# GENERAL PRINCIPLES OF SURGERY

ROBERT C. SHAMBERGER
TOM JAKSIC
MORITZ M. ZIEGLER

## INTRODUCTION

Surgery remains a critical component in the multimodal therapy of childhood cancer. Accurate staging and successful resection of tumors is of vital importance as we strive to minimize the morbidity of treatment as survival rates improve. Decisions regarding biopsy and resection are most accurately made by surgeons who are trained to address these specific issues. This chapter presents an introduction to the significant considerations for surgical patients, including their metabolic response, nutritional support, and vascular access. Critical issues regarding anesthetic management, staging, biopsy, and preoperative adjuvant therapy are also discussed. A brief summary of some of the specific surgical issues for each solid tumor concludes the chapter.

## GENERAL PRINCIPLES

### Metabolic Response to Malignancy

Weight loss is frequently seen in children with malignancy. This form of malnutrition, termed *anorexia-cachexia syndrome*, is associated with higher early cancer relapse rates, decreased tolerance to chemotherapy, and a poorer prognosis.[1] Although reduced food intake is an important component of the syndrome, cancer patients, unlike starved individuals, have elevated protein turnover and lose the ability to conserve skeletal muscle mass.[2] Although these changes are seen in most malignancies, the extent of the response may be more pronounced in those with high cell turnover. Other notable metabolic changes with malignancy include increased rates of gluconeogenesis and lipolysis. There is also a failure to downregulate energy expenditure in response to reduced nutrient intake, although actual increases in resting energy expenditure are only evident in patients with large tumor burdens.[3] Surgical stress or infection tends to further exacerbate the net protein catabolism found in these patients.[4]

The pathogenesis of childhood cancer cachexia is complex and incompletely understood. Elaboration of host cytokines in response to the tumor, such as tumor necrosis factor-alpha, interleukin-1, interleukin-6, and interferon-gamma, promote catabolism, which in certain instances is further enhanced by specific tumor generated mediators.[5] The cytokine-independent ubiquitin-proteasome pathway has also been linked to muscle protein loss in cancer patients.[6,7] Compounding this catabolic process is a reduction in enteral intake and, on occasion, malabsorption of nutrients that may be caused by the tumor itself, antineoplastic therapy, or a combination of both.

### Nutritional Support

In the absence of efficacious pharmacologic interventions to combat the anorexia-cachexia syndrome, nutritional support remains the primary therapy. Children are particularly susceptible to the deleterious effects of cancer-induced catabolism due to their relatively reduced stores and high baseline requirements. The concern that the provision of nutrition may stimulate tumor growth in children is not supported by clinical data. There is also no evidence that the administration of macronutrients and micronutrients in excess of those recommended for other ill patients is required.

The use of preoperative nutritional support in children with malignancy has not been systematically studied; however, extrapolation from the adult literature would indicate that preoperative nutritional repletion should be considered only in those patients with preexisting malnutrition. Postoperatively, any child who is anticipated to have inadequate nutritional intake for more than 3 days should be considered as a candidate for nutritional support.

Enteral nutritional support is more physiologic, has lower complication rates and is less costly than parenteral nutrition. The advent of pliable, narrow bore, nasogastric feeding tubes and percutaneously placed endoscopically guided gastrostomy tubes has facilitated this option in children with cancer. The latter tubes have been shown to be safe in pediatric cancer patients and should be considered if protracted nutritional support is anticipated.[8] The conversion of gastrostomy tubes to gastrojejunal tubes is occasionally necessary to limit gastroesophageal reflux. Parenteral nutritional support is recommended for those children who are not suitable for enteral nutrition and adequate amounts of protein, glucose, lipid, trace minerals, and vitamins, commensurate with a metabolic stress state, should be administered.[4]

### Vascular Access

Vascular access procedures in oncology patients continue to be a dominant and critically important component of the total care plan.[9] In a child who must experience 6 to 24 months of primary or adjunctive chemotherapy, radiotherapy, and operative procedures, predictable as well as long-standing central venous access is important for obtaining diagnostic blood samples as well as for administering fluid and electrolytes, blood products, parenteral nutrient solutions, antibiotics, and other medications, as well as the anticancer therapies themselves.

Venous access selection for an oncology patient must take into consideration duration of projected need, frequency and duration of projected access into the vascular system, availability of patent veins for puncture, coagulation status of the patient, as well as experience of the surgeon. Typically, central venous catheters can be defined as external or implantable (subcutaneous infusion port). Furthermore, external catheters may be inserted directly into a central vein—subclavian, internal jugular, saphenofemoral—by percutaneous or cutdown techniques or a new technique of peripheral insertion of a central venous catheter that has also evolved.[10]

Totally implantable ports offer the advantage of no external catheter, thus improving body image and removing a putative limitation of physical activity. However, any potential for enhanced protection from infection when the device has been totally internal has been controversial. [11,12] Another important consideration in pediatric vascular access is the need for general anesthesia for central catheter placement, selected tunneled catheter removal, and for the removal of all implanted subcutaneous infusion ports.

Peripherally inserted central lines are typically placed at the bedside using topical and injectable analgesia, sterile technique, and chest radiograph to confirm catheter position. Most commonly, antecubital veins are the first choice for access, and the catheter exit site is maintained with frequent dressing changes and topical antibiotics with coverage by a transparent adhesive bandage, which permits visualization of the catheter at the site of entry. The major limitation of this technique is a greater likelihood of catheter malposition, mechanical catheter damage, inadvertent dislodgement, and phlebitic change in the smaller peripheral access vein. [10]

Central venous catheters are most commonly placed using the percutaneous Seldinger technique accessing the subclavian vein via the infraclavicular approach. A cuffed catheter is exited through a remote tunnel, the cuff and the tunnel both being mechanical factors that may limit the progression of bacteria along the catheter. Alternate access sites for catheter placement include the internal jugular, external jugular, and femoral veins, but ease of directing the catheter tip into the vena cava–right atrial junction along with achieving tunneling of the catheter is most effectively achieved with subclavian vein access. In contrast to venous selection for percutaneous access, if an open cutdown technique is instead selected to minimize placement complications, then the external or internal jugular veins and the saphenofemoral junction are preferred access routes.

Placement of a totally implantable device is optimal for the adolescent receiving intermittent cyclic chemotherapy. Again, venous access is obtained by either a percutaneous or cutdown technique, and the catheter is tunneled to the port's subcutaneous pocket placed either superior or inferior to an incision on the chest wall. The diaphragm of the port is placed in a palpable position, which allows ease of puncture by a metallic Huber needle, and the body of the port is secured by a series of sutures to the underlying muscle fascia.

Complications of central venous access are mechanical (related to the venous access procedure or the catheter itself), infectious, or infusion related. With percutaneous subclavian vein access, the greatest patient risk is pneumothorax, hemorrhage from either arterial puncture or vein laceration, pericardial tamponade secondary to atrial or ventricular penetration, or needle puncture–related neurologic (vagus, phrenic, or sympathetic trunk) or thoracic duct injury. Percutaneous access to the jugular vein carries similar risks, carotid artery penetration being a not uncommon event. Of concern is the very real risk of a life-endangering event from the vascular access procedure alone, a risk that approximates 1 such event per 1,000 access procedures. [11]

Infectious complications of pediatric central venous access remain most ommon.[12] Definition of such catheter-related bloodstream infections as opposed to local exit-site, tunnel, or pocket infections is important to analyze. The local site infections typically account for $^1/_5$ to $^1/_2$ of all central access infections and present with local signs and symptoms, including fever, erythema, tenderness, and drainage. In contrast, bloodstream infections are diagnosed when a presumptive diagnosis of bacteremia or sepsis is made and there is congruence of the cultured organism from a catheter segment and a venous blood culture. [13] However, as transcatheter antibiotics are typically initially administered in an effort to salvage the infected line, the presumption of a catheter-related infection is usually made on clinical suspicion with an inability to culture the catheter itself. The pediatric age group has remained a high-risk group for such infections. The microbiology of such infections are predictable, coagulase-negative staphylococci almost uniformly being the most common offending organism. [12,13] In all series, but especially for the immunocompromised population of oncology patients, the spectrum of causal organisms includes other gram-positive, many gram-negative, and, not infrequently, fungal species. Factors that may protect patients from infection historically included the aseptic technique of the operating room, the tunnel, and the catheter cuff. To these have been added antibacterial substances bonded to catheters in which minocycline and rifampin supply an added advantage. [14]

Risk factors for the pediatric patient that influence central catheter infections have been carefully analyzed. [12] Early infection occurred in 12% of children (53 of 437), and factors that adversely influenced this rate included moderate (absolute neutrophil count <1,000) or severe (absolute neutrophil count <500) neutropenia and failure to use perioperative prophylactic systemic antibiotics. Type of catheter and site of placement did not influence infectious risk. In this series, as in many others, transcatheter antibiotics as an initial therapy in presumed central line infection was effective in treating that infection and preserving the catheter in 70% of the patients.[12] Such transcatheter antiinfective agents worked less well for the child with fungemia. Furthermore, because of the demonstrated relationship between thrombosis and infection, thrombolytic agents, anticoagulants, as well as antibiotics, have been used to treat the infected catheter. [15]

## ANESTHESIA

### Principles of Perioperative and Anesthetic Management

Although the perioperative and anesthetic management of children with malignancy is generally similar to other ill pediatric patients, the following aspects warrant more detailed consideration: coagulation and transfusion, tumors that result in anterior mediastinal masses, and pheochromocytomas. In patients already treated with chemotherapy, a careful assessment of cardiac, pulmonary, renal, and electrolyte status is particularly warranted. Patients who have received cardiotoxic chemotherapy regimens, such as those including adriamycin, often require echocardiography to quantitatively document cardiac function before surgery.

#### *Coagulation and Transfusion*

Thrombocytopenia is the most commonly encountered clinical coagulation problem in children with malignancy requiring surgery. Platelet counts of 150,000 per $mm^3$ are the lower limit of the normal range in children, whereas normal neonates may have platelet counts as low as 80,000 per $mm^3$. Patients with platelet counts greater than 10,000 per $mm^3$ have a low risk of spontaneous bleeding if they are without evidence of other medical complications. [16] If surgery is contemplated, however, a platelet count of 50,000 per $mm^3$ is usually sought before incision. This guideline is empirically based and has not been formally studied; hence, lower levels may be acceptable to the operating surgeon in specific clinical contexts. In children, the transfusion of 0.1 units of platelet concentrate for each kilogram of body weight may be anticipated to raise the platelet count 40,000 per $mm^3$.

No specific hemoglobin concentration or hematocrit level mandates blood transfusion in an oncologic surgical patient. Children with hemoglobin levels of 6 g per dL are often free of adverse physiologic sequelae. The specific clinical scenario governs the need for transfusion, as rapid blood loss, infection, pulmonary dysfunction, cardiomyopathy, and central nervous system compromise may all mandate early transfusion. Immunodeficient patients should receive irradiated blood products and, if the patients are serologically cytomegalovirus-negative, they should receive cytomegalovirus-negative or leukocyte-poor blood products. Packed red blood cells are the usual blood product used for both acute blood loss and chronic anemia. Although with massive hemorrhage whole blood is a suitable choice, it is rarely available.

Elevations in prothrombin time (PT) and partial thromboplastin time (PTT) are acquired defects in most surgical patients. Vitamin K deficiency manifests with a marked prolongation of the PT and PTT and normal platelet and fibrinogen levels. In older children, this may be due to malabsorption, dietary deficiency, or drug antagonism. The subcutaneous administration of vitamin K results in improvement within several hours and correction within a day. For immediate correction, fresh frozen plasma is required. If the platelet count and fibrinogen are also low, disseminated intravascular coagulation must be considered, particularly in patients with sepsis or leukemia. Peripheral blood smears, platelet count, thrombin time, fibrin degradation products, fibrin monomers, and D-dimer levels are all useful in confirming the diagnosis. Treatment of disseminated intravascular coagulation consists of correction of the underlying disease and supportive care. If hemorrhagic manifestations are present without major thrombosis, fresh frozen plasma may be indicated. Liver disease with decreased synthetic capacity may also result in an elevated PT and PTT refractory to vitamin K.

#### *Evaluation of Anesthetic Risk of an Anterior Mediastinal Mass*

Respiratory collapse on induction of general anesthesia is a well-recognized complication of an anterior mediastinal mass ( Fig. 12-1). Identification of which patients are at significant risk remains a major challenge. Orthopnea, respiratory stridor, and wheezing are all ominous signs of significant major airway obstruction ( Fig. 12-2). Several patients with no respiratory symptoms, however, have been reported to develop major respiratory complications. [17]

**FIGURE 12-1. A:** An 11-year-old girl presented with a several week history of cough and dyspnea on exertion and a 3-day history of puffy eyes and orthopnea. The chest radiograph reveals a large anterior mediastinal mass and a right pleural effusion. **B:** Computed tomogram showed a tracheal area that was 82% of predicted. **C:** However, scans obtained lower in the chest revealed significant narrowing of both bronchi. This finding probably explains the marked reduction in her peak expiratory flow rate, which was 42% of predicted while sitting and only 24% of predicted in a supine position. The diagnosis of lymphoblastic lymphoma was established by aspiration of her pleural effusion.

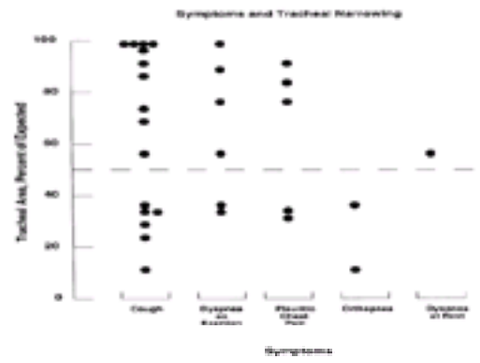

**FIGURE 12-2.** Correlation of symptoms and tracheal areas from a cohort of 42 children and adolescents with an anterior mediastinal mass. (From Shamberger RC, Holzman RS, Griscom NT, et al. CT quantitation of tracheal cross sectional area as a guide to the surgical and anesthetic management of children with anterior mediastinal mass. J Pediatr Surg 1991;26:138–142, by permission of the publisher, W.B. Saunders, Co.)

Computed tomography (CT) is useful in defining the cross-sectional area of the trachea, and a reproducible technique for defining the tracheal area has been published.[18,19 and 20] The cross-sectional area is measured from the CT slices showing the trachea at its narrowest dimension. The percentage of narrowing is then calculated by comparing the measured area with established standard values. [21]

The use of pulmonary function tests in evaluating children with an anterior mediastinal mass is also important. The predominant distortion of the flow loop for intrathoracic obstruction is a marked reduction in the maximum expiratory flow rate. For extrathoracic obstruction, it is a reduction of the maximum inspiratory flow rate. A fixed lesion usually produces an equal reduction of the inspiratory and expiratory peak flows. The high-flow portion of the forced expiratory loop near total lung capacity, best represented by the peak expiratory flow rate (PEFR), is the first to be distorted.

The PEFR can be easily obtained in patients using a hand-held device. A prospective evaluation of pulmonary function and tracheal area in 31 children with mediastinal masses was performed before 34 surgical procedures.[22] The tracheal area (as a percent of the predicted area) was determined by CT. In this study, criteria for administration of local anesthesia were either a tracheal area of less than 50% of predicted or a PEFR of less than 50% of predicted. All children administered anesthetics following these guidelines had an uneventful intraoperative course ( Fig. 12-3). The study did not prove that children with a PEFR of less than 50% of predicted would experience respiratory collapse with general anesthesia, because all children who met this criterion were excluded from receiving general anesthesia. It did confirm, however, that general anesthesia could be safely used in children who met the minimum criteria of PEFR and tracheal area of greater than 50% of predicted. As treatment began and the masses shrank, the pulmonary function tests and total lung capacity improved.

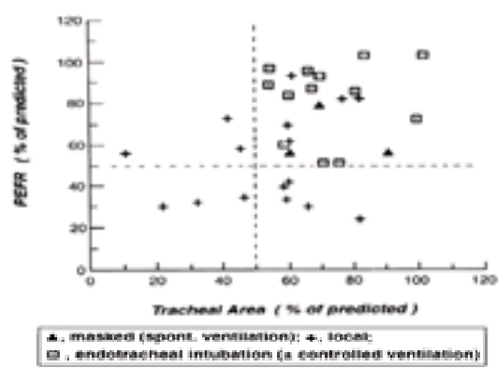

**FIGURE 12-3.** This graph shows the correlation between peak expiratory flow rate (PEFR) and tracheal area in a cohort of 31 children prospectively evaluated with an anterior mediastinal mass. Children with PEFR and tracheal area less than 50% of predicted, to the left of and below the dashed lines, all received local anesthetic and did well. Those children with PEFR and tracheal area greater than 50% of predicted received predominantly general anesthesia and did well. The five children with tracheal area greater than 50% of predicted, in the lower right box, might have been considered for general anesthesia if tracheal area was the only parameter considered to assess risk. Although the study could not demonstrate that these children would have had anesthetic problems, it did confirm that these parameters (greater than 50% of PEFR and tracheal area) were safe for the administration of general anesthesia. (From Shamberger RC, Holzman RS, Griscom NT, et al. Prospective evaluation by computed tomography and pulmonary function tests of children with mediastinal masses. Surgery 1995;118:468–471, by permission of the publisher Mosby-Year Book, Inc.).

In patients with Hodgkin's and non-Hodgkin's lymphoma (NHL) who had their pulmonary status evaluated, those with NHL appeared to be more impaired. [23] Respiratory symptoms were more common in the children with NHL than in those with Hodgkin's disease. The pulmonary function tests were also worse in the NHL cohort, and these tumors were shown to account for a disproportionate number of the larger masses. A correlation between the size of the mass and the impairment in pulmonary function was also noted.

Children will inevitably be encountered with significant respiratory compromise that require biopsy, but will not tolerate a general anesthetic. The presence of extrathoracic tissue for biopsy, particularly cervical lymphadenopathy, should be sought in all cases, but in some children it will be entirely lacking. It was demonstrated in the late 1990s that children with lymphoblastic lymphoma have a significantly higher incidence of an associated pleural effusion than in children with Hodgkin's disease.[24] This study has also demonstrated that aspiration of the effusion was helpful in providing a diagnosis of lymphoblastic lymphoma in all three children in whom it was performed. The diagnosis of T-cell lymphoblastic lymphoma has also been established by immunocytochemical studies of pleural fluid in two childhood cases presenting with strictly intrathoracic lesions. [25] Cytogenetic evaluation of cells obtained from pleural fluid can be helpful and diagnostic as well. The (t 8; 14) (q 24; q11) translocation is particularly associated with T-cell lymphoblastic leukemia and the related T-cell lymphoblastic lymphomas, and its identification will

facilitate their diagnosis.[26] Immunophenotyping of the cells obtained from pleural fluid can also show a predominance of T- versus B-cell markers, supporting the diagnosis of lymphoblastic lymphoma.

In children with significant respiratory compromise and no pleural effusion for aspiration and no extrathoracic disease, then either an intrathoracic biopsy under local, a percutaneous radiographically guided needle biopsy, or preliminary treatment with radiotherapy with shielding of an area for future biopsy must be performed. Needle biopsies are often successful in establishing a diagnosis of NHL, but are less helpful in cases of Hodgkin's disease. At our institution, local biopsies using a transthoracic anterior thoracotomy (Chamberlin procedure) have been performed successfully in four children under local anesthetic as young as 10 to 12 years of age. This can be done with the children in the semiupright position with spontaneous ventilation. The partially upright position will maximize the compromised respiratory function, as has been shown in the previous studies of pulmonary function.[22] Spontaneous ventilation minimizes collapse of the trachea by the negative pressure exerted by the chest wall. By following these guidelines for the use of general or local anesthesia, and the biopsy techniques described, a safe biopsy can be obtained on essentially all children and adolescents with an anterior mediastinal mass ( Fig. 12-4).

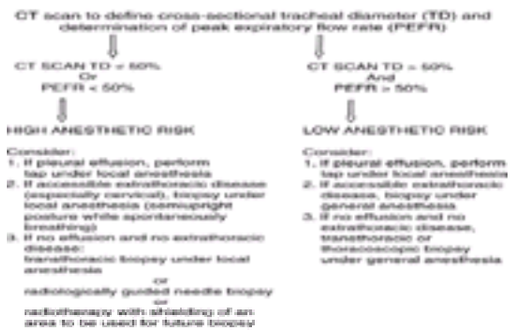

**FIGURE 12-4.** Algorithm for management of a child or adolescent presenting with an anterior mediastinal mass. CT, computed tomography.

### *Management of Pheochromocytomas*

Pheochromocytomas in children generally present with hypertension and associated symptoms.[27] Once the diagnosis is confirmed by a 24-hour urine collection for catecholamines and localization is performed, surgical removal is the definitive therapy. The principles of preoperative management are blood pressure control and the repletion of intravascular volume. Alpha-adrenergic blockade should begin at least 1 week before the surgery and is usually accomplished through the use of phenoxybenzamine. This is a long-acting alpha-adrenergic antagonist that is administered orally and is usually well tolerated by children. The usual starting dose for phenoxybenzamine is 0.25 mg per kg per day divided into a twice-a-day dose. The amine synthesis inhibitor metyrosine may be effective in children with hypertension unresponsive to phenoxybenzamine. The intravenous administration of phentolamine, with its short half-life, may on occasion also be useful in the control of bouts of hypertension. Beta-adrenergic blockade should be reserved for the treatment of persistent sinus tachycardia and arrhythmias associated with prior alpha-blockade and should never precede alpha-blockade. Adequate intravascular volume expansion is required preoperatively, as patients with pheochromocytoma often manifest reduced intravascular fluid and decreased red cell mass. The surgical removal of the pheochromocytoma is coincident with a drop in circulating catecholamines and possible hypotension, which may require further fluid administration. Conversely, the induction of anesthesia or the manipulation of the tumor(s) during resection can result in hypertensive episodes that are best treated with intravenous sodium nitroprusside.

## CANCER SURGERY

### Staging

It is critical to establish the correct stage of a tumor for optimal treatment of pediatric solid tumors. All protocols are based on stage of the tumor, which determines such factors in treatment as use and extent of radiotherapy and intensity of chemotherapy. In an era when cure can be achieved in the majority of patients, efforts to limit therapy to minimize the long-term sequela of treatment assume a prominent role. Correct staging is essential to our ability to minimize therapy and yet maximize cure. It has been demonstrated in several tumors that treatment of children based on inadequate or incorrect staging results in an increased incidence of relapse.[28,29] Only in the management of Hodgkin's disease has surgical staging decreased in importance as systemic therapy has been uniformly used.

A unique staging system is used for each of the solid tumors, and these will be presented in the appropriate chapters. It is important to note that these staging systems are not static tools, but that they have evolved over time as the significance of specific criteria for staging and treatment have been established. Hilar lymph node involvement in Wilms' tumor was initially considered as a criterion for stage II in the initial two National Wilms Tumor Study Group (NWTSG) protocols. Based on the demonstrated increased incidence of local recurrence in children with hilar lymph node involvement in the National Wilms Tumor Study-2, hilar lymph node involvement became a criterion in subsequent studies for stage III.[30,31] A new staging system for neuroblastoma, the International Neuroblastoma Staging System (INSS), was created in the 1990s by a committee of international experts on neuroblastoma based on the results of prior studies.[32] The treatment for neuroblastoma has progressed even further of late so that not only stage, but the biologic markers of the tumor now determine the intensity of treatment in many protocols.[33]

The surgeon is critical to the proper assignment of stage. A surgical staging system is used for most tumors. In these systems, the extent of residual disease after resection as well as lymph node involvement define the stage. In Wilms' tumor, lymph nodes must be sampled from not only the perihilar region, but from along the aorta or vena cava to adequately stage the child. It is of note that it has been well established in Wilms' tumor that assessment of lymph node involvement by gross inspection has a very poor correlation with the histology of the node. Othersen and his colleagues demonstrated a false-negative rate of 31.3% and a false-positive rate of 18.1% in a prospective series.[34] In a similar review by Jereb and associates, a false-positive rate of 72% and a false-negative rate of 7% occurred in a series of International Society of Paediatric Oncology (SIOP) patients.[35] It was demonstrated in a more recent review from NWTS-4 that an increased incidence of local recurrence occurred in children in whom lymph node sampling was not performed. The recurrence rate was actually higher than that of children with hilar lymph node involvement who had been appropriately treated.[28] The reason for the increased local recurrence was presumed under treatment of the children; the increased risk of recurrence occurred primarily in children with stage I disease who receive minimal chemotherapy and no radiotherapy.

The new INSS is also a surgical staging system in which the size of the tumor, extent of residual disease, and involvement of ipsilateral and contralateral nonadherent lymph nodes define the stage.[32] Again, the gross assessment of lymph node involvement is not adequate for evaluation. Wilson and associates reported a sensitivity of 76% and a specificity of 77% for lymph node involvement by neuroblastoma based on gross inspection of the nodes.[36]

The staging of rhabdomyosarcoma is complex because of the multiple primary sites of involvement. Response of this tumor to therapy is very site specific. Rhabdomyosarcoma is staged on both tumor, node, metastases (TNM) and clinical group systems by the Intergroup Rhabdomyosarcoma Study (IRS). The TNM system is thought to best define the pretreatment extent of disease and allow comparison between results of various studies.[37] The clinical group system is a surgical staging system in which the extent of resection and the presence of nodal involvement are prime components. An initial incisional biopsy should be performed in most cases of suspected rhabdomyosarcoma. The biopsy site and direction of the incision should always be planned with future resection in mind. Injudicious attempts at initial resection of an extremity lesion, leaving tumor at the margins of resection, can greatly complicate future resection.[38]

The need for lymph node biopsy in rhabdomyosarcoma is determined by the primary site. Children presenting without evidence of distant metastases have an overall 10% incidence of lymphatic spread. The frequency is highest for primary lesions arising in the prostate (41%), paratesticular (26%), and genitourinary sites (24%).[39] Extremity lesions have an intermediate frequency (12%) whereas nonorbital head and neck sites (7%), truncal sites (3%), and the orbit (0%) had the lowest frequency. In extremity and genitourinary sites, it is particularly important to establish lymph node involvement to allow appropriate design of radiation fields. A representative sample of lymph nodes from the draining nodal group should be biopsied in these lesions. A lymph node resection should not be performed, however, because it may produce lymphedema, which will complicate radiotherapy and subsequent surgical resection of the primary lesion.

Radiologic evaluation of lymph node involvement has been demonstrated to have a low sensitivity. A total of 121 boys with paratesticular rhabdomyosarcoma treated

on IRS III had a retroperitoneal lymph node dissection to evaluate nodal status. [40] Lymph nodes were assessed to be negative based on CT in 18% of the boys, 14% of whom had positive nodes when biopsy or retroperitoneal lymph node dissection was performed. Of the clinically positive boys, 94% were confirmed to be positive pathologically. Retroperitoneal relapse occurred in only 2 of the 121 boys, one of whom had pathologically negative lymph nodes and did not receive radiotherapy. Although CT was very accurate if lymph node abnormalities were identified, it was not extremely sensitive in identifying nodal involvement. In a subsequent study, Wiener and colleagues from the IRS have reported an increased incidence of retroperitoneal relapse in children treated during IRS IV. [29] In this study, the use of abdominal irradiation was based on thin-cut CT scans in 98% of cases as compared with children treated during IRS III in which 94% had retroperitoneal biopsy or lymph node dissection. A decrease in stage II disease (positive lymph nodes) was seen between IRS III and IV from 35% to 17%, with a corresponding decline in the use of irradiation. This resulted in a fourfold increase in retroperitoneal lymph node recurrence. This is another example of increased local failure resulting from inadequate staging.

Regional lymph node involvement is an extremely important prognostic variable in children with extremity rhabdomyosarcoma. In one study by Mandell and associates, excluding children with metastatic disease, survival in those without nodal involvement (11 of 12) was significantly better than in those with lymph nodes involved with tumor (one of ten; $p = .001$).[41] A similar finding to that in Wilms' tumor was demonstrated in children who had a distal extremity rhabdomyosarcoma with no evidence of distant metastasis. Survival was significantly better in those with biopsy-proven negative nodes than in those in whom nodes were not biopsied. [38] These findings highlight the essential nature of proper staging to achieve maximum survival.

### Biopsy

Use of a correct biopsy technique is critical to a child with a solid tumor. Fundamental considerations when selection of the method and incision are made must include (a) creation of an incision that may be incorporated in the future incision used for resection, (b) avoidance of contamination of an uninvolved body cavity, (c) avoidance of contamination of otherwise uninvolved lymphatic drainage, and (d) adequate staging must be accomplished at the time of biopsy if the child is to receive preoperative chemotherapy.

Some tumors will be appropriate to biopsy by percutaneous needle technique often with ultrasound guidance. Examples are chest wall tumors, metastatic neuroblastoma, and extensive hepatic tumors. The definitive diagnosis in these lesions can be obtained in most cases with adequate material obtained for both cytogenetic studies and biologic markers, which are critical to the complete characterization of solid tumors. [42,43] The primary tumors on which needle aspirate or core biopsy may fail to provide the diagnosis are the lymphomas, particularly Hodgkin's disease. In many of these cases, an incisional biopsy will be required to obtain a conclusive diagnosis.

In most extremity lesions in which the benign or malignant nature of the tumor is not known, a preliminary incisional biopsy is important. An injudicious attempt to remove the lesion with narrow margins may require a more extensive resection to obtain adequate margins than if the resection had been performed after an incisional biopsy. The importance of obtaining negative microscopic margins in rhabdomyosarcoma has been well established by Andrassy and his colleagues in the IRS.[39] A longitudinal incision is optimal in almost all extremity lesions. It will allow the scar to be easily removed when the definitive resection is performed. A transverse scar will require a larger amount of the skin to be resected.

Examples of avoiding contamination of an uninvolved body cavity at biopsy are Ewing's sarcoma of the chest wall and Wilms' tumor. Percutaneous or open biopsy of a chest wall Ewing's sarcoma will avoid the pleural cavity being contaminated as would occur if a thoracoscopic biopsy were performed. Contamination of the pleural cavity in most cases of Ewing's sarcoma will necessitate its irradiation. In most cases of Wilms' tumor, it is best to resect the primary without a preliminary biopsy. This will avoid potential extensive contamination of the abdominal cavity, which would advance the child to stage III and on NWTSG protocols would require the use of irradiation to the abdomen. The infrequent exceptions to this policy are discussed in the section Wilms' Tumor.

An important example of avoiding contamination of an uninvolved lymphatic system occurs in boys with testicular masses. The vital importance of performing a transinguinal biopsy and not a transscrotal biopsy has been long stressed. A transinguinal approach allows proximal control for high ligation of the spermatic cord, which is the route of both lymphatic and hematogenous extension from the testes. A transscrotal approach will contaminate the scrotum, which has lymphatic drainage via the inguinal and iliac system. This approach also does not provide access to the proximal spermatic cord for high ligation.

## PREOPERATIVE ADJUVANT THERAPY

The role of preoperative adjuvant therapy has been established based on completed studies, and its use is very disease specific. Several important questions must be addressed when preoperative therapy is considered. First, will information regarding stage or histology be lost, adversely affecting ultimate therapeutic decisions? Second, will children receive chemotherapy who do not otherwise require it? Third, will adjuvant therapy facilitate surgical resection and decrease the risks of complications? These issues are considered for several of the solid tumors.

### Wilms' Tumor

The two principal multiinstitutional groups with therapeutic trials in Wilms' tumor have adopted quite different approaches to the use of adjuvant therapy. Primary nephrectomy has been recommended for patients with Wilms' tumor by the NWTSG. In contrast, initial chemotherapy has been used extensively by members of the SIOP. The potential benefit of preoperative therapy must be balanced against the disadvantages. Treatment without any biopsy has been difficult to support when both NWTSG and SIOP series have reported a 7.6% to 9.9% rate of benign or other malignant diagnosis in children with a prenephrectomy diagnosis of Wilms' tumor.[44,45 and 46] Zuppan and associates have shown that the histologic diagnosis after preoperative treatment in a group of children followed on NWTSG studies did not appear to have been significantly distorted by pretreatment, but loss of evidence of lymph node involvement has been of significant concern. [47] “Downstaging” of tumors was seen in two consecutive but nonrandomized SIOP studies in which the proportion of low-stage disease increased after preoperative therapy when compared with earlier studies using primary surgery. These findings suggested that the preoperative treatment significantly decreased the apparent stage of the children.[48] The proportion of stage I patients at surgery rose from 22% to 48% after chemotherapy. The third SIOP study of Wilms' tumor randomized the use of local radiotherapy (20 Gy) in children treated preoperatively with chemotherapy (vincristine and dactinomycin) who had stage II lymph node–negative disease at resection. All children received vincristine and dactinomycin for 38 weeks. A high rate of stage I tumors (52%), was found in this study, with a low frequency of ruptures (7%). The study was terminated after randomization of 123 children because of an increased incidence of abdominal recurrence during the first year of follow-up in the children not receiving radiation (6 of 59 versus 0 of 64). [49] This suggested that prenephrectomy treatment altered the pathologic findings, which would have led to a diagnosis of stage III disease (i.e., lymph node involvement) and to the standard administration of local irradiation. The absence of this finding in the posttherapy specimens, however, did not obviate the apparent need for radiotherapy to prevent local recurrence.

