with paclitaxel (200 mg/m$^2$) and carboplatin (AUC = 6) in a phase I combination study. The expected chemotherapy-associated adverse events included rash, dysgeusia, and myalgia. Other combination studies examined Prinomastat with mitoxantrone and prednisone.[375] Phase III studies in patients with NSCLC and advanced hormone-refractory prostate cancer are evaluating 15 mg twice-daily dosing in conjunction with chemotherapy.

## ANGIOGENESIS

Angiogenesis is stimulated by VEGF receptor signaling pathways ( Fig. 11-7). These signaling pathways enhance cellular survival through Akt/PKB, stimulate proliferation and enhance vasopermeability by PLC and DAG, activate transcription through Ras [428] using the mitogen-activated protein kinases and c-*Jun*,[429] and cause cell migration and cytoskeletal rearrangement via FAK.[430,431] The preceding molecular events all lead to angiogenesis. Vascular endothelial cell receptors primarily involved in angiogenesis are Flt-1, an *fms*-like kinase, a 180-kd tyrosine kinase, and a 200-kd human kinase KDR (kinase insert domain-containing receptor), homologue of the mouse Flk-1.[432] VEGF expression increases in the presence of hypoxia and tumor necrosis.[433,434,435 and 436]

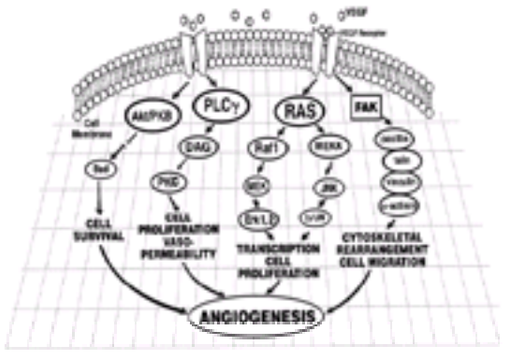

**FIGURE 11-7.** Angiogenesis activation by vascular endothelial growth factor (VEGF) receptor–signaling pathways. Activation of the Akt/PKB, PLCg, Ras, and FAK pathways lead to cell survival, cell proliferation and vasopermeability, transcription and cell proliferation, and cytoskeletal rearrangement and cell migration, respectively. Each of these events contributes to the angiogenic phenotype of the tumor cell.

Tumor cells are also able to inhibit endogenous angiogenesis at a distance. Stimulators and inhibitors modulate the process of angiogenesis and define the switch to an angiogenic phenotype.[437,438,439 and 440] Folkman's hypothesis that tumors may stimulate neovascularization locally and inhibit this process distally was borne out by the discovery of endostatin,[441,442 and 443] angiostatin,[427,444,445,446 and 447] angiopoietins,[448,449,450,451,452,453,454,455,456 and 457] VEGF,[458,459,460,461 and 462] and other molecules.[432,463,464]

Targeting the inhibition of angiogenesis as a therapeutic strategy is challenging because of the multifactorial nature of this intricate process. Functionally, the agents that specifically inhibit angiogenesis ( Table 11-5) block matrix breakdown, inhibit endothelial cells directly, block activators of angiogenesis, inhibit endothelial-specific integrin/survival signaling, or have other mechanisms of action.

| Agent | Mechanism of action | Sponsor |
|---|---|---|
| **Agents that block matrix breakdown** | | |
| Marimastat | Synthetic inhibitor of MMPs | British Biotech (Annapolis, MD) |
| Prinomastat (AG 3340) | Synthetic MMP inhibitor | Agouron (Salella, LA) |
| COL-3 | Synthetic MMP inhibitor: tetracycline derivative | Collagenex (Newtown, PA) |
| Neovastat | Naturally occurring MMP inhibitor; inhibits VEGF activity | Aetema (Sainte-Foy, Canada) |
| BMS-275291 | Synthetic MMP inhibitor | Bristol-Myers Squibb (Wallingford, CT) |
| **Agents that inhibit endothelial cells directly** | | |
| TNP-470 | Synthetic analog of fumagillin; inhibits endothelial cell growth | Tap Pharmaceuticals (Deerfield, IL) |
| Thalidomide | Blocks VEGF; inhibits angiogenesis and tumor necrosis factor pro-duction | Commercially available, approved for leprosy (Celgene Warren, NJ) |
| Squalamine | Extract from dogfish shark liver; inhibits sodium hydrogen exchanger (NHE) | Magainin Pharmaceuticals (Plymouth Meeting, PA) |
| Combretastatin A-4 prodrug | Induction of apoptosis in proliferating endothelial cells | Oxigene (Boston, MA) |
| Endostatin | Inhibition of endothelial cell function | Entremed (Rockville, MD) |
| 2-Methoxyestradiol | Inhibits cellular proliferation; inhibits tubulin function; up-regulates death receptor 5 | Entremed (Rockville, MD) |
| Angiostatin | Inhibits endothelial cell function | Entremed (Rockville, MD) |
| IL-12 | Inhibits endothelial cell function<br>Up-regulation of interferon-γ and IP-10 | Entremed (Rockville, MD)<br>Genetics Institute (Bethesda, MD) |
| **Agents that block activators of angiogenesis** | | |
| SU5416 | Blocks VEGF receptor signaling (kinase insert domain-containing receptor-specific) | Sugen (South San Francisco, CA) |
| SU6668 | Blocks VEGF-R2, FGF receptor 1, and PDGF receptor signaling | Sugen (South San Francisco, CA) |
| Interferon-α | Inhibition of basic FGF and VEGF production | Commercially available |
| Anti-VEGF antibody | Monoclonal antibody to VEGF prevents receptor ligation | National Cancer Institute (Bethesda, MD); Genentech, (San Francisco, CA) |
| **Agents that inhibit endothelial-specific integrin/survival signaling** | | |
| EMD121974 | Small molecular blocker of integrin receptor present on endothelial cell surface $\alpha_v\beta_3$, $\alpha_v\beta_5$ | Merck KGaA (Darmstadt, Germany) |
| Vitaxin | Antibody, blocks human $\alpha_v\beta_3$ | MedImmune Inc (Gaithersburg, MD) |
| **Agents with other mechanisms of action** | | |
| CAI53 | Antiviral mechanism; inhibits VEGF, stimulates IL-12 | Cytran (Kirkland, WA) |

VEGF, vascular endothelial growth factor.