A major driving force for the use of preoperative therapy by SIOP was the high rate of operative tumor rupture in their early series employing primary resection of the tumor. The rupture rate decreased from 33% (20 of 60) to 4% (3 of 72) with preoperative abdominal irradiation (20 Gy) in the first randomized SIOP study. [45] It must be noted, however, that 33% is an extremely high frequency of rupture. Survival was not affected, and the incidence of local recurrence was not reported. In NWTS-1 and -2, operative rupture occurred in 22% and 12% of children, respectively. [44,50] In a subsequent SIOP randomized study, the rate of rupture was essentially the same for children receiving abdominal irradiation (20 Gy) and actinomycin D (9%, 7 of 76) and those receiving vincristine and actinomycin D (6%, 5 of 88). [45]

A second consideration in the use of preoperative chemotherapy in Wilms' tumor has been whether it will allow the safe performance of partial nephrectomy in some cases. This has been evaluated in several centers. McLorie and associates in Toronto obtained percutaneous biopsy in 37 children with Wilms' tumor and then administered multi-agent chemotherapy for 4 to 6 weeks. A partial nephrectomy was then performed in nine children (four with unilateral and five with bilateral tumors).[51] Two children experienced intraabdominal relapse. Only 4 of the 30 unilateral tumors (13.3%) were amenable to a partial nephrectomy. Another analysis of the feasibility of partial nephrectomy was performed at St. Jude Children's Research Hospital. [52] Preoperative computed tomograms (CT scans) of 43 children with nonmetastatic unilateral Wilms' tumor were reviewed retrospectively. Criteria to allow partial nephrectomy were involvement by the tumor of only one pole and less than one-third of the kidney, a functioning kidney, no involvement of the collecting system or renal vein, and clear margins between the tumor and surrounding structures. Utilizing these criteria, only 2 of 43 scans (4.7%) suggested that partial nephrectomy was feasible.

The primary concern regarding use of preoperative chemotherapy, as reported in the studies of Cozzi and Moorman-Voestermans and their colleagues, to shrink small tumors to allow partial nephrectomy is that these children may be curable by surgical resection alone without subjecting them to the toxicity of additional treatments.[53,54]

Preoperative treatment of Wilms' tumor is generally accepted in certain instances. These include the occurrence of Wilms' tumor in a solitary kidney, bilateral renal tumors, tumor in a horseshoe kidney, a massive tumor that would require resection of other involved organs, and respiratory distress from extensive metastatic tumor. Pretreatment biopsy should be obtained. The aim of treatment before surgical resection in the bilateral tumors and when tumor occurs in a solitary kidney is to preserve maximum renal tissue and function. In the NWTSG review of the 55 children who developed renal failure treated on NWTS-1 to -4, 39 had bilateral tumor involvement. Increasing efforts to preserve renal parenchyma in bilateral cases in the series of NWTSG studies resulted in a decline in the incidence of renal failure from 16.4% in NWTS-1 and -2 to 9.9% in NWTS-3 and 3.8% in NWTS-4. [55] In most cases, preliminary treatment after biopsy and staging produces a significant decrease in size of the tumor and facilitates resection of the tumor with preservation of a portion of the kidney. One hundred and thirty-four kidneys in 98 children with bilateral Wilms' tumors were managed with renal salvage procedures during NWTS-4. [56] Complete resection of gross disease was accomplished in 118 kidneys (88%). A higher incidence of positive surgical margins (16%; 19 of 134) and local tumor recurrence (8.2%; 11 of 134) was seen in this group of children than in those with complete nephrectomy. This was justified, however, by the desire to preserve renal tissue and thus avoid renal failure. Overall, portions of 72% of the kidneys were preserved, and the 4-year survival rate was 81.7%.

A final indication for preoperative therapy in Wilms' tumor may be in children with intravascular extension of the tumor. Some studies have demonstrated a decreased incidence of complications in children with atrial extension receiving preoperative chemotherapy compared with children with primary surgical resection. [57]

**Neuroblastoma**

The surgical approach to neuroblastoma is determined to a great extent by the size and location of the tumor. Many low-stage tumors with favorable biologic markers will be cured by surgery alone, even with positive microscopic margins or residual tumor. [58] Regrettably, the vast majority of children with neuroblastoma presents with large stage 3 primaries that cross the midline or with metastatic disease. Consideration of preoperative adjuvant therapy is appropriate in these cases. All of these children will require adjuvant chemotherapy, so its administration before resection will not subject them to treatment they would not otherwise receive. Biopsy and staging can generally be achieved with limited surgical procedures and radiographic demonstration of distant metastasis if they are present. It is critical that adequate tissue be obtained to allow evaluation of the histology and biologic markers to fully characterize the tumor.

Large primary tumors often encircle critical vessels such as the celiac axis, the superior mesenteric artery and vein, and the renal vessels. Although two studies have shown no difference in the surgical complication rate between initial and postinduction resection, [59,60] others have demonstrated a higher incidence of complications, including nephrectomy, in the group undergoing initial resection. [61,62,63] and [64] Preoperative chemotherapy decreases the vascularity and friability of the tumor and facilitates resection, particularly in developing a dissection plane between the tumor and the great vessels ( Fig. 12-5).[65] Preoperative therapy may be of particular importance to preservation of renal function. Many current protocols for children with stage 4 disease have significant nephrotoxicity, and loss of a kidney from surgery can significantly limit the intensity of therapy. A multiinstitutional review of children treated over an 11-year interval demonstrated a 14.9% (52 of 349 children) incidence of nephrectomy or renal infarction during surgery for local control. [64] There was a 25% incidence among those with initial resection (29 children) and a 9.9% incidence in the post-chemotherapy resections (23 children). In children undergoing initial resection, the risk of nephrectomy was more than twice that compared with those undergoing resection after chemotherapy ($p$ = .012). Hence, the approach for neuroblastoma regarding primary therapy of large lesions is quite different from that in Wilms' tumor.

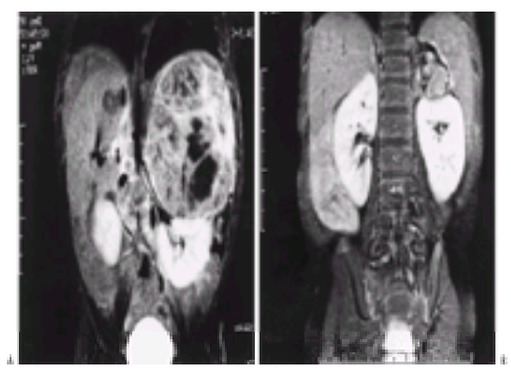

**FIGURE 12-5. A:** This magnetic resonance imaging scan of a 9-month-old boy with neuroblastoma who presented with a palpable left abdominal mass shows a large left adrenal tumor. The child was not found to have metastatic disease, but did have N- *myc* amplification. **B:** Dramatic response of the tumor to adjuvant chemotherapy is shown in the follow-up scan.

**Ewing's Sarcoma**

Another tumor in which preoperative adjuvant chemotherapy has been found to be of benefit is Ewing's sarcoma/primitive neuroectodermal tumor. Adjuvant therapy is required for all children with this diagnosis because of the very high incidence of local and distant relapse without such therapy. Its use preceding surgery has been of benefit in decreasing the size of the tumor as well as its friability and extremely vascular nature ( Fig. 12-6).[66] Recent multiinstitutional studies of children with chest wall primaries have demonstrated a major benefit of preoperative therapy. Complete resection with negative pathologic margins is more frequently achieved in children who have received preoperative chemotherapy. [67] This is of particular importance for children with chest wall primaries because they can then avoid the use of radiotherapy to the chest with its attendant risks of pulmonary and cardiac injury.

**FIGURE 12-6. A:** Chest radiograph of a 14-year-old girl with Ewing's sarcoma, who presented with a cough, reveals a mass in the apex of the right chest. **B:** Computed tomography showed a large mass of varying density without bone erosion. Biopsy was achieved by percutaneous technique. The chest radiograph after 2 months of therapy was normal, and computed tomography **(C)** showed a small residual soft tissue mass (*arrow*). No viable tumor was found in the mass on pathologic examination after resection.

**Hepatoblastoma**

Resection remains critical in the cure of hepatoblastoma. Even with current multi-agent chemotherapy, cure is rarely accomplished without successful resection. There have been multiple reports from single institutions describing the benefit of preoperative doxorubicin or cisplatin–based chemotherapy converting “unresectable” tumors into tumors that can be safely resected ( Fig. 12-7).[68,69,70,71] and [72] Several prospective multiinstitutional trials have also supported the role of adjuvant chemotherapy in shrinking large “unresectable” hepatoblastomas. King and associates reported the experience from the Children's Cancer Group protocol,

which included both hepatoblastoma and hepatocellular carcinoma.[73] In that study, 34 children were deemed to be “unresectable.” Twenty had successful resection after preliminary therapy. There was no difference in survival between children resected initially and those with delayed resection, but a higher incidence of surgical complications was seen in children with delayed resection. In a similar study reported by Reynolds and colleagues from the Pediatric Oncology Group, 37 children with “unresectable” tumors received preoperative therapy.[74] Twenty-nine of those responded to chemotherapy with a cisplatin-based regimen, and 26 underwent delayed surgical resection. An increased incidence of surgical complications was again seen in those children with delayed resection, but the overall survival of the primary resection and delayed resection groups remained equivalent. Results from the German Cooperative Pediatric Liver Tumor Study were reported by von Schweinitz and coauthors.[75] Chemotherapy reduced the size of the tumor in 33 of 37 children (89%) with hepatoblastoma. This study identified a potential risk to a prolonged course of preliminary chemotherapy. Drug resistance developed in 6 of 11 children treated with four or more courses before resection. It was demonstrated by regrowth of the primary tumor and rise in the serum alpha-fetoprotein (AFP) levels.

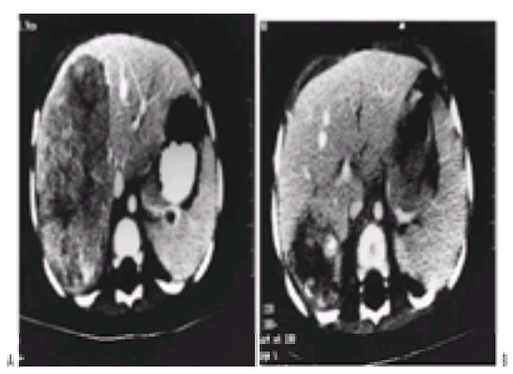

**FIGURE 12-7. A:** Computed tomogram of a 16-month-old boy who presented with a palpable upper abdominal mass. Percutaneous biopsy confirmed the diagnosis of hepatoblastoma. **B:** Tomogram after four cycles of cisplatin-based chemotherapy revealed excellent response to treatment; a formal right hepatic lobectomy achieved complete resection of the tumor.

Postoperative chemotherapy will be utilized in most children with hepatoblastoma because of the risk of distant relapse. Preliminary treatment should therefore be considered after biopsy in a child with a large primary that the surgeon thinks would present a significant risk for resection. Preoperative therapy should not be continued, however, beyond the third or fourth course if possible because of the potential development of drug resistance.

## MINIMALLY INVASIVE SURGERY

Over the past decade, minimally invasive surgical techniques using laparoscopic and thoracoscopic techniques have become common practice. Improved cameras, new trocar systems, and specifically designed instruments now allow a wide spectrum of operations to be performed without the use of large thoracotomy or laparotomy incisions. In the realm of pediatric surgical oncology, these methods have been most broadly applied to biopsies and the excision of selected small masses. A CT scan or magnetic resonance imaging is very helpful in planning the appropriate surgical approach. Oncologic surgical principles, such as adequate exploration, complete excision of a mass with an appropriate margin, and minimizing the risk of a tumor spill, are still paramount. Although rare and possibly technique-related, trocar site tumor implantation has been reported.[76,77]

Thoracoscopic surgery is usually performed under general anesthesia in a full lateral position to allow for visualization of all the lobes of the lung. Nodules that are located peripherally in the lung, along the parietal pleura, or on the diaphragm are particularly suitable for biopsy. In larger patients, a double lumen endotracheal tube allows for selective lung ventilation and, hence, permits more facile surgery. Thoracoscopic surgery to excise small tumors of the lung is frequently accomplished with the aid of an intracorporeal stapling device. Although thoracoscopy is often suitable for the removal of secondary lung tumors, osteogenic sarcoma metastatic to the lung is usually best managed by standard thoracotomy. This is because thoracoscopy and CT scan often miss small intraparenchymal osteogenic sarcoma secondaries that may be easily palpated. The mediastinum is also accessible by minimally invasive techniques and excisional or incisional biopsies, or thoracoscopically guided needle biopsies may be performed.

Laparoscopic surgery is performed under general anesthesia and relies on $CO_2$ insufflation of the peritoneal cavity to permit visualization. Staging laparoscopy and biopsies of primary and secondary tumors have frequently been performed. If oncologic principles are not compromised, tumor resection may also be considered in selected cases. Laparoscopic splenectomy, nephrectomy, adrenalectomy, lymph node dissection, and colectomy have all been performed in patients with malignancies. At present, no large-scale prospective trials to evaluate these approaches have been completed.

## SPECIFIC TUMOR CONSIDERATIONS

### Wilms' Tumor

Resection continues to play a major role in the local control of Wilms' tumor. The importance of complete staging has already been stressed. In most cases, except those previously discussed, the initial management of a renal mass is nephrectomy. Despite the fact that most Wilms' tumors present as a large mass, safe resection is generally feasible. Wilms' tumor, in contrast with neuroblastoma, is less likely to directly invade surrounding organs, complicating resection. It is important that an appropriately sized transverse upper abdominal or thoracoabdominal incision be used. A flank incision does not allow examination of the contralateral kidney or adequate lymph node biopsy, and a small incision in all too many cases results in rupture of the tumor and requires subsequent abdominal irradiation.

The vital importance of lymph node biopsy has already been stressed. There is no role, however, for an extensive lymph node resection, as this has not decreased the incidence of local recurrence or improved long-term, event-free survival.[34,35] One additional consideration during resection of Wilms' tumor is intravascular extension. This has been documented to occur in 4.1% to 6.0% of children treated on NWTS-3 and-4, respectively, and it should always be suspected.[78] Preoperative imaging should be evaluated for evidence of intravascular extension, but it is not invariably found. Before ligation of the renal vein, it should be palpated to make certain that there is not intravascular extension of the tumor that might embolize with ligation of the vein. Second, if unexplained hypotension occurs during the course of nephrectomy, the possibility of a pulmonary embolism must always be entertained. Current recommendations from the NWTSG are that children with intravascular extension to the atrium or inferior vena cava extension to the level of the hepatic veins should have a biopsy of the tumor followed by chemotherapy before resection of the tumor.

### Neuroblastoma

Neuroblastoma is an enigmatic tumor in its clinical and biologic behavior; on the one hand, it is a tumor characterized by spontaneous regression, but, in contrast, it is commonly present in a clinical form resistant to all forms of antitumor therapy, with a result being little improvement in disease prognosis over the past several decades. The most frequent locations for neuroblastomas include the abdomen in suprarenal or paraaortic sites and, less frequently, in a thoracic paraspinal location or along the cervical sympathetic chain. Pelvic and retro-orbital intracranial locations have also been reported as sites for this neural crest tumor. Neuroblastomas have a propensity to invade surrounding tissues, especially enwrapping nerves and vessels in the renal hilum and pancreatic areas, and in the paraspinal location there is a unique characteristic of this tumor to grow through vertebral foramina into the spinal canal itself.[79]

Clinical neuroblastomas are characterized by several unique features that may influence operative therapies. These tumors metabolize catecholamines and as a result excrete various markers of catecholamine metabolism, and therefore tumor activity, including vanillylmandelic acid or homovanillic acid, and quantitative ratios can indicate tumor differentiation and can impact on tumor prognosis. Such catecholamine marker excretion is used for mass population screening. Neuroblastomas also have the propensity to spontaneously differentiate, or they can be stimulated to differentiate from a malignant neuroblastoma into a benign ganglioneuroma. Such latter tumors potentially can occur anywhere a neuroblastoma might be found, but they most commonly are located in the thoracic paraspinal region. The most unusual behavior of neuroblastoma is its propensity for spontaneous regression. This predilection is seen in two unique tumor populations. First, there is the mass infant population neuroblastoma-screened patients in whom a high incidence of stage 1 tumors are found, which seem to have a characteristic “benign” and even

regressive pattern. A second group is the child typically younger than 1 year of age who presents with a primary tumor as well as evidence of tumor in the skin, liver, and bone marrow, the so-called Evans stage IVS. In approximately three-fourths of such patients, with or without treatment directed at the primary tumor, spontaneous regression of the neuroblastoma found in these sites occurs, and recovery and cure is the outcome. [2]

The role of operation in neuroblastoma remains controversial. Although complete resection of the tumor is associated with the best survival in patients with localized neuroblastoma, the role of operation may be less important in the care and treatment of most neuroblastomas. In fact, the value of complete tumor removal in localized neuroblastomas may be overestimated, as the ability to resect the tumor may be an expression of a favorable biology of the tumor with a propensity to either spontaneously regress or clinically behave less aggressively. [80] In fact, the mass screening findings of localized neuroblastomas as currently reported in Japan has resulted in a portion of such patients being treated by observation only, without resection, and the outcomes seem quite favorable. [81] The role of operation is uniquely beneficial in selected patients with compressive symptoms, including those with spinal cord compression, mediastinal distortion, celiac axis enwrapment, or even renal artery encasement with secondary hypertension. On rare occasion, hollow visceral compression results in symptoms of obstruction. Because more than one-half of the patients at the time of presentation with neuroblastoma have either advanced local or metastatic disease, multimodal therapy is an absolute requirement for the total management plan. Because the definitive treatment plan for neuroblastoma is influenced to a great degree by cytogenetics, tumor oncogene amplification, and histology, the role of an adequate surgical biopsy specimen to help define an appropriate treatment plan cannot be underestimated.

Though there is substantive experimental evidence that a variety of surgical adjuncts, such as electrocauterization or laser therapy, may be immune response enhancing for a tumor known to be potentially influenced by an augmented host tumor relationship, the benefit of such techniques to the removal of clinical neuroblastoma is less certain.[79] The application of minimally invasive surgery in the resection of neuroblastomas is in its infancy, and to date minimally invasive technique has largely been confined to a role for tumor biopsy from primary or metastatic sites and as an adjunct to tumor staging.

The principles of operative therapy for neuroblastoma are largely stage related ( Fig. 12-8). For INSS stage 1, a complete resection of localized neuroblastoma may be the only therapy required. Regional lymph nodes should be excised during operation for accurate staging, but adjacent normal organs should be spared. After complete operative resection, observation is the only required follow-up.

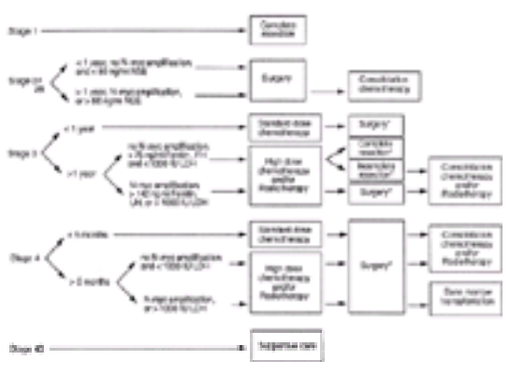

**FIGURE 12-8.** Schema for operative intervention in neuroblastoma. *Second look or delayed primary surgery. FH, favorable histology; LDH, lactic (acid) dehydrogenase; NSE, neuron-specific enolase. [Modified from Ishizu H, Ziegler MM. Neoplasms. In: Levine BA, Copeland EM, Howard RJ et al. (eds). Current practice of surgery. New York: Churchill Livingstone, 1992;3.]

For INSS stage 2A and 2B, such localized neuroblastomas are also treated to achieve complete operative resection. Because of microscopic residual disease, however, second look or even delayed primary operation may be planned after tumor reduction with chemotherapy or radiation therapy, or both. Lymph node resection is beneficial for reducing tumor burden as well as precisely staging the disease, and depending on associated risk factors, such as age, N- *myc* amplification, histology, serum ferritin, and neuron-specific enolase, adjunctive chemotherapy will likely be considered.

For INSS stage 3 tumors, chemotherapy is often the first treatment, and delayed primary or second look resection may be scheduled after initial therapy. At delayed operation, total tumor removal or debulking (cytoreduction) may be done, taking care to preserve adjacent normal organs. Almost three out of four localized neuroblastomas previously deemed unresectable will be able to be resected after induction chemotherapy. [82]

For INSS stage 4 metastatic neuroblastomas, aggressive multimodal therapy is indicated to improve an otherwise dismal outcome. Primary or delayed resection is of uncertain benefit in metastatic neuroblastoma. There are data that suggest a favorable benefit of complete resection of the primary tumor as well as involved regional lymph nodes, but there are also contrasting data that suggest no favorable impact on outcome of these resections. Cytoreduction seems preferable to biopsy alone, however, and surgical resection with removal of as much tumor as possible is clearly beneficial for those patients who are eventually treated by autologous or allogenic bone marrow transplantation after high-dose chemotherapy and radiation. [83]

Perhaps most controversial is the treatment of INSS stage 4S. This tumor group may best be observed only with the use of supportive therapy while awaiting spontaneous regression. Because selected infants present with life-threatening hepatomegaly and intraabdominal compression, either minimal resection and/or auxiliary procedures, such as operative placement of a silastic pouch on the abdominal wall to expand the cavity, may be indicated to control diaphragmatic elevation and respiratory distress or vena caval obstruction. [84] Such palliative procedures carry an extensive risk of infection and local wound problems that may further complicate the clinical course of infants with this rapidly changing tumor, which, eventually, if time can be spared, will spontaneously regress in three out of four cases. In series comparing resection versus no resection of the primary tumor in stage 4S patients, little difference in outcome is noted; but what is less clear is the role of aggressive operation for those stage 4S patients with adverse tumor markers. Finally, for patients with localized neuroblastoma found by neonatal screening, observation alone may be most appropriate operative therapy for stage 1 disease, and a current multiinstitutional prospective study is evaluating this hypothesis.

Neuroblastomas that penetrate the spinal canal or that enwrap vascular structures have to be individualized in their operative management. When children present with spinal cord compression, immediate spinal cord decompression is indicated by either laminectomy or radiation therapy. Transthoracic resection of the posterior paraspinal component of such tumors requires the removal of the majority of tumor with an effort to remove its intravertebral dumbbell extensions in a conservative yet as complete a fashion as is possible. Certainly, intraspinal bleeding or cerebral spinal fluid leak must be avoided. Residual foraminal disease typically does not carry an adverse prognosis. Those tumors enwrapping vascular structures, such as the celiac axis or renal vessels, or both, are best treated not by en bloc removal with vascular reconstruction, but rather by tumor separation, division, and vascular dissection with preservation such that the tumors at times are removed piecemeal. This operative technique is based on the premise that such patients require adjunct therapies for disease control and cure after their operation.

Tumor outcomes (Fig. 12-8) are largely a product of tumor stage, patient age, and various biochemical and oncogenic markers. Other than those exceptions noted, there is not substantive data available suggesting the advantage of one operative technique versus another with an influence on tumor outcome because operative resection is coupled with multimodal antitumor therapy. Tumor resection of massive celiac axis or pararenal neuroblastomas, or both, at times results in the unavoidable removal of an adjacent kidney, a not preferred outcome in patients eventually facing bone marrow transplantation. Outcomes for patients after resection of high intrathoracic paraspinal neuroblastomas almost routinely includes the development of an ipsilateral Horner's syndrome because tumor removal requires resection of the sympathetic chain and the stellate ganglion. [85] Whether there is advantage in patient outcomes from the application of minimally invasive surgical removal of localized neuroblastoma is speculative, but early reports suggest shorter lengths of stay and less perioperative morbidity when such techniques are applied.

**Hepatoblastoma**

Malignant liver tumors in infancy and early childhood typically are hepatoblastomas, whereas in older adolescents or those children with metabolic derangement or postviral illness, the tumor histology is typically a hepatocellular carcinoma. Despite further refinement in adjuvant therapies, the goal of operation remains clean-margin tumor resection if any opportunity for cure is to be achieved. Therefore, once the tumor in the liver is found, the initial main step is accurate preoperative imaging assessment to determine the optimal operative approach.

For tumor volumes and location that encroach or cross the anatomic plains that define lobectomy or extended lobectomy, or for multicentric bilobar tumors, preoperative chemotherapy may be optimal.[86,87] For resistant tumors, innovative therapies have included intraarterial chemotherapy or even chemoembolization. [88,89]

Hepatic lobectomy is the preferred operation for primary liver tumors, and though technically more exacting, an extended right or left lobectomy (trisegmentectomy) may also be indicated.[90,91] Nonanatomic resections that cross anatomic plains at times become a technical necessity when removing large tumors deep within the substance of the liver and for postresection locally recurrent disease. The need for perioperative chemotherapy and the extent of resection, at least in experimental animals, does not influence postoperative liver regeneration. [92] Finally, for those primary or recurrent tumors not amenable to resection, yet whose disease extent is confined to the liver, total hepatectomy followed by liver transplantation is a therapeutic alternative, though eventual disease-free outcomes are suboptimal. [93]

**Rhabdomyosarcoma**

Rhabdomyosarcoma is a tumor of mesenchymal origin that can present in almost any site but most commonly is found in the head and neck (35%), genitourinary tract (26%), and limbs (19%).[94] Approximately 250 new cases of pediatric rhabdomyosarcoma are diagnosed annually in the United States. The embryonal pathologic type is the most common form of rhabdomyosarcoma and in general has a better prognosis than the alveolar type. Although histology is an important predictor of survival, tumor site and the presence of distant metastases are even more significant determinants. Tumors of the orbit, superficial head and neck, testes, vagina, and uterus all have 4-year survivals of approximately 90% whereas tumors of the parameningeal area, bladder, prostate, and limbs have substantially lower survival rates that approximate 65%.

The successful treatment of this diverse group of tumors often requires multimodal therapy, including chemotherapy, radiotherapy, and surgery. The tissue diagnosis of rhabdomyosarcoma is usually made by surgical biopsy, although needle biopsy is considered in selected cases if surgical biopsy is deemed to have too high a morbidity. Surgical biopsy ensures that adequate tissue is available for histochemical and cytogenetic analysis. If the tumor is present in an extremity, care must be taken to place the initial biopsy along the long axis of the limb to allow for subsequent excision with an adequate margin. Effective surgical therapy of tumors in most sites consists of complete resection of the malignancy with pathologic margins that are free of tumor. If microscopic residual remains after an attempted curative resection, re-excision does appear to proffer a survival benefit. [95,96] Neoadjuvant chemotherapy followed by surgery may sometimes be used advantageously to preserve organ function and cosmesis while allowing for adequate oncologic surgery. Debulking procedures are not indicated.

**Germ Cell Tumors**

Pediatric germ cell tumors are rare. They occur in the gonads (testes and ovaries) as well as extragonadal sites (sacrococcygeal, anterior mediastinum, pineal gland, retroperitoneum, neck, and stomach), frequently elaborate serum markers (AFP and human chorionic gonadotropin), and with application of multimodal therapy, have a favorable outcome.[97] Germ cell tumors take their origin from the fetal yolk sac, and the produced lineage migrates to either the gonad or to the extragonadal sites noted. Teratomas, the most common germ cell tumor, contain all three embryonic layers; ectoderm, endoderm, and mesoderm. Though uncommon in the testes, teratomas are the most common ovarian germ cell tumor, and they are typically most prevalent in extragonadal sites, particularly the sacrococcygeal area. Teratomas are classified as mature or immature, the latter being further graded I to III based on the density of primitive neuroepithelium.

Testicular germ cell tumors in prepubertal children are in aggregate infrequent, with the endodermal sinus tumors being the most common subtype. [97] Seminomas are typically more common in young adults, occurring both in normally descended testes or in undescended testes at an even higher incidence (ten to 30 times greater incidence).[98]

Mature teratomas are the most common ovarian germ cell tumor, and they are benign. In rare circumstances, peritoneal and omental implantation with mature glial tissue occurs (i.e., gliomatosis peritonei), but this is also a benign finding. [99] The most common malignant ovarian germ cell tumor is the AFP-secreting endodermal sinus tumor. Dysgerminomas, like their male counterpart seminomas, are more common in adolescents and young adults. Embryonal carcinomas are the least differentiated of the ovarian germ cell tumors. Choriocarcinoma and mixed tumors are even less common. Patients with a variety of intersex anomalies are at increased risk for developing a gonadoblastoma, a tumor capable of malignant transformation, and such Y-chromosome–bearing gonads are best removed to prevent such transformation, which increases in incidence with age.[100]

The extragonadal germ cell tumors account for almost two-thirds of pediatric germ cell tumors. Such teratomas vary from mature to various grades of immaturity, and transformation to frank malignancy is age related.[101]

The method of operative therapy for a solid testicular tumor requires a transinguinal approach and initial atraumatic occlusion of the cord structures. On delivery and inspection of the testis, enucleation of the mass is acceptable if a teratoma is suspected and proven by frozen section. In contrast, a radical orchiectomy would be done with ligation of spermatic cord structures at the internal inguinal ring along with subsequent retroperitoneal lymph node resection for a malignant testicular tumor. Chemotherapy would accompany all radical procedures for control of stage II, III, and IV tumors.

The standard operative approach for ovarian tumors is not dissimilar (i.e., gonadal sparing for teratomas and a progressively more aggressive approach for malignant tumors).[97] In the latter instance, the operation typically includes aspiration of ascites or peritoneal washings for cytology, peritoneal surface inspection and sampling for suspicious lesions, unilateral salpingo-oophorectomy, contralateral ovarian biopsy if suspicious (bilaterality most common for dysgerminoma followed by teratoma), omentectomy, and retroperitoneal lymph node sampling. Again, adjuvant chemotherapy is the rule for malignant tumors; its role in immature teratomas is less certain.[102]

The main operative challenge in extragonadal teratomas is dictated as much by their size and location as by their likelihood of associated malignancy. The sacrococcygeal teratomas may have a profound hemodynamic influence on the fetus, which may produce fetal hydrops and death. [103] *In utero* tumor ligation or ablation may be appropriate to prevent this outcome, whereas delay of delivery, if possible, to allow for further fetal development is best. [104] At resection, control of the blood supply via the middle sacral artery is most important to minimize intraoperative hemorrhage, but morbidity related to size and location (e.g., neurogenic bladder and rectal compression) remains a significant issue that likely cannot be prevented. [105]

Mediastinal germ cell tumors are typically mature teratomas, and they are best treated by resection. Rarely, when presenting in adolescence, such tumors may be malignant. The biggest operative challenge posed by anterior mediastinal tumors is their compression of either the trachea or superior vena cava.

Cervicofacial teratomas are very rare, but if sizable and located in a site that compresses the airway *in utero*, perinatal management becomes critical. In this scenario, the safe application of *ex utero* intrapartum treatment (EXIT procedure) can safely be applied, assure a secure airway, and permit safe neonatal excision. [106]

**Lymphoma**

The role of the surgeon in Hodgkin's disease and lymphoma is in most cases to establish the diagnosis by biopsy. In the past, staging laparotomy in which the spleen was removed, the liver was biopsied, and multiple abdominal lymph nodes were sampled was frequently used for children with Hodgkin's disease to provide the pathologic stage. One series showed that even with current imaging techniques, a change between the clinical and the pathologic stage occurred in 25% of children and adolescents in whom a staging laparotomy was performed.[107] Nonetheless, current Hodgkin's disease protocols are based primarily on clinical staging guidelines. It must be accepted that a significant percentage of children will be understaged using clinical staging, but with improved systemic chemotherapy and the rare use of radiotherapy as a single modality, this seems to be the sole disease in which accurate staging is now considered less important. It does make it exceedingly difficult, however, to compare series in which pathologic staging has been performed with those with clinical staging alone.

In the NHLs, surgery is also important for diagnosis. In the past, it had been claimed that resection of the primary tumor might improve the long-term survival of children with Burkitt's lymphoma. [108] Recent single and multiinstitutional studies, however, have refuted this claim. [109,110] Extensive surgery often results in surgical complications that delay the onset of treatment and often allow the regrowth of these rapidly dividing tumors. Anesthetic considerations for biopsy of children with mediastinal involvement of Hodgkin's or NHL are discussed in the section Evaluation of Anesthetic Risk of an Anterior Mediastinal Mass.

### Metastatic Disease

In selected pediatric cancers, surgery may be useful for the treatment of metastatic disease. If the primary tumor has been eradicated and no other sites of metastatic disease are evident, pulmonary metastases are excised in children with osteogenic sarcoma. A more favorable prognosis is present in patients with fewer than four pulmonary nodules and a complete resection of all pulmonary metastases. [111] As a practical point, the number of pulmonary metastases found on palpation at surgery often exceeds the number present on CT scan. The overall disease-free survival appears to be approximately 40% for patients with metachronous osteogenic sarcoma metastases.[112,113] The excision of other selected metastatic sarcomas has not been found to be nearly as beneficial, and the indications for surgery are far less clear. Wilms' tumor pulmonary metastases rarely require surgical excision, as there is no apparent survival advantage to surgical metastasis removal compared to the results of chemotherapy and radiation therapy alone. [114]

# GENERAL PRINCIPLES OF RADIATION ONCOLOGY

NANCY J. TARBELL
HANNE M. KOOY

## INTRODUCTION

The goal of cancer therapy is to free the patient of local, regional, and distant disease. Radiation therapy is a highly effective treatment modality for many pediatric malignancies. An important advantage of radiation is that major vessels, nerves, connective tissues, and hollow viscera can be included in the treatment volume with relatively low risk of producing complications, thus improving cosmetic and functional outcome. However, in pediatric patients the use of radiation therapy demands special attention to both the overall benefits and indications for the use of this treatment and the potential long-term toxicities peculiar to the growing child. [1]

The optimal use of radiation, as a sole treatment modality or as a part of a multi-modality program, requires an understanding of the action of radiation at the physical, molecular, cellular, tissue, and organ level. In general, there are two strategies to enhance the efficacy of radiation therapy. These include (a) improving the physical dose distribution so as to increase dose in the tumor relative to normal tissues and (b) increasing the differential response to radiation between tumors and normal tissues. The former strategy relates to physical parameters, whereas the latter pertains to biologic considerations.