**TABLE 11-5. COMPOUNDS WITH SPECIFIC ANTIANGIOGENESIS ACTIVITIES**

### Direct Inhibitors of Endothelial Cells

#### *Thalidomide : An Angiogenesis Inhibitor*

#### Background

Thalidomide is an old agent that has developed a new life as an immunomodulating agent and as an angiogenesis inhibitor ( Table 11-5). Initial attempts to license this agent in the United States were denied because of its teratogenic effects on limb development. The teratogenic effects appear to involve a species-specific hepatic metabolite.[376] Using the rabbit corneal micropocket assay, investigators have demonstrated that thalidomide inhibits both VEGF and basic fibroblast growth factor (bFGF)–stimulated angiogenesis.[377] Attribution of the antitumor activity of thalidomide to an anti-angiogenic mechanism is complicated by the multiple other biologic activities of this agent,[378] including oxidative damage to DNA,[379] inhibition of TNF-a production,[380] T-cell costimulation accompanied by increases in interleukin-2 and interferon-g production,[381] and modulation of adhesion molecule profile.[382]

#### Clinical Experience

Thalidomide is administered as a single oral dose at night. Its primary toxicities are sedation, constipation, and peripheral neuropathy. Activity for thalidomide was observed in patients with HIV-associated Kaposi's sarcoma, with 47% achieving an objective response.[383] Activity was also observed for patients with renal cancer who received low-dose thalidomide (100 mg daily), with 3 of 18 patients showing partial responses, but no responses occurred among 48 adults with other cancer types who received low-dose thalidomide.[384] Similarly, no objective responses were noted among 28 heavily pretreated breast cancer patients randomized to receive either a low dose (200 mg) or a high dose (800 mg) of thalidomide.[385] A study of thalidomide in 39 patients with relapsed high-grade gliomas demonstrated two partial responses and two minor responses and a median time to progression of only 10 weeks.[386] Thalidomide has substantial activity against multiple myeloma.[387,388 and 389] In a study of 84 patients with previously treated multiple myeloma, including those treated with high-dose chemotherapy, 32% had at least a 25% reduction in serum or urine paraprotein levels at a median time of 29 days (range, 4 days to 6 months).[389] Decrease in paraproteins was associated with a bone marrow response (a 50% reduction in the number of plasma cells) in 81% of all evaluable patients.

Thalidomide has been evaluated with a variety of chemotherapy agents in phase I/pilot studies, including carboplatin,[390] carboplatin and paclitaxel,[391]

cyclophosphamide and dexamethasone,[392] and temozolomide.[393] In general, thalidomide has been well tolerated in combination with standard chemotherapy. Three phase III trials in newly diagnosed stage III NSCLC, in multiple myeloma that has progressed following initial therapy, and in previously untreated renal cell carcinoma are evaluating whether overall survival is altered by the addition of thalidomide to standard treatment. A combination study combining thalidomide with temozolomide will be studied in children with recurrent brain tumors.

### *Combretastatin: An Endothelial Cell Interactive Agent*

#### Background

Combretastatin A4 (CA4P) is administered as a prodrug (Table 11-5) and has direct endothelial cell interactions. CA4P inhibits tubulin polymerization through its interaction with the colchicine binding site of microtubules.[394] Using a radiometric assay to measure activity, CA4P demonstrated *in vitro* activity against a variety of cell lines, including breast, colon, and lung tumor cell lines.[395] *In vivo*–selective antivascular activity has been shown in murine and rat models. This selective antivascular activity was associated with altered tumor perfusion by magnetic resonance imaging (MRI), intratumoral acidosis and hypoxia, diminished cellular energy status by magnetic resonance spectroscopy, and enhanced intratumoral necrosis.[396,397 and 398] Combretastatin is mainly active against proliferating endothelium selectively resulting in disruption of endothelial cell function.[396,399,400] Combretastatin causes apoptosis in proliferating endothelial cells[399] by inducing caspase-3 activity.[400] In murine models with established tumors, combination studies of combretastatin and cytotoxic therapies, including radiation therapy, cisplatin, or 5-FU, showed additive or synergistic activity compared to single-agent/modality treatments.[401,402 and 403]

#### Clinical Experience

Initial trials with combretastatin using three different schedules demonstrated toxicities, including shortness of breath, reversible mild cardiac ischemia thought secondary to coronary artery vasospasm, and pain at the tumor site.[404,405] Reductions in tumor blood flow demonstrated by MRI have been also been described.[405]

### *Endostatin: An Anti-Angiogenic Agent*

#### Background

Endostatin is a 20-kd protein fragment of the carboxy-terminal end of collagen XVIII (Table 11-5) that was isolated initially from supernatants of cultured murine hemangioendothelioma cells.[406] Endostatin preparations inhibit proliferation and migration of endothelial cells *in vitro* but do not affect other cell lines.[406,407] Murine endostatin induced dose-dependent regressions and prolonged growth inhibition against several murine tumors as well as human xenografts.[406] Remarkably, when tumors that had regressed were allowed to regrow to their original size, resumption of treatment with endostatin again induced complete regressions.[408] No resistance was noted following up to six cycles of regrowth and retreatment. Tumors eventually failed to regrow after multiple cycles of tumor recrudescence and treatment with endostatin, demonstrating sustained tumor dormancy.

Instability of the endostatin protein and formulation issues confounded preclinical evaluation of the agent. Initial studies were done with a precipitated form of endostatin administered as a suspension.[406,408] Recent studies have used recombinant endostatin expressed in the yeast *Pichia pastoris* system, which allows posttranslational modifications and production of soluble endostatin.[407,409] Recombinant human endostatin produced in this way inhibits the proliferation and migration of endothelial cells and induces endothelial cell apoptosis.[409] t can induce regressions *in vivo*, although the effect is not as dramatic as that initially reported using the precipitated form of murine endostatin.[408,409]

Endostatin's mechanism of action is unknown. It induces endothelial cell apoptosis *in vitro*.[410,411 and 412] Human endostatin is reported to interact with $a_5$- and $a_V$-integrins on the surface of endothelial cells.[412] Endostatin inhibits cell migration on immobilized gelatin (an $a_V b_3$ integrin ligand) but not on immobilized collagen I (a non-RGD–binding b1 integrin ligand),[412] consistent with the hypothesis of $a_5$- and $a_V$-integrins as potential targets for endostatin.

#### Clinical Experience

Phase I clinical trials with endostatin are ongoing in adult patients with advanced cancer. In one study, patients have been treated using a daily i.v. schedule at doses ranging from 15 to 180 mg/m$^2$.[413] The $C_{max}$ at the 180 mg/m$^2$ dose level was 5 µg/mL, which is approaching the target $C_{max}$ as estimated from preclinical studies of recombinant human endostatin.[414] For comparison, normal healthy controls have serum endostatin levels of approximately 15 ng/mL.[415,416] Endostatin dose escalation continues in the absence of any reported DLT. The phase I studies are evaluating tumor biopsies, noninvasive functional imaging, and pharmacokinetics to provide information for determining a biologically effective dose.[413]

### *2-Methoxyestradiol: An Estrogen Metabolite with Anti-Angiogenic Activity*

2-Methoxyestradiol (2-ME), a minor metabolite of human estradiol (Table 11-5), demonstrates anti-angiogenic activity in chick chorioallantoic membrane (CAM) model and in the corneal micropocket assay.[417,418] This relatively nontoxic orally administered agent reduced xenograft growth and tumor vascularization in murine models.[418] 2-ME inhibits lung metastases in a pancreatic cancer metastatic model[419] and has activity in breast xenograft models that are estrogen receptor negative.[417]

Induction of apoptosis in tumor and endothelial cells may in part be mediated by 2-ME binding to the colchicine site of microtubules,[420,421] leading to inhibition of proliferation. 2-ME may also induce apoptosis via expression of the death receptor 5 (DR5) gene in human umbilical vein endothelial cells and tumor cell lines regardless of the p53 status.[422] DR5 up-regulation is linked to activation of intracellular caspases in a cell type–specific fashion. Thus, 2-ME may exert its pro-apoptotic effects in various cell types by different mechanisms. Phase I clinical development of 2-ME started recently.