## BASIC PRINCIPLES OF RADIATION THERAPY

### Physical Considerations

Modern clinical radiation therapy uses external radiation beam delivery techniques with x-ray (photon) or electron fields. Beam energies range from 4 to 25 MeV and are produced using clinical linear accelerators. Clinical linear accelerators accelerate electrons to the desired energy. These electrons are than scattered over a broad area to produce a clinically useful electron field. The clinical electron field contains electrons of a near-uniform energy equal to the acceleration energy. This energy determines the penetration depth of the field into the patient, with higher energies penetrating more deeply into the patient. Alternatively, to produce an x-ray field, the electrons strike a high-density target (usually tungsten), resulting in the production of photons. These photons then pass through a flattening filter to produce a clinically useful x-ray field. The x-ray field contains photons of varying energies up to the peak energy of the accelerated electrons. It is customary to denote the energy of an electron field in MeV and to denote the energy of an x-ray field in mV, because of the near-uniform energy of the electron fields and the varying energy of the x-ray fields. High energy x-ray fields (greater than 10 mV) produced by modern high-energy linear accelerators offer the advantage of deeper dose penetration and lower skin doses, compared to old lower energy equipment such as cobalt-60 units. The higher energies are of clear advantage in the treatment of deeply seated tumors, especially those in the thorax, abdomen, and pelvis. In contrast, cranial lesions are often better treated with lower energy x-ray beams (approximately 6 mV) to ensure coverage to shallow lesions and the meninges.

Both x-ray and electron fields interact inside the patient by an ionization process, in which electrons from the atomic shells are released into the cellular environment. These released electrons interact with the cellular molecules, including the DNA molecules, which results in the disruption of the cell's operation. X-rays and electrons, as well as gamma rays emitted by the nuclear decay of radioactive elements, are all forms of ionizing radiation. The energy released in the ionization process relates to the dose deposited in the patient. Radiation absorbed dose is defined as energy, in joules, deposited per unit mass, in kg, and has the unit of J per kg denoted as gray (Gy) in the international system of units (SI units). The gray is named in honor of L. H. Gray, the noted British radiobiologist, and replaces the older unit of rad, where 1 Gy equals 100 rads.

A clinical linear accelerator has many degrees of geometric movement and can position a treatment field at almost any orientation relative to the patient. This is achieved by mounting the radiation production source on a gantry that fully rotates around the patient. In addition, the patient is positioned on a treatment couch that permits the patient to pivot with respect to the gantry rotation plane. This degree of movement is necessary both to permit an optimal approach to the target volume and to permit multiple fields to approach the target volume. The radiation field can be shaped to geometrically conform the target volume intersection with the field by a collimator assembly mounted on the gantry. The field shape can be adjusted by inserting manually produced apertures that block the radiation in selected sections of the radiation field or by adjusting the settings of a multi-leaf collimator, which is a device that has a large number of opposing vanes, or leafs, that span the field. The adjustment of individual leafs permits the multi-leaf collimator to assume a large variety of radiation-blocking patterns. The multi-leaf collimator is the key to the latest development in delivery technology that permits the radiation field itself to be spatially modulated in a technique called *intensity modulated radiation therapy* (IMRT) in contrast to the “conventional” radiation fields that have a constant, or fixed, intensity profile across the field area. It is expected that IMRT will have a significant clinical impact.

A patient treatment, in general, involves multiple nonoverlapping treatment fields, each of which enters the patient and focuses on the target volume containing the tissues to be treated. The set of multiple fields reduces the dose to non-involved tissues by, in effect, spreading the dose outside the target volume over a much larger volume. Sophisticated treatment field configurations, or treatment plans, are designed with computer-based techniques using patient-specific computed tomography (CT) and magnetic resonance imaging (MRI) information in combination with models for managing the treatment field geometry with respect to the patient anatomy and models for computing the dose inside the patient. Such treatment planning techniques result in dose distributions that can precisely conform to the target volume. These important technical advances are discussed in the section on Recent Advances in Radiation Therapy.

In addition to conventional external beam irradiation, other specialized modalities are available for the treatment of some malignancies. One such technique is the brachytherapy implant technique. Brachytherapy places one or more radioactive sources into a body cavity (i.e., intracavitary implants), such as the vagina, or directly into the tumor (i.e., interstitial implants). For permanent implants, radioactive sources are placed into tumors under ultrasound, CT, or MRI guidance. For temporary implants, hollow catheters or other loading devices are positioned at the time of surgery, and remotely loaded, and emptied, with radioactive sources. Both techniques allow for high doses of radiation to be delivered to relatively small volumes of tissue. Brachytherapy techniques can deliver high doses to target tissues, with excellent sparing of nearby healthy tissues. Iridium-192 and iodine-125 are the most frequently used radionuclides. Cesium-137 has been largely replaced in favor of iridium-192, with the availability and popularity of automated remote afterloading equipment. Radionuclides are embedded in seeds and sealed in thin plastic strands that can be inserted into implanted catheters. Iodine-125 has a short half-life of 57 days and is often used as a permanent implant, especially in prostate and central nervous system treatments. Iridium-192 has a half-life of 70 days and permits reuse of the seeds in some case, notably when used with the automated remote afterloaders.

Brachytherapy treatments and external beam treatments differ in radiobiology. [2] Implanted sources deliver continuous doses of 30 to 100 cGy per hour over the duration of the implant. The target volume is thus treated continuously with a low dose rate over a long period. This is in contrast to an external beam treatment, in

which the target volume receives a short pulse of dose (on the order of 100 to 200 cGy) once or twice a day over many (5 to 7) weeks. The different dose rates and delivery patterns affect cell kill for a given total dose because of a difference in repair of sublethal damage. Thus, using a low dose rate may result in less damage to normal tissue.[2]

Brachytherapy in the form of intracavitary or interstitial implants has been used for some pediatric malignancies. For example, brachytherapy has been used in rhabdomyosarcomas of the genitourinary tract as well as in retinoblastoma[3] and central nervous system tumors in an attempt to limit the dose to surrounding normal tissues.[4,5,6,7] and [8]

**Biologic Considerations**

Cells vary considerably in their radiosensitivity depending on their position in the cycle. Cells in mitosis (M) and early in the DNA synthesis phase (S) have the greatest sensitivity whereas cells in late S phase as well as in $G_2$ have the least sensitivity.[2] The target for radiation-induced damage in tumor cells is the DNA. Unrepaired or misrepaired double strand breaks presumably lead to cell killing although several factors modify the response of tumor cells and normal tissues to radiation. These include: (a) the inherent radiosensitivity of the cells in question (b) the capacity of these cells to repair radiation damage, (c) the oxygen and nutrient status of the tumor, (d) the position of an individual cell in the cell cycle, and (e) the capacity for repopulation. To improve the therapeutic differential between tumor cells and normal tissues, radiation treatments are given as a series of equal-sized fractions over a number of weeks, in part exploiting these factors.

The basis for the exquisite sensitivity of certain tumor cells to radiation, such as seminoma, in contrast to relatively radioresistant tumors, such as osteogenic sarcoma, is poorly understood. Genetic factors may play a role in determining the response of cells to radiation. There has been a wider recognition of the process of programmed cell death or apoptosis. Apoptosis appears to be one mechanism for interphase death at very low doses of irradiation.[2] This process of cell death is not linked to mitosis, was first appreciated in lymphocytes, and is known to occur to varying degrees in normal and tumor tissues. Of interest, the normal p53 gene has been shown to be required for this process.[9] Tumor cells lacking a normal p53 gene may therefore be more resistant to cell killing if this process is turned off.

In general, both normal tissues and tumor cells are capable of repair of a portion of the radiation damage between doses of radiation. Normal tissues may possess greater capacity for repair although they may require more time to do so. Therefore, spacing radiation fractions by at least 6 hours (usually 24 hours) may give a greater advantage to normal tissues. Even small therapeutic gains, when amplified exponentially over a course of treatment, can become very significant. Molecular oxygen is a potent radiosensitizer, and therefore tumor cells at low oxygen tensions are relatively resistant to radiation. This situation can occur because a fraction of tumor cells are positioned progressively further from the capillaries. With tumor growth, they can outgrow their blood supplies. As cells closer to the capillaries are most sensitive, they will be preferentially killed. Thus, there are fewer cells metabolizing oxygen, and those that remain will be “re-oxygenated” and more sensitive. Therefore, fractionated radiotherapy would be beneficial in providing the opportunity for a net improvement in oxygenation and hence tumor cell sensitivity.

The phenomenon of repopulation occurs in acutely responding normal tissue, such as the gut epithelium, but also occurs in tumors. A therapeutic advantage would occur if the rate of repopulation was more rapid in normal tissues than in tumors. In general, it is best to deliver a course of radiation in the shortest period that will be tolerated by acutely responding normal tissues. Delays in treatment beyond this time, due to radiotherapy toxicity or elective breaks, may adversely affect prognosis.[10]

***Radiation Interactions with Chemotherapeutic Agents***

A number of chemical substances will alter the radiation response of a cell.[11,12,13,14,15] and [16] The effect may be additive, such as with most alkylating agents and antimetabolites, or it may be synergistic, such as with the antibiotic dactinomycin.[14] Doxorubicin and dactinomycin markedly reduce the “shoulder” region of the radiation cell survival curve.[14,15,16,17] and [18] Dactinomycin also steepens the slope of the exponential portion of the cell survival curve and potentiates the radiation effect; thus, it is thought to be a true radiation sensitizer.[14]

An interesting clinical phenomenon known as “recall” has been demonstrated with combinations of radiation and either doxorubicin or dactinomycin. Even with time intervals as long as 3 weeks between the use of radiation and dactinomycin, a brisk reaction can be seen with striking recurrence of the prior radiation reaction.[13] Such “recall” reactions are usually used to describe skin erythema that returns with each subsequent dose of chemotherapy. Radiation may also alter drug metabolism, thereby increasing the combined toxicity.[16] This has been shown in children with right-sided Wilms' tumor, in which hepatic irradiation combined with dactinomycin resulted in veno-occlusive disease, although veno-occlusive disease is also seen without radiation therapy at a 2% incidence. The incidence in the National Wilms' Tumor Study-4 for both the standard regimen of dactinomycin and the pulse regimen was 10 times more frequent than that in the National Wilms' Tumor Study-3 despite no change in the radiation therapy.[17] In addition, the neurotoxicity of vincristine is enhanced, presumably because of delayed metabolism of the drug by the liver.

Etoposide (VP-16) inhibits cell replication. Sublethal lesions produced by radiation become lethal lesions with etoposide, resulting in increased cell killing when this agent is used with radiation therapy. In addition, cells that are arrested in $G_2$ by irradiation are particularly sensitive to etoposide.[18]

Among other chemotherapy agents frequently used in pediatric malignancies which interact with radiation are the antimetabolites. Methotrexate (MTX) is the most widely used clinically. It is a cycle-specific agent, altering the cell kinetics of the surviving cells. Cells in mitosis are more sensitive to irradiation. This leads to an enhanced response to the combination of MTX and irradiation. MTX selectively kills cells in S phase, leaving a greater proportion of cells in G1. As the surviving cells proceed through the cell cycle, they are differentially more or less sensitive to subsequent irradiation. MTX also inhibits repair of DNA strand breaks, which acts to enhance the toxicity of irradiation. The combination of cranial irradiation followed by systemic administration of MTX can produce a subacute syndrome known as *necrotizing leukoencephalopathy*, characterized by lethargy, seizures, and cognitive and cerebellar dysfunction.[19,20] Careful attention to the sequencing of MTX and cranial irradiation as well as the dose and route of administration (i.e., intrathecal versus intravenous) can minimize the likelihood of this devastating toxicity.

Paclitaxel (Taxol) blocks progression of the cell into mitosis. This drug blocks cells in $G_2$ per M by inhibiting depolymerization of tubulin.[21] *In vitro* studies have shown a significant radiosensitization with paclitaxel, even at less than cytotoxic doses.[22] Several clinical trials are ongoing to assess the combined use of paclitaxel and MTX as radiosensitizers.

***Dose Rate and Fractionation Effects***

The dose rate (Gy per minute) as well as the fraction size are major factors in determining the biologic effect of a given absorbed dose of radiation.[2] As the dose rate is reduced, the slope of the survival curve becomes less steep while the extrapolation number tends toward unity. This dose rate effect may be primarily due to repair of sublethal damage and is most dramatic between 1 and 200 cGy per minute. There is tremendous variation in the magnitude of the dose rate effect. For example, normal bone marrow stem cells generally demonstrate little dose rate effect and are characterized by a small shoulder (i.e., little repair capacity).[23,24] This is in contrast to the gastrointestinal tract, which has a broad shoulder and a correspondingly large dose rate effect.[2] It is this differential sensitivity in repair capacity between gastrointestinal tract and bone marrow stem cells that permits a differential effect of total body irradiation for bone marrow transplantation.[2,26] Pulmonary alveolar cells also demonstrate a significant repair capacity, and the incidence of pneumonitis at whole body doses of 9 to 10 Gy decreases significantly as the dose rate decreases to 2 to 5 cGy per minute.[25] One example of the importance of fractionation in clinical practice was shown with the use of total body irradiation for bone marrow transplantation. Cyclophosphamide along with single fraction total body irradiation of 9 to 10 cGy delivered at approximately 5 cGy per minute resulted in some long term remissions; however, most patients died of complications or recurrence of leukemia.[26] A prospective randomized clinical study comparing single-dose total body irradiation to a fractionated schedule of daily radiation was initiated.[27] Patients with acute nonlymphoblastic leukemia were randomized to receive either 10 Gy in a single fraction in 1 day or 12 Gy given in 2 Gy fractions over 6 days. Survival was significantly better in the fractionated group. The incidence of leukemic deaths was identical; the improved survival was due to a decrease in deaths from complications. This study demonstrated that 12 Gy given over 6 days was equivalent to 10 Gy in a single dose for leukemic cell kill, but allowed greater repair of dose-limiting normal tissues such as the lung. Various combinations of fractionated and low-dose rate techniques have become widespread.[26,27,28] and [29] Whereas the optimal schedule is still uncertain, it is clear that fractionation spares normal tissue toxicity to a greater extent than single-fraction total body irradiation. Low dose rate allows repair of normal tissues; however, the use of fractionation appears to allow greater repair and to decrease the late effects over that achieved with low-dose-rate, single-fraction radiation.[30,31,32,33] and [34]

*Fractionation* refers to the amount of radiation given at each session (i.e., fraction size) and the overall number of treatments ( Table 13-1). *Hyperfractionation* refers to the use of a larger number of fractions with smaller than conventional doses per fraction over the same treatment time.[31] The use of standard fraction sizes given

more than once a day is referred to as *accelerated fractionation*. Theoretically, hyperfractionation will result in an improvement in the therapeutic ratio when late normal tissue reactions are dose-limiting.[31] Clinically, hyperfractionation and accelerated fractionation schedules are being used in most total body irradiation regimens to decrease the overall time of irradiation (i.e., number of days) while giving the same or greater total dose.

| Conventional fractionation | Once-daily treatment with radiation usually given in 1.5–2.0 Gy/fraction per day |
|---|---|
| Hyperfractionation | Total dose is increased, size of dose per fraction is reduced. Overall treatment time is relatively unchanged. Usually given as twice-a-day treatment. |
| Accelerated fractionation | Overall time is reduced, the dose per fraction is unchanged or somewhat reduced. |
| Accelerated hyperfractionation | Incorporates features of both accelerated and hyperfractionation. |

**TABLE 13-1. RADIATION FRACTIONATION SCHEDULES**

Laboratory evidence supports the potential benefit of hyperfractionation in the pediatric population.[33,34] The clinical trials to date are limited, and so far, have not shown a benefit with respect to improved tumor control.[35,36,37 and 38]

### Clinical Considerations

Radiation is a highly active antitumor agent. Virtually all tumors respond favorably to irradiation, and a significant number are permanently controlled. However, the rate of response is not always predictable. For many tumors, response can be seen over years.[39] The criteria such as “complete response” or “partial response” have limited value, and permanent or long-term, local control relapse-free survival and overall survival are usually a better gauge of treatment efficacy.

The general relationship between dose and the probability of curing a tumor is shown in Figure 13-1. The delivery of the physical dose to the tumor is controlled by the physical factors discussed under Physical Considerations, whereas the shape of the curve is determined by the biologic factors. Normal tissues also display similar sigmoidal dose response curves, although fractionated therapy generally places this curve to the right of the tumor curve. At doses that produce no level of complications, cure rates are low, whereas tumor doses that produce greater than 90% cure rates may produce unacceptable morbidity. In general, intermediate doses are chosen that balance benefits and risks. Of note, the addition of chemotherapy may markedly shift these curves. As a guiding principle, it is often the balance of these potential risks and benefits, the therapeutic ratio, that determines the doses given for a particular patient.

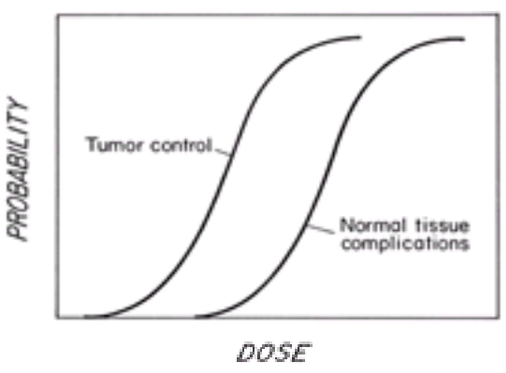

**FIGURE 13-1.** Idealized sigmoid curves depicting the probability of tumor control compared with the probability of normal tissue complications. The therapeutic ratio refers to the balance between these two curves. In general, as the dose increases, the risk of complications increases.

The optimal balance between control and complications varies in different clinical settings depending on the consequences of local relapse or the severity of the complications engendered. When the complication results in severe morbidity (e.g., radiation myelitis), then it must be avoided even if the price is an increased rate of tumor relapse. However, if patients who develop local tumor failure after irradiation cannot be salvaged and normal tissue complications can be managed by medical or surgical means (e.g., small bowel obstruction), then a significant rate of complications may be a reasonable price for a higher proportion of cured patients. For example, in pediatric Hodgkin's lymphoma, irradiation of smaller volumes with planned chemotherapy produces an equivalent rate of tumor control with less morbidity than the previous use of wide-field irradiation.[40] In early-stage Hodgkin's disease, irradiation alone results in an excellent disease-free survival.[41] However, in the pediatric age group this decision is complicated by the direct effect of radiation therapy on bone growth.[42,43] Thus, in patients with early-stage disease with significant growth remaining (those younger than 14 years of age), chemotherapy, usually with involved field, low-dose radiation therapy, is the standard of care.[44,45,46,47 and 48]

Parameters that can be varied during a course of treatment include the volume irradiated, the total dose, the fraction size, and the dose rate used at each treatment session. Also, the time interval between each radiation fraction and the overall time between initiation and completion of radiation can be varied.[49,50] Each of these features has significant bearing on both tumor control probability and normal tissue complications. In general, as treatment volumes increase, the total dose must decrease to maintain a given level of complications. Similarly, an increase in radiation fraction size also results in an increase in late complications of the total dose, or volume is not reduced.[51,52]

The total dose required for tumor control is largely dependent on the number of tumor cells that are present and the specific tumor in question. Table 13-2 shows some examples of the total dose used for various diseases. Most hematologic malignancies are radiosensitive and require only a moderate total dose for local control. For example, doses of 36 Gy provide excellent local control in Hodgkin's disease when radiation alone is used, whereas doses of greater than 50 Gy are required for soft tissue sarcomas. Generally, these principles of total dose and radiation schedule are not age related. No data are available to justify a variation in radiation dose based on age. The one exception appears to be neuroblastoma in the child younger than 12 months old, in which the biology of the disease seems to be different than in older children. Modifications of total dose may, however, be justified by age-related toxicity. For example, dose reductions in the treatment of brain tumors in infants have been recommended. This is because myelinization is incomplete, and the functional impairment in this age group is of great concern. In this case, lower control rates may be justified by the decrease in complications.

| Tumor | Radiation dose (Gy) |
|---|---|
| Hodgkin's disease | |
| Radiation therapy alone | 36–40 |
| Combined modality | 15–25 |
| Rhabdomyosarcoma | 40–55 |
| Neuroblastoma | |
| <12 mo | 15 |
| >12 mo | 20–35 |
| Histiocytosis | 4.5–10.0 |
| Acute lymphoblastic leukemia (central nervous system treatment) | 18–24 |
| Medulloblastoma | |
| Craniospinal | 23–40 |
| Posterior fossa | 54–55 |

**TABLE 13-2. GENERAL RADIATION DOSES FOR SPECIFIC TUMORS**

## RECENT ADVANCES IN RADIATION THERAPY

A modern linear accelerator is mechanically accurate and offers precise control of the delivery of the radiation dose to the patient. An early high-precision application of the linear accelerator was in small-field, high-precision stereotactic therapy. Stereotactic therapy was first practiced by proton and gamma knife techniques. [53] The concomitant availability of sufficiently powerful computers and the development of image-based radiation therapy treatment planning software permitted stereotactic therapy to move from a special-purpose technique only available at selected centers to the radiotherapy community at large. Stereotactic therapy uses a large number of narrow beams of radiation delivered as single-fraction stereotactic radiosurgery or as multiple-fraction stereotactic radiotherapy. The large number of narrow fields permit an exquisite focus of radiation dose on the target volume with little dose to the healthy tissues. (This can be compared to, by analogy, the effect of focusing sun rays through a magnifying glass, in which the focus point intensity is much higher compared to any other point.) The large number of beams is typically delivered by continuously rotating the radiation source, located in the gantry/collimator assembly of the linear accelerator, across the patient. This rotation movement is a basic parameter of the linear accelerator and is achieved by rotating the gantry over multiple intervals at multiple positions of the patient treatment couch. A fundamental feature of stereotactic therapy is a stereotactic frame that attaches rigidly to the patient. This frame is surgically attached to the cranium for single-fraction, single-day treatment, radiosurgery. Stereotactic radiotherapy, in contrast, requires that the patient return for many consecutive days and relies on a relocatable frame that typically uses the patient's upper dentition to achieve rigid positioning and accurate reproducibility. The stereotactic frame forms the basis for an absolute reference system in which all geometric parameters, such as patient setup and beam approach, are defined. The patient is imaged with the frame and a fiducial (marker) reference system. This image procedure permits a volumetric image reconstruction based on the fiducials with a precision above and beyond the precision of the CT or MRI scanner. Stereotactic therapy provides a complete operational model for high-precision treatment delivery and defines procedures for patient imaging, volumetric reconstruction of the patient's anatomy, modeling of the required radiation fields to satisfy the clinical prescription, and the delivery of the treatment.

Arteriovenous malformations were the original indications for stereotactic radiosurgery, [54] as these could be located with angiographic procedures and did not require CT imaging for treatment definition. The availability of CT imaging dramatically expanded the applicability of stereotactic radiosurgery. Currently, the most common indication is in adult patients with metastatic disease to the brain. In pediatric patients, in whom metastases to the brain are rare, single-fraction stereotactic radiosurgery is largely used as a “boost” after conventional fractionated radiation therapy or for recurrent brain tumors that have been previously treated with conventional radiation therapy. [55,56 and 57]

Multiple-fraction stereotactic radiotherapy, in contrast to the large single fraction of stereotactic radiosurgery, delivers corresponding focal doses but with conventional fractionation and the use of a noninvasive frame to reproduce accurate patient setup over the course of several weeks of treatment. [58] The patient shown in Figure 13-2 is a 12-year-old girl with a symptomatic low-grade astrocytoma. This figure shows the dose distribution and beam arrangement for a stereotactic plan. This dose distribution, for the same patient as in Figure 13-2, was obtained by applying five arc rotation segments (Fig. 13-3), in which each arc segment had a collimated shape determined by a circular aperture trimmed by the linear accelerator collimator jaws. The treatment plan incorporated CT imaging under stereotactic guidance and incorporated MRI for accurate definition of the low-grade neoplasm. The MRI was obtained without stereotactic localization and was fused to the CT image data using an automated fusion technique. [59,60 and 61] All stereotactic technology produces highly focal dose distributions, making the treatment ideal for treating localized lesions that are not widely infiltrative. Stereotactic technology is most often applied to tumors of the brain, as the cranium affords excellent immobilization and presents no internal organ motion. More recently, stereotactic treatment principles have been applied to thoracic and abdominal sites. [62] Tumors well suited for treatment with stereotactic radiotherapy are small (generally 5 cm or less), noninvasive, radiographically distinct, and known to be well controlled with conventional radiation therapy. [62]

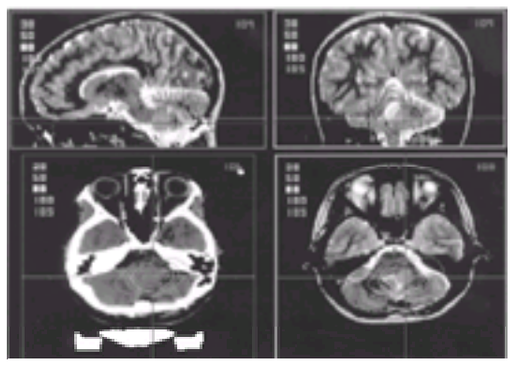

**FIGURE 13-2.** The patient is a 12-year-old girl with a low-grade astrocytoma. The dose distribution is shown superimposed on the sagittal, coronal, and transverse magnetic resonance (MR) sections through the center of the radiation field (radiation isocenter). The corresponding transverse computed tomography (CT) slice is also shown (*lower left*) in contrast to the soft tissue contrast of MR (*lower right*). Radiation treatment planning relies on both CT and MR modalities. The CT is required to accurately calculate the radiation inside the patient, whereas the MR in this case is required to reconstruct the target volume and the nearby brainstem. Dose lines are shown in percent of dose prescription of 50.4 Gy delivered in 25 fractions of 1.8 Gy. (See Color Figure 13-2.)

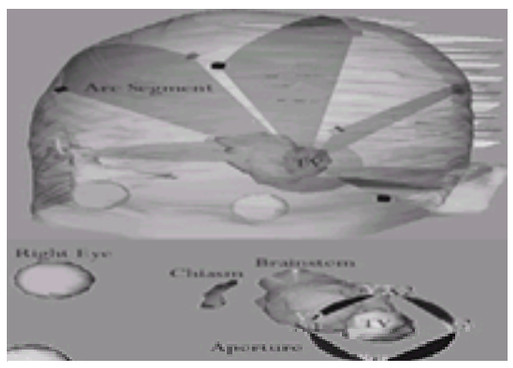

**FIGURE 13-3.** The three-dimensional reconstruction of the same patient as in Figure 13-2. The patient's external surface together with the eye globes, the brainstem, and the target volume (TV) as shown in the top part. The patient is treated with five arc segments of radiation therapy indicated by the pie-shaped wedges. The shape denotes the traversal of the central axis of the radiation field through the patient's anatomy. All five axes intersect at the radiation isocenter inside the target volume. The bottom part illustrates (for one angle for one arc segment) the view obtained by placing the observer's eye at the radiation source and showing the relationship of all organs and the radiation field. The radiation field is emitted only through the opening formed by the circular aperture and the four standard accelerator collimator jaws (labeled X1, X2, Y1, and Y2). The target volume is clearly included in the opening and thus receives full dose from this approach. Some brainstem is unavoidably involved but is kept below the tolerance dose for radiation complications. This view is called the “beam's eye view” and is checked for all radiation approaches to obtain a minimal shape for each arc segment.

The goals of stereotactic therapy are a high rate of tumor control and minimization of normal tissue exposure, goals that are ideally suited for treatment of pediatric patients. [56,57,63,64,65 and 66]

**Intensity Modulated Radiation Therapy**

A fundamental development in radiation oncology is the recent introduction of IMRT. IMRT uses many radiation fields, more than conventional focal radiotherapy, and each field has a unique radiation intensity profile that varies arbitrarily as a function of position within the field. This is in sharp contrast to conventional radiotherapy in which each field has either a uniform intensity or a standard, predetermined, intensity profile. IMRT delivery, in general, uses the multi-leaf collimator to vary the intensity locally during the delivery of the field. This is achieved by precisely controlling both the shape of open regions within the field and the amount of radiation, or intensity, that is emitted in those regions. The combination of geometric control and radiation delivery can create an intensity profile over the field of almost arbitrary shape.

The ability to control the intensity over the field area dramatically increases the number of treatment parameters that control the actual dose delivered in the patient. A conventional treatment field typically has four parameters for the treatment. In contrast, an IMRT field, with its fine control over the intensity distribution, has on the order of 100 to 1,000 parameters, in which each parameter represents a local value of the intensity inside the radiation field. This number is beyond the capability of a human treatment planner and can only be determined through the use of computer-based algorithms. These algorithms take as primary input the geometric shape and location of the target volume and other dose-critical structures together with the dose parameters, such as maximum and minimum dose, for each structure. In addition, the algorithm takes the set of field approaches to expedite the execution of the algorithm. In fact, IMRT solutions are somewhat dependent on the choice of treatment field approaches. The algorithm then manipulates the set of intensity values for all fields until the desired dose of radiation to the target volume is achieved, whereas the dose outside the target volume, and especially any critical structures, is minimized. The set of intensity values is then converted to the set of parameters required to control the multi-leaf collimator that delivers the IMRT fields.

IMRT treatments require much of the same delivery framework as used in stereotactic radiotherapy (i.e., precise imaging and accurate, reproducible setup). This is a complicated task, as IMRT is used in noncranial sites where internal organ motion and patient fixation are major concerns. A prime example of the use of IMRT is the dose escalation study at Memorial Sloan-Kettering Cancer Center, which used 81 Gy in prostate cancer patients to improve control rates. [67] Such high dose levels would not be achievable using standard radiation techniques. IMRT treatments are effective in reducing dose to a critical structure, especially when the critical structure indents the target volume (Fig. 13-4). The ability to create concave dose distributions is perhaps the most dramatic feature of IMRT. IMRT can also be effective in reducing dose to normal tissues. There is, however, a relationship between the target volume size, the resolution of the multi-leaf collimator, and the achievable reduction to healthy tissues. A typical multi-leaf collimator has a resolution of 1 cm (i.e., the intensity can be controlled within an area of 1 cm by 1 cm) and the whole radiation field is subdivided into subareas of 1 cm by 1 cm, in which each subarea can deliver a different intensity to control the shape of the delivered dose distribution in the patient. A typical conventional target volume is on the order of $10 \times 10 \times 10$ cm $^3$ and the number of subareas typically is on the order of 100 per field. A typical IMRT treatment involves on the order of seven fields, and an optimization algorithm therefore must compute on the order of 1,000 intensity values for a treatment. If, however, a target volume is “small,” on the order of 3 to 5 cm, the number of 1 cm by 1 cm subareas per field that irradiate the volume can be as small as 10, and the number of intensity values is on the order of 100. This is a dramatic reduction in the number of parameters that the algorithm can control to achieve an optimal solution and can reduce the effectiveness of IMRT compared to conventional focal treatment. Conversely, if the target volume is too “large,” reduction in dose to healthy tissues is compromised simply by geometric constraints, as the ratio of healthy volume to target volume becomes small and dose cannot be effectively distributed over the healthy volume to achieve adequate reduction. These considerations will require considerable study to optimize IMRT delivery for specific treatment sites.

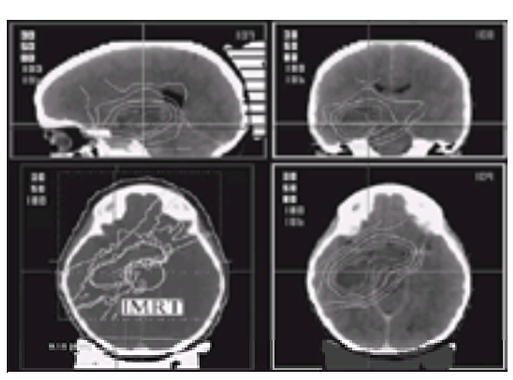

**FIGURE 13-4.** The dose distribution from four static fields is shown for a 16-year-old girl with an optic glioma. The optic glioma is shown as a darkened area on the top and right bottom slices and as a white contour on the intensity modulated radiation therapy (IMRT) slice. The dose distribution for the top and bottom-right panels is obtained by nonintensity modulated fields (conformal radiation). The dose distribution in the IMRT slice uses the same set of four fields but uses an IMRT optimization to obtain field-specific intensity for each of the four fields. Note that the IMRT dose distribution visibly reduces the dose to the brainstem compared to the bottom-right section.

Consider for illustration purposes a 16-year-old girl with an optic glioma. A typical conformal plan might use four static fields and yield the acceptable, but perhaps not optimal, dose distribution shown in Figure 13-4. The optic glioma is highly irregularly shaped, and the four-field dose distribution will, of necessity, involve the brainstem. The bottom left panel in Figure 13-4 uses the same set of four fields, but has used an IMRT optimization to adjust the intensities in each of those four fields. Note that the IMRT optimized dose distribution is able to noticeably spare the brainstem compared to the non-IMRT dose distribution. Beyond the brainstem, however, it is hard to evaluate whether there is an improvement for the IMRT dose distribution. It should be noted that a four-field configuration is a minimal set for IMRT delivery.