### *Angiostatin: An Anti-Angiogenic Agent*

Working at the level of the endothelial cell,[423] angiostatin is formed by cleavage of plasminogen and consists of kringle loops 1 to 4. Local tumor-infiltrating macrophages or the tumor may secrete elastase which cleaves plasminogen via digestion by elastase.[424] Some angiostatin preparations inhibit *in vitro* endothelial cell proliferation and *in vivo* tumor growth and induce dormancy in established tumors *in vivo*.[425] Angiostatin may induce apoptosis in proliferating endothelial cells[426]; it may also potentiate the antitumor effects of radiation therapy, in part through increasing the sensitivity of endothelial cells to radiation.[427] Development of this agent is ongoing.

### Blockade of Activators of Angiogenesis

Blockade of stimulatory factors of angiogenesis is another approach to the inhibition of angiogenesis. Angiogenesis inhibition may be accomplished by prevention of release of the factor, binding of free circulating factor, blocking binding of the factor to its receptor, or inhibiting postreceptor signaling. Basic fibroblast growth factor (FGF) and vascular endothelial growth factor (VEGF) appear to be the most important stimulators of angiogenesis. Inhibition of VEGF can inhibit tumor growth and prevent metastasis in animal models. The development of small molecules that inhibit the VEGF/Flk-1/KDR (kinase insert domain-containing receptor) RTK and block signal transduction through the VEGF signaling pathway has been a major focus in new agent development.

### *SU5416: Selective Inhibitor of Vascular Endothelial Growth Factor Receptor 2 (Flk-1/KDR) Receptor Tyrosine Kinase*

#### Background

SU5416 is a synthetic molecule that is a potent and selective inhibitor of VEGF receptor 2 (Flk-1/KDR) RTK ( Table 11-2 and Table 11-5).[458] SU5416 inhibits VEGF-dependent proliferation of endothelial cells but demonstrates little effect on tumor cell growth.[465] SU5416 inhibits growth of human, rat, and murine tumor

xenografts at nontoxic doses *in vivo*.[465,466 and 467] SU5416 effects on cultured endothelial cells occur within minutes and persist longer than 3 days after washout, as compared to the short half-life (30 minutes) in rats when administered intravenously. [468] This long-lasting inhibition is attributable to the intracellular accumulation and persistence of SU5416[468] and may explain the similar level of antitumor activity for SU5416 whether administered on a twice-weekly or a daily schedule. [468]

### Clinical Experience

Phase I evaluations of SU5416 in adults explored dose levels ranging from 4.4 to 190.0 mg/m $^2$.[469] The MTD of SU5416 was 145 mg/m$^2$, with DLTs of projectile vomiting, headache, and nausea that resolved within 24 to 48 hours. Systemic exposure at the MTD achieved the AUC required for growth inhibition in animals. [469] The b-elimination half-life of SU5416 is approximately 30 minutes, and there is an approximately 70% induction of clearance of SU5416 after 1 month of twice-weekly treatments.[470] Objective responses in the phase I setting were observed for Kaposi's sarcoma, metastatic basal cell carcinoma, colorectal carcinoma, and lung cancer.[458,469,471,472] Single-agent phase II trials and studies of SU5416 in combination with chemotherapy agents are ongoing in adults. [458]

## *SU6668: Receptor Tyrosine Kinase Inhibitor That Inhibits Flk-1/KDR, Fibroblast Growth Factor Receptor 1, and Platelet-Derived Growth Factor Receptor*

### Background

SU6668 is a synthetic small molecule RTK inhibitor ( Table 11-2 and Table 11-5) that inhibits Flk-1/KDR, fibroblast growth factor receptor 1 (FGFR1), and PDGF receptor.[473] It inhibits *in vitro* proliferation of endothelial cells stimulated by FGF or VEGF, and it suppresses tumor angiogenesis *in vivo*.[473] *In vivo* testing of SU6668 revealed growth inhibition, and in some cases tumor regression, against a range of human tumors, including glioma, melanoma, and lung, colon, ovarian, and epidermoid tumor cell lines.[473] SU6668 is taken up at a slower rate than that of SU5416, and unlike SU5416, SU6668 does not persist intracellularly and does not have long-lasting activity in functional assays of VEGF inhibition following washout. [468] Studies in rats demonstrated that SU6668 is an orally bioavailable agent (approximately 50%) with a half-life of 2 to 3 hours.[474]

### Clinical Experience

A phase I trial of daily, orally administered SU6668 has been initiated in adults, with doses between 100 and 1,600 mg/m $^2$ evaluated with only moderate toxicity observed.[475]

## *rhuMAB Vascular Endothelial Growth Factor (Bevacizumab): An Inhibitor of Vascular Endothelial Growth Factor–Induced Endothelial Cell Mitogenesis*

### Background

Inhibition of VEGF signaling using an anti-VEGF monoclonal antibody blocks VEGF-induced endothelial cell mitogenesis, [476] and inhibits the *in vivo* growth of a number of human cancer cell lines, including prostate cancer,[477] glioblastoma,[478] colorectal cancer,[479] and rhabdomyosarcoma.[480] The combination of anti-VEGF antibody and chemotherapy in nude mice injected with human cancer xenografts results in an increased antitumor effect compared to either antibody or chemotherapy alone.[6]

### Clinical Experience

A phase I study evaluated bevacizumab at doses from 0.1 mg/kg to 10.0 mg/kg in adults with advanced malignancies.[481] Therapy was generally well tolerated without drug-related grade 3 to 4 or acute infusion-related toxicities, although three patients did experience tumor-related hemorrhagic events. In a second phase I study, weekly bevacizumab (3 mg/kg/dose) was given with one of three cytotoxic chemotherapy regimens (5-FU/leucovorin, carboplatin/paclitaxel, or doxorubicin). [482] The addition of bevacizumab to chemotherapy was well tolerated without apparent long-term synergistic toxicity. No antibodies to bevacizumab were detected in either study. The pharmacokinetics of bevacizumab in the single-agent study were linear for doses of greater than or equal to 1 mg/kg, with a half-life of approximately 17 days.[481] Coadministration of bevacizumab with cytotoxic chemotherapy did not appear to result in altered systemic concentrations of the cytotoxic agents. [482]

Single-agent phase II studies were conducted in women with relapsed metastatic breast cancer [483] and men with hormone-refractory prostate cancer,[484] and phase II studies combining bevacizumab with chemotherapy were conducted in adults with NSCLC[485] and metastatic colorectal cancer.[486] In the single-agent studies, objective responses were observed in patients with breast cancer[483] but not in patients with prostate cancer.[484] In the NSCLC and colorectal cancer trials with bevacizumab in combination with standard chemotherapy, there was preliminary evidence for increased response rates and prolonged time to disease progression for patients receiving bevacizumab plus chemotherapy compared to those treated with chemotherapy alone.[485,486] The most worrisome toxicities were observed in the NSCLC study, in which six subjects among 67 who received bevacizumab had life-threatening hemoptysis or hematemesis, and four of these patients died. Hemorrhage that was not life threatening was seen in the other phase I and II studies. Both venous and arterial thromboses, ranging in severity from catheter occlusion to fatal pulmonary embolus, were seen in subjects treated with bevacizumab in the colorectal cancer trial and, to a lesser extent, in the NSCLC trial.