The quantification of the appropriate technique, albeit conventional conformal with or without IMRT, requires quantification indices. One such index is the tissue-volume ratio defined by Nedzi et al. [68] as the ratio of the volume of healthy tissue to target volume tissue at the prescription level. It is not clear what the best technique is given the physical presentation of the treatment geometry (notably the size and location of the target volume) and the delivery device. Bues et al. [69] discuss the use of IMRT for small intracranial lesions (approximately 6 cm maximum dimension) and compares the efficacy of three competing techniques: conventional arc delivery described by Hacker et al., [61] IMRT delivered with a 1.0 cm resolution, and IMRT delivered with a 0.5 cm resolution ( Fig. 13-5). Figure 13-6 shows the dose-volume histogram, a graph that indicates how much volume (in cc or percent total volume) receives a given dose or more, for the brainstem volume for these three delivery options. A clear advantage for both IMRT delivery modes is quantified, compared to the qualitative assessment from Figure 13-4. Figure 13-7 shows the dose-volume histogram for other healthy tissue (i.e., excluding the brainstem) for the 1.0-cm and 0.5-cm resolution IMRT modes. The high-resolution IMRT delivery achieves a significant reduction in healthy tissue dose by a factor of 2! To assess the efficacy of a particular treatment delivery mode, it is useful to consider the distribution over a particular patient population as a whole. Figure 13-8 shows the range of tissue-volume ratios achieved with each treatment mode for a patient population presenting with cranial neoplasms having a maximum dimension up to 6 cm. Although for the patient in Figure 13-5 the 1-cm IMRT delivery was clearly superior overall, in general, 1-cm IMRT does not significantly improve the treatment for the population as a whole. In contrast, the 0.5-cm IMRT mode does improve the treatment for all patients.

**FIGURE 13-5.** The intensity maps for a single field for 1-cm resolution intensity modulated radiation therapy (IMRT) **(A)** and 0.5-cm resolution IMRT **(B)** are shown. Note that both fields outline the target volume shape along the beam direction.

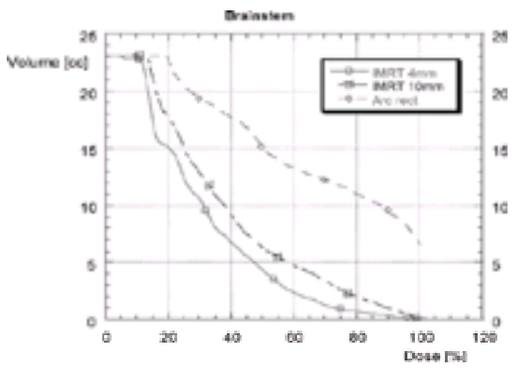

**FIGURE 13-6.** The dose volume histogram shows what volume (in cc or in percent total volume) receives a given dose of radiation. Three treatment delivery scenarios are considered for the patient shown in Figure 13-4: a collimated stereotactic delivery method,[61] conventional intensity modulated radiation therapy (IMRT) at 1.0 cm resolution, and high-resolution IMRT at 0.5 cm resolution. As was visually apparent in Figures 13-4 and 13-5, IMRT can significantly reduce the dose to a critical structure, such as the brainstem adjacent to the target volume in this case.

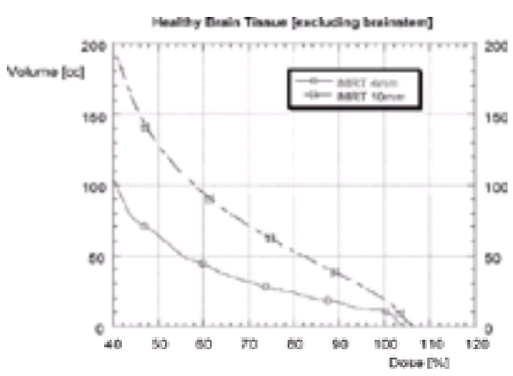

**FIGURE 13-7.** The dose-volume histogram for healthy brain tissue, but excluding the brainstem, indicates a significant reduction (by a factor of 2) for the higher resolution intensity modulated radiation therapy (IMRT) delivery mode.

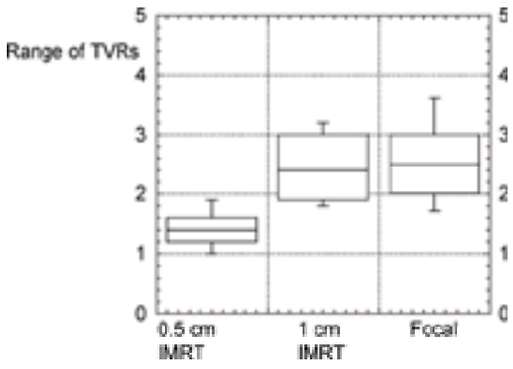

**FIGURE 13-8.** Range of tissue volume ratios (TVRs) across the patient population for each treatment modality shown as boxplots. A boxplot shows the median and the quartile extents. Note the broader variation in TVR values for 1-cm intensity modulated radiation therapy (IMRT) and focal delivery compared to 0.5-cm IMRT.

IMRT, as well as other focal techniques, will play a significant role in the treatment of pediatric tumors, as dose reduction to normal tissues is considered of direct benefit to this population in whom growth is a significant issue.

**Proton Radiation Therapy**

The state-of-the-art technique for achieving precise dose localization in a tumor and reducing normal tissue irradiation is proton radiation therapy. Protons are charged particles with a mass of one. Protons deposit their energy over a short distance known as the *Bragg peak*. Their biologic effectiveness is similar to x-rays, resulting in similar cell killing effects. The advantage of protons lies in this physical dose distribution. Because of the defined range of protons, dose distributions can be designed that conform more closely to a tumor volume. This advantage is illustrated in Figure 13-9. The result is a much greater ability to reduce radiation dose to nontarget normal tissues and allows a greater dose to be delivered to the tumor. Clinical studies of proton beam therapy for cancer patients have been ongoing since 1974 at the Harvard Cyclotron Laboratory in Boston, Massachusetts. Other centers that have subsequently commenced proton therapy for cancer patients include: Loma Linda University, California; PSI near Zurich; Uppsala, Sweden; ITEP, Moscow; Capetown, South Africa; Tsukuba, Japan; and Orsay, France. The proof of principle of proton therapy has been in the treatment of skull base chondrosarcomas and chordomas and uveal melanomas.[70,71] Because of the high capital costs required to establish a proton treatment facility, this will likely remain a specialized type of treatment.

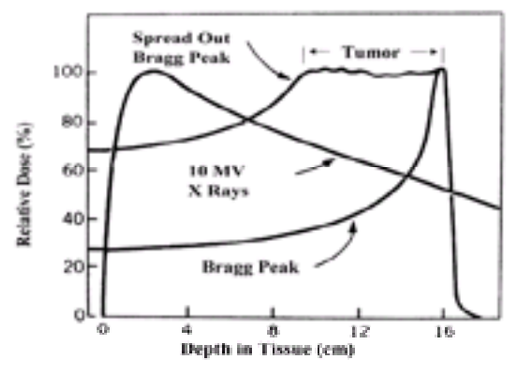

**FIGURE 13-9.** This chart illustrates the differences in protons compared to photons. The curve for the 10 mV x-rays shows more dose deposited before the tumor and continuing dose given to normal tissue beyond the tumor. Note that on the curve labeled “Bragg Peak,” the dose is too narrow to treat the tumor. But the dose shown in the curve labeled “Spread Out Bragg Peak” treats this idealized tumor and has no exit dose beyond the tumor.

The use of protons in pediatric tumors, such as medulloblastoma, is of great interest. [63,72,73] The standard treatment requires the use of craniospinal irradiation followed by a boost to the tumor bed. Acute effects (e.g., nausea and vomiting) as well as late effects to the heart and lungs should be decreased by protons in place of photons for this technique. Figure 13-10 demonstrates the exit dose from conventional photons in contrast to protons. There is no exit dose to the stomach and bowel using protons as compared to 60% of the radiation dose with conventional photons. In addition, there would be no scatter dose to the ovaries in female patients.[74]

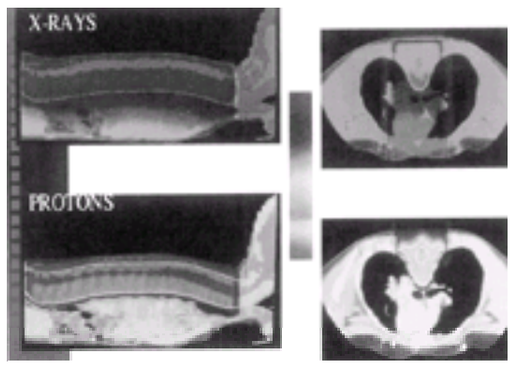

**FIGURE 13-10.** Shown here is the radiation dose in a 43-month-old child with medulloblastoma. The top figures demonstrate the dose from conventional x-rays given to the spine. Because x-rays deposit their energy over a greater distance, 60% of the dose exits to the stomach and intestine. The bottom figures are for protons showing no exit dose to the gastrointestinal tract, lung, or heart. (See Color Figure 13-10.)

### Intraoperative Radiation Therapy

Conventional radiation treatment, delivered to the thoracic, abdominal, and pelvic cavities, is limited by the tolerance of normal tissues such as the heart, lung, stomach, liver, and bowel. For example, it is difficult to deliver doses of greater than 50 Gy to a pelvic tumor because of the risk of injury to the small bowel. However, doses that minimize normal tissue injury are sub-optimal for tumor eradication. One method of escalating radiation dose, beyond that which can be achieved with conventional external beam techniques, is to give the radiation treatment during a surgical procedure. With the tumor bed or gross tumor surgically exposed and normal tissues packed out of the way, a beam of radiation can be delivered during the operation, in the operating room theater. This technique is available at a growing number of institutions.[75,76,77,78,79,80 and 81]

## GENERAL RADIATION THERAPY

Most pediatric malignancies are managed with combined modality therapy. There are only a few tumors in which radiation therapy after surgery is used in the pediatric population. One such example is with some of the nonmalignant brain tumors such as craniopharyngioma and low-grade astrocytomas. [82]

There are also a number of rare benign entities of bone and soft tissue in which radiation therapy has shown efficacy in local control. These include aggressive fibromatosis (desmoid) of soft tissue and giant cell tumors of bone.[83,84] Despite these generally good results, surgery should be considered as the first treatment option for most benign diseases. When surgery is not feasible or if patients have had recurrences after adequate cancer surgery, or if surgery will produce a significant functional decrement, then radiation should be considered.

Radiation has also been used in a number of nontumorous conditions. For example, radiation can prevent coronary artery restenosis after angioplasty. In this application, a temporary dwelling radioactive source is introduced after balloon angioplasty or a permanently-dwelling radioactive stent is placed. [85] In these two instances, the mode of radiation delivery is by brachytherapy. Radiation can also prevent renal allograft rejection [86] and the formation of heterotopic bone formation after total hip arthroplasty.[87]

### Palliative Therapy

Radiation therapy is an effective means of palliating cancer pain that is not responsive to analgesics, narcotics, or other therapies. Patients sometimes notice pain relief after several treatments. The goal of any palliative therapy should be to improve the status of the cancer patient without causing side effects from the treatment. Also, the patient should not have to spend an unreasonable period traveling to the hospital for treatment. A number of radiation regimens are available from single-fraction treatment to extended courses of treatment lasting 4 weeks. The precise regimen should depend on the life expectancy of the patient. Radiation therapy may also be useful for preventing pathologic fracture in long bones, may obviate the need for surgical repair, and may be used to palliate such emergent or urgent conditions as spinal cord compression and superior vena cava syndrome.

### General Effects of Radiation on Normal Tissues

In addition to its effects on tumors, radiation therapy also produces effects on normal tissues. These effects can be seen during treatment or many years after treatment. Reactions that occur during or soon after treatment are referred to as *acute effects* whereas reactions seen more than 3 months after a course of radiation therapy are referred to as *late effects*. The tolerance of normal tissues to fractionated radiation therapy is a function of the volume of normal tissue or organ being irradiated, the dose that the tissue or organ receives, and the time course of the treatment. For a given dose of radiation, a more protracted course of treatment produces fewer side effects. Because volume is a critical determinant of normal tissue tolerance, new delivery methods, such as IMRT, may be important in reducing normal tissue effects. When chemotherapy and radiation are combined, acute and late effects of treatment can be more severe. Radiation doses are generally lowered in combined modality therapy.

The early and late effects of radiation are generally limited to the area of the body that is being irradiated. One exception to this rule is that some patients undergoing treatment will notice fatigue. This usually begins several weeks into a course of treatment and can persist for several months after treatment. An example of acute and late effects of radiation is seen in head and neck treatment. The acute effect of this treatment may be an inflammation of the mucosal tissues (i.e., mucositis), whereas the late effect may be a dry mouth. Another example of acute and late effects is seen in abdominal radiation. Irradiation of the bowel may produce bowel movement alterations during treatment, whereas a late effect (albeit rare) is a bowel obstruction. Generally, acute effects of radiation require supportive care, and the patient should be reassured that these effects will improve after the completion of treatment. Mucositis is generally treated with hydration, topical anesthetics, and narcotics. Acute skin reactions, which can occasionally be severe, are treated with topical creams prescribed by the radiation oncologist and rarely require antibiotics. Cloth dressings can sometimes worsen these reactions and are generally not recommended.

### Late Effects

It is important that clinicians pay attention to complaints by patients that are referable to an area of the body that has been treated with radiation. This may signify tumor recurrence or the appearance of a late effect of treatment. With more modern tumor imaging and radiation treatment techniques that permit smaller volumes of normal tissue to be irradiated, untoward complications should be reduced in the future. Nonetheless, late effects will be with us for many years to come. In general, tolerance to the acute and subacute effects of irradiation is improved in pediatric patients, but children are susceptible to a wider range and number of late complications.

In contrast to acute reactions, the late effects of radiation are observed from months to years after irradiation. Although the exact mechanism is unknown, late radiation complications have been thought to be related to either vascular endothelial damage or damage to parenchymal stem cells of the irradiated organ. Each

organ appears to have a unique radiation tolerance, and, thus, vascular injury may not entirely explain the long-term effects of radiation. The late complications of radiation therapy are often the most critical dose considerations in clinical practice. [1,36,42,43,50]

Late effects appear to be dependent primarily on the total dose of radiation and the fraction size. [2,32] When the total dose or fraction size is increased, unacceptable late complications can ensue.

In the child, irradiation before full development of various tissues can result in failure of normal development. This is most evident in neurocognitive sequelae in brain tumor survivors. In addition, bone growth may be affected. The severity of growth retardation is related primarily to the age at treatment, the dose of radiation used, and the location treated. Doses of more than 20 Gy generally have a significant effect on bony growth. [42,43] However, the younger the patient, the greater the effect because there is more growth remaining. In brain tumors such as medulloblastoma with the potential for cerebrospinal fluid spread, the entire craniospinal axis is treated. With such treatment, the growth retardation is manifested primarily as a reduction in sitting height. [43] In addition, irradiation to the brain can result in a decrease in growth hormone with resulting short stature.

One of the most devastating late effects of radiation therapy is the development of a treatment-associated second cancer. [88,89 and 90] This event has been well documented in survivors of childhood cancers. By definition, a radiation-associated malignancy must occur after some latency period within the prior radiotherapy volume and be a different histology than the original tumor. A variety of factors influence the risk of a second tumor, including the patient's underlying genetic predisposition, the dose of radiation, the tissue irradiated, the sex of the patient, and the age at treatment. The thyroid gland, for example, appears sensitive to second cancer after low radiation doses. Breast tissue appears to be particularly sensitive in young women who receive radiation to the breast area. [85]

The volume receiving radiation may be critical to the risk of second tumors as well. For example, the current standard in the treatment of childhood Hodgkin's disease is to limit the dose as well as the volume needing radiation by the use of combined modality therapy, with the expectation that the risk of second tumors will be reduced compared to historical wide-field irradiation. Please see Chapter 49 for a more detailed discussion of second malignancies.

## SUMMARY

Radiation therapy has made important contributions to modern cancer therapy. As a single modality, it has produced impressive cure rates at a number of disease sites. In combined modality therapy, radiation can improve cancer control rates that are achievable with surgery and chemotherapy. Modern delivery techniques, such as proton therapy and IMRT therapy, should continue to improve cure rates and reduce the acute and late effects of treatment.

# PRINCIPLES OF IMMUNE AND CELLULAR THERAPY

NAI-KONG V. CHEUNG
CLIONA M. ROONEY

## INTRODUCTION

Immunotherapy exploits leukocytes, antibodies, and cytokines for tumor destruction. The potential for target specificity renders this approach highly attractive. Early efforts at immune stimulation using bacterial extracts and BCG have been superseded by more sophisticated approaches built on an expanded understanding of the immune system and tumor cells. Clinical availability of genetically engineered antibodies, cytokines, and tumor vaccines has facilitated the evaluation of the toxicities and therapeutic potentials of these agents. Active immunotherapy attempts to induce effectors with immunologic memory, an assurance of long-term protection that is unique in the armamentarium of medical therapeutics. Nevertheless, during the period of immunosuppression by CA and its treatment, passive immunotherapy can have a distinct role. Despite the increasingly intensive use of traditional antiCA treatment modalities that have been effective in rendering patients clinically free of disease, cure remains elusive for many children. It is likely that the role of immunotherapy is to supplement what dose-intensive treatments have failed to accomplish—namely, the eradication of microscopic disease.

Autoimmune or alloimmune reactions can completely destroy organ systems.[1] Conversely, the catastrophic consequences of a defective immune system are evident in various immunodeficiency states, especially in AIDS. Tumor-specific immunity can be induced *in vivo* (i.e., active immunotherapy) or induced and amplified *in vitro* before administration into a patient (i.e., passive immunotherapy). Tumor cells can stimulate a cellular immune response consisting of helper T cells and CTLs. The helper T cell releases cytokines, recruits other effectors, and regulates antibody production by B lymphocytes (i.e., humoral immunity). CTLs kill targets by cytotoxic granules or programmed cell death. Other effector cells of the immune system, including monocytes, granulocytes, NK cells, and eosinophils, are not by themselves tumor specific, but they can be armed with specific antibodies and be rendered tumor selective, a process called *antibody-dependent cell-mediated cytotoxicity* (ADCC). Tumors can also stimulate the formation of antibodies, which kill by complement activation or by mediating ADCC.

## HUMORAL IMMUNOTHERAPY

### Monoclonal Antibodies

Serotherapy using heterologous serum has been largely replaced by the use of MoAbs ( Fig. 14-1), a technology first introduced by Kohler and Milstein.[2] Through somatic cell hybridization, individual plasma cells, each secreting a monoclonal species of antibody, can be immortalized. MoAb offers multiple advantages (e.g., specificity, precision, purity, and quantity) that can be scaled up in pharmaceutical plants. The clinical utility of MoAb for *in vitro* diagnosis and *ex vivo* purging of bone marrow/stem cells is well recognized. This chapter focuses on their clinical applications *in vivo*. Optimal targeting of MoAbs demands high tumor antigen density with homogeneous expression, antigen persistence on tumor cell surface, noninterference by circulating free antigens, low HAMA titer, minimal cross-reactivity with normal tissues, adequate vascularity to allow tumor penetration, and low RES uptake. In practice, few MoAb-antigen-tumor systems possess all of these attributes.

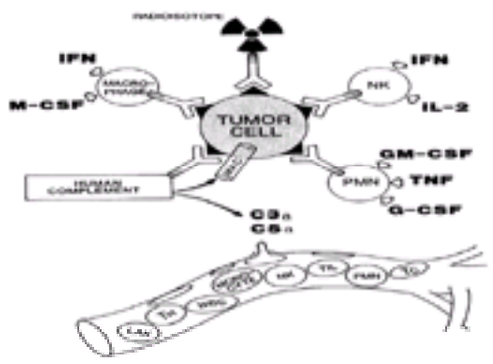

**FIGURE 14-1.** Monoclonal antibody targeted therapy. Antibodies (Y) bind to tumor-associated antigens ( *solid triangles*) and activate complement to form C3a and C5a (chemotactic factors and anaphylatoxins) as well as membrane attack complex (MAC). They also adhere to Fc receptors on leukocytes, including neutrophils (PMN), natural killer cells (NK), and macrophages. G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL-2, interleukin-2; LAK, lymphokine-activated killer cells; M-CSF, macrophage colony-stimulating factor; Tc, cytotoxic T cells; $T_H$, T helper cells; TIL, tumor-infiltrating lymphocytes; TNF, tumor necrosis factor; WBC, white blood cells. (Modified from Cheung NK. Immunotherapy: neuroblastoma as a model. In: Horowitz ME, Pizzo PA, eds. Pediatric solid tumors: pediatric clinics of North America, vol. 2. Philadelphia: WB Saunders, 1991:425–441, with permission.)

#### *Target Antigens*

#### Gangliosides

Gangliosides[3] are acidic glycosphingolipids found on the outer surface of most cell membranes; they are particularly concentrated in gray matter and synaptic junctions in the nervous system, especially during brain development. In serum, gangliosides are found in low concentrations and are transported by lipoproteins. Only trace amounts of gangliosides are found in the cerebrospinal fluid. The lipophilic ceramide portion of the ganglioside is inserted into the lipid bilayer of membranes, and the hydrophilic carbohydrate moieties are exposed to the external environment. They are relatively nonimmunogenic and, although antiganglioside antibodies are found only in neurologic disorders and malignancies, their pathologic significance is unknown. Many tumors have abnormal glycolipid composition and structure. $G_{D2}$, $G_{D3,}$ $G_{M2}$, and O-acetyl-gangliosides have been found in a wide spectrum of human tumors, including neuroblastomas, [4,5] osteosarcomas,[6] soft tissue sarcomas,[7] medulloblastomas, high-grade astrocytomas,[8] melanomas,[9] and small cell lung CAs.[10] They are ideal targets for MoAb because of their high antigen density and persistence on cell membranes. In addition, the only normal tissues with high ganglioside expression are neurons, which are protected from intravenous MoAbs by the intact blood–brain barrier. R24,[11] specific for $G_{D3}$, and 3F8[4] and 14.18,[12] both specific for $G_{D2}$, are examples of MoAbs that have shown successful targeting and antitumor effects in patients with melanoma and neuroblastoma (Table 14-1). KM8969, a recently humanized anti-$G_{M2}$ MoAb, may have clinical potential

given its highly restricted normal tissue distribution. [13]

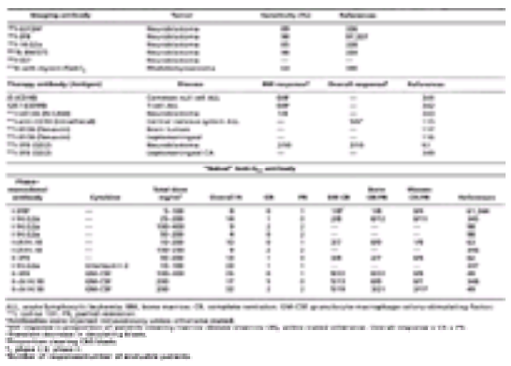

**TABLE 14-1. USE OF MONOCLONAL ANTIBODIES FOR *IN VIVO* DIAGNOSIS AND THERAPY IN PEDIATRIC IMAGING**

### Idiotypes

B-cell tumors express monoclonal surface immunoglobulins that contain idiotypes, [14] which are unique tumor targets. Murine antiidiotypic antibodies, either alone or in combination with IFN-a, IL-2, or chlorambucil, have produced major responses (18% CR) against adult B-cell lymphomas, some of which were durable. [14,15] Tumor regression can be delayed up to 4 weeks after completion of therapy and prolonged with continuing tumor response for 1 year after treatment. [14] HAMA response was uncommon,[14] and the exact antitumor mechanism is still unclear. The persistence of malignant clones despite clinical remission and the emergence of idiotype-negative variants [15,16] have remained obstacles to cure. Although highly successful in adult follicular lymphoma, this strategy is not feasible in pediatric leukemias and lymphomas, in which surface idiotype expression is usually rare.

### Growth Factor and Receptors

Tumor cells proliferate in response to paracrine and autocrine signals. These include insulin-like growth factors and their receptors [17] (in neuroblastoma[18] and rhabdomyosarcoma[19]); nerve growth factor and its receptor TrkA (neuroblastoma)20; p75, or brain-derived nerve growth factor, and its receptor TrkB (neuroblastoma)[20]; or neurotrophin-3 and its receptor TrkC (medulloblastoma and neuroblastoma). [20] MoAbs can potentially stop tumor growth by removing the cytokine or by blocking its specific receptors. However, the ubiquitous nature of these ligands and receptors interferes with their selective tumor targeting. Most clinical experience of receptor-specific MoAb was gathered in adults: anti-IL-2/IL-2R (anti-TAC) in T-cell leukemia and lymphomas; anti-EGF receptor (anti-EGF-R) in lung, breast, bladder, and glial CAs [17]; and anti-HER2/neu/c-*erb* B-2 in breast CA[17] and osteosarcoma.[21] Anti-IL-2R (anti-TAC) MoAbs can target effectively to activated T cells in GVHD and human T-lymphotrophic virus type 1–associated adult T-cell leukemia. [22] Clinical trials using anti-EGF-R antibody in patients with lung CA have shown very few side effects.[17] The antiproliferative effect of anti–EGF-R synergizes with chemotherapy in preclinical models [17] and clinical trials.[23]

### Death-Signaling Receptors

Apoptosis or programmed cell death occurs in T cells during normal thymocyte development and in target tumor cells after CTLs deliver their lethal hit. Fas/APO-1 is a 52-kd cell surface protein capable of inducing apoptosis upon specific antibody engagement in lymphomas and neuroblastomas. In human B-cell lymphoma xenografts, MoAb to APO-1 induces tumor regression histologically suggestive of apoptosis. [24] Because Fas is a ubiquitous death-signaling receptor, however, the clinical utility of Fas-MoAb remains uncertain.

### P-Glycoprotein and Multidrug Resistance

Many human tumors, including neuroblastoma,[25] rhabdomyosarcoma,[26] and osteosarcoma,[26] have overexpression of MDR-1 protein, a P-glycoprotein involved in drug transport and pleiotropic resistance. MRP[27] is also associated with poor clinical outcome in neuroblastoma. MoAbs against MDR-1 or MRP can potentially block the drug efflux pump or directly eliminate cells that overexpress such proteins.

### Tumor Angiogenic Receptors

First proposed by Folkman in 1972,[28] tumor vasculature has become an important target in CA therapy.[29] Both pro-angiogenesis and anti-angiogenesis factors and receptors have been cloned. MoAb to such factors or their receptors [e.g., VEGF receptor, flk-1/KDR (type2)] can inhibit the growth of tumor vessels. [30,31] The antivascular effects of low-dose chemotherapy (e.g., vinblastine) were selectively enhanced when VEGF function was blocked by such MoAbs, [31] producing striking tumor regression in xenograft models.

### Lineage-Specific Lymphoid and Myeloid Antigens

Several lineage-specific antigens on lymphoid cells [CD5, CD19, CD20, CD22, CD25 (IL-2R-alpha), CD52] and myeloid cells (CD33, CD45) have served as useful targets for MoAbs. Most of these antigens except CD20 and CD52 are rapidly internalized when bound to antibody, allowing endocytosis of MoAb conjugates, whether radioisotopes or toxins. CD20, an unglycosylated phosphoprotein, is an optimal target because it does not shed or modulate when bound to MoAb. As a calcium channel, CD20 may regulate B-cell activation. Except for CD20 and CD25, the functions of most of these surface antigens are not entirely clear.

### Intracellular Antigens

Although surface antigens are the usual targets for *in vivo* MoAb diagnosis and therapy, intracellular antigens have also been successfully exploited. TNT-1 is an antibody directed against nuclear histones. Iodine 131–TNT-1 produced regressions of human carcinoma xenografts with no detectable normal tissue toxicity in animals, and it was successful in imaging epithelial carcinoma in humans. [32] Presumably, TNT-1 binds to histones released from necrotic cells, and these antigens are generally not exposed in normal tissues. Nuclear antigens may be attractive candidates for targeted therapy because of their preferential expression in proliferating cells.

### Other Tumor-Associated Antigens

A natural IgM antibody directed at a protein of 260 kd was recently described in normal children. [33] This antibody was absent in infants who had neuroblastoma. When purified, this antibody induced apoptosis of neuroblastoma cell lines *in vitro* and inhibited xenograft growth *in vivo*.[33,34] and [35] Treated xenografts showed massive perivascular complement activation and neutrophil accumulation after 24 hours. Trials are ongoing to test the clinical efficacy of such polyclonal antibodies in treating neuroblastoma. Another antibody, 8H9, directed at a novel glycosylated antigen of approximately 58 kd, was recently described. [36] This antibody reacted strongly with human brain tumors, childhood sarcomas (including osteosarcoma, Ewing's sarcoma, rhabdomyosarcoma, and various sarcomas), and neuroblastomas but was highly restricted in normal human tissues.[36] In biodistribution, it targeted human rhabdomyosarcoma xenografts with favorable tumor to nontumor ratio. [37]

## *Antibody Effector Functions and Conjugates*

### Receptor Cross-Linking and Receptor Blockade

By virtue of their multivalency, MoAbs can cross-link cell-surface receptors activating downstream signals ( Fig. 14-1). In the case of anti-TrkA MoAb, it mimics the

natural ligand, nerve growth factor,[38] leading to trophic signaling. Alternatively, MoAbs can block receptor functions by interfering with binding of the natural ligand (e.g., EGF-R[39] and VEGF-R[30,31,40]).

**Cytophilic Antibodies and Antibody-Dependent Cell-Mediated Cytotoxicity**

Lymphoma, leukemia, neuroblastoma, melanoma, and colon CA cells are effectively killed *in vitro* by lymphocytes, granulocytes, and activated monocytes in the presence of specific MoAb.[41,42,43,44,45 and 46] Human $IgG_1$ or $IgG_3$, and murine $IgG_3$ are most efficient in mediating ADCC. Antibodies function as bivalent ligands, bringing together tumor targets and effector leukocytes. Antibodies can also bind to Fc receptors to activate effector cells. Because the Fc receptors on leukocytes are occupied by normal IgG in blood and tissue fluids, a large amount of MoAb may be required to compete for binding.

To mediate ADCC, FcRIII and adhesion molecule LFA-1 are required for human NK cells. Low concentrations of IL-2 (10 to 100 U per mL) can augment such ADCC. Granulocytes mediate nonoxidative killing of human tumor cell lines *in vitro* (e.g., neuroblastoma in the presence of MoAb 3F8) and require the presence of FcRII, FcRIII, and adhesion molecules CD11b, CD11c, and CD18.[47] Because recombinant human GM-CSF (rhGM-CSF) (2 to 20 ng per mL) and IFN-g can increase granulocyte ADCC *in vitro* by severalfold,[43,44] their local concentrations in tumor tissues may be critical. Because the production of GM-CSF by endothelial cells and monocytes is regulated by activated or immune T lymphocytes, T lymphocytes may play an indirect role in amplifying these antitumor mechanisms. rhGM-CSF induces neutrophilia in patients[48] and may be useful in expanding the effector pool for tumor cytotoxicity. Although MoAb and cytokines appeared to have synergistic antitumor properties *in vitro*, it is uncertain whether their combination will translate into superior clinical results.[49] Antibody sequestration by the cytokine-activated RES can be a limitation. One would hope that cytokines targeted directly to tumor sites via antibody fusion proteins (e.g., ch14.18-IL-2[50] and ch14.18-GM-CSF[51]) would be more selective.[52,53] Activation of T-cell–mediated immunity in rodent tumor studies appeared promising.[54]

Recombinant human M-CSF induces human peripheral blood monocytes to differentiate into large macrophagelike cells *in vitro*. These monocyte-derived macrophages mediate efficient antibody-dependent and antibody-independent cytotoxicities by phagocytosis[46] through the FcRII or FcRIII receptors.[55] In patients, cells of the monocyte-macrophage lineage have been found in some primary tumors and tumor metastases. Local tissue production of factors such as M-CSF may be important in regulating their immunologic functions. In phase I studies, M-CSF induced monocytosis, monocyte cytotoxicity,[56] and thrombocytopenia. However, there was no antitumor effect.

**Complement Activation**

Many tumor cell lines (e.g., leukemia, neuroblastoma, and medulloblastoma) are sensitive to CMC (Fig. 14-1). The terminal pathway of complement activation inserts membrane channels into tumor cells, leading to ionic loss and cell death. However, some tumor cell lines are resistant to complement because of anticomplement surface proteins, including DAF (CD55),[57] homologous restriction factor (CD59),[58] and membrane cofactor protein (CD46).[59] It is also believed that the effect of complement activation extends beyond direct tumor lysis. After complement activation, surface-bound C3b is rapidly cleaved by plasma protease factor I to iC3b. Through CR3 (Mac-1 or $a_Mb_2$-integrin) and CR4 (CD11c/CD18, $a_Xb_2$-integrin) receptors on leukocytes, tumor cells can become opsonized. C3a and C5a, by-products of complement activation, are potent mediators of inflammation[60] and are chemotactic for phagocytic leukocytes. Under normal conditions, leukocytes can be dispatched to any site in the body because of the strong chemotactic signals originating from sites of inflammation. Tumors, however, do not normally release attractants to lure circulating white cells. MoAb (e.g., R24 and 3F8), which activates complement efficiently, has the potential of recruiting effectors to the tumor sites. In addition, C5a enhances lymphocyte function and augments the secretion of IL-1a, IL-1b, and TNF-a from mononuclear cells *in vitro*. These secondary effects can enhance vascular permeability and reduce the transport barriers to MoAb and effector cells.