### Inhibitors of Endothelial-Specific Integrin/Survival Signaling

Endothelial cells express multiple cell surface integrins that bind to ECM and matrix breakdown products. The vitronectin receptor $a_Vb_3$ integrin is expressed on stimulated, angiogenic endothelial cells but has limited expression on normal endothelial cells and other normal cell types. [487] A few tumor types express high levels of $a_Vb_3$ integrin, including melanoma[488] and high-grade gliomas.[489] The $a_Vb_3$ integrin binds to the Arg-Gly-Asp (RGD)-specific amino acid consensus sequence found in matrix proteins, including vitronectin, fibronectin, fibrinogen, and proteolyzed collagen. Antibodies that block a $_Vb_3$ integrin inhibit *in vivo* angiogenesis induced by basic FGF and by implanted tumors in the CAM assay.[490] Cyclic peptides that block the $a_Vb_3$ integrin RGD binding site also inhibit *in vivo* angiogenesis and caused regressions of transplanted human tumors in the CAM assay.[491] Both the monoclonal antibody strategy and the RGD cyclic peptide strategy for blocking a $_Vb_3$ integrin binding have entered clinical evaluation.

## *Vitaxin: A Humanized Monoclonal Antibody against a $_Vb_3$ Integrin*

Vitaxin is a humanized derivative of the mouse monoclonal antibody LM609 that targets the human a $_Vb_3$ integrin. In a phase I study in adults, Vitaxin given weekly for 6 weeks, the dose was escalated from 0.1 to 4.0 mg/kg/week without observing DLT.[492] Levels sufficient to saturate $a_Vb_3$ integrin were achieved at doses greater than or equal to 1 mg/kg/week, and the half-life at higher doses was in excess of 5 days. A partial response was observed in a patient with leiomyosarcoma, but no objective responses were observed among 15 patients treated in a subsequent phase II trial using a relatively low dose of Vitaxin (0.25 mg/kg/week). [493]

## *EMD 121974 (Cilengitide): A Selective Antagonist of the a $_Vb_3$ Integrin*

EMD 121974, a cyclic pentapeptide containing the RGD sequence, [494] is a potent, selective antagonist of the a $_Vb_3$ integrin. It inhibits *in vivo* angiogenesis in preclinical models of retinal neovascularization and antigen-induced arthritis, [495] and it inhibits tumor growth in xenograft models of melanoma and brain tumors.[496,497] A phase I trial in adults of EMD 121974 given twice weekly has evaluated i.v. doses of 30 to 1,600 mg/m $^2$/infusion.[498] The toxicities observed in this dose range included nausea, anorexia, fatigue, and malaise. They have been mild in nature. Dose-related, linear pharmacokinetics were observed, with a terminal half-life of 3 to 5 hours. Renal clearance of unchanged EMD 121974 accounted for most of the total clearance of unchanged EMD 121974. At the 120 mg/m $^2$/infusion dose, concentrations that optimally inhibited tumor growth in preclinical studies were achieved. [498]

### Pediatric Applications of Angiogenesis Inhibitors

A concern with the development of anti-angiogenic agents in children is the potential for increased susceptibility to toxic effects resulting from angiogenesis inhibition in the developing child. VEGF is necessary during embryonic development, with loss of a single VEGF allele being lethal in the mouse embryo. [499,500] Inactivation of the VEGF gene in embryos leads to impairments in blood vessel development, heart formation, and endochondral bone formation. [499,501] VEGF is also required for

postnatal growth and survival in mice.[502] In newborn mice, high degrees of VEGF inhibition resulted in nearly complete growth arrest and lethality, an effect that diminished with maturation.[502]

Postnatal inhibition of VEGF activity also inhibits endochondral bone formation. [503] The process of endochondral bone formation at the epiphyseal growth plate involves blood vessel invasion of the zone of proliferating chondrocytes. VEGF inhibition blocks the blood vessel invasion and leads to an expanded zone of hypertrophied chondrocytes.[503] Similar effects on the epiphyseal growth plate have been observed for small molecule inhibitors of VEGF and for anti-VEGF monoclonal antibodies.[504,505] The effects of VEGF inhibition on endochondral bone formation are at least partially reversible after cessation of VEGF inhibition. [505]

The basic rationale for studying inhibitors of VEGF signaling and inhibitors of endothelial cell function in pediatric tumors is similar to that for adults. Preclinical studies have demonstrated that antitumor activity can be achieved by inhibiting angiogenesis for a number of pediatric tumors, including neuroblastoma, [6] neurogenic sarcomas,[506,507] Wilms' tumor,[508] rhabdomyosarcoma,[480] and glioblastoma.[509] A phase I trial evaluating SU5416 has been initiated in pediatric patients with primary brain tumors, and clinical evaluations of other agents targeting the VEGF pathway are anticipated. An important strategy to evaluate in using anti-angiogenic agents in children and adults is their combination with chemotherapy and radiation therapy. [510]

One way of combining anti-angiogenic agents with conventional chemotherapy agents is to use the latter at low, frequent doses to take advantage of the anti-angiogenic activities of the agents. [511] In a preclinical neuroblastoma model, the combination of low-dose vinblastine with a monoclonal antibody against the Flk-1/KDR receptor for VEGF resulted in sustained regressions, an effect not seen with either agent used alone. [6] SU5416 is also a potent inhibitor of c-kit, the RTK receptor for stem cell factor, and hence could play a role in the treatment of cancers in which the c-kit receptor is activated. [512]

In terms of studying $a_Vb_3$ integrin antagonists for their anti-angiogenic effect, several pre-clinical studies using pediatric tumor model systems support the potential benefit for this approach in the pediatric setting. For neuroblastoma, expression of a $_Vb_3$ integrin in microvessels of high-risk neuroblastomas is common but occurs much less frequently in low-risk neuroblastomas.[513] In a murine syngeneic neuroblastoma model, EMD 121974 in combination with a tumor-specific antibody–interleukin-2 fusion protein–induced primary tumor regressions, whereas either agent alone induced only growth delays. [5] In an orthotopic nude mouse model for medulloblastoma and glioblastoma, daily treatment with EMD 121974 markedly inhibited tumor growth and caused regressions in some cases. [496] Using the same cell lines, EMD 121974 had no activity when tumor cells were implanted subcutaneously, suggesting that the brain environment was a critical determinant of brain tumor susceptibility to growth inhibition by EMD 121974. As these agents enter clinical trials in newly diagnosed pediatric patients with favorable prognosis, tumor growth delay and arrest will need to be carefully monitored.