***Clinical Application of Monoclonal Antibodies***

**First Generation "Naked Antibodies"**

Initial studies of MoAbs have largely focused on their acute toxicities and immunogenicity. In general, toxicities have been tolerable and self-limited. Perhaps the most severe (although self-limited) side effects noted so far have been the pain reaction associated with anti-$G_{D2}$ antibody treatment[61,62 and 63] and the massive cytokine release (leaky capillary leading to hypotension and respiratory distress) associated with anti–T cells MoAb (e.g., patients with chronic lymphocytic leukemia treated with $IgG_{2a}$ MoAb T101). Common acute reactions associated with murine MoAb include fever, blood pressure fluctuations, urticaria, and anaphylactoid reactions and are short-lived. Few long-term toxicities have been observed (e.g., no long-term neurologic toxicities have been seen after intravenous 3F8 treatment in patients followed for as long as 10 years).[64]

Clinical trials using unmodified MoAb in patients with various malignancies have generally been disappointing. Objective responses of large tumor masses are rare. Lymphoid malignancies are more the exception than the rule. Here, antiidiotypic, anti-CD20, and anti-CD52 MoAbs have produced major clinical responses (CR and PR).[14,15,65,66] The chimeric human-mouse anti-CD20 MoAb Rituximab, when used alone or in combination with chemotherapy,[65,67] has produced 55% CR among low-grade lymphomas, with 74% of patients remaining in remission (29 or more months median follow-up). CAMPATH-1H, a humanized rat IgG1 anti-CD53 MoAb, was active against recurrent B lymphoma and T-cell prolymphocytic leukemia.[66] Opportunistic infections, including bacterial sepsis and marrow aplasia, were some of the complications. For neuroectodermal antigens, MoAbs against $G_{D3}$ (R24)[11] and $G_{D2}$ (3F8, 14.18)[61,62 and 63] have been tested most extensively. $G_{D2}$ is particularly relevant for pediatric CA because it is present on a variety of solid tumors. Although the clinical efficacy of anti-$G_{D2}$ antibodies was modest (Table 14-1), response of marrow disease was generally more consistent. During anti-$G_{D2}$ MoAb treatment, most patients had reductions in their serum complement levels, suggesting that complement consumption had occurred. Although the antitumor effect appears to be associated with CMC and possibly ADCC, additional mechanisms are likely in view of the length of time required for response (i.e., 4 to 16 weeks after the initiation of treatment), the continued response long after treatment has ended, and the absence of late relapse after 3 years (Fig. 14-2). Antiidiotype network or T-cell response against antibody-modified tumors could have contributed to the tumor regression.[68,69,70 and 71]

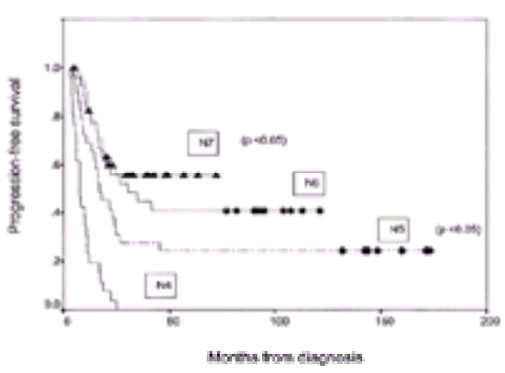

**FIGURE 14-2.** Kaplan-Meier plots of progression-free survival among 121 consecutive patients with stage 4 neuroblastoma diagnosed at age older than 1 year and initially treated at Memorial Sloan-Kettering Cancer Center. A, Adriamycin; C, cyclophosphamide; N4, CAV + ABMT; N5, CAV/PE + ABMT; N6, CAV/PE + 3F8; N7, N6 + 131-I-3F8; P, cisplatin; V, vincristine; E, etoposide.

The clinical role of "naked" MoAb may be in the adjuvant setting for eradicating micrometastases. This was recently demonstrated in patients with colorectal CA[72] and in neuroblastoma.[64] The murine $IgG_{2a}$ 17-1A, specific for gp37–40 on malignant and normal epithelial cells, was administered in a randomized trial to 189 patients with adenocarcinoma of colon or rectum metastatic to regional lymph nodes. At a median follow-up of 5 years, overall death and recurrence rates were substantially reduced. The role of anti-$G_{D2}$ MoAb treatment of minimal residual disease was tested in stage 4 neuroblastoma diagnosed at age older than 1 year.[64] Thirty-four patients were treated with 3F8 at the end of chemotherapy, 23 were in CR, eight in very good partial remission (VGPR), one in PR, and two with histological evidence of marrow disease. Twenty-five of 34 (74%) patients had evidence of disease by more sensitive measures: 14 were $^{131}$I-3F8 scan–positive, nine had marrow disease

by immunocytology, and 12 by reverse transcriptase-polymerase chain reaction of molecular marker *GAGE*. Thirty-eight percent were progression-free (40 to 148 or more months from the initiation of 3F8 treatment). After 3F8 treatment, six of nine patients with positive immunocytology reverted to undetectable, 7 of 12 turned *GAGE*-negative, and all six post–3F8 treatment $^{131}$I-3F8 scans showed resolution or improvement.

### Bispecific Antibodies

Because not all antibodies are cytophilic, by joining two antibodies, one specific for effector cells and one for targets, close contact of effector to target can be achieved.[23] NK cells, granulocytes, or T lymphocytes can be redirected to tumor cells. For example, joining anti-FcRIII (anti-CD16) to antitumor antibodies (anti-CD30) can enhance granulocyte- or NK-ADCC against Hodgkin's lymphoma.[73] The antigen CD3 found on peripheral blood T cells is closely associated with the TCR. MoAb binding to CD3 can activate these T cells to form CTLs. Anti-CD3 conjugated to antitumor MoAbs (e.g., anti-CD19, anti-ErB-2, and anti-CD30) can direct CTLs against human B lymphomas, ErB-2–positive tumors, and HD, respectively.[74,75 and 76] Approximation of leukemia cells (e.g., through anti-CD19, anti-CD20, or anti-CD30) and T-cell costimulatory receptor (anti-CD28) using bispecific antibodies can also enhance specific T-cell immunity. [76,77 and 78]

### Conjugated Antibodies

To enhance the effector functions of MoAbs, conjugation to drugs, toxins, and radionuclides has been explored extensively. Doxorubicin, melphalan, methotrexate, and vinca alkaloids, when conjugated to MoAbs, had limited clinical success. [79] Direct administration of MoAb-melphalan conjugates through the hepatic artery induced mixed response in metastatic colon CA. Tyrosine kinase inhibitors (e.g., Genistein) can be targeted by MoAb (e.g., anti-CD19) to lymphoid malignancies. [80,81] Another novel approach uses MoAb to deliver a covalently conjugated enzyme to the tumor, which can then activate a nontoxic prodrug. [82,83]

***MoAb-Toxin.*** MoAbs have also been used to target toxins derived from plants or bacteria. Once internalized, these toxins are potent inhibitors of protein synthesis. Ricin and diphtheria toxins each consists of two polypeptide chains (A chain and B chain). RTA inactivates the 60S ribosomal subunit whereas the A chain of diphtheria toxin destroys the elongation factor 2 (EF2). RTA or blocked ricin is unable to enter the cells because it lacks a cell attachment site (i.e., the B chain of ricin binds to galactose on cell surfaces). Through a covalent linkage to the MoAb, these toxins can accompany the MoAb-antigen complex when it is endocytosed. Even for poorly endocytosed antibody-antigen systems (e.g., $G_{D2}$), RTA-MoAb has shown striking antitumor effects *in vitro* and in xenografted mice.[84] Pseudomonal exotoxin is a single polypeptide, which causes ADP-ribosylation of EF2, preventing its participation in protein synthesis. The calcium channel blocker verapamil and its analogs have been shown to enhance the *in vitro* cytotoxicity of MoAbs conjugated to *Pseudomonas* exotoxin.[85] In patients with B-cell chronic lymphocytic leukemia, anti-T101-MoAb-RTA had a short half-life and produced minimal toxicity while achieving a transient decrease in circulating tumor cells. It elicited no HAMA and no anti-RTA antibodies, unlike a colon-MoAb-RTA trial in which antibodies were found in all patients. [86] Anti-CD19–blocked ricin induced an overall 21% response (four CR, 20 PR) in 116 patients.[14] The most significant toxicity was vascular leak syndrome, characterized by marked fluid overload, dyspnea, and sensorimotor neuropathies.[87] Deglycosylated RTA devoid of mannose and fucose has been developed to reduce hepatic clearance. With longer serum half-lives, major responses were seen in 25% of patients with lymphoma after anti-CD22-deglycosylated RTA treatment.[85] Recombinant toxins (e.g., pseudomonas exotoxin PE40 and diphtheria toxin $DAB_{486}$), where the cell-binding domains are replaced by single chain Fv or cytokines (IL-2 or IL-6), are in various stages of preclinical and clinical development.[22,85] Pokeweed antiviral protein, a potent inactivator of ribosomes, successfully induced remission in preclinical models when targeted with anti-CD19 [88] and anti-CD7 MoAb.[89] More recently, anti-CD33 antibody conjugated to calicheamicin achieved a high response rate in refractory AML, with tolerable side effects, including fever, chills, and reversible neutropenia. [90,91]

***Radiolabeled Monoclonal Antibody.*** MoAbs have the potential to target tumor-ablative RIT.[92] Radioimaging studies help define the biodistribution of MoAb and estimate the relative amounts of MoAb deposited in various tissues and organs, a prerequisite for therapeutic studies. In preclinical models, ablation of established xenografts is rare but possible [e.g., in neuroblastoma ($^{131}$I-3F8 whole antibody),[93] colon CA [$^{131}$I-$F(ab')_2$ fragments],[94] or lymphoma.[95] Patient responses after RIT have been rarely seen in solid tumors but are seen more commonly in lymphomas and leukemias. Unlike in CMC and ADCC, the bystander effect of RIT is of great importance in understanding the efficacy and toxicity of individual isotopes. Although $^{131}$I has been the most widely used isotope, $^{90}$Y and $^{67}$Cu may have more favorable physical characteristics.

***Imaging Studies.*** Tumor imaging using radiolabeled antibodies can provide valuable information about the extent of disease and for planning targeted radiotherapy. Although quantitation of radioactivity is imprecise with planar imaging, single-photon emission computed tomography, and positron emission tomography in particular, have offered significant improvements.[92] Because radiolabeled MoAbs can inflict significant toxicity, nonspecific uptake in normal organs can degrade therapeutic ratios. In pediatric patients, few antibodies are available for radioimmunoscintigraphy. The ganglioside $G_{D2}$ and gp190 protein, both neuroblastoma antigens, have been the most studied. 3F8 is a murine MoAb specific for $G_{D2}$. In 42 patients with neuroblastoma, $^{131}$I-3F8 localized to neuroblastomas at their primary sites as well as to metastatic disease in the lymph nodes, bone marrow, and bone (Fig. 14-3).[96] A comparison with $^{131}$I-metaiodobenzylguanidine suggests that 2 mCi $^{131}$I-3F8 was more sensitive and specific in detecting metastatic sites of disease. [97] The magnitude of tumor uptake in patients was 0.04% to 0.08% of the injected dose per gram. Imaging studies using 14.2a and ch14.18 antibodies (both anti-$G_{D2}$ MoAb) have also yielded positive results.[98,99] CE7 is a murine antibody against gp190.[100] Its chimeric form, chCE7, is effective in detecting human neuroblastoma.[101,102] More recently, MoAb 8H9 directed at a novel antigen on a broad spectrum of pediatric solid tumors has also shown promise in preclinical models.[37]

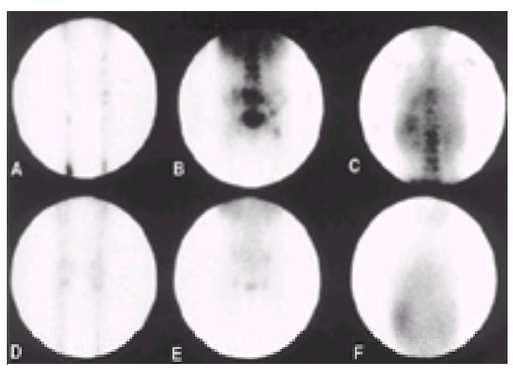

**FIGURE 14-3.** A patient with stage 4 neuroblastoma refractory to myeloablative therapy imaged with $^{131}$I-3F8 before **(A, B,** and **C)** and after **(D, E,** and **F)** 3F8 treatment. **A** and **D**, lower extremities; **B** and **E**, posterior abdomen and pelvis; **C** and **F**, posterior chest. Diffuse disease in spine and pelvis resolved after 3F8 treatment. (From Cheung NK. Immunotherapy: neuroblastoma as a model. In: Horowitz ME, Pizzo PA, eds. Pediatric solid tumors: pediatric clinics of North America, vol. 2. Philadelphia: WB Saunders, 1991:425–441, with permission.)

***Radioimmunotherapy.*** Although many childhood tumors are radiosensitive, the experience of RIT in children is rather limited. In a phase I study, 24 patients (12 boys and 12 girls, 0.3 to 24.2 years of age at diagnosis) with refractory neuroblastoma (23 stage 4, one stage 3 unresectable primary with ascites) at Memorial Sloan-Kettering Cancer Center completed treatment with $^{131}$I-3F8 at seven dose levels, namely 6, 8, 12, 16, 20, 24, and 28 mCi per kg.[92] Twenty-two of 24 patients were rescued with cryopreserved autologous bone marrow; one patient received GM-CSF without marrow rescue; and one died of progressive disease before marrow reinfusion. Acute toxicities of $^{131}$I-3F8 treatment included pain (20 of 24) during the infusion, fever (19 of 24), and mild diarrhea. All patients developed grade 4 myelosuppression. Thyroid uptake despite oral potassium iodide led to hypothyroidism in four patients. Six patients survived longer than 20 months from the time of $^{131}$I-3F8 treatment; none encountered late extramedullary toxicities. Responses were seen in both soft tissue masses and bone marrow.[92] The use of $^{131}$I-3F8 (20 mCi per kg) to consolidate remission was tested in the N7 protocol at Memorial Sloan-Kettering Cancer Center among 35 patients with newly diagnosed (age greater than 1 year) stage 4 neuroblastoma.[103] The median time to engraftment was not substantially different between the newly diagnosed and prior treated group: Approximately 15 days from the day of rescue to reach absolute neutrophil count greater than 500 per µL, 45 days to reach a platelet count greater than 20,000 per µL, and almost 3 months to reach a platelet count greater than 50,000 per µL. Aside from fever and neutropenia plus subsequent infections, there were no extramedullary toxicities other than hypothyroidism, which occurred despite aggressive thyroid protection using oral potassium iodide, liothyronine sodium (Cytomel), and potassium perchlorate. One patient died of infectious complications 2 months after $^{131}$I-3F8 treatment. The overall progression-free survival on N7 is projected to be greater than

50%, compared to 40% in N6 (Fig. 14-2).

Other therapeutic studies using $^{131}$I included anti-EGF-R for grade IV gliomas,[39] anti-CD33 for AML,[104] anti-CR2,[105] anti-CD20 (anti-B1),[106,107] anti-CD37,[108] Lym-1,[109] and anti-CD22 (LL2)[110] in non-Hodgkin's lymphoma primarily in adults. To overcome RES uptake in the liver, a greater than 400-mg dose of naked anti-B1 antibody was used to reduce liver uptake before RIT. Seventy-five cGy was the maximal nonmyeloablative total body dose. Among 28 patients receiving 34 to 161 mCi, 50% achieved CR and 29% PR, with a median response duration of 12 months and median survival of 50 months. HAMA response was found in only 12% of patients. Using myeloablative doses (280 to 785 mCi) calculated to deliver 25 to 27 Gy to critical organs, $^{131}$I-anti-B1 achieved 79% CR and 7% PR,[111] with an overall survival and progression-free survival of 68% and 42%, respectively. Hypothyroidism developed in 60% of patients 6 to 12 months after therapy, and secondary leukemia was not observed. Similarly, myeloablative doses (10 to 31 Gy) of anti-CD37 MoAb also produced 84% CR and 11% PR, with eight patients in continual remission 46 to 95 months after therapy. Extramedullary toxicities were mild at doses of less than 23 Gy, beyond which cardiopulmonary toxicity became dose limiting.[112] In a phase I trial of $^{131}$I-Lym-1 murine antibody, greater than 100 mCi per $m^2$ was myeloablative[113]; 30% had CR and 30% developed HAMA. $^{131}$I–LL2 (anti-CD22)[114] also showed activity against relapsed B-cell lymphoma.

Intraventricular and intrathecal $^{131}$I-anti-CD10 has also been tested in children with central nervous system ALL,[115] whereas intraventricular and intratumor $^{131}$I-81C6 (antitenascin) have prolonged patient survival.[116,117] Clinical trials using intraventricular $^{131}$I-3F8 have also shown favorable dosimetry and minimal side effects in patients with leptomeningeal GD2-positive cancers.[349]

Although $^{131}$I is not the ideal radioisotope for RIT because of *in vivo* dehalogenation, its method of conjugation to proteins is widely accepted and its late toxicity is uncommon. Alternative isotopes [$^{90}$Y-murine anti-CD20 in a phase I/II trial,[118] $^{90}$Y-murine (10 to 54 mCi) anti-idiotypic MoAb,[119] $^{90}$Y-anti-T101 (CD5),[120] $^{90}$Y-anti-TAC (CD25),[121] and $^{67}$Cu-Lym-1[122]] have all produced major responses among patients with advanced lymphoma. Alpha-particles emitting isotopes [e.g., astatine 211 and bismuth 213 ($^{213}$Bi)] carry high linear energy transfer at a short pathlength (0.04 to 0.05 mm) and can destroy tumors more effectively and with more precision. Patient studies of $^{213}$Bi-HuM195 (anti-CD33) have confirmed these predictions.[123] These clinical trials highlighted the utility of RIT in radiosensitive tumors, the limitations of low MoAb tumor penetration, and the dose-limiting myelotoxicity of isotopes. Nevertheless, the relative lack of extramedullary toxicities should encourage further refinement of this targeting technique.

**Pretargeting**

To improve tumor uptake and reduce systemic toxicity, a multistep procedure to pretarget the antibody before the cytotoxic ligand has been successfully used. Generally, a tumor-specific antibody is conjugated to a ligand binder, such as streptavidin or avidin (with high affinity for biotin [124,125]) or ligand-specific antibody (binding to metal chelators such as diethylenetriamine pentaacetic acid,[126] triethylenetetramine,[127] or tetraazacyclododecanetetraacetic acid[127]). In the first step, these conjugates (approximately 200 kd) are allowed to localize to tumors *in vivo*, and any excess is allowed to clear from the blood. The appropriate small radiolabeled ligand (e.g., $^{67}$Cu-triethylenetetramine, $^{90}$Y-tetraazacyclododecanetetraacetic acid, $^{111}$In-diethylenetriamine pentaacetic acid, or radiolabeled biotin) is then injected intravenously in a subsequent step. By virtue of the high affinity interaction, the ligand penetrates tissues rapidly and is taken up strongly by the antibody conjugate at the tumor site. Unbound ligand is quickly excreted through the kidneys. Because of the short transit time of the toxic ligand (radionuclides or toxins), a substantial improvement in the therapeutic ratio without sacrificing the percent dose injected per gram is possible. A three-step approach, which uses biotinylated MoAb followed by avidin/streptavidin then biotinylated chelator, has also been successful.[128] Early clinical trials are showing some promising results.[128,129] This pretargeting concept can also be extended to antibody-directed enzyme prodrug strategies.

**Idiotype Network**

The role of MoAb in pediatric patients can differ substantially from that in adult CAs. Most pediatric CAs are chemoresponsive: MoAb is particularly useful at the time of minimal residual disease. The increasing intensity of chemotherapy can greatly attenuate HAMA response, thereby allowing repeated administrations (e.g., MoAb 3F8 in neuroblastoma).[64] The region of an Ig unique to the antibody is called an *idiotype* (Fig. 14-4). It encompasses the antigen binding site (CDR). Immunization with an antibody (Ab1) specific for an antigen can activate B lymphocytes, producing antiidiotypic antibodies (Ab2) with variable regions bearing the internal image of the first (Ab1) antibody and mimicking the original antigen. Ab2 can in turn induce anti-antiidiotypic antibody (Ab3). This network of antibody responses was first proposed by Jerne.[130] As the immune system recovers from chemotherapy, exposure to tumor-selective MoAb (Ab1) can induce Ab2 and Ab3 and thus bias the recovering repertoire toward the specific antigen network. The potential for biasing the immune system toward specific antigens has been well documented in murine models[131] and human disease states.[132] If true, one would expect such idiotype networks to be particularly useful after intensive immuno- and myelosuppressive therapy. Ab3 was associated with prolonged survival among patients who received $^{131}$I-3F8 imaging pre-ABMT for metastatic neuroblastoma.[133] In a subsequent analysis of patients consolidated with 3F8 in their first or subsequent remission, HAMA response was strongly correlated with prolonged survival and progression-free survival, except in patients with early high titer, which prevented repeat 3F8 treatment.[64] This HAMA may be responsible for the induction of Ab3 and Ab3' (anti-$G_{D2}$) antibody formation, a marker of the host idiotype network thought to be responsible for preventing late relapses after 3 years (e.g., N5, N6, and N7 in Fig. 14-2).[71] Similar observations suggestive of idiotype network were previously reported after MoAb treatment with 17-1A (colon CA)[69,134] and CA125 (ovarian CA).[135]

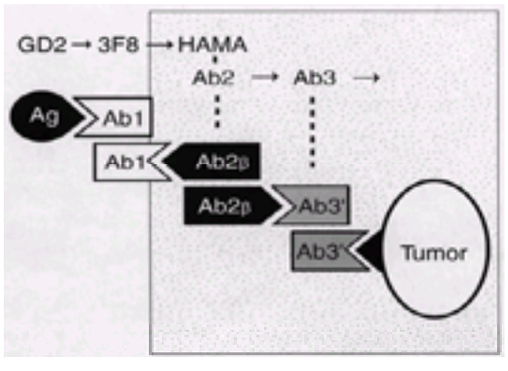

**FIGURE 14-4.** Idiotype network. Antiidiotypic antibodies (Ab2) are a subset of the human antimouse antibody (HAMA) response. Among the Ab2, a subset (Ab2b) bears the internal image of Ab1 (3F8), mimicking the original antigen (Ag). Ab2 can induce anti-antiidiotypic antibodies (Ab3), a subset of which (Ab3') reacts with the original target tumor antigen $G_{D2}$. Shaded box represents the patient.

***Genetically Engineered Antibodies***

Genetically engineered antibodies with potential use in clinical oncology are shown in Figure 14-5.

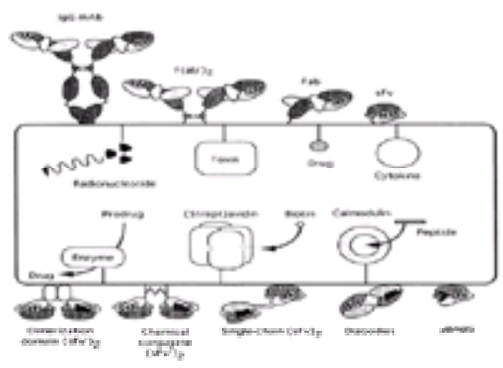

**FIGURE 14-5.** Antibody derivatives with potential use in clinical oncology; heavy chains ( *solid black*), light chains (*light shading*), and complementarity-determining regions (CDRs) (*circles, open or solid*). Progressively smaller antibody molecules can be produced by chemical or recombinant methods ( *top*). Effector molecules (*inside box*) can be conjugated chemically or fused genetically to these recombinant antibodies to provide novel effector functions. Bivalent and bispecific antibodies (*bottom*) can also be made. cBABS, chimeric bispecific antibody–binding sites, in which the bottom loops of sFv, are replaced genetically by the CDRs from antibody of a second specificity[334]; diabodies, bispecific sFv[335]; mAb, monoclonal antibody; sFv and scFv, single chain Fv. [From George AJT, Spooner RA, Epenetos AA. Applications of monoclonal antibodies in clinical oncology. *Immunol Today* 1994;15(Dec):559–561, with permission.]

### Humanization and Chimerization

Human MoAb, being less antigenic in patients, should be superior to mouse MoAb if multiple injections are planned. Success in making human hybridoma has so far been limited by poor fusion efficiency with myeloma partners. The specificity and affinity of an antibody is determined by the variable region, which carries within it small hypervariable sequences called *complementarity-determining regions* (CDRs). These variable regions from murine MoAbs can be genetically joined to human Ig constant domains, producing chimeric MoAbs (e.g., ch14.18 specific for $G_{D2}$).[136,137] A more refined approach uses CDR sequences to graft into human Ig genes.[138] Besides rendering such antibodies humanlike and thus less immunogenic in patients, different Fc can now be selected or modified for a particular immune function. CAMPATH-1 is a rat MoAb that reacts with an antigen expressed by human lymphocytes and monocytes. The CDRs of CAMPATH-1 have been grafted into human heavy and light chain genes to create a series of humanized MoAb of human IgG1, 2, 3, and 4 subclasses. Humanized CAMPATH-1 has been tested *in vitro* for marrow T-cell depletion to prevent GVHD in allogeneic bone marrow transplant and in patients with non-Hodgkin's lymphoma with no detectable neutralizing antibody response.[138] Similar successes in circumventing the HAMA response was reported in other clinical trials using humanized antibodies (e.g., anti-CD33 in AML) [139] and anti-HER2/neu in metastatic breast CA.[140] Most recently, transgenic mice engineered with human Ig loci containing the majority of the human antibody gene repertoire in nearly germline configuration have succeeded in making fully human monoclonal antibodies of both the IgMk and IgGk classes. [141]

### Functional Modifications

With further refinement, the affinity and specificity of an antibody can also be modified by manipulating nucleotides within or around the CDRs. [142] Joining antibody to cytokines (e.g., IL-2,[143] GM-CSF,[144] and IL-12[145]) can further enhance effector functions.[146] In a murine model, antibody targeted IL-2 to eradicate hepatic and pulmonary melanoma metastases in severe combined immunodeficiency mice.[147] Even the Fc regions of MoAb can be exploited by grafting onto virus-binding proteins (e.g., the gp120 binding site of CD4) to produce an immunoadhesin that binds to HIV-infected cells for ADCC. [148]

### Single Chain Fv

Antibody fragments, because of their smaller size, penetrate tumors better than the whole Ig molecule. The single chain Fv (scFv) fragment is a single chain containing the $V_H$ and $V_L$ chains joined by a linker peptide, synthesized by *Escherichia coli* or eukaryotic expression systems such as myeloma cells.[149] ScFv can be synthesized from the complementary DNA of existing myelomas or directly from phage display technology. [150] The binding characteristics of the scFv fragment, including affinity and specificity, can be made similar to those of the whole Ig. [151] Its clearance is more rapid (5 to 15 times faster than the Fab or whole Ig), whereas its tumor uptake is comparable to that of Fab. ScFv fragment of anti-TAC MoAb has been fused genetically to a modified portion of the pseudomonal toxin PE40, which lacks a cell binding site and is nontoxic when free. [152] This novel conjugate killed IL-2R–positive cells but not IL-2R–negative cells *in vitro*. Genetic fusions of scFv to itself (oligomers for improved avidity), to other scFv (bispecific antibodies), to streptavidin (for pretargeting followed by radiolabeled biotin), to enzymes that activate prodrugs, and to other proteins have greatly expanded the repertoire of the antitumor armamentarium ( Fig. 14-5).[151,153] The possibility of producing these recombinant antibody-based proteins in plants will facilitate clinical development of these novel agents. [154]

### T Bodies Can Redirect Lymphocyte against Human Tumors

With the advent of efficient retroviral gene transduction methods, antibody-derived fusion genes can now be introduced into potent killer cells to redirect them specifically to tumor cells.[155] Previous successes of adoptive T-cell therapy (see the section on cellular immunotherapy) exploited the strength of human immune response against viral antigens, where T-cell clonal frequency is high. They are ideal targeting vehicles because they home appropriately to tumors and carry out their cytotoxic functions. They can amplify the antitumor response by recruiting other immune cells. When provided with the primary activation signal (e.g., through engagement of the TCR) and a costimulatory signal (e.g., through CD28), both helper T-cell expansion and cytolytic T-cell expansion are sustained. When transduced into T cells, ScFv are called *T bodies*. Chimeric immune receptors joining tumor-selective ScFv to T-cell signal transduction domains (e.g., Fc-gamma-chain or TCR-zeta-chain[156,157] and CD28[158]) can couple antigen-specific tumor recognition with T-cell activation. When ScFv recognizes tumor cell–surface epitopes, the chimeric immune receptor triggers the release of cytokines, tumor lysis, and tumor rejection. [155,157,159,160,161] and [162] This approach has many advantages. It bypasses the requirement of tumor MHC for T-cell activation. For tumors like neuroblastoma, their downregulation or absence of MHC can disable classic T-cell–based strategies. In addition, human tumor targets often lack costimulatory molecules (e.g., CD80) or overstimulate inhibitory receptors (e.g., CTLA4 on T cells). Furthermore, chimeric immune receptor approach can greatly expand the list of potential antigen targets, many of which are exquisitely specific and most of which have never been targeted by CTLs. Although this strategy uses peripheral blood T cells, it does not depend on preexisting antitumor immunity in CA patients. T bodies have been tested in several tumor models. In ovarian CA, a chimeric construct of scFv against neu/HER[156,157] and human IgGFcR-gamma chain was cloned into retroviral vector for gene transfer into T lymphocytes. GM-CSF secretion and CTL activity against the tumors were detected. [155,156] Anti-ErB2R-Fc-gamma was successfully introduced to retarget CTLs.[159,163] ScFv-Fc(epsilon)RI-gamma chain was used to arm CTL against renal cell carcinoma. [161] Although scFv gene transduction puts a new recognition unit on a lymphocyte to guide its trafficking to the tumor, lymphocytes can be preselected for specific functions such as T helper, CTL, Th1, or Th2. It can also carry genetically engineered properties, such as the ability to secrete cytotoxic cytokines, as was done with TIL cells [164]; to secrete tumor-selective toxins[165]; to metabolize or activate prodrugs (e.g., thymidine kinase and gancyclovir [166] or P450-2B1 that converts cyclophosphamide to 4-hydroperoxycyclophosphamide[167]), or to resist alkylators (e.g., carmustine[168]) or even MDR-1–regulated drugs.[169] The limitation of low clonal frequency of adoptive T cells in TIL and LAK strategies may now be overcome by the T-body approach.

### Diabody and Bispecific Antibodies

Multivalent recombinant antibody fragments have achieved high-avidity binding and novel combinations of specificities. [170] In scFv, $V_H$ and $V_L$ are joined by a linker peptide. A linker of greater than or equal to 12 residues produces predominantly monomers. A linker of three to 12 residues disables scFv folding, forcing its association to form bivalent dimer (diabody of 60 kd).[171] At linker length of less than three, trimers (triabodies, 90 kd) or tetramers (120 kd) predominate, with increasing binding avidity.[171] Most important, compared to monomers (25 kd), molecules of 60 to 120 kd have optimal retention and clearance properties *in vivo*. When the four variable domains ($V_H$ and $V_L$) derived from MoAb of different specificities are linked together (tandem diabody), a bispecific recombinant antibody of 114 kd is created (cross-linking $CD19^+$ malignant B cells and $CD3^+$ T cells).[172] Diabody strategy can also combine antibody fragments specific for different epitopes on the same antigen (e.g., VEGF-R2).[173]

### Humoral Cancer Vaccines

#### *Tumor Antigen Vaccines*

Most antigens can induce antibodies only with the help of T cells. Other antigens (including many carbohydrates) induce immunity without T-cell help, but the antibody response is generally restricted to the IgM class, and without persistent antigen, it is short-lived with no secondary responses. Antibody response to tolerated antigens resembles that of T-independent antigens. If T-cell help is reestablished in tolerant hosts by adoptive immunity, however, the response to these same antigens can be strengthened. Many tumor antigens are believed to lack helper T-cell epitopes (e.g., carbohydrates or glycolipids) and thus are often tolerogens or poor immunogens. Tumor antigens from chemically or virally induced tumors are exceptions. For example, methylcholanthrene- or polyomavirus-induced tumors can sensitize mice against subsequent tumor engraftment. Tumor rejection is mediated and adoptively transferable by T lymphocytes. It is augmented by bacterial products injected into growing tumor nodules or mixed with irradiated immunizing tumor cells.[174] Immunogenicity of cells can also be increased by mutagens,[175] viral or chemical antigens

(i.e., xenogenization),[176] enzymatic unmasking with neuraminidase,[177] or transduction of cytokine/costimulator genes (see the section Cellular Immunotherapy).

### *Tumor/Tumor Antigen Selection*

To identify the tumor antigens for humoral immunity, a serologic approach called *autologous typing* has been employed using autologous tumor cell lines (to avoid alloantibodies) to screen for antitumor serum antibodies in adult patients with melanoma, renal CA, astrocytomas, and leukemia. At least three types of antigens have been defined: (a) mutated antigens restricted to tumor cells, such as EGF-R in glioma[178]; (b) antigens on tumors of common origin but highly restricted among normal tissues, including differentiation antigens such as gangliosides $G_{M2}$, $G_{D2}$, and $G_{D3}$[179] found in neuroectodermal tumors, a-fetoprotein in hepatomas, as well as CEA, TF, and sialylated Tn[180] expressed on a variety of epithelial carcinomas; and (c) antigens widely distributed among normal and malignant cells. The relative contribution of humoral versus cellular immunity in tumor surveillance in patients remains unclear.[181] Furthermore, specific antibodies can inhibit antitumor response by blocking CTL target antigens.[182] Because circulating IgM antibodies specific for selective tumor-associated antigens (e.g., $G_{M2}$, TF, and sialylated Tn) have correlated strongly with longer survival in patients with melanoma and epithelial CAs, a substantial effort has been devoted to the development of humoral vaccines.[183]

### *Carrier Proteins and Adjuvants*

To enhance immunogenicity, covalent attachment of antigen to carrier proteins [e.g., keyhole-limpet hemocyanin (KLH)] to induce T-cell immunity may be required, similar to the experimental models of autoimmune diseases.[183] A less specific approach in increasing immunogenicity uses adjuvants to activate APCs (e.g., macrophages) and T lymphocytes. Examples of such adjuvants include BCG, muramyltripeptide, muramyldipeptide, monophosphoryl lipid A (an analog of endotoxin), Detox (a combination of monophosphoryl lipid A and mycobacterial cell wall skeletons),[184] pluronic triblock copolymers (e.g., L121), and saponin QS-21.[185]

Adjuvants have been incorporated into tumor vaccines to heighten the antitumor humoral response. Early clinical trials combined whole tumor cells or fractions thereof with BCG, complete Freund's adjuvant, Detox, or xenogens. Many of these studies included concomitant chemotherapy without prospective randomization. Therapeutic effects were uncommon (fewer than 10% of the trials showing response) or difficult to reproduce.[181,183] The biochemical/molecular identities of the tumor antigens in these vaccines were uncertain. Immune responses consisted mainly of tumor-nonspecific antibodies against HLA, viral antigens, fetal calf serum, or other common tissue antigens. Specific antibodies have been reported in a high percentage of melanoma patients receiving purified gangliosides in vaccine trials, especially when KLH carrier and QS-21 adjuvant were used.[183]

### *Antiidiotypic Antibodies as Vaccines*

An alternative to using tumor antigens as vaccines exploits antiidiotypic (Ab2) antibodies.[186] Immunization with Ab2 antibodies can induce anti-antiidiotypic antibodies (Ab3) that can cross-react with the original target tumor antigen (Fig. 14-4). As antitumor vaccines, Ab2 antibodies have advantages over native antigens (e.g., carbohydrates) because they induce better T-cell help and stronger antibody response. Because they can be easily manufactured and modified by genetic engineering, they are preferable to difficult chemical synthesis (e.g., complex carbohydrates). Antiidiotype vaccines have been used successfully in experimental infections and tumors and are being evaluated in patients with colon CA (against CEA),[187] melanoma (against $G_{D2}$),[188] and lymphoma. An alternative strategy unique for B-cell lymphomas exploits the clonal expression of cell surface idiotypes. Immunizing patients with their tumor-specific autologous idiotype proteins conjugated to KLH has produced humoral and cell-mediated antiidiotypic responses as well as tumor regressions.[189]

## Cytokines for Cancer Immunotherapy

Cytokines have pleiotropic effects on the immune system. They stimulate the proliferation of effector cells, augment effector cells' tumoricidal properties, enhance the APC function of monocytes and macrophages, and modulate target antigen expression on tumor cells. The use of cytokines for CA immunotherapy is primarily focused on T-cell and NK-cell activation by ILs and IFNs, APC activation (also see the section Cellular Immunotherapy), tumor growth inhibition plus tumor lysis, and granulocyte/macrophage activation of ADCC (also see antibody functions in the section Monoclonal Antibodies).

### *Interleukin-2*

IL-2 is released by T cells following antigen encounter.[190] It binds to a bimolecular receptor complex (i.e., 55-kd alpha chain and 70-kd beta chain) expressed by T cells stimulated by antigen or mitogen. NK cells and large granular lymphocytes bear only the beta chain receptor, which binds IL-2 slowly and with less affinity. After activation by IL-2, however, NK cells express TAC (alpha chain) on their cell surface. IL-2 stimulates lymphoid proliferation *in vitro* and *in vivo*. In preclinical models, IL-2 can expand antigen-specific T lymphocytes *in vitro* before adoptive transfer into tumor-bearing animals. It can also expand lymphocyte pools in tumor-bearing animals. Tumor specific T cells can be found in spleen, in lymph nodes, or as TIL. Because most spontaneous syngeneic tumors are poorly immunogenic, however, tumor-specific T cells in patients are usually rare and difficult to boost.

Although NK cells can kill tumor cell lines *in vitro*, most fresh tumors are resistant to unactivated NK cells. After exposure to high concentrations of IL-2, however, a heterogeneous population of peripheral blood–derived NK (and probably other lymphoid) cells acquire the LAK cells' ability to lyse fresh tumor cells, endothelial cells, lymphocytes, monocytes, and cells that are virally infected or hapten modified. Unlike NK cells, LAK cells are IL-2 dependent.[190] Distinct from that of T cells, their cytotoxicity is not MHC restricted, and they lack mature T-cell markers. IL-2–activated NK and LAK cells have increased surface Fc receptors that enhance their ability to mediate ADCC. The best tumor responses in animal models were achieved if IL-2 treatment was administered over several days or weeks, and when higher doses of IL-2 were used.[190]

IL-2 administered intravenously has produced significant biologic effects.[191] It causes rapid egress of lymphocytes into tissues, resulting in lymphopenia during IL-2 treatment and rebound lymphocytosis after IL-2 is stopped. It increases the synthesis and release of IL-2 receptors, induces secondary cytokine (e.g., IFNs, TNF-a, IL-6) release into blood, decreases PMN chemotaxis and Fc expression, increases endothelial-leukocyte adhesion molecules on endothelial cells, produces eosinophilia, and activates LAK activity. Side effects include nausea, vomiting, diarrhea, rash, thrombocytopenia, cholestasis, increased sepsis, and capillary leak syndrome, leading to pleural and pericardial effusion, neurologic deficits (disorientation, somnolence, coma), peripheral edema, oliguria, and weight gain. Severe cardiopulmonary toxicities in children have been observed at doses greater than or equal to $3 \times 10^6$ units per $m^2$ per day. Continuous IL-2 infusion is less toxic than bolus therapy. Most studies report a 20% remission rate (usually a partial response lasting a few months) in patients with renal cell carcinoma or metastatic melanoma. In AML, IL-2 administration after myeloablative chemotherapy may prolong remission[192]; however, it is not effective against ALL. Except for minor responses (e.g., transient decrease in urine catecholamines and disappearance of skin nodules) in patients with neuroblastoma treated with IL-2 alone after marrow transplantation,[193] no antitumor effect of IL-2 was found in four pediatric phase I trials, irrespective of drug schedule (continuous infusion versus two to three weekly bolus injections).[194,195 and 196]

### *Interferons*

IFN-a and -b[197] can activate NK and monocyte functions and are active clinically against a variety of adult CAs, including bladder CA, AIDS-related Kaposi's sarcoma, renal cell carcinoma, malignant melanoma, solid tumors, hairy cell leukemia, chronic phase CML, low-grade NHL, multiple myeloma, and cutaneous T-cell lymphoma.[198] However, complete responses are rare. The impact on survival has been small, and no cures have been achieved. The combination of 13- *cis*-retinoic acid and IFN-a has produced major responses in 47% of patients with advanced squamous cell carcinoma of the cervix.[199] However, attempts to show a direct correlation between laboratory assessments of NK, ADCC, and T-lymphocyte activities with clinical efficacy have been unsuccessful.

IFN trials in children have been limited. *In vitro*, IFN-g up-regulates MHC class I and adhesion molecules in neuroblastoma.[200,201 and 202] In neuroblastoma patients[203] treated with 0.05 to 0.10 mg per $m^2$ IFN-g intravenously three times each week for 4 weeks, a transient increase in NK activity and expression of MHC antigens in neuroblastoma cells was seen in four of six patients. However, no significant clinical response was observed. Children with recurrent brain tumors treated with IFN-b (50 to $600 \times 10^6$ IU per $m^2$ three times per week for 14 weeks) demonstrated a partial response radiographically in 4 of 21 patients (including two with brain stem glioma and two with anaplastic astrocytoma), with a median duration of response of 4 months.[204] The efficacy of IFN-a in osteogenic sarcoma, ALL (two partial responses among 31 patients), and posttransplant lymphoproliferative disorders needs confirmation.[205,206 and 207]

Common toxicities of IFN treatment are flulike symptoms, including fever, chills, rigors, myalgia, and malaise, which usually respond to acetaminophen. Labile blood pressure at the initiation of treatment can be lessened by a slow dosage escalation. Neutropenia is occasionally dose limiting. Other side effects include hepatic enzyme elevations (common at the outset, usually reversible even with continued treatment), thrombocytopenia, headache, minor cognitive impairment with a decreased ability to concentrate, and distal paresthesias. The dose-limiting toxicities of IFN-b in children with brain tumors include marrow suppression, seizures, stupor, and coma.

### *Tumor Necrosis Factor*

TNF-a[208,209] inhibits the proliferation of 30% to 40% of malignant cell lines. It exerts pleiotropic effects on phagocytes, endothelial cells, and the immune system: it activates granulocytes and monocytes, up-regulates adhesion molecules on endothelium, stimulates B- and T-cell proliferation, and up-regulates IL-2 receptor expression on T cells. Toxic reactions include fever, rigor, nausea, vomiting, slight depression of platelet and granulocyte counts, neurologic deficits (e.g., confusion and seizures), elevation of serum hepatic enzymes, blood urea nitrogen, and creatinine, as well as dose-limiting hypotension. In animals, intravenous TNF-a causes tumor necrosis and cachexia, but its *in vivo* activity in humans has been limited even at maximum tolerated doses. In contrast, the use of TNF in isolation perfusion technique for extremity melanoma or sarcoma, especially in combination with IFN and melphalan, has substantial clinical activity (90% CR). [210] Clinical trials to explore the role of TNF in regional perfusion therapy are being pursued, and TNF gene–modified TIL cells have also been tested in melanoma patients. [211]

### Ex Vivo *Use of Cytokine and Cytokine Fusion Proteins*

The clinical benefit of cytokines in immunomodulation and in directly inhibiting or killing tumor cells *in vivo* has been modest. However, the use of cytokines for *ex vivo* maturation and expansion of APC (GM-CSF, IL-4, TNF-a) or T cells (IL-2) before adoptive cell therapy is a clear example of how cytokines may be most optimally used. Alternatively, cytokines (e.g., IL-2 or IL-12) targeted to tumor sites using chimeric antibodies or scFv provide yet another approach to activate effector cells in the tumor microenvironment. Among the new generation of ILs, IL-12 has clinical potential because of its ability to augment cytolytic activity and to stimulate T helper cells.[212] IL-12 also induces T-dependent protective immunity in syngeneic models of murine neuroblastoma. [213] Chimeric MoAb-IL-12 fusion proteins have shown promising antitumor effects in mouse models.[145,214] Nevertheless, the broad distribution of cytokine receptors on normal cells and tissues can shorten the half-lives of most administered cytokines and limit their clinical efficacy. [215] In addition, systemic toxicity remains a limiting factor when high doses are used, especially for cytokines that increase vascular permeability, sometimes causing fluid leak and major organ insufficiencies.

## CELLULAR IMMUNOTHERAPY

The cellular immune response, which is designed to kill virus-infected cells before they are able to release the infectious virus, can also prevent the malignant outgrowth of tumor cells. There is now abundant evidence that tumors, even those not associated with viruses, can be immunogenic—that is, they frequently express antigens in a form recognizable by the host immune system. Nonspecific killer cells, such as NK cells and LAK cells, recognize abnormalities at the cell surface, such as low expression of MHC class I molecules or carbohydrate anomalies. CTLs recognize “foreign” peptides derived from cytosolic proteins and presented at the cell surface by MHC molecules. The immune system may perceive proteins as foreign not only if they are expressed by a virus but also if they contain a novel peptide created within an oncogenic fusion protein, or if they are expressed at higher than normal levels or represent proteins not normally expressed in adult tissues. This ability has been demonstrated not only in experimental animals but also for spontaneously occurring human tumors. Despite their expression of immunogenic antigens, some tumors evade immune responses by mutating those antigens, by releasing inhibitory cytokines, or by interfering with the antigen-presentation pathway; others simply down-regulate cell adhesion or costimulatory molecules, resulting in failure to activate specific immune responses. Immune defenses are much more likely to fail if immune function is compromised (e.g., after organ or stem cell transplantation or in patients with immunodeficiency disorders). Improved understanding of immune escape mechanisms has led to strategies that seek to counteract the immune evasion tactics of tumor cells. This section discusses the mechanisms and results of current modes of cellular immunotherapy, which aim to generate responses to inadequately presented antigens or to boost existing responses with the goal of recruiting a larger “army” of immune effectors.

### Requirements for the Activation and Expansion of Antigen-Specific T Cells

The activation of antigen-specific T lymphocytes is a multistep process requiring antigen-specific triggering of the TCR complex on the T cell and additional signaling via costimulatory molecules (Fig. 14-6). The TCR is triggered by the specific recognition of foreign peptides complexed with MHC class I or class II molecules at the cell surface. CTLs classically recognize peptides presented on class I molecules. Class I peptide loading occurs in the endoplasmic reticulum and requires proteasome-mediated antigen processing in the cytosol (Fig. 14-7). Thus, for class I presentation, antigens must gain access to the cytosol. This is usually a prerogative of endogenously expressed proteins, because even professional APCs have a limited capacity to phagocytose soluble antigens and process them for MHC class I presentation.[216] Proteins can gain access to the cytosol by other means, however (e.g., by virus transduction or physical transfection methods). [217] In addition to peptide/MHC binding, a key costimulatory signal results frombinding of the CD28 receptor on T cells with CD80 (B7-1/BB1) and CD86 (B7-2/B70) ligands on the APCs (Fig. 14-6). Inhibition of this pathway in the presence of antigenic stimulation results in T-cell anergy. [218] The CD40–CD154 (CD40L) pathway was also shown to contribute to the regulation of T-cell activation, both by independently costimulating T cells and at least in part by up-regulating CD80/CD86 molecules on APCs.[219] Adhesion molecules, such as LFA1, LFA3, and ICAM-1, are also important in the initial binding of CTLs to APC. For example, LFA1 on target cells lowers the threshold amount of antigen necessary for T-cell activation. [220] Whether adhesion molecules have costimulatory effects remains unclear. [221,222] Tumor antigens may be presented to immune effector cells by the tumor or virus-infected cell itself, but cross-priming by professional APCs is thought to be more common, because most tissues do not have an adequate APC phenotype. Thus, dying tumor cells are taken up by local professional APCs, which then present the tumor antigens to the immune system. The mechanism of cell death is thought to play a critical role in this process: Whereas DCs phagocytose both apoptotic and necrotic cells, the latter induce DC maturation, an important step in T-cell activation. [223,224,225] and [226] Finally, CTLs must receive the appropriate help before expansion can occur. Antigen-specific T helper cells with Th1 activity must be coactivated by the APCs. [225] Th1 cells release Th1 cytokines, such as IFN-g and IL-12, which are also necessary for CTL activation, and IL-2, which is necessary for CTL expansion. [227] A tumor cell that induces the secretion of Th2 cytokines, such as IL-4 and IL-10, may promote antibody instead of CTL responses.

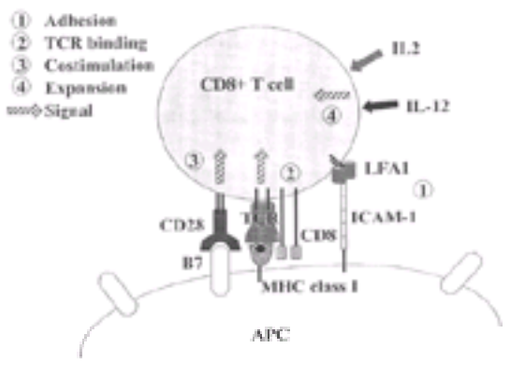

**FIGURE 14-6.** Requirements for T-cell activation and expansion. Adhesion molecules, such as leukocyte function antigen 1 (LFA1) on the cytotoxic T cell (CTL) and intracellular adhesion molecule 1 (ICAM-1) on the target cell facilitate the interaction of CTL and tumor cell (step 1). In the second phase, the T-cell receptor (TCR) must bind to its cognate peptide presented by the appropriate HLA molecule (step 2). In the third phase, the T cell must receive costimulation, commonly by binding of B7 (CD80/86) on the target cell to CD28 (step 3). Other receptor ligand pairs, such as CD137 or CD40L and their ligands, can fulfill this function. If this signal is not received, the T cell can be energized. In step 4, the T cell must be exposed to growth factors such as IL-12 (released by DCs) and IL-2 (released by T helper 1 cells). APC, antigen-presenting cell; MHC, major histocompatibility complex.

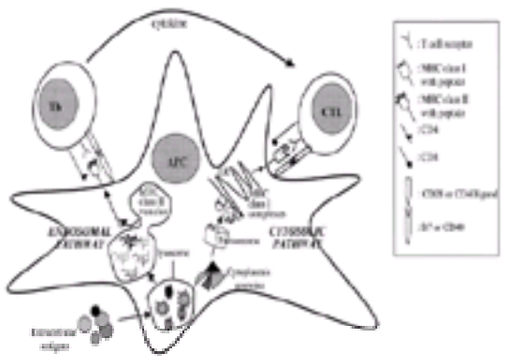

**FIGURE 14-7.** Class I and class II antigen-presenting pathways. $CD8^+$ T cells recognize peptides expressed on major histocompatibility complex (MHC) class I molecules. For MHC class I loading, intracellular proteins are degraded in the cytosol through the ubiquitin pathway. The resultant peptides are carried by transporter-associated proteins 1 and 2 (TAP1 and 2) to the endoplasmic reticulum (ER), where they are loaded onto nascent class l molecules and carried to the cell surface. By contrast, class II peptides are usually derived from extracellular proteins that are phagocytosed by antigen-presenting cells (APCs) and digested in endosomes, where they are loaded onto class II molecules. At the cell surface, they are recognized by $CD4^+$ T cells (CTLs). Th, T helper.

### Immune Evasion Tactics and Their Circumvention

As mentioned earlier, tumor cells use a variety of tactics to avoid immune responses. They can down-regulate critical cell surface activation molecules or release inhibitory cytokines and chemokines that inactivate not only T helper cells and CTLs but also local professional APCs that otherwise might be able to compensate for the tumor cell's poor ability to present its own antigens. A tumor cell that presents a tumor peptide–MHC complex but does not provide a costimulatory signal will anergize peptide-specific T cells.[228] Conversely, a tumor expressing tumor antigens and costimulatory molecules may not present the tumor peptides because of interference with the antigen-processing pathway. The peptide transporter molecules TAP1 and TAP2 are inhibited in Burkitt's lymphoma and melanoma, whereas anchoring of class I molecules in the endoplasmic reticulum is a mechanism commonly used by viruses.[229,230] Tumors may also inhibit cross-priming by professional APCs by secreting cytokines such as IL-10, which down-regulates MHC class II molecule expression on macrophages and DCs and prevents their release of inflammatory cytokines.[231] Even if a CTL receives appropriate activating signals from the tumor cell or APC, the tumor may inhibit or divert the expansion phase. Many tumor cells secrete TGF-b, which inhibits CTL activation in part by inhibiting early signaling events essential to the induction of IFN-g, IL-12, and TNF-a.[232,233] Others secrete chemokines that selectively recruit Th2 cells, which in turn inhibit the Th1 CTL response, perhaps explaining why some CA patients, such as those with neuroblastoma or HD, produce tumor-specific antibodies.[234,235,236] and [237] It seems likely that most tumors in immunocompetent individuals rely on a combination of immune evasion strategies.

Selecting an effective immunotherapy for a particular tumor requires a full understanding of the immune evasion strategies the tumor uses. If a tumor cell does not present a target antigen on its surface because of defective TAP expression, it will not respond to tumor-specific CTLs, regardless of the number of cells infused. If it secretes inhibitory factors, T cells activated by vaccination may fail to expand or will be diverted along the Th2 pathway despite an initial tumor-specific response. For example, although RS cells in HD express viral target antigens and have a good antigen-presenting phenotype, they secrete inhibitory cytokines. This disease may therefore require the use of adoptive therapy with *ex vivo*–expanded CTLs to circumvent this *in vivo* inhibition. Similarly, vaccine strategies often fail in immunodeficient or immunosuppressed individuals who cannot mount an adequate immune response to the vaccine. The best clinical results of immunotherapy with CTLs were obtained in immunodeficient patients for diseases effectively controlled in normal individuals.[238] and [239] Indeed, the EBV-associated lymphomas that occur with increased frequency after solid organ or stem cell transplantation can be prevented or treated simply by infusing of EBV-specific CTLs.[240] and [241]

### Induction of Cytotoxic T Cell Responses by Vaccination

Vaccination has been a powerful tool to combat viral infections. Most protein vaccines elicit only humoral (antibody) immune responses, which can prevent viral infections or render them subclinical by neutralization. For other viruses, neutralizing antibodies are insufficient to protect the host against infection or to prevent the reactivation of latent viruses. For example, serum antibodies that effectively neutralize EBV do not prevent reinfection with new viral strains via mucosal routes, nor do they prevent the outgrowth of EBV-associated lymphomas in patients. These failures can be attributed to the proteins expressed by EBV-associated tumors, which either have a nuclear location or occupy an integral position within the surface membrane and therefore are not accessible to antibodies. In fact, only a few tumor-specific antigens have been identified on the surface of tumor cells, and the majority of these are idiotype related and found only on T-and B-cell tumors. Thus, for many tumors, vaccination strategies must induce CTLs that are able to recognize internally expressed antigens. This approach can be especially effective in cases in which the tumor itself fails to fulfill the requirements for antigen presentation or fails to elicit an immune response by cross-priming of professional APCs. To elicit CTL responses *in vivo*, either the requisite antigens must be expressed by professional APCs, or the tumor cell itself must be transformed into an APC. The strategy of choice depends in part on whether the sequence of the tumor antigen is known, whether CTL epitopes have been mapped, and whether tumor material is available and amenable to genetic modification.

#### *DNA Vaccines*

When tumor antigens have been identified and cloned, naked DNA vaccines injected directly into skin, muscle, or mucosal surfaces have proved capable of inducing both CTL and antibody responses. The type of response depends on the route of immunization, the immunogen, and the species immunized.[242] Most of the immune response to DNA vaccines is thought to result from expression of antigen by nonlymphoid tissues and subsequent transfer to and cross-presentation by professional APCs. However, direct antigen presentation by transduced nonlymphoid cells and direct transduction of APCs themselves may also occur.[243] The advantage of DNA vaccines is that they are stable and inexpensive and relatively simple to administer. Furthermore, the type of immune response elicited may be manipulated by coinnoculation with cytokines, cytokine DNA, or immunostimulatory molecules, such as CD80 or CD40L.[244,245] The potential disadvantages are that because the DNA is expressed long term in normal cells, the immunogen must be safe (it should lack oncogenic potential, in particular), the recipient must have a competent immune system to be able to respond to the immunogen, and the tumor antigen must have been cloned and characterized. Melanoma, prostate CA, and virus-associated tumors are potential candidates for this strategy. There have as yet been few clinical trials of DNA vaccination, and most of the animal studies have focused on the treatment of infectious diseases. Nevertheless, DNA vaccination promises to be an important advance in the prevention of disease and the treatment of CA.[246] In addition, for self-antigens, autoimmunity is a possibility.

#### *Antigen- or Peptide-Pulsed Dendritic Cells*

### Expressing Antigens in Dendritic Cells

One way to ensure that an immunogen is presented in the optimal way is to infuse APCs that have been generated and “loaded” with antigen *in vitro.* Because DCs are the most potent APCs and are capable of inducing primary immune responses and overcoming immune tolerance, they have been used in many preclinical and clinical studies to induce immune responses to tumors. They can be generated from precursors in peripheral blood or bone marrow by culture in cytokine cocktails, most commonly IL-4 and GM-CSF.[247] Between 1% and 3% of PBMCs can differentiate into DCs, and although this percentage can be dramatically increased by G-CSF mobilization, only $CD11c^+$ DC precursors increase in numbers in response to G-CSF, and this subset has been reported to stimulate Th2 CD4 T cells preferentially.[248] Activated DCs efficiently phagocytose and process dying cells and particulate matter, but for efficient activation of T cells, they need an additional maturation step. This can be achieved *in vitro* by the addition of TNF-a or cytokine cocktails or by engagement of the CD40 or Fc receptors on the DC surface.[249,250] and [251] DCs can be loaded with antigen in many ways. The simplest method, if adequate CTL epitopes have been identified, is to incubate the DCs with the peptide epitopes, which then are presented in association with MHC molecules at the cell surface. Use of peptides is limited by the HLA phenotype of the patient, however, and if few target epitopes have been identified, the chances for immune evasion by mutation of the target antigen may be high. Furthermore, only a few of the class II helper epitopes that may be required to provide T-cell help have been identified. Whole protein loading could overcome these problems and ensure that the full repertoire of class I and class II peptides are available for any HLA phenotype.

Even with this strategy, methods are needed to direct the protein into the cytosol for class I processing. Osmotic lysis of pinosomes, liposome formulations, and Fc

receptor targeting have all been shown to allow protein targeting to the class I pathway, although mostly in murine systems. [252],[253] and [254] Antigen coupled to beads or to VLPs induces phagocytosis by professional APCs, resulting in MHC class I presentation. [255] A promising approach for introducing antigens into the cytosol of DCs is to use virus- or toxin-derived fusion proteins, which have endosomolytic activity resulting in the release of proteins into the cytosol. [256] For example, a fusogenic peptide derived from HIV-TAT effectively carries genetically linked proteins into the cytosol of almost any cell. [257],[258] There is now much interest in the generation of synthetic endosomolytic peptides for both protein and gene delivery. [259],[260] Alternatively, viral vectors can be used to introduce cloned antigens into DCs. The transgene is naturally translated in the cytosol and thus enters the class I processing pathways. Adeno- and lentiviral vectors can efficiently transduce and express transgenes in DCs at high multiplicities of infection. [261],[262] Retroviral vectors cannot transduce DCs but can transduce the $CD34^+$ precursors from which DCs can be derived if bone marrow or mobilized stem cells are available. [263] Additional advantages of viral vectors are that they can be used to express multiple antigens, which should reduce the incidence of escape mutations, and to improve the immunogenicity of the desired antigen by manipulating its structure. For example, when mice were vaccinated with DCs transduced with the retrovirus-encoded protein of hepatitis B virus, they generated only an antibody response. If the DNA was modified so that the encoded protein contained a secretory signal and an Fc receptor, then the protein was secreted and reinternalized by the DCs via the Fc receptor pathway *in vitro.* Mice immunized with DCs expressing this construct generated both CTL and antibody responses. [264] Target antigens have not been identified for most tumors. This limitation can be overcome by pulsing activated DCs with tumor lysates, peptides eluted from tumors, or apoptotic or necrotic tumor cells. Immature DCs possess unique pathways for the uptake and presentation of peptides and antigens from apoptotic and necrotic cells, and all of these antigen sources have been used successfully to generate $CD8^+$ CTLs *in vitro* and *in vivo.* Whole tumor extracts provide additional advantages in that they permit multiple tumor antigens to be presented, minimizing the chances for the evolution of CTL escape mutants, they overcome HLA phenotype restrictions, and they allow antigens to be presented on both class I and class II molecules.[265] Melanoma lysates were shown to be as effective as peptides in the induction of $CD8^+$ CTL responses from melanoma patients *in vitro* but less effective than apoptotic tumor cells. [266],[267] The most stringent requirement with these procedures is the need for fresh or cryopreserved tumor material.

### Clinical Trials with Dendritic Cell Vaccines

The majority of human clinical trials of DC therapy have tested peptide or tumor lysate–modified DCs in the treatment of melanoma and prostate CA. These tumors were chosen largely because they possess recognized tumor antigens that can elicit an immune response. Although these tumors are uncommon in children, the lessons learned from these diseases may be applicable to pediatric tumors. When GM-CSF–induced monocytes pulsed with a single melanoma-specific peptide were infused into patients, they produced CTL responses *in vivo* but no clinical responses.[268] Infusion of bona fide DCs pulsed with two HLA-A2–restricted prostate-specific peptides were more promising.[269] Thirty percent of the patients were partial responders, and 58% of these were still responsive at the end of the follow-up period. Mackenson and co-workers[270] reported on the treatment of 14 HLA-A1 or -A2 melanoma patients with pools of HLA-A1– and -A2–restricted peptides from the *MAGE-1*, *MAGE-3*, Melan-A, tyrosinase, and gp100 proteins, noting only mild toxic reactions, immunologic responses in four patients, and tumor responses in two. Nestle and co-workers[271],[272] used DCs pulsed with melanoma lysates or peptide cocktails (to diminish the chances of immune escape) selected according to HLA type to vaccinate 30 patients who had relapsed on standard protocols. All patients developed strong delayed-type hypersensitivity immune responses, which correlated with the eight clinical responses (27%), including three CRs. Tumor regression was noted in multiple tumor locations, even in patients with large tumor burdens, and toxicity was mild to moderate. Responses were not related to whether patients were treated with peptide or tumor lysate-pulsed DCs. The authors documented various immune escape mechanisms, including defects in the expression of proteasomal enzymes, TAP deficiency, antigenic loss variants, and down-regulation of HLA expression, commenting that these factors should be considered limitations of therapy. Additional escape mechanisms were identified in studies of melanoma-specific CTL precursor frequencies in patients with metastatic melanoma.[273] In one study, circulating CTLs were identified in 6 of 11 patients, and in one of these, 2.2% of the T cells were specific for a single tyrosinase peptide. This population was isolated and shown to be functionally unresponsive. [274] Strategies to overcome immune escape mechanisms are under consideration, including the combination of peptide-pulsed DCs with systemic recombinant IL-2 to enable DC-activated CTLs to expand and function *in vivo*.[275] One caveat concerning the use of DCs with other immunostimulatory molecules to "superactivate" the immune response is that it may break immunologic tolerance to self-antigens and produce autoimmunity. This risk is well illustrated by our experience with the lethal murine B-lymphoma A20 cell line, which failed to induce an immune response in syngeneic mice. If the mice were first vaccinated with syngeneic DCs pulsed with peptides eluted from the tumor in combination with syngeneic fibroblasts engineered to express CD40 ligand and IL-2, however, they were protected against lethal doses of the tumor but developed autoimmune disease.[276] A similar although not life-threatening response was observed in melanoma patients, who developed vitiligo (depigmented skin) after vaccination with melanoma peptide–pulsed DCs.[270]

## *Tumor Vaccines*

### Generating Immunogenic Tumors

An alternative strategy, when tumor antigens have not been identified, is to genetically modify the tumor cells themselves to improve their ability to induce an immune response. This strategy, termed *tumor vaccination*, has many variations. Tumors can be modified either *in vivo* or *ex vivo* with a range of gene transfer methods, including retroviral and adenoviral vectors, lipofection, or bioballistic techniques. [277] The advantage of *ex vivo* modification is that it permits early evaluation of transgene expression, control of the number of modified tumor cells infused, and escalation of the vaccine dose. *Ex vivo* modification is particularly appropriate for tumors such as neuroblastoma that can be expanded in tissue culture.[278] A potential disadvantage is that the tumor cells growing in culture may not represent the tumor cells that grow *in vivo.* Modification of tumors *in vivo* is more difficult to control, because it is impossible to determine the number of tumor cells that have been modified, and this end point varies from patient to patient, even when the same dose of viral vector is used. Nevertheless, small numbers of tumor cells modified *in vivo* should be able to induce a specific, systemic immune response that can target unmodified tumors at distant sites.

Tumors can be modified to improve one or multiple phases of CTL activation and expansion ( Table 14-2). The first phase is the attraction and activation of professional APCs, for which GM-CSF and CD40 ligand are the preferred molecules. The second phase is the recruitment of T cells with use of chemokines such as lymphotactin.[279] The third phase, T-cell activation, has been achieved by modifying tumor cells with B7 and CD40 to improve antigen presentation. IL-2 and IL-12 have been used to provide T-cell help to secure the fourth phase, T-cell expansion. In the fifth (or effector) phase, activated CTLs may be anergized or killed by factors released by the tumor or even killed directly by tumor cells. For example, tumor cells expressing FAS ligand can trigger CTL apoptosis by engaging the death receptor, FAS, on CTLs.[280] Influencing this phase may not be a realistic goal of tumor vaccine studies, but the possibility is addressed later in the section Antigen-Specific Cytotoxic T Cell. Although most tumor vaccine strategies are directed at one or two phases of immune activation, improving one phase usually improves other phases as well. GM-CSF affords a particularly good example of this principle. Tumors expressing recombinant GM-CSF recruit and activate macrophages and DCs, which in turn secrete inflammatory cytokines that recruit T cells. The activated DCs can then phagocytose dying tumor cells and activate the recruited $CD4^+$ and $CD8^+$ T cells. The $CD4^+$ T cells produce IL-2 and help CTL expansion. So although used primarily to influence the first phase of CTL activation and expansion, GM-CSF also acts on the three subsequent phases. This may explain why GM-CSF has been the most effective cytokine for boosting immune responses to tumors.

| Step | Function | Ligand | Cytokine | Inhibitory factor |
|---|---|---|---|---|
| 1 | Activation of antigen-presenting cells | Dying cells, viruses | Granulocyte-macrophage colony-stimulating factor, IL-4, tumor necrosis factor-α | IL-10, TGF-β |
| 2 | Attraction of T cells (T helper 1 type) | Costimulatory molecules | Lymphotactin, chemokine ligand 2, macrophage inflammatory protein 1-α,β | Thymus and activation-regulated chemokine |
| 3 | T-cell activation | Major histocompatibility complex-peptide, CD86, CD40 | Interferon-γ | TGF-β |
| 4 | T-cell expansion | – | IL-2, IL-12, IL-7 | TGF-β |
| 5 | Tumor cell killing | – | IL-10 | FAS ligand |

IL, interleukin; TGF-β, transforming growth factor β.

**TABLE 14-2. MOBILIZATION OF THE CELLULAR IMMUNE RESPONSE TO TUMORS**

### Preclinical Studies of Tumor Vaccines

The first studies of tumor vaccines showed, in a murine model, that influenza virus–infected tumors could elicit enhanced immune responses to uninfected tumors. [281]

This outcome likely resulted partly from the virus-mediated induction of an inflammatory response and partly from the assistance of T helper cells specific for strong influenza epitopes. Similarly, the introduction of allogeneic MHC molecules boosted immune responses to tumors, probably because of inflammation caused by allostimulation and subsequent stimulation of infiltrating tumor-specific T-cell precursors. Autologous MHC class II molecules have also been used to stimulate help for MHC class II–negative murine tumors.[282] This strategy proved successful and could be improved by comodification with costimulatory molecules, such as B7, superantigens, and cytokines.[283] For example, mice with established metastatic mammary tumors responded to vaccination with tumor cells modified with B7 plus MHC class II antigens, injected together with IL-12. This combination was far superior to any one or two modifications alone. However, a major limitation to the systemic use of cytokines has been their toxicity. IL-2, IL-12, and GM-CSF are highly toxic if given in concentrations strong enough to produce local effects, although high local concentrations of cytokines with only slight systemic toxicity can be achieved by engineering tumor cells to secrete the cytokines. [284] If tumor cells are unavailable or are unamenable to gene transfer, autologous fibroblasts modified to express cytokines can be substituted. [285] There is a wealth of data in animal models to show that IL-4, IL-7, IFN-g, and TNF-a can also be used to improve tumor-specific immunity.[286] The results of vaccination with tumor cells depend on a host of interacting factors, including tumor type, type of immune evasion strategy used by the tumor (usually not known), vaccine dose, level of transgene expression, challenge site, and vaccine schedule. Hence, it has been difficult to identify a “best strategy” for translation into human trials.