## MODIFIERS OF CHROMATIN STRUCTURE: HYPOMETHYLATING AGENTS AND HISTONE DEACETYLASE INHIBITORS

### DNA Methylation

Methylation of cytosine residues in genomic DNA is quite common and usually occurs at cytosine residues adjacent to guanosine (CpG sites). [514] DNA methylation is important in transcriptional repression of imprinted genes and genes subject to X-inactivation, in transcriptional silencing of transposons and viral genes, and in establishing the chromatin structure of some satellite DNA regions. [515] The role of methylation in controlling tissue-specific gene expression is complex, as the promoter regions of these genes often contain CpG islands (regions of DNA with an unusually high frequency of the dinucleotide CpG) that are unmethylated, regardless of the transcriptional status of the genes. However, methylation does appear to play a role in silencing developmentally regulated genes [516] and in some types of tissue-specific gene expression.[517] Methylation results in transcriptional silencing through a linkage between methylation and histone deacetylation, which results in part from methyl-CpG–binding proteins attracting HDAC complexes that then modify chromatin structure, leading to transcription repression. [518,519]

A number of cancers have aberrant methylation patterns, with characteristic patterns of CpG island methylation observed for each type. [520] Abnormal methylation of normally unmethylated CpG islands in the promoter regions of tumor suppressor genes leads to inappropriate silencing of these genes in cancer cells. [521] Tumor suppressor genes and genes involved in apoptosis that are inactivated by abnormal methylation include p16, [521] $p14^{ARF}$,[522,523] caspase-8,[524,525] death-associated protein kinase,[526] and Apaf-1.[527] Treatment of cancer cells with demethylating agents can in some instances lead to reexpression of these genes. [521,523,525,526,527] and [528] Reexpression of components of the apoptotic pathway can increase sensitivity to chemotherapy agents and to other inducers of cell death (e.g., TRAIL). [525,527,528] Thus, demethylating agents may allow reversal of critical steps in oncogenic transformation and reversal of tumor drug resistance.

#### *5-Azacytidine and 5-Aza-2'-Deoxycytidine (Decitabine): Remethylation Inhibitors*

### Background

Agents that inhibit or decrease DNA methylation, for example, 5-azacytidine and 5-aza-2'-deoxycytidine (decitabine), have generated renewed interest because they may allow gene reexpression (Table 11-6). Both 5-azacytidine and decitabine are metabolized to 5-aza-dCTP and subsequently incorporated into newly synthesized DNA, with decitabine being more potent because of its more direct pathway to DNA incorporation. They inhibit DNA methyltransferases by causing an irreversible linkage between enzyme and 5-aza-dC–substituted DNA.[529,530] 5-Azacytidine and decitabine induce differentiation in some cell lines and inhibit cell growth or induce cell death in others.[531,532] and [533] The hypomethylating and differentiating effects of these agents can be observed at concentrations not associated with toxicity and can be isolated from the cytotoxic effects, as the latter are proportional to the quantity of enzyme covalently bound to DNA rather than to the percentage of enzyme inhibition.[533,534] As discussed in the section on HDAC inhibitors, the combination of demethylating agents with HDAC inhibitors can markedly increase reactivation of silenced genes.[535]

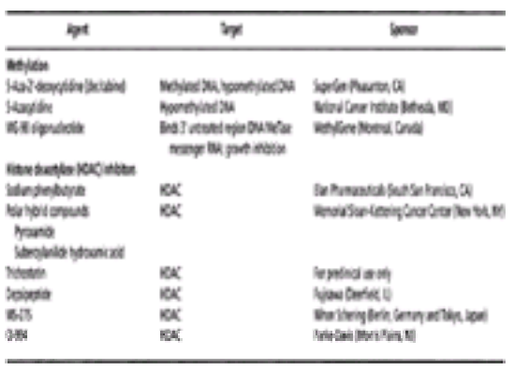

**TABLE 11-6. METHYLATION AND HISTONE DEACETYLASE INHIBITORS**

### Clinical Experience

Although 5-azacytidine and decitabine have been studied in humans for more than 20 years, [532] much of this work was done in the context of developing these agents for their cytotoxic activity rather than for their hypomethylating activity and ability to reactivate silenced genes. Of particular relevance is their use at lower doses for adults with myelodysplastic syndrome, with both 5-azacytidine and decitabine producing hematologic responses in phase II studies. [536,537] and [538] A randomized controlled trial of subcutaneous 5-azacytidine in adults with MDS demonstrated hematologic responses for patients receiving the agent and a trend toward improved survival compared to patients on the observation arm.[539] Both low-dose 5-azacytidine[540,541] and low-dose decitabine[542] have been used in patients with hemoglobinopathies to increase fetal hemoglobin production. Increases in hemoglobin F levels, preceded by DNA hypomethylation, were observed in some patients at doses that had little hematologic toxicity,[540,542] serving as proof of principal demonstrations that noncytotoxic doses of these agents can modify gene expression in a

clinically relevant manner.

### Histone Deacetylase

#### *Histone Deacetylase Inhibitors*

#### Background

Chromosome structure can be modified to alter transcriptional activity by two general mechanisms[543]: (a) histone modification posttranslationally and (b) chromosome remodeling in an energy-dependent fashion.[544] Histone acetyl transferases (HATs) and HDACs regulate the extent of histone acetylation, with transcription being either activated or repressed by recruitment to promoter regions of HATs or HDACs, respectively.[545,546] Given the ubiquitous involvement of HATs and HDACs in controlling gene transcription, it is not surprising that disruption of these chromatin remodeling mechanisms is associated with specific cancers. For example, in acute promyelocytic leukemia (APL), the promyelocytic leukemia (PML)–retinoic acid receptor a (RARa) fusion protein disrupts normal RARa function by enhancing the interaction between PML-RARa and an HDAC co-repressor complex, thereby blocking normal retinoic acid–induced differentiation ( Fig. 11-8).[547] Similarly, in leukemia cells with the t(8;21) translocation and the AML1-ETO fusion protein, there is inappropriate transcriptional repression mediated by the recruitment of HDAC complexes by the fusion protein.[547] Leukemias may also result from translocations resulting in aberrant HAT activation, such as those involving the CREB-binding protein.[547] A more general role for HDACs in cancer is through gene silencing associated with aberrant methylation of CpG islands, a process involving recruitment of HDACs to methylated sequences through the interaction of HDAC complexes with methyl-CpG–binding proteins or with DNMT1.[518,548,549] This interaction between proteins involved in DNA methylation and HDAC complexes provides a conceptual framework for understanding the apparent synergistic gene reexpression observed when hypomethylating agents and HDAC inhibitors are combined.[535,550]