### Clinical Studies

When used in patients, tumor vaccines have produced little systemic toxicity, with only local inflammation and sometimes patches of vitiligo in melanoma patients. [287] In human clinical trials, tumors have been modified with IL-2, IL-4, IL-7, IFN-g, and GM-CSF. Infusion of unmodified melanoma cells mixed with IL-2–expressing autologous fibroblasts resulted in infiltration of $CD4^+$ and $CD8^+$ T cells, which produced tumor cell lysis after culture *in vitro.* Some mixed responses and disease stabilization were seen in approximately 10% of patients. Autologous neuroblastoma cells expanded *in vitro* and transduced with an adenoviral vector expressing IL-2 were infused into children with advanced neuroblastoma.[288] Of ten children, one had a CR, one had a partial response, and three had stable disease. Four of five responders had an increased frequency of tumor-specific CTLs, compared with only one of five children who did not have a tumor response. Neuroblastoma cells cannot be cultured to large numbers in every case. Therefore, because DCs can phagocytose tumor cells and present shared antigens in association with their own MHC molecules by cross-priming, allogeneic HLA-A2–matched IL-2–transduced neuroblastomas were also used to vaccinate 15 children from whom autologous tumors could not be grown. Although the responses were not as good as those obtained with autologous tumors, one child had a partial response and seven had stable disease.[289] The authors suggested that combinations of cytokines and costimulatory molecules are likely necessary to improve response rates, and such studies are planned. Cross-priming with allogeneic tumors can also produce alloimmunity, but this reaction should not pose problems except in recipients of organ or marrow transplants. Hematopoietic tumors have been less amenable to the tumor vaccine approach because of their poor transduction rates with currently available, clinically acceptable vectors. Disabled herpes simplex virus vectors can efficiently transduce a wide range of cell types, including hematopoietic cells, but they have not yet been used in clinical trials. [281] An interesting combination of tumor and DC vaccination was recently tested in 17 patients with advanced renal cell carcinoma. After immunization with hybrids of autologous tumor and allogeneic DCs generated by electrofusion, four patients completely rejected all metastatic lesions, one had a mixed response, and two had a greater than 50% reduction in tumor mass.[290]

### *Ex Vivo* Induction of Cytotoxic Lymphocytes for Clinical Use

*Ex vivo* expansion of tumor-specific killer cells has been evaluated with the intent of overwhelming tumor cells by infusing large numbers of killer cells. Such adoptive transfer strategies have used LAK cells, TILs, donor leukocytes, and tumor-specific CTL lines and clones.

#### *Lymphokine-Activated Killer Cell Therapy*

LAK cells are NK cells that have been activated and expanded in IL-2–containing cultures. They have HLA-unrestricted cytotoxic activity against a range of human tumors *in vitro*, but their role *in vivo* is unclear. In the first clinical applications, LAK cells were infused with IL-2 into patients with advanced renal carcinoma and melanoma, resulting in some clinical responses, including a complete response in a patient with metastatic melanoma. [291] LAK cells with IL-2 were subsequently compared with IL-2 alone in patients with end-stage CA.[292],[293] and [294] Although results of these initial studies were disappointing, the potential of this combination is being explored further in the treatment of early or minimal residual disease, as adjuvant therapy to prevent leukemic relapse after stem cell transplantation, or after activation with other combinations of cytokines.[295] Because LAK cells have not produced satisfactory response rates, they have been replaced whenever possible by TILs, with the thought that these cell populations would contain tumor antigen–specific CTLs.

#### *Tumor Infiltrating Lymphocyte Therapy*

Many tumors contain “infiltrating T cells,” whose presence is associated with the regression of melanoma and cervical carcinoma, to cite two examples. If these T cells could be expanded *in vivo*, they might produce greater antitumor responses; however, not all tumors possess TILs, and such cells have often proved difficult to extract and grow. TILs may be extracted by needle biopsy, but then must be expanded to greater than or equal to $1 \times 10^{11}$ for therapeutic use.[296] This *ex vivo* expansion may result in the overgrowth of nonspecific cells because of the lack of specific antigen stimulation. For these reasons, TIL therapy has been restricted in part by the tumor type and location. $CD8^+$ TILs that specifically recognize autologous tumor tissue can be grown from 50% of melanomas and have been used to identify more than 30 new melanoma-specific peptides.[297],[298] and [299] Tumor-specific $CD4^+$ TILs have also been grown from melanomas and from breast, ovarian, and colon CAs.[296],[300] Such cells may exert cytotoxic action either directly or by releasing cytokines, such as TNF-a, GM-CSF, and IFN-g, in response to the autologous tumor in a class II–restricted fashion.

The presence of tumor-specific CTLs in actively growing tumors raises the question of whether they play any role in tumor regression. Evidence to support an antitumor function of TILs comes from the association of these cells with a better prognosis and the tendency of TIL-containing tumors to undergo spontaneous regression.[301] Tumor progression may in fact result from the anergization of tumor-specific CTLs *in situ* by tumor antigen expression in the absence of costimulatory molecules or by inhibitory cytokines released by the tumor cells. By activating and expanding these specific cells *in vitro* in the absence of inhibitory signals, it may be possible to restore their function in culture so that they remain active and able to produce antitumor effects when returned to the patient. Although responses to TIL therapy have been better than those to LAK cells, the response rates are still low, and toxicity, although less severe than with IL-2, remains clinically significant. Current efforts are attempting to improve the efficacy, persistence, and specificity of TIL infusions by genetic modification of cytokine production and expression of tumor-specific single-chain antibodies. Finally, tumor-specific CTLs can be isolated from the TIL population and specifically expanded for use as CTL therapy.

#### *Donor Leukocyte Infusions*

The curative effects produced by allogeneic HSCT for malignant disease entail not only high-dose chemotherapy and radiotherapy administered as bone marrow conditioning but also GVL reactions. The presence of GVL was originally suggested by the higher relapse rates in recipients of syngeneic or T-cell–depleted transplants and lower relapse rates in patients who developed GVHD. [302] These immune-mediated antileukemic effects are probably mediated by several different mechanisms, including recognition of alloantigens such as major or minor histocompatibility complex molecules or tumor-specific antigens expressed by tumor cells.

Adoptive immunotherapy with DLIs provides a means of augmenting the GVL response after HSCT to eliminate residual disease. In 1990, Kolb and co-workers [303] reported on three patients with relapsed CML who attained complete cytogenetic remissions after treatment with IFN-a and DLI. In larger series, approximately 70% of all relapsed CML patients treated in the chronic phase achieved complete cytogenetic remission, in contrast to only 11% of those in the accelerated phase or blast crisis.[304] For patients with other hematologic malignancies relapsing after transplant therapy, DLI has resulted in a much lower response rate: only 29% of patients with AML and 5% of these with ALL.[305]

DLI is associated with toxicity and treatment-related complications that include GVHD and pancytopenia. [306] Attempts have been made to separate the GVL effect from unwanted alloreactivity by administering either smaller doses of cells or subsets of lymphocyte. In one series in which the risk of alloreactivity was reduced by administering smaller doses of cells, some patients who received $1 \times 10^7$ $CD3^+$ cells per kg attained remission without developing GVHD. [306] Because of varying degrees of alloreactivity with different donor-recipient pairs, however, it is probably not possible to identify a dose that always produces GVL without GVHD. When lymphocyte subsets are used as an alternative approach, either CD8-depleted or CD4-selected cells can induce remission in CML patients with only a low incidence of GVHD.[307],[308] Immunostimulatory cytokines, such as IL-2, may amplify GVL mechanisms and induce remissions in patients who have failed to respond to DLIs. Slavin and co-workers,[309] using DLI with or without IL-2–activated cells for remission induction after leukemic relapse after HSCT, reported CR in 10 of 17 patients, nine of whom responded only after donor cell activation with IL-2. [309] A shorter median time to CR has also been described with the addition of IFN-a to DLI in the

treatment of relapsed CML after allogeneic HSCT.[310]

### *Antigen-Specific Cytotoxic T Cells*

#### Cytotoxic T-Cell Generation

Although vaccination strategies can overcome poor tumor-antigen presentation, they are unlikely to overcome the problem of tumor-mediated inhibition of CTL expansion. Thus, although CTLs can be activated by vaccination, they may not expand *in vivo.* One way to resolve this problem is to infuse tumor-specific CTLs that have been activated and expanded *in vitro.* Expansion of CTLs *in vitro* provides additional advantages: CTL reactivity with tumor and normal target cells can be analyzed before the cells are infused, and the CTL dose can be escalated in a controlled fashion. Thus, infusion of auto- or alloreactive CTLs can be avoided, an important consideration in stem cell recipients requiring DLI for leukemic relapse.

The activation of CTLs *in vitro* requires APCs expressing only the antigens that will stimulate the desired CTLs without activating unwanted T cells, which might overgrow the culture or possess auto- or alloreactivity. Similarly, neither the culture medium and growth factors selected for expansion of CTLs nor the antigens used for restimulation should expand unwanted T cells. This remains a major challenge, especially when the CTL precursor frequency is low or the tumor antigens weak (Fig. 14-8). As for the activation of CTLs *in vivo,* DCs modified with peptides, proteins, RNA, or viral transgenes have been used to stimulate secondary and, occasionally, primary CTL responses.[311,312 and 313] Again, if tumor antigens have not been identified and tumor material is available, DCs pulsed with apoptotic or necrotic tumor cells or extracts can be used to reactivate tumor-specific CTLs.[226] DCs can also overcome immunologic tolerance to self-antigens expressed on tumor cells, provided they express high levels of antigen. For example, PSA-specific CTLs were generated from healthy volunteers by stimulation with autologous DCs transfected with messenger RNA encoding PSA.[314] The danger of this approach is that if tolerance to self is broken, then autoimmunity may be induced.[276] Thus, when using a “self” antigen as a tumor target, it is important to know its tissue distribution. Although CTLs can be tested for autoreactivity against normal target cells before infusion, few tissue types are usually available as targets.

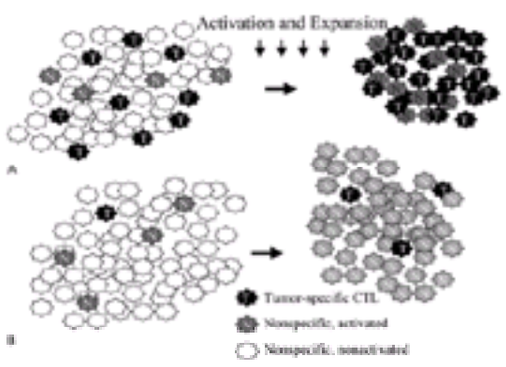

**FIGURE 14-8.** Bystander activation can overwhelm the cytotoxic T-cell (CTL) response to specific antigen. **A:** When there is a high frequency of tumor-specific CTL precursors, the coexpansion of small numbers of bystander cells is irrelevant and does not inhibit CTL function. **B:** Conversely, in a culture in which the CTL precursor frequency is vanishingly small, then the same number of bystander cells can overwhelm the culture so that CTL function cannot be detected.

Less has been published about ways to substantially expand activated CTLs *in vitro* without losing specificity. It may not be feasible to restimulate CTLs repeatedly with DCs owing to the large amounts of blood required for DC generation. Furthermore, although DCs efficiently activate T cells, they do not provide good help for expansion (unpublished observation). Nonspecific activation with stimulatory antibodies to CD3 and CD28 in the presence of allogeneic PBMC feeders is effective for CTL clones but specificity can be lost when this method is applied to polyclonal cultures.[315]

The generation of EBV-specific CTLs for adoptive therapy has been relatively simple because most individuals are persistently infected with this virus and have a high prevalence of EBV-specific CTL precursors, which can readily be reactivated and expanded *in vitro* by coculture with an autologous EBV-transformed B-cell line (LCL).[316] If bystander cells are activated, they represent only a small proportion of the culture. LCLs are excellent APCs, as they can be generated from any normal individual as well as from most patients, and they provide an infinite source of APCs cells and target cells against which to test CTL function.[317] Although we have been able to coinduce responses to EBV and adenovirus (both strong recall immunogens), using adenovirus-pulsed LCLs, LCL cannot be used to stimulate responses to weak antigens or to reactivate low-frequency CTLs because the strong antigens are likely to dominate the response.[318]

#### Immunotherapy with Antigen-Specific Cytotoxic T Cells

Riddell and co-workers[238] pioneered the use of antigen-specific CTLs to prevent CMV reactivation in marrow recipients. Donor-derived $CD8^+$ CTL clones activated by coculture with CMV-infected autologous fibroblasts and specific for the viral tegument proteins pp65 and pp150 proved safe and protected recipients of T cell–replete HSCT against the reactivation of CMV. However, the persistence of the $CD8^+$ clones was dependent on the recovery of endogenous $CD4^+$ CMV–specific T cells.[315] Later studies showed that coinfusion of $CD4^+$ clones with the $CD8^+$ clones was sufficient to ensure persistence of the latter.

We have used donor-derived, polyclonal CTL lines to prevent and treat EBV-LPD in children receiving T cell–depleted stem cell transplants. These CTLs were genetically marked with a retroviral vector so that their fate *in vivo* could be determined. The CTLs expanded several logs *in vivo* after infusion and then persisted for up to 7 years,[239,241] most likely because of the presence of both $CD4^+$ and $CD8^+$ T cells in the lines, the continued presence of EBV, and the fact that the CTLs were infused into an empty niche in a regenerating immune system. The infused CTLs were safe and effective, and all patients who received prophylactic CTLs were protected from EBV-LPD. This outcome contrasts with the 11.5% of children who did not receive CTLs and developed posttransplantation lymphoproliferative disease.[241] The infused CTLs rapidly and permanently reconstituted immune responses to EBV and reduced the virus load to the point at which EBV-LPD became likely. EBV-specific CTLs were also effective in three of four patients with bulky disease who received CTL therapy. A single patient who did not respond illustrates one of the recurring problems of immunotherapy: mutation of CTL target epitopes on tumor cells leading to the evasion of cytolysis. This patient had two types of circulating viruses at the time of diagnosis. One had a deletion in the *EBNA3B* gene of EBV that removed two immunodominant HLA-A11–restricted CTL epitopes. The major cytolytic activity of the CTL line from the HLA-A11–positive donor was directed at the two deleted epitopes. After CTL infusion, the virus with wild-type *EBNA3B* disappeared from the patient's circulation, whereas the virus with the deletion persisted.[105] Thus, the infused CTL line selected for an escape mutant. That a CTL escape mutant could occur in a virus with a remarkably stable genome indicates that the problem may be much greater in tumors, whose genomes are generally more unstable. Indeed, as mentioned previously, CTL escape mutants have also been described in melanoma.[319,320] To avoid this phenomenon, it will clearly be necessary to target multiple epitopes, preferably on essential proteins that cannot be down-modulated.

EBV-specific CTLs have also proved effective in an autologous setting in solid organ recipients and in a patient with DiGeorge syndrome.[319,320] Thus, even in severely immunocompromised individuals whose CTLs cannot effectively control EBV *in vivo*, CTLs can be reactivated and expanded in culture and returned in sufficient numbers to control the underlying disease. It should be emphasized that EBV-associated tumors arising in severely immunocompromised individuals require only minimal immune evasion strategies, as they are highly immunogenic and are readily eliminated by normal CTLs. By contrast, immunogenic tumors that arise in immunocompetent individuals rely on multiple immune evasion strategies, posing a much greater obstacle to treatment with infused CTLs. For example, the EBV-carrying RS tumor cells in HD express viral target antigens, high levels of MHC class I and class II, and costimulatory molecules, and have an intact antigen-presenting machinery. Furthermore, patients with HD have a normal frequency of circulating EBV-specific CTLs and control their normal EBV-infected B cells effectively. However, the RS cells secrete a variety of inhibitory chemokines and cytokines, including IL-10, TGF-b, and TARC, that function locally in the tumor environment and inhibit EBV-specific CTL function (Fig. 14-9A and Fig. 14-9B).[321,322] IL-10 is a “schizophrenic” cytokine with both Th1 and Th2 effects depending on the target cell.[323,324,325 and 326] Its function in Hodgkin's tumors is likely to deactivate local professional APCs by down-regulating their expression of class II molecules and inhibiting their release of inflammatory cytokines. This, in turn, will prevent cross-priming of Hodgkin tumor antigens, including EBV antigens, by APCs and the resultant recruitment of T cells. TGF-b also has pleiotropic effects depending on the target cell type, but it inhibits the development of CTL responses via early signaling pathways and can directly induce apoptosis in some cell types.[232,327] TARC is a chemokine that specifically recruits $CD4^+$ Th2 cells that can contribute to a pro-Th2 and anti-Th1 environment. In addition, RS cells express FAS ligand, a death receptor that may induce apoptosis in FAS expressing $CD8^+$ CTLs (Fig.

14-9B).[328] Thus, Hodgkin's tumors protect themselves against CTL lysis by relying on several mechanisms, some or all of which must be circumvented in any adoptive transfer strategy.

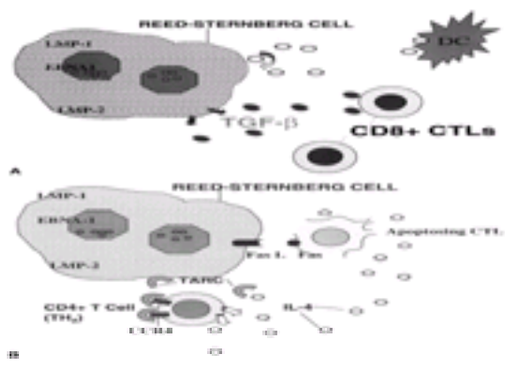

**FIGURE 14-9.** Multiple immune evasion strategies used by Hodgkin Reed-Sternberg (H-RS) cells. **A:** The H-RS cells express only a subset of the viral latency-associated proteins, LMP1 and 2 and EBNA1. The immunodominant EBNA3 proteins are not expressed. The tumor cells also secrete interleukin 10 (IL-10), which may prevent the maturation of local professional antigen-presenting cells by down-regulating major histocompatibility complex (MHC) class II expression and preventing the release of inflammatory cytokines. Thus, cross-priming of tumor antigens is inhibited. The tumor cells also secrete transforming growth factor b (TGF-b), which prevents T-cell activation and inhibits the release of interferon-g in response to IL-12. **B:** H-RS cells release thymus- and activation-regulated chemokine (TARC), a chemokine that recruits T helper 2 (Th2) cells, which secrete IL-4 and help antibody responses while inhibiting cytotoxic T cell (CTL) responses. Finally, H-RS cells express Fas ligand, which may induce apoptosis in Fas-expressing CTLs that may penetrate the other immune evasion strategies and make contact.

Despite these potential obstacles, we have used gene-marked autologous EBV-specific CTLs to treat patients with multiply relapsed EBV-positive HD. Five patients with aggressive disease at the time of CTL infusion survived for 3 to 12 months, and three patients are still alive 6 to 14 months after infusion. Three of four patients had resolution of B symptoms after infusion, and four had a mixed response, including tumor responses at some sites but not others. The two patients who received CTLs after autologous transplants remain in remission for 4 and 5 months postinfusion.[329] These studies demonstrate that the infused CTLs had antiviral effects (e.g., reduction in virus load), improved the CTL precursor frequency, and persisted for up to 5 months after infusion. Furthermore, gene-marked CTLs homed to malignant sites. Nevertheless, none of the patients was cured, clearly indicating a need for improvements through strategies based on our current knowledge of the tumor's immune evasion tactics described earlier. Successful treatment may ultimately require CTLs made resistant to some or all of the inhibitory factors by genetic modification.

Leukemia-specific antigens have been identified as CTL targets in patients undergoing allogeneic HSCT for leukemic relapse. These include minor antigens differentially expressed on hematopoietic cells or lineage-specific antigens, such as WT1 or proteinase 3, that are selectively expressed in malignant cells.[262,330,331] The minor histocompatibility antigens HA1 and HA2 induce HLA-A*0201–restricted CTLs *in vivo* and are selectively expressed on hematopoietic cells, including leukemic cells and their precursors. Mutis and co-workers[332] investigated the feasibility of *ex vivo* generation of HA1- and HA2-specific CTLs from HA1- or HA2-negative donors, using peptide-pulsed DC cells as APCs.[333] The resulting HA1- and HA2-specific CTLs lysed leukemic but not nonhematopoietic cells from patients with AML or ALL. Such lines could therefore potentially mediate cytotoxic activity directed at recipient hematopoiesis (and leukemia) but not at donor hematopoiesis, when the donor was HA1 or HA2 negative and the recipient HA1 or HA2 positive. Two recent reports have investigated the use of the WT1 antigen, which is expressed at higher levels in acute and CMLs than on normal hematopoietic progenitors.[330,333] WT1-specific CTLs killed leukemic cell lines and selectively inhibited the growth of leukemic colonies, suggesting the potential of this reagent for immunotherapy. Another differentiation antigen overexpressed in tumor cells is proteinase 3, found in high concentrations in granules of malignant myeloid blasts. A recent report demonstrated the feasibility of selecting CTLs that recognize the PR1 peptide derived from this protein using HLA-peptide tetramers.[331] Expanded lines selectively lysed CML blasts cells.

## FUTURE PERSPECTIVES

There are now many exciting bioengineering strategies and animal models that demonstrate how the immune system can be beneficially manipulated with immunoreactive molecules. However, such models cannot always predict the outcome of immunotherapy for human tumors, so clinical testing of emerging concepts will likely be a major preoccupation during the coming years. It is important to understand why tumors evade immune responses, because only by understanding these mechanisms will we be able to develop strategies to overcome them. Immunotherapy for widespread or bulky CA will likely be most effective when used in combination with standard treatments, although in cases in which it can be used alone, it offers the possibility of sparing children major short- or long-term toxicities. Establishing the efficacy of this new modality at the time of minimal disease requires novel methods of evaluation, because randomized clinical trials are often impractical for rare CAs such as pediatric malignancies. The feasibility and cost of immunotherapy is frequently questioned. With few exceptions, most immunotherapies require sophisticated *in vitro* manipulations, some demanding pharmaceutical-grade “clean facilities” as well as experienced technical staff. Nonetheless, in view of the current cost of acute and late effects of cytotoxic therapy, continued effort to improve immunotherapeutic strategies seems highly worthwhile.

# INFANTS AND ADOLESCENTS WITH CANCER: SPECIAL CONSIDERATIONS

GREGORY H. REAMAN
ARCHIE BLEYER

## INTRODUCTION

The diagnosis and management of cancer in children at the extremes of the pediatric age group pose significant challenges to care providers and clinical investigators. The care of the infant with cancer is particularly challenging due to the exceptional vulnerability to the acute complications associated with aggressive, multimodal therapy and to the potential long-term sequelae of antineoplastic therapy on growth and development.

Cancer in the first year of life is relatively rare. [1,2] Infants with cancer often have a different clinical presentation from older children with the same disease, and their response to therapy also differs, indicating unique biologic properties of cancer in infants that explain the different clinical outcomes. [3,4 and 5] Although it is rare, cancer in the newborn and young infant has the potential to provide important insights into early human developmental oncobiology and suggests an intimate relation between oncogenesis and teratogenesis.[6]

The effect of very young age on prognosis and therapy depends on the specific diagnosis.

Cancer in the population of pediatric patients at the opposite extreme of age (i.e., adolescents and young adults) presents a completely different set of challenges. This group also has a distribution frequency of tumor types that differs from the general pediatric population. They have unique psychosocial and developmental issues, which must be sensitively and adequately addressed during therapy. Furthermore, access of adolescents to clinical trials and, therefore, to acceptable standard of care, is significantly inferior to the experience of younger children.

This chapter reviews the epidemiology of cancer in infants and adolescents and provides some guidelines for professionals faced with the challenge of treating these populations of patients. Also discussed are some of the unique biologic and clinical features of cancer in infants that have prognostic and therapeutic implications, as well as strategies to assure that adolescents and young adults gain access to appropriate multidisciplinary care and to improve their recruitment to clinical trials.

## CANCER IN INFANTS

### Epidemiology

Incidence data from the National Cancer Institute's (NCI) Surveillance Epidemiology and End Results (SEER) program indicate that the overall rate of cancer in U.S. children younger than 1 year of age is 218.4 cases per 1 million infants. [1] These data also suggest that the incidence is increasing ( Table 15-1).[2,7] The most common cancer in infants is neuroblastoma, followed by central nervous system (CNS) tumors, leukemia, retinoblastoma, renal tumors, germ cell tumors (including malignant teratomas), sarcomas, and hepatic tumors.[2] Unlike older children, female infants have a higher incidence of cancer than male infants, although rates for male infants are increasing.[2]

| Histology | 1970[a] | 1980[b] | 1990[b] |
|---|---|---|---|
| Neuroblastoma | 62.7 | 51 | 60 |
| Leukemia | 31.8 | 29 | 30 |
| Central nervous system | 14.0 | 24 | 33 |
| Retinoblastoma | 15.9 | 22 | 29 |
| Renal | 19.7 | 26 | 24 |
| Sarcoma | 17.8 | 10 | 11 |
| Germ cell | 0 | 5 | 6 |
| Teratoma | 2.8 | 4 | 13 |
| Hepatic | 7.5 | 4 | 8 |
| Lymphoma | 1.0 | 1 | 1 |
| Other | 9.3 | 13 | 5 |
| Total | 183.4 | 189 | 220 |

[a]Adapted from Bader JL, Miller RW. U.S cancer incidence and mortality in the first year of life. Am J Dis Child 1978;132:157. Incidence determined from the Third National Cancer Survey (10% sample of U.S. population) 1969 to 1971; rates per million live births per year in the United States.
[b]Adapted from Kenney LB, Miller RA, Reis LAG, et al. Increased incidence of cancer in U.S. infants, 1980 to 1990. Pediatr Res 1995; 37:159A. Incidence determined from Surveillance Epidemiology and End Results program of the National Cancer Institute (10% sample of U.S. populations) 1979 to 1988 and 1989 to 1991; rates per million children younger than 1 year of age in U.S. population 1980 and 1990.

**TABLE 15-1. INCIDENCE OF CANCER IN U.S. INFANTS**

As shown in Table 15-2, there is a difference in the percent distribution of tumor types in newborns and infants compared with all children younger than 15 years of age.[2,7,8] There have also been changes in the percent distribution over time. This change in percent distribution reflects stable rates of leukemia and renal tumors, and increased rates of CNS tumors and retinoblastoma.[2]

| | Children | Newborns | Infants |
|---|---|---|---|
| Histology | <15 yr (%) | <30 d (%) | <1 yr (%) |
| Leukemia | 31 | 13 | 14 |
| Central nervous system | 18 | 3 | 15 |
| Neuroblastoma | 8 | 54 | 27 |
| Lymphoma | 14 | 0.3 | 1 |
| Renal | 6 | 13 | 11 |
| Sarcoma | 11 | 11 | 5 |
| Hepatic | 1.3 | 0 | 3 |
| Teratoma | 0.4 | 0 | 6 |
| Retinoblastoma | 4 | 0 | 13 |
| Other | 6.3 | 5.7 | 5 |

**TABLE 15-2. PERCENT DISTRIBUTION OF THE MAJOR TYPES OF CANCER IN CHILDREN, NEWBORNS, AND INFANTS**

A report from the International Agency for Research on Cancer that compares population-based registry data from more than 50 nations demonstrates remarkable differences in international rates for cancer in infants. [9] Overall, the highest rates were found for Japanese infants, 252.81 cases per million child years, and the lowest were found for New York black infants, 109.28 cases per million child years. Israeli Jewish infants had the highest rate of neuroblastoma, and Swedish infants had the highest rate of retinoblastoma.[9,10] Comparison of incidence data from different nations has limitations, but it does serve to emphasize the relative contributions of genetics and environment to cancer in infants.

## Etiology

Although it is a rare event, cancer in infants presents a unique situation to study cancer etiology. In infants, the process of oncogenesis occurs in close temporal relation to embryogenesis. The time from the initiation of the malignant process to the clinical diagnosis of cancer in the infant is relatively short and easily delineated. Factors that should be considered as causes of cancer in infants include genetic susceptibility, acquired or constitutional; parental, intrauterine, and immediate postnatal environmental exposures; and transplacental metastasis.

Clinical evidence supports an inherited genetic susceptibility to developing cancer in infancy. For example, familial cases of Wilms' tumor and retinoblastoma occur at an earlier age than sporadic cases.[11,12] Moreover, some genetic syndromes are associated with cancer at an early age, such as Down syndrome with leukemia and familial adenomatous polyposis with infantile hepatoblastoma.[13,14] Genetic abnormalities have been identified that are frequently found in infants with cancer, such as chromosome band 11q23 breakpoint mutations (location of the MLL genes) in infant acute lymphoblastic leukemia (ALL), low N- *myc* oncogene copy in good-risk neuroblastoma in infants, and abnormalities in WT1 and the RB1 genes that are more commonly associated with the Wilms' tumors and retinoblastomas that occur in younger children.[11,15,16] and [17] A report on three pairs of infant twins with concordant leukemia and nonconstitutional gene rearrangements at 11q23 chromosome band breakpoint provides strong evidence for *in utero*–acquired genetic susceptibility to cancer. [18]

Taken together, this clinical and molecular evidence suggests that the cause of cancer in infants is related to an acquired or constitutional abnormality of cancer-predisposing genes that are critical during embryogenesis. The activation or suppression of these genes causes dysregulation of the normal developmental process and may lead to a malignant transformation in the infant. The fact that fetal and neonatal malignant tumors clinically manifested in the first few months of life can spontaneously regress or cytodifferentiate supports speculations about the physiologic expression of oncogenes by embryonal cells and their role in modulation of oncogenesis (see Chapter 3).[19]

Many studies have shown an association between parental exposure to environmental agents and cancer in the very young child ( Table 15-3).[20,21,22,23,24,25,26,27,28,29] and [30] Although these studies are not conclusive, they do suggest that some malignancies occurring in infants can result from preconceptional or *in utero* exposure of the developing fetus to environmental agents. Characteristics of the infant, such as preterm birth, have been associated with a relatively lower risk for neuroblastoma, but low birth weight in term infants is associated with increased risk. [31,32] These findings suggest a critical role for the timing of the environmental exposure during gestation and the consequent relation between teratogenesis and carcinogenesis.

| Cancer | Risk factor | Reference |
|---|---|---|
| ALL | Maternal history of prior fetal loss | 20 |
| | Paternal exposure to x-rays | 21 |
| | Maternal exposure to naturally occurring topoisomerase II inhibitors | 25, 26 |
| AML | Maternal use of marijuana | 22 |
| | Maternal exposure to topoisomerase II inhibitors | 25–30 |
| CNS (PNET) | Maternal diet deficient in fruits, vegetables, vitamin C, folate, nitrate | 23 |
| Hepatic | Maternal occupational exposure to metals, hydrocarbons, paints, and pigments | 24 |
| | Paternal occupational exposure to metals | 24 |

ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; CNS, central nervous system; PNET, primitive neuroectodermal tumor.

**TABLE 15-3. PARENTAL FACTORS ASSOCIATED WITH INCREASED RISK OF CANCER IN INFANTS**

A documented, yet rare, cause of cancer that is unique to infants results from metastases of cancer in the mother to the fetus. Infant cases of leukemia and melanoma have been transplacentally acquired *in utero* from the mother.[33,34]

Studies that combine current knowledge of the unique genetic properties of cancer that occurs in infants with a focused epidemiologic investigation into specific environmental agents that could disrupt the normal expression or function of cancer-predisposing genes will be important in understanding oncogenesis and the cause of cancer in infants.

## Diagnosis

### *Symptoms and Signs*

Recognizing symptoms without having the benefit of subjective patient complaints presents a challenge. In young infants, particularly in newborns, the nonspecific findings of lethargy, somnolence, irritability, feeding difficulties, vomiting, fever or hypothermia, and failure to thrive could be caused by significant pathology, such as a malignancy. Although cancer is rarely the cause of these signs or symptoms in infants, it is still important to consider the possibility of this diagnosis.

There are findings on physical examination that should alert the examiner to the diagnosis of cancer in an infant. However, it may be difficult to differentiate benign from possibly malignant lesions, given the relative infrequency of cancer and the more common occurrence of developmental anomalies or nonmalignant conditions. Table 15-4 summarizes some clinical and laboratory abnormalities commonly associated with cancer and with the more frequent nonmalignant conditions observed in neonates and infants.

**TABLE 15-4. DIFFERENTIAL DIAGNOSIS OF MALIGNANT AND NONMALIGNANT CONDITIONS IN INFANCY**

### *Laboratory and Diagnostic Studies*

Laboratory techniques that require a minimal amount of whole blood, serum, and plasma have facilitated the diagnostic tests necessary for the evaluation of specific organ dysfunction and the existence of tumor markers. Radiographic investigations, including ultrasonography, computed tomography, magnetic resonance imaging, and radionuclide scans, are best performed in specialized pediatric centers, which provide technical and interpretive expertise in the diagnosis and management of infants and newborns (see Chapter 9). These radiographic studies guide the pediatric surgeon in determining the nature and extent of the operative procedure (i.e., biopsy or resection) required to establish a definitive diagnosis.