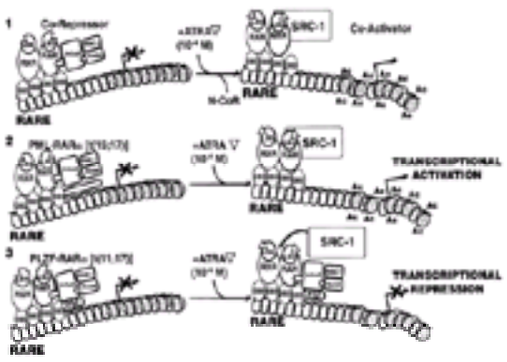

**FIGURE 11-8.** Models for interpretation of the molecular events that are modulated by therapeutic interventions with differentiating agents [all- *trans*-retinoic acid (ATRA)] and histone deacetylase (HDAC) inhibitors in acute promyelocytic leukemia (APL). **1:** The co-repressor complex binds with the retinoic acid receptor a (RARa), promyelocytic leukemia (PML)-RARa, or PLZF-RARa chromosomal DNA translocation site through DNA binding domains (DBD). Binding of the co-repressor complex [RARa, PML-RARa, or PLZF-RARa and nuclear receptor co-repressor (N-CoR), Sin3A, and HDAC1] blocks transcription. Physiologic concentration of ATRA ($10^{-8}$ M) results in release of the co-repressor complex after a conformational change in RARa and attachment of the co-activator, SRC-1, that has histone acetyl transferase activity. After histone acetylation, RARa is transcribed. **2:** In patients with a t(15;17) translocation, therapeutic concentrations of an ATRA ($10^{-6}$M) are necessary for release of the co-repressor complex and subsequent transcription activation after SRC-1–associated acetylation. **3:** In patients with a t(11;17), an ATRA ($10^{-6}$ M) resistant form of APL, therapeutic concentrations of ATRA are not sufficient to cause release of the co-repressor complex (N-CoR or Sin3A and HDAC1) that is bound to POZ. POZ binding makes the ligand binding domain (LBD) insensitive to ATRA and apparently blocks SRC-1 co-activator binding, thus inhibiting histone acetylation, leading directly to transcription repression. The role HDAC inhibitors play in release from transcription repression needs to be determined. Ac, histone acetylation; ARC-1, co-activator with histone acetyltransferase activity; Rare, retinoic acid response element; RXR, retinoic acid receptor. (Adapted with permission from Collins SJ. Acute promyelocytic leukemia: relieving repression induces remission. Blood 1998;91:2631–2633 and Guidez F. Ivin S, Zhu et al. Reduced retinoic acid—sensitivities of nuclear receptor corepressor binding to PML- and PLZF-RARa underlie molecular pathogenesis and treatment of acute promyelocytic leukemia. Blood 1998;91:2634–2641.)

Several classes of HDAC inhibitors have been studied, including hydroxamic acid–based hybrid polar compounds, for example, suberoylanilide hydroxamic acid and pyroxamide,[551] synthetic benzamide derivatives (e.g., MS-27-275),[552] short-chain fatty acid derivatives (e.g., butyric acid, phenylbutyrate, and phenylacetate),[553,554] and cyclic peptides (e.g., depsipeptide)[555] (Table 11-6). Inhibitors of histone deacetylation have multiple effects *in vitro*, including inducing growth arrest, differentiation, and apoptotic cell death.[556,557 and 558] *In vivo* testing of the HDAC inhibitors has demonstrated marked inhibition of tumor growth in a number of tumor models (e.g., prostate, colorectal, and ovarian tumor lines).[552,559]

#### Clinical Experience

A butyric acid derivative, phenylbutyrate, was the first HDAC inhibitor to enter clinical evaluation, but it has the disadvantage of requiring millimolar concentrations for HDAC inhibition. Although the biologic effects of phenylbutyrate are not restricted to inhibition of histone deacetylation,[560] the clinical experience with this agent does suggest the potential anticancer utility of targeting HDACs to alter gene expression. Phenylbutyrate induced fetal hemoglobin production in patients with hemoglobinopathies,[561,562] and phenylbutyrate was able to overcome resistance to all-*trans*-retinoic acid (ATRA) in a patient with APL, an effect presumably related to phenylbutyrate inhibition of the HDAC complex recruited by PML-RARa.[563] Current clinical research focuses on the more potent HDAC inhibitors that show activity at nanomolar or micromolar concentrations.[557] Among the more potent HDAC inhibitors that are in early clinical development are depsipeptide,[564] MS-27-275,[560] and suberoylanilide hydroxamic acid.[557]

#### Pediatric Applications

Demethylating agents may have a particularly important role for pediatric tumors such as neuroblastoma and medulloblastoma, in which silencing of the caspase-8 gene occurs and is associated with resistance to apoptosis.[524,525,565] Reexpression of caspase-8 by decitabine leads to increased sensitivity to TRAIL-induced apoptosis[525,565] and increased sensitivity to chemotherapy,[527] suggesting the strategy of using demethylating agents in combination with apoptosis-inducing agents to increase the efficacy of the latter. Transcriptional silencing by methylation occurs in other pediatric cancers, for example, p15 and p16 inactivation in T-cell ALL,[566] and demethylating agents may warrant evaluation for these diagnoses.

HDAC inhibitors may be particularly relevant for pediatric leukemias caused by fusion proteins that recruit HDAC complexes to promoter regions, including APL with RARa fusion proteins,[567] AML with AML1-ETO fusion proteins,[568] and ALL with TEL-AML1 fusion proteins.[569] HDAC inhibitors may also be active against pediatric solid tumors, as illustrated by the ability of a hybrid polar HDAC inhibitor to inhibit cell growth and induce apoptosis in neuroblastoma cell lines[556] and to enhance retinoid sensitivity in neuroblastoma cell lines.[570] As seen in adults, the enhanced ability to reexpress silenced genes through the combined use of a demethylating agent and a HDAC inhibitor[535,550] is a promising approach for those tumors in which gene silencing plays a role in cancer development or in resistance to therapy.

## REACTIVATION OR PERSISTENT ACTIVATION OF TELOMERASE

The primary role of the telomere is to protect the chromosome from recombination, fusion, or recognition as damaged DNA.[571,572] Telomerase is an RNA/protein complex. With every cell division, the chromosome becomes fused, lost, or unstable in normal cells compared to cancer cells as the telomere is shortened. Telomere shortening leads to lack of cell division and proliferation and eventually apoptosis.[573] Cellular senescence usually occurs because the molecular cap, the telomere, wears away after multiple replications. Replication of telomeric DNA is a cellular survival mechanism. The cancer cell appears to be able to repair eroded telomeres and, therefore, its survival is enhanced. Chromosomal degradation and DNA ligation by DNA repair enzymes is prevented by the presence of the telomere.

Maintaining the length of the telomere is one of the factors that allows for unrestricted proliferation in tumor cells. [574]

Alteration in cellular life span is circumvented in cancer, germ cells, and embryonal cells by the reactivation or persistent activation of telomerase. [575] Telomerase activity is lost after birth in human somatic cells.[576] Poor-prognosis neuroblastoma, melanoma, breast, esophageal, and pancreatic cancer exhibit telomerase activity.[577,578,579,580,581 and 582] Cellular immortalization occurs with telomerase activity, and Rb and p16 $^{ink4a}$ inactivation.[583]

Telomerase copies DNA using an RNA template repeat, TTAGGG, that may be up to 1,000 bases long.[575] These template repeats bind to TRF1,[584] and TRF2,[585] telomere repeat-binding factors. Approximately 80% to 90% of cancer cells contain telomerase, specifically the hTERT catalytic subunit. [575] Telomerase also has telomerase reverse transcriptase activity that catalyzes TTAGGG synthesis. Diminished telomere length, arrested cell growth, senescence, and apoptosis are inhibited in a competitive fashion by an inactive telomerase reverse transcriptase. [572]

### Antisense Oligonucleotides or Peptide Nucleic Acid Oligomers

Telomerase inhibitors include antisense oligonucleotides or peptide nucleic acid oligomers targeted to hTR or hTERT, and elongation of guanine-quadruplex structures. Inhibitors of the telomerase complex include 2'-O-methylated RNA and peptide nucleic acid oligomers that bind or compete with the consensus sequences.[586] Telomerase activity has been inhibited by a hammerhead ribozyme with the catalytic domain flanked by sequences complementary to RNA telomerase and by 2'-O-methyl-modified ribozyme.[586] The 5' peptide nucleic acid ends conjugated with cationic peptides have $IC_{50}$ values in the 0.14 µM range.[586,587] Antisense approaches are limited by ineffective membrane transport of these agents.

### Amidoanthraquinones

Three isothiazolones inhibit telomerase with $IC_{50}$ values of 130 to 140 nM. These agents bind near the active site or modify cysteine residues. [588] The amidoanthraquinones inhibit telomerase by binding the primer strand of the telomere and preventing the formation of the guanine-quadruplex structures during elongation.[589,590,591 and 592] Many other agents inhibit telomerase, including tetrapyridyl-substituted cationic porphyrins, [593] peryline derivatives,[594,595] acridines,[596,597] fluorenones, and regioisomers of bis-substituted amido-anthraquinones. [590,591 and 592]

### Alkaloid Berberines

Using the COMPARE analysis program from the Developmental Therapeutics Program of the National Cancer Institute, [598] other telomerase small molecule inhibitors were identified. Alkaloid berberines and mitochondria-accumulating agents were tested for their ability to inhibit telomerase. A rhodacyanine derivative, MKT077, [598] was chosen as a lead compound. Using MKT077 as the lead for the COMPARE analysis, a highly potent compound, FJ5002, with an $IC_{50}$ of approximately 2 µM was identified; this agent has not been tested in humans yet. FJ5002 demonstrates the characteristics of specific telomerase inhibitors: telomere erosion, chromosomal abnormalities, and senescence.

#### *MKT077*

MKT077 was administered as a 30-minute infusion weekly for 4 of 6 weeks in a phase I clinical trial. [593] Thirteen patients received treatment, using doses ranging from 42 to 126 mg/m$^2$/week. Because nephrotoxicity was observed in rodent models, forced diuresis with mannitol was started at the 84 mg/m$^2$ dose. The adverse events observed on study included emesis, edema, cumulative renal magnesium wasting, and renal dysfunction. A three-compartment model best describes the pharmacokinetic data for the first two dose levels. The elimination half-life a and g ($t_{1/2}$ a and the $t_{1/2}$ g) were 1.0 to 2.5 minutes and 25 to 30 hours, respectively. The mean AUC was 1,000 mg·h/mL at the 42 mg/m$^2$/week dose level and 1,850 mg·h/mL at the 56 mg/m$^2$/week dose level. The $C_{max}$ was 1,140 and 2,870 mg/mL for the two dose levels tested thus far. The clearance of MKT077 was 39.2 ± 11.4 L/hour/m$^2$ and was independent of the dose. This study confirms a tolerable dose and schedule that achieves a plasma concentration similar to the $IC_{50}$ concentrations required to sensitize human tumor cell lines. The primary *in vivo* mechanism of action of MKT077 may not be telomerase inhibition, but the alkaloid berberines have provided leads for the identification of more active inhibitors of telomerase in preclinical screens.[593,598]

## DEVELOPMENT OF MOLECULAR-TARGETED AGENTS FOR CHILDHOOD CANCERS

Four key steps in identifying and prioritizing molecular-targeted agents for pediatric indications are (a) identifying critical survival and apoptotic pathways in childhood cancers, (b) identifying agents that modulate these signaling pathways, (c) defining appropriate doses and schedules for these agents in children, and (d) incorporating these agents into the multi-agent, multimodality regimens used to treat children with cancer.

### Identifying Critical Survival and Apoptotic Pathways in Childhood Cancers

The first step in prioritizing a molecular-targeted therapy for evaluation in children is identifying the alterations in cell death signaling that specific cancers have acquired (either before or after treatment) and identifying the cell survival signaling pathways that are activated. Overexpression of bcl-2 and other anti-apoptotic members of the bcl-2 family (e.g., Bcl-$X_L$) may play a role in cell survival and treatment resistance for AML [28,30,31] and neuroblastoma.[25] Signaling through the IGF-1 receptor appears to be an important proliferation and survival pathway for rhabdomyosarcoma, [599,600] neuroblastoma,[601,602 and 603] Wilms' tumor,[604,605] desmoplastic small round cell tumor,[130,606,607] and Ewing's sarcoma.[608] These examples of potential targets may be exploitable for therapeutic gain in the treatment of childhood cancers.

### Identifying Agents That Modulate Critical Signaling Pathways

A second step in applying molecular-targeted therapies for children with cancer is to identify agents that modulate key steps in cell survival and cell death pathways. For some agents there may be relatively high specificity for a specific pathway activated in cancer cells. The prototypical example of a molecular-targeted therapy is STI571, which by inhibiting Bcr-Abl tyrosine kinase associated with CML and Ph$^+$ ALL, induces cells expressing this fusion protein to undergo apoptosis. [110,113,609] Clinical trials of single-agent STI571 demonstrated the ability of the agent to induce complete remissions in both CML and Ph$^+$ ALL,[125,126] serving as a proof of principle that specific inhibitors of critical signaling pathways can be effective anticancer agents. For other molecular-targeted agents, the linkage between the effect of an agent on its target and cell survival/cell death pathways is less direct. For example, HDAC inhibitors induce apoptosis in a number of different cell types *in vitro* (including AML cells and neuroblastoma cells). [556,558] Their activity is probably the result of the induction of the transcription of genes (as yet unidentified), leading to eventual apoptosis. Proteasome inhibitors induce apoptosis in a number of tumor cell lines *in vitro*, including Ewing's sarcoma,[304] chronic lymphocytic leukemia,[610] Jurkat T cells,[611] and AML.[612] Multiple changes occur in cells treated with proteasome inhibitors that may affect cell growth and survival, including stabilization of p53,[613] inhibition of NF-kB activity,[288,610,614] accumulation of the cdk inhibitors p21 and p27,[611] and accumulation of the pro-apoptotic protein Bax.[615]

### Defining Dose and Schedule for Molecular-Targeted Agents

A third step in the development of molecular-targeted therapies for pediatric cancers is defining an appropriate dose to take into phase II and subsequent evaluations. Given the limited number of children with cancer eligible for early phase trials, defining optimal dosing and scheduling to modulate an agent's target will most often be done in adults. Dose-finding studies in adults have traditionally escalated to DLT. For some targeted agents, however, there may be a large difference between the doses that cause modulation of the agent's target and the doses that cause significant toxicity in patients, and for these agents, a biologically active dose may be determined rather than an MTD.

In the ideal setting of an agent that is specific for a target critical for the survival of the cancer cells, decisions about dosing can be based primarily on antitumor activity. The application of STI571 for Ph$^+$ leukemias is an example in which high levels of antileukemia activity were observed in phase I trials, and the selection of dose could largely be based on response rate.[112,125,126] In the absence of antitumor activity, investigators must develop direct measures of target effect on tumor cells or target effect on normal tissue (e.g., peripheral blood mononuclear cells, buccal cells, skin). Potentially useful biologic correlative end points for molecular-targeted agents include binding or receptor saturation, expression at the RNA or protein levels, receptor activation or phosphorylation in tumor tissue, or measurement of

circulating proteins. Generally such tissue measurements should be correlated with pharmacokinetic studies. Again, biologic activity documented by functional imaging needs to be developed and validated for digital-contrast enhanced MRI; positron emission tomography using isotopes including oxygen-15, carbon-11, and fluorine-18; Doppler ultrasound; helical computed tomography; and three-dimensional radiolabeled imaging (single-photon emission computed tomography). Imaging modalities may be especially applicable for evaluating the biologic effects of anti-angiogenic agents. [616]

The decision-making algorithm for determining optimal dosing based on biologic activity as measured in tumor tissue after treatment is complex and may be based on assumptions of unknown validity. For example, the degree of target inhibition required to obtain the maximum antitumor effect and the duration of target inhibition required for optimal antitumor activity may be unknown. The effect of interpatient tumor heterogeneity may be difficult to characterize in limited numbers of patients. The impact of intrapatient tumor heterogeneity and the possibility of introducing sampling error from serial biopsies of a heterogeneous tumor must also be considered. Furthermore, the putative target may not be the only biologically relevant target for the drug, and higher doses might be required to inhibit other unrecognized targets that contribute to antitumor activity. Given all of these uncertainties, in many cases it will be deemed beneficial to escalate to doses with clear biologic effects (i.e., responses or toxicities) or to provide a substantial cushion above the minimal dose modulating the agent's target.

### Incorporation of Molecular-Targeted Agents into Multi-Agent, Multimodality Regimens

A final general consideration in the development of molecular-targeted therapies is how they should be incorporated into regimens with standard therapy. For many targeted agents, rationale for combining targeted new agents with conventional agents comes from preclinical data demonstrating enhanced antitumor activity for the combinations. Of particular interest for use in combination therapy are the targeted agents that in some way tilt the balance of survival and death signals in favor of apoptosis. For example, STI571 not only induces apoptosis in Bcr-Abl expressing cells but also potentiates the cytotoxic activity of conventional cytotoxic agents such as Ara-C and doxorubicin.[119] UCN-01, a staurosporine analog that inhibits the DNA damage checkpoint kinase hChk1, [200,201] markedly potentiates the cytotoxic activity of a number of chemotherapy agents,[617] including topoisomerase I inhibitors, [618] Ara-C,[619] and cisplatin.[620] Similarly, proteasome inhibitors potentiate the cytotoxic activity of cisplatin,[621] doxorubicin and etoposide,[283] and ionizing radiation.[285] Other examples illustrating the potential benefit for combining molecular-targeted agents with cytotoxic agents are described in the discussions of individual agents.

The development of combinations of standard agents with chemosensitizing molecular-targeted agents is complicated by the difficulty in obtaining preliminary evidence for benefit for the addition of the targeted agent. The ideal solution (in terms of obtaining a reliable answer) is to conduct a randomized trial of the combination with and without the targeted agent, but this is impractical to do for all of the possible combination regimens of interest. An alternative method that can be used to screen new combinations that include a molecular-targeted agent is comparison of outcome (e.g., response rate and event-free survival) for patients receiving the combination with the molecular-targeted agent to outcome for historical controls. Alternative solutions to historical controls are reviewed elsewhere. [622] This requires a well-characterized control population and evidence for comparability between the historical control group and the experimental group.

### Pediatric Molecular Markers

Researchers have sought prognostic and predictive markers of tumor behavior to guide both the design of clinical trials and the selection of therapy for individual patients. Prognostic markers indicate the likelihood of recurrence or survival regardless of treatment. Only recently has the research effort into prognostic and predictive markers for childhood cancers begun to intersect the research effort into targets of therapy. Marker studies generally have not been pursued with the rigor applied to clinical trials of therapeutic agents. The literature is replete with reports of research on markers in small groups of patients. Rarely is a comparable study performed to replicate results, and even more rarely is a prospective, randomized clinical trial designed with sufficient statistical power to test the utility of a marker. There is enormous scope for future research into both the basic cancer biology of childhood cancers and into the clinical application of current and future knowledge.

## CONCLUSIONS

The development of molecular-targeted therapies for childhood cancers will need to address the therapeutic window, as cancer cells may be preferentially dependent on the survival pathways or preferentially susceptible to the cell death pathways targeted by the agent when compared to normal cells. Many of the molecular-targeted agents modulate protein activity in normal and malignant tissues. Molecular-targeted agent specificity for tumor cells may not be dramatically different from currently used agents such as vincristine, topotecan, and etoposide. These agents target ubiquitous proteins, tubulin, and topoisomerase I and II, respectively. Other molecular-targeted agents modulate the activity of proteins that have more limited effects and limited distribution. Even though the targets are expressed on many normal cells, agents that inhibit RTKs may have a more limited effect on many normal tissues. Many molecular-targeted agents may be safely administered at doses that modulate their target. Alterations in the balance of cell death and survival in normal, nonhematopoietic tissue may lead to events that produce significant long-term effects.

The multiple mechanisms by which cancer cells promote their own survival and avoid cell death underscore the opportunities available for therapeutic intervention; the determination of which pathways are central to treatment resistance for specific cancer types should be given careful consideration as pediatric development of molecularly targeted therapies are undertaken. The understanding of essential survival and cell death pathways continues to expand; as an increasing number of agents that target specific pathways enter the clinic, molecular-targeted therapies may lead to more effective treatments for children with cancer.