### *Pathologic Considerations*

The ultimate histopathologic diagnosis of cancer in infants requires the expertise of a pediatric pathologist. Specialized cytochemical, ultrastructural, and immunocytochemical techniques required to establish accurate diagnoses are discussed in Chapter 8. Although the pathologic findings of most tumor types are not unique to this age group, there are potential pitfalls in the pathologic diagnosis. For example, some tumors in infants can appear malignant microscopically but have a benign clinical course (e.g., infantile fibromatoses). [35,36]

## Management

### *Surgery*

The surgical management of the infant with cancer encompasses two major facets of care: fastidious attention to metabolic and physiologic details and adaptation of the extent of the surgical procedure to the unique biologic behavior of the specific tumor in this age group. Surgical care during the preoperative, operative, and postoperative periods must focus on temperature regulation; blood volume; fluid and electrolyte control (including calcium and phosphate); gestational development in the case of newborns; and the integrity of cardiac, pulmonary, and renal function. [37] Surgical care must be integrated into the overall treatment plan with regard to preoperative and postoperative chemotherapy and radiation therapy, which can alter nutritional status, wound healing, and immunologic function.

Maintenance of fluid and caloric intake is imperative. Feeding should be sustained as long as possible without interruption. If the infant is to be kept *non per os*, an intravenous glucose solution with maintenance sodium and potassium should be supplied. The rate of infusion should provide somewhat higher than maintenance fluid requirements to ensure good renal function, particularly if hyperosmolar contrast materials have been used for radiographic studies. Strict attention to the integrity of the coagulation system is also required in the young infant. Although vitamin K is routinely given at birth, additional doses may be needed to establish normal levels of vitamin K–dependent clotting factors.

In newborns, particularly those who are premature or small for gestational age, hypoglycemia, hypocalcemia, and environmental temperature must be observed and regulated. The infant's relatively thin skin, with a diminished layer of insulating subcutaneous fat, and the proportionately large surface area to weight ratio create a pronounced vulnerability to large heat losses. [37] Metabolic acidosis, vasoconstriction, and depleted plasma volume can result from increased metabolic rate induced by hypothermic stress. Temperature regulation requires avoidance of heat loss and may necessitate transporting infants on beds with overhead servocontrolled heating units.

In the operating room, the infant should be placed on a heated mattress, or heating lights should be used, and skin areas that can be covered should be wrapped. Another potential source of heat loss is the evaporated water from the respiratory tract. Effective temperature exchange from endotracheal ventilation during anesthesia can be used to control evaporative water and heat loss. A heated nebulizer should be used to saturate the ventilated gases with water vapor and to maintain the temperature of the inhaled gases. Intravenous fluids and transfused blood should also be warmed. [38]

Adequate venous access must be ensured. If significant pulmonary compromise or metabolic acidosis is apparent or anticipated or if significant blood loss is likely, an indwelling temporal, radial, or tibial artery cannula should be placed to monitor arterial blood gases and possible hypotension.

During the course of surgery, blood loss must be monitored closely. Sponges should not be wetted so that they can be weighed to estimate their blood content. The volume of blood loss from suction should be collected in a reservoir. The volume of “dead space” in the suction tubing between the patient and the calibrated measuring container should be minimized to provide greater accuracy of the blood loss estimate. [37] Hypocalcemia can occur as a result of the citrate in transfused blood, and effective levels of ionized calcium can also be lowered during administration of sodium bicarbonate to correct metabolic acidosis. [37] Prolonged operative procedures require an indwelling urinary catheter to monitor urinary output and to avoid overdistention of the bladder.

If large serosal surfaces, such as the thorax or abdomen, are exposed during the operation, a significant volume of serous fluid is sequestered in the third space. Replacement with 5% dextrose and Ringer's lactate approximates the composition of serum lost into the wound. The rate of infusion ranges from 5 to 15 mL per kg per hour, depending on the magnitude of loss. Rates of 150% to 200% of those used for maintenance fluids may be required. [37] The status of volume replacement postoperatively should be determined by assessing tissue perfusion. If there is concern, central venous pressure should be monitored. After major abdominal, thoracic, and neurosurgical procedures, most infants recover their preoperative status by the fifth postoperative day, with the resolution of ileus after abdominal surgery, return to oral feedings, and the beginning of wound healing. [37]

### *Radiation Therapy*

Radiation therapy plays a major role in the management of most pediatric cancers. Because of the potential for acute and chronic side effects, radiation must be used cautiously in infants. The severity of the side effects is assumed to be inversely related to the age of the child and directly related to dose. [39] Acute morbidity, such as gastrointestinal dysfunction, bone marrow suppression, and skin reactions, is seldom a limiting factor if radiation therapy is used alone, and the changes produced are usually reversible. However, pronounced late effects are not readily reversible. Scant published data exist on side effects unique to infants and newborns. Estimates of potential damaging effects generated from established specific tissue dose tolerances and guidelines formulated to avoid these effects are based on evidence derived from animal studies and experience with older children.

The major late effect of irradiation is growth disturbance (see Chapter 13 and Chapter 49). The possibility of bone and soft tissue deformity in children secondary to radiation therapy is recognized, but the normal growth pattern of any organ or structure in the young child can be severely disrupted by therapeutic doses of radiation. [40] Examples include mental retardation, aortic arch dysgenesis, and agenesis of the female breasts after irradiation of relevant structures. [41,42,43 and 44] The oncogenic effect of therapeutic irradiation has also emerged as a major problem. [42] There are no data to suggest that infants are particularly vulnerable to this effect.

It is generally believed that, because of ongoing development, radiation sensitivity of certain structures and organs in infants is increased. One such organ is the brain. The brain of the young infant is still immature. There is a very high mitotic activity in spongioblasts, and many of the major nerve tracts have not been myelinated, particularly in the frontal lobes. [43] Intellectual functioning is significantly lower in infants with brain tumors who received cranial irradiation as part of their therapy than in infants treated without irradiation. [44] Other major organ systems are also particularly vulnerable to damage, including the skeleton, kidney, liver, and lung. Skeletal growth has been shown to be more severely affected, dose for dose, with younger age. [45] Acute and chronic nephropathy can be caused by relatively low-dose radiation therapy given at any age, and the kidney of the newborn may be even more sensitive to irradiation because of its immaturity, as demonstrated by low glomerular filtration rates during the first 6 months of life. [46] Radiation damage to the liver can result in acute and chronic changes that may prove lethal. The liver's limited ability to conjugate bilirubin during the first week of life demonstrates immaturity, which suggests an increased radiation sensitivity. [47,48] Radiation therapy would also be expected to reduce the potential for normal development of the lung of the young infant and newborn. It can again be assumed that susceptibility to chronic pulmonary insufficiency increases with decreasing age at treatment. [49]

Because pediatric tumors are generally quite radiosensitive, relatively low total doses can be used. Protraction of therapy, using low-dose fractions and split-course techniques, coupled with alternating or simultaneous courses of chemotherapy, may be useful in preventing some of the late effects in infants. [39] The total dose, daily dose, and duration of treatment given to infants and newborns must be based on the natural history of the specific disease process. Chemotherapy given for systemic benefit probably provides an element of local tumor control as well, which may permit a significant reduction in total dose of radiotherapy required. [39] The volume irradiated should be kept as small as possible. Beam-shaping blocks, electron therapy, and other technical maneuvers should be used to avoid irradiating especially sensitive structures and to decrease the risk of long-term sequelae. “Shrinking fields” are also advantageous. This method minimizes the volume that receives the highest dose, avoiding the delivery of damaging doses of radiation to vulnerable structures. Surgical procedures can be performed after preliminary courses of chemotherapy or after administration of part of the total planned radiation dose. This provides time during which relatively normal growth and development can occur. Reexploration permits accurate localization of the tumor volume that must be irradiated. In some situations, a second-look operation allows direct implantation of radioactive materials into residual tumor, further minimizing the volume treated. [39]

Often, technical difficulties exist in ensuring immobility during treatment planning and delivery. Physical restraints, sedation, and even short-term general anesthesia may be required.

### *Chemotherapy*

The rationale for the use of cancer chemotherapeutic agents in the newborn and infant is no different from that for older children with disseminated solid tumors and acute leukemia. Because of the difficulties associated with surgery and radiotherapy in infants, however, chemotherapy also plays an important role in reducing the size of massive tumors that clinically appear local. Chemotherapeutic debulking may make these tumors more amenable to surgical or radiotherapeutic ablation and prevent systemic spread or suppress the growth of occult micrometastatic disease present at diagnosis. [50]

Several reports in the literature identify chemotherapy-related toxicities that are of special concern for infants. Infants are known to experience excessive vincristine-related neurotoxicity, manifested in extreme cases by hypotonia, poor cry, inability to feed, and fatal flaccid paralysis. [51] Increased myelosuppression in infants with Wilms' tumor given regimens containing vincristine, dactinomycin, and doxorubicin (Adriamycin) was seen in the second National Wilms' Tumor Study (NWTS-II). This resulted in the recommendation that dosages of all drugs be reduced by 50% in infants younger than 1 year of age. [52] This dosage reduction has not resulted in an increased rate of recurrence or metastasis. [52] These guidelines were also adopted by the Intergroup Rhabdomyosarcoma Study Committee for the management of solid tumors in infants and have been used in the intensive myeloablative regimens for the treatment of acute myelogenous leukemia (AML). [53] In a large series of infants with ALL, however, excessive chemotherapy-related toxicity, other than vincristine neurotoxicity, was not observed, and reduction of induction dosages for anticipated toxicity had an unfavorable impact on rates of remission induction and on remission duration. [3] A retrospective study of infants treated with a median of six cycles of 2 mg per kg cisplatin did show more acute toxicity, including electrolyte disturbances, but they did not have more long-term toxicity compared with older children.[54]

Reduction of initial dosages to prevent toxicity does not lessen the need for continued vigilance in monitoring possible toxic reactions. To maximize therapeutic efficacy, judicious incremental increases of subsequent doses should be considered if toxic effects have not developed. Chemotherapy-induced toxicity to specific organ systems (e.g., liver, lung, heart, and kidney) has rarely been reported in infants. In the few cases of hepatotoxicity, the use of multiple chemotherapeutic agents or of simultaneous radiation therapy to the target organ makes it difficult to implicate specific drugs. [52,53]

Data are lacking on the clinical pharmacology of most chemotherapeutic agents in newborns and infants. The optimal use of chemotherapy in this age group is best accomplished with pharmacokinetic monitoring. There are distinct technical difficulties in monitoring small infants, however, and the rapid changes in physiologic parameters that affect pharmacokinetics, particularly in the newborn, make such investigations difficult. Virtually every aspect of the distribution, excretion, and metabolism of anticancer drugs is quantitatively and qualitatively altered in newborns and young infants. Aspects unique to the pharmacology of the neonate include the rapid change in relative volume of fluid compartments that occurs after birth; different rates of hepatic metabolism; decreased efficiency of renal excretion; decreased protein-binding capacity; increased volume of cerebrospinal fluid, brain, and spinal cord tissue relative to body surface area (BSA); increased permeability of blood–brain barrier; and erratic gastrointestinal absorption. [55]

Rapid changes in the volumes of body water compartments occur during the first 9 months of life. In newborns, total body water constitutes almost 80% of body weight, and values similar to those in adults (50% to 55%) are seen in the older child. [56] Extracellular water volume is approximately 45% of body weight at birth but decreases to 20% in older children. Most of the drugs used in cancer chemotherapy are distributed in total body water or extracellular water. The convention of using BSA for drug dosing results in a standardization of the concentration of chemotherapeutic agent originally in the drug's volume of distribution, but it does not account for the changes in the distribution of body water compartments with age. [57] The BSA method therefore may not be appropriate for the very small infant (less than 6.0 kg), for whom calculations of dosage based on body weight may be more physiologic. [58]

The renal function of very young infants is less than would be predicted on the basis of body weight or surface area. Renal blood flow is lower in newborns, the ability of the renal tubules to concentrate or acidify the urine is restricted, glomerular filtration rate is low, and the organic ion transport system for active tubular secretion is underdeveloped, resulting in an increased reabsorption rate of weakly acidic drugs. [59,60] The maturation of various renal functions proceeds at different rates; therefore, chemotherapeutic agents that are not extensively metabolized and depend on renal excretion for elimination are cleared slowly in the newborn and young infant. This may result in prolonged plasma half-lives, with an increased risk of toxic reactions.

It has been demonstrated that neonates can metabolize drugs, but the ability of the immature liver to metabolize depends on the specific drug. [61] There are also wide interindividual variations in plasma clearance of specific drugs during the first few days of life, and a knowledge of the statistical mean rate of metabolism may be of little value to the clinician in choosing a drug dosage and regimen for a given infant. [55]

Because of the lower concentration of plasma proteins, the presence of a qualitatively different (fetal) albumin, high serum concentrations of competing substances such as bilirubin and free fatty acids, and lower blood pH, the binding of drugs by plasma proteins is lower in the neonate, resulting in a higher volume of distribution.[60,62]

Intrathecally administered methotrexate and cytarabine (Ara-C) are widely used for the treatment or prevention of meningeal leukemia. It has been demonstrated that age-related pharmacokinetics differences exist and that BSA does not accurately reflect the volume of the CNS. [63] The substantially greater ability of drugs to enter the CNS of the newborn compared with the adult has been thought to reflect incomplete myelination. Increased cerebrospinal fluid levels of methotrexate, despite normal renal clearance, have been demonstrated in infants receiving very-high-dose systemic infusions of methotrexate compared with levels in older children. [64]

The absorption of drugs from the gastrointestinal tract largely depends on pH-related diffusion and gastric emptying time. Low gastric pH and prolonged gastric emptying time in infants may result in relative inefficiency of orally administered chemotherapeutic agents. [65] Diminished bile acid metabolism due to hepatic immaturity may also result in prolonged clearance of chemotherapeutic agents normally excreted in bile and in unanticipated toxicity. [66]

Recommendations for dosage modifications in situations in which excessive myelosuppression should be avoided in newborns and young infants are provided in Table 15-5. These guidelines are based on the limited data available and must be applied within the context of the specific cancer being treated and the individual clinical situation. Unless otherwise stated, “decreased dose” implies a 50% reduction of the reference dose for older children when calculated on the basis of BSA. For infants weighing less than 6.0 kg, doses calculated on a mg per kg basis, using reference doses in milligrams derived for a $1m^2$ individual divided by 30 (assuming that a $1m^2$ individual weighs 30 kg), result in approximately the same 50% reduction. As many of these recommendations are empiric and not based on detailed pharmacology studies, escalation of subsequent doses should be considered if initial doses are well tolerated.

| Drug | Reason for modification | Dose modification* |
|---|---|---|
| 6-Mercaptopurine | Clearance dependent on levels of hepatic enzymes; decreased until 3 mo | Decrease by 50% until ≥3 mo |

ALL, acute lymphoblastic leukemia; AraC, methotrexate and cytarabine; DTIC, dacarbazine; GFR, glomerular filtration rates; VM-26, teniposide; VP-16/VM-26, etoposide.
*Many of these modifications have been derived empirically and are not based on detailed pharmacokinetic studies.
†According to Children's Cancer Group dosing criteria.

**TABLE 15-5. DOSAGE MODIFICATIONS OF CHEMOTHERAPEUTIC AGENTS IN INFANTS AND NEWBORNS**

The use of hematopoietic growth factors has reduced the myelosuppressive toxicity of most chemotherapeutic agents.[67] Growth factors should be considered in the treatment plan for infants undergoing myelosuppressive therapy to reduce toxicity and avoid further dose reductions.

***Pain***

The evaluation and management of pain in pediatric oncology patients present a unique challenge. This is especially true for infants who are nonverbal and have a limited ability to express physical discomfort.[68] Studies have documented that infants have physiologic stress responses to painful procedures and have improved outcomes when pain is treated.[69,70] Effective pain management in infants depends on a high level of awareness by health care providers. The sources of pain to consider in infants with cancer are their underlying disease process and invasive diagnostic or therapeutic procedures. Signs of pain in very young infants include cry, grimace, irritable behavior, withdrawal of affected body part, tachycardia, sweating palms or soles, elevated blood pressure, stress hyperglycemia, and decreased oxygen saturation. Older infants may developmentally be able to physically resist painful procedures and develop anticipatory fear.[69] The strategies for managing pain in infants include palliative or curative therapy to eliminate the source of pain, and pharmacologic analgesia. This is similar to the approach used for older children and is discussed further in Chapter 43.

***Supportive Care***

Management of the infant with cancer is best accomplished in a specialized pediatric tertiary care setting, wherein the unique medical, surgical, anesthesia, blood-banking, and nutritional requirements of seriously ill newborns and infants can be met.

Because venous access often becomes a problem very early in the management of infants, the elective placement of a tunneled indwelling right atrial catheter (i.e., Hickman and Broviac) should be considered to facilitate the administration of parenteral alimentation, blood products, and chemotherapy.[71] Cannulation of the external jugular vein rather than the usual cephalic vein is generally recommended for infants. Depending on the treatment plan, subcutaneous implantable devices are a possible alternative to tunneled indwelling central venous access. Specific guidelines to prevent and treat the infectious and thrombotic occlusive complications of these indwelling catheters are presented in Chapter 12 and Chapter 41.

Early empiric institution of nutritional support should be considered before the initiation of intensive therapies. Because there is growing suspicion that a malnourished state impairs host ability to tolerate anticancer therapy, possibly decreasing response to treatment, the early use of parenteral alimentation is warranted if less invasive approaches are precluded by gastrointestinal dysfunction.[72] This is necessary to prevent the added morbidity of multimodal therapy until it is safely established that normal weight gain and growth can be accomplished without supplementation.

Of great importance is the immediate availability of blood products with the lowest possible shelf life and methods to provide maximal transfusion support without risk of excessive volume overload and unnecessarily increased donor exposures (e.g., infant quadpacks and quintpacks, quadruple or quintuple blood collection systems, centrifugation of platelet-rich plasma, plateletpheresis, and directed donor programs).[73] All blood products administered to infants receiving intensive chemotherapy should be irradiated (at least 1,500 cGy) to prevent graft-versus-host disease.[74] Use of blood products that are negative for exposure to cytomegalovirus has also been recommended.

Potential long-term, organ-specific, treatment-related toxicities, anticipated to occur with increased frequency in infants with cancer, warrant the early institution of a coordinated, longitudinal evaluation of growth and specific organ (e.g., lung, skeletal, liver, and kidney) function to identify subclinical problems that may respond to early therapeutic intervention. Most important, longitudinal assessment of neuropsychologic development in infants at risk for neurotoxic sequelae may delineate early signs of learning disabilities that can benefit from remedial intervention.

**Specific Neoplasms in Infancy**

***Neuroblastoma***

Neuroblastoma is the most common cancer in infants (see Chapter 31).[1,2] It accounts for more than one-third of the malignancies observed in the first year of life and more than one-half of those in the neonatal period.[1,2,75] Between 21% and 35% of all neuroblastomas occur in infants younger than 1 year of age. The incidence of neuroblastoma in infants is probably underestimated because many tumors spontaneously regress before detection. Small neuroblastomas have been found incidentally during routine necropsies of young infants dying of other causes with a frequency 40 times greater than expected for clinically overt neuroblastoma.[76]

More than one-half of neuroblastomas in infants present in the abdomen, presumably originating in the adrenal gland. The extent of disease at diagnosis, as demonstrated by the most widely used staging system, is different for infants compared with older children. Most infants present with stage IVS (30%) or local disease (40%), and most older children (55%) present with distant metastases (i.e., stage IV disease).[5,77] Stage IVS patients are a unique group of infants who have small localized primary tumors that do not cross the midline and evidence of distant spread to liver, skin, bone marrow, or combinations of these sites, without radiographic evidence of cortical bone metastases.

The patient's age at diagnosis and stage of disease have a dramatic impact on treatment outcome in neuroblastoma. The overall disease-free survival for infants with neuroblastoma approximates 75%. Historically, survival rates for infants with stage IV disease have been dismal, but regimens using intensive multiagent therapy have greatly improved outcomes.[78,79]

Although age and stage have important prognostic implications, these two variables alone cannot predict outcome. Other important prognostic variables in infants include serum levels of neuron-specific enolase, serum ferritin, histopathology, cellular DNA content, and metastatic bone marrow disease detected by immunocytology.[80,81,82,83,84,85] and [86] Molecular genetic characteristics of neuroblastoma that are often found in infants and predict a favorable prognosis include tumor cell hyperdiploidy, absent karyotypic abnormalities (specifically chromosome 1p deletions), no amplification of the MYCN proto-oncogene, and absence of increased TRKA expression.[87,88,89] and [90]

The importance of these factors in predicting prognosis is demonstrated by the difference in survival for two groups of infants with stage III neuroblastoma. Infants with stage III disease, favorable histopathology, less than ten copies of N-*myc*, and normal ferritin have a 3-year progression-free survival rate in excess of 70%. In comparison, infants with stage III disease, unfavorable histopathology, increased ferritin, and more than ten copies of N-*myc* have a less than 30% 3-year rate of survival.[89] These prognostic factors have been evaluated prospectively in formulating treatment plans for infants with advanced-stage neuroblastoma.[78]

The management of infants with stage I or stage II neuroblastoma may be surgical resection only, depending on biologic characteristics. Some infants with stage II neuroblastoma have posterior mediastinal primaries not amenable to total surgical resection. Radiation therapy in doses of 900 to 1,800 cGy has been successfully

used as an alternative or adjuvant to surgical resection to treat intraspinal disease in these infants, but should be reserved for patients failing chemotherapy. [91,92] Stage III and IV are treated with a combination of surgery, radiation, and intensive multiagent chemotherapy. Infants younger than 1 year of age with stage IV neuroblastoma have a much improved outcome compared with children older than 1 year of age. Infants with non-MYCN–amplified tumors have a 93% 4-year event-free survival, whereas those with MYCN–amplified tumors have a dismal prognosis.

Few other clinical situations in pediatric oncology have been as controversial as the management of infants with stage IVS neuroblastoma. The finding of hyperdiploid cells by flow microfluorometric DNA analysis provides convincing evidence that this is a malignant lesion rather than a hyperplastic proliferation resulting from a one-mutation event in germinal cells, as previously proposed. [83,93] Among 165 stage IVS patients for whom adequate follow-up data are available, the survival rate is 77%.[94,95] Only 24% of the deaths in this group resulted from progression of disease to stage IV. The remainder were caused by respiratory compromise secondary to massive hepatomegaly, coagulopathy, or therapy-related complications. More than 50% of these patients received some form of chemotherapy, and some received radiotherapy. Of those who received no chemotherapy, 80% exhibited spontaneous regression of tumor. In the 7-year Children's Cancer Group (CCG) experience with 44 infants with stage IVS neuroblastoma, the only deaths were three patients younger than 2 months old at diagnosis, and the 2-year disease-free survival for infants 3 to 12 months of age was 97%. No significant influence of chemotherapy or radiotherapy on ultimate survival could be demonstrated. A nonrandomized study by the Pediatric Oncology Group (POG) demonstrated that chemotherapy consisting of cyclophosphamide and doxorubicin accelerated tumor regression but had no impact on overall survival.[96] In a subsequent nonrandomized POG study in which patients received either observation or immediate chemotherapy, the overall actuarial survival for all IVS patients was 90%.[97] In a small series of infants with stage IVS neuroblastoma, amplification of MYCN was strongly correlated with survival outcome. Although initial tumor regression was observed in some stage IVS patients with amplified N-*myc*, later progression occurred.[98]

Because chemotherapy does accelerate tumor regression, treatment with cyclophosphamide (5 mg per kg per day for 5 days) or the sequentially scheduled regimen of cyclophosphamide (150 mg per $m^2$ for 7 days) and doxorubicin (35 mg per $m^2$ on day 8) are warranted to initiate regression and to prevent life-threatening complications related to mass disease.[92,93] Radiotherapy in doses of 450 cGy (150-cGy daily fractions using lateral opposing fields) has also been effective. [92]

The biologic and genetic characteristics that have demonstrated prognostic significance in neuroblastoma must be taken into consideration when deciding on treatment options for stage IVS patients. A prospective correlation of clinical and biologic factors with natural history of stage IVS neuroblastoma is being undertaken by the CCG and POG to identify stage IVS infants who may require more intensive therapy. Until these data are available, it is recommended that infants younger than 1 year of age with clinical stage IVS disease, normal karyotype, nonamplified MYCN, and no complications due to the mass of their disease be closely followed without therapy. Infants with clinical stage IVS, abnormal karyotypes, amplified MYCN, or complications due to the mass of their disease should be aggressively treated. Ultimately, resolution of the controversy over how to treat clinical stage IVS neuroblastoma requires redefining of stage IVS to include genetic characteristics of the tumor.

There is considerable interest in the early detection of neuroblastoma in infants through mass screening programs using urinary catecholamine measurements at 6 months of age. Despite initial reports of a beneficial impact of such screening on survival, no population-based data from controlled studies exist to demonstrate reduced mortality.[99,100] The incidence of the disease in the first year of life has increased considerably in Japan, where a nationwide screening program has been in place since 1985.[101,102] However, the incidence of neuroblastoma among children older than 1 year of age has not changed, suggesting that a high proportion of prognostically favorable cases (many of which may have spontaneously regressed) are being detected. [103] Because mass screening has not been shown to reduce mortality, widespread implementation of this practice cannot be recommended.[104]

### *Brain Tumors*

Primary tumors of the CNS account for approximately 15% of cancer in infants (see Chapter 27).[2] There has been an increased incidence of CNS tumors observed in U.S. infants, and CNS tumors are now the second most common cancer in infants.[1,2] This unexplained increase in incidence is seen largely in male infants and therefore cannot be solely attributable to improved diagnostic techniques or reporting. [2]

The most common presenting feature of CNS tumors in infants is rapidly expanding head size and bulging fontanelle. Because of the expandability of the cranial vault, symptoms referable to increased intracranial pressure, other than vomiting, are rare in infants. Papilledema is rarely observed. Other clinical signs observed with greater frequency include paresis, seizures, cranial nerve palsies, lethargy, and nuchal rigidity. [105] In contrast to the experience in older children, an increased frequency of supratentorial rather than infratentorial tumors has been observed in infants, partially because of an increased relative frequency of cerebral hemispheric tumors.[106] Medulloblastoma and ependymal tumors account for approximately 50% of the histologic subtypes.

Overall, the prognosis for children with brain tumors is poor, and infants represent a subset of patients with particularly high morbidity and mortality. [107] The primary treatment of brain tumors in children is surgical resection and radiation therapy. Because of the doses of radiation used, serious sequelae are almost a certainty in infants with primary CNS tumors.[106] Several small studies have used various chemotherapy combinations in an attempt to defer radiotherapy in young infants until patients are at least 24 to 36 months of age.[108,109] These approaches have demonstrated efficacy without excessive toxicity in early follow-up reports. A CCG study of infants younger than 18 months of age with medulloblastoma or ependymoma treated with intensive chemotherapy and delayed or no radiation therapy extended survival for 20% of patients.[110] A similar POG study of brain tumor patients younger than 3 years of age treated with a cyclophosphamide/vincristine and cisplatin/etoposide combination of chemotherapy with delayed or deferred irradiation had an improved progression-free survival of 39% for infants younger than 24 months old.[111] Both studies demonstrated that deferred radiation therapy did not negatively impact progression-free survival. The POG study also showed that extent of surgical resection was an important prognostic factor. [111] Current treatment strategies for infants with brain tumors therefore include chemotherapy with delayed or deferred irradiation, intensification of dose and timing of initial chemotherapy, and incorporation of a second surgical resection as indicated. These strategies should continue to improve survival and long-term neuropsychologic outcome for infants with brain tumors.

### *Acute Lymphoblastic Leukemia*

Infants account for approximately 3% of all children with ALL, and they experience the worst prognosis of any group of children with this disease (see Chapter 19). In a series of early clinical trials of the CCG, fewer than 25% of patients survived without relapse at 3 years from diagnosis. Infants present with a constellation of clinical features associated with a poor prognosis, including hyperleukocytosis, hepatomegaly, splenomegaly, CNS leukemia at diagnosis, thrombocytopenia, and poor early response to treatment determined by day 14 bone marrow examination.[3]

The blasts of infants with ALL more frequently have a common ALL antigen (CALLA-CD10)-negative phenotype.[112] Infants with ALL also have increased frequencies of cytogenetic abnormalities: pseudodiploidy and hypodiploidy and translocations involving chromosome 11 with a break at band q23, associated with rearrangements of the MLL gene.[113,114 and 115] The specific 11q23 breakpoint abnormality, t(4;11), is the most frequent structural karyotypic abnormality in infants with ALL, detected in 30% to 50% of patients using standard cytogenetic techniques.[15,114] This specific translocation results in the synthesis of a protein that is a fusion product of the transcripts from the ALL-1 gene on chromosome 11 (also known as *HRX*, *MLL*, and *HTRX-1*) and the AF-4 gene on chromosome 4,[115,116] which plays a pivotal role in leukemogenesis. The prognosis is dismal in this subgroup.[116] Using molecular analysis, the MLL gene is uniformly rearranged in cases with t(4;11) and has been reported in 70% to 80% of infants with ALL.[116]

Particular focus on the molecular epidemiology of infant leukemia results from the frequent association of both ALL and AML with rearrangements of the MLL gene in up to 80% and 50% of infants, respectively. Identical abnormalities of the MLL gene at band 11q23 are involved in these rearrangements, [117] which may involve a variety of partner chromosomes, including 4, 9, and 19. Rearrangements of the MLL gene have also been observed in treatment-related AML, specifically cases associated with DNA topoisomerase II inhibitors, such as the epipodophyllotoxins, etoposide and teniposide. [118,119] The strong association between exposures to topoisomerase II inhibitors and the development of acute leukemia with MLL rearrangements has led to the intriguing hypothesis that maternal exposure to naturally occurring topoisomerase II inhibitors during pregnancy could increase the risk of infant leukemia. [120,121] A number of natural and synthetic topoisomerase II inhibitors exist, including flavonoids, catechins, caffeine, quinolones, thiram (an agricultural fungicide), certain benzene derivatives, and Chinese herbal medicines. [121] Preliminary data strongly suggest that maternal exposure to topoisomerase II inhibitors, particularly in the diet, is positively associated with AML in infants. [122,123]

Understanding the role of the MLL gene in the etiology of leukemia in infants has been significantly advanced by investigations of monozygotic infant twins. [124] Although the incidence of acute leukemia in infant twins is rare, detailed cytogenetic or molecular studies, or both, have demonstrated unique and identical clonal

molecular MLL gene rearrangements in cases of ALL with the t(4;11) and t(11;19).[125]

An unresolved question regarding the molecular etiology of infant leukemia, specifically ALL with the t(4;11), is whether expression of the MLL-AF4 fusion gene is sufficient to lead to the fully transformed phenotype.[126,127] The latency period to leukemia onset in the murine knockout mouse model and observations of human latency suggest that leukemogenesis requires genetic changes in addition to MLL translocations.

A recent finding of homozygous deletions of exons of the Ikaros gene with expression of dominant-negative Ikaros isoforms in six of seven infants who exhibited MLL-AF4 fusion suggests that disruption of normal Ikaros function may contribute to leukemogenesis associated with the t(4;11).[127] Inappropriate expression of non-DNA–binding Ikaros isoforms during early lymphopoiesis may dysregulate normal lymphocyte development, leading to maturational arrest at discrete stages of lymphocyte ontogeny, predisposing lymphocyte precursors to "second hits" and leukemic transformation.[128,129] Previous studies in mice have demonstrated that germline mutant mice expressing dominant-negative isoforms of Ikaros also develop ALL.[130] An abundance of dominant-negative mutant Ikaros isoforms that no longer bind DNA could interfere with centromeric recruitment and expression of specific genes during lymphocyte development. A lack of lineage-specific gene silencing could also explain the "lineage infidelity" demonstrated by myeloid antigen expression in ALL in infancy.[131,132] Obviously, further investigations of other molecular genetic abnormalities will be important in clarifying the leukemogenic role of such rearrangements and may provide clinically exploitable information for developmental therapeutics as well as disease prevention.

Despite major advances in cure rates for the general patient population, achieved through the identification of prognostic factors and the implementation of risk-adjusted therapy, the long-term event-free survival of infants with ALL approximates 40%.[133,134,135,136,137,138] and [139] This result, although only one-half that being achieved in standard-risk ALL patients, or in high-risk patients treated with intensified therapy regimens, represents an improvement over the historical experience. This modest success was accomplished through clinical trials and efforts to explore the biologic differences between leukemias in infants and older children. Retrospective reports of several series of infants with ALL, the largest dealing with infants treated on a number of consecutive clinical trials of the CCG, revealed 3-year, event-free survival rates of only 20%. Early treatment failure, characterized by both systemic and extramedullary relapse, rather than therapy-related toxicity, explained this poor outcome.[3]

The improvement in treatment outcome in infants with ALL, although decidedly less impressive than improvements seen in older children, have been accomplished through progressive intensification of systemic chemotherapy. Another significant accomplishment was the prevention of CNS relapse with the use of high-dose systemic, as well as intrathecal Ara-C, eliminating the need for cranial irradiation and resulting in a cumulative risk for CNS relapse of only 3%, despite a 14.2% prevalence of CNS leukemia at diagnosis. Intensification of therapy for infants has also included the combination of mitoxantrone and cytarabine,[136,138] intermediate-dose methotrexate infusions,[139] and combinations of cytarabine and etoposide.[135,140] Substantial reduction in the rate of isolated CNS relapse in two consecutive studies of the CCG have been observed in patients receiving CNS-directed therapy consisting of protracted (24-hour), very-high-dose (33.6 g per $m^2$) methotrexate infusions with leucovorin rescue plus intensive intrathecal therapy with Ara-C. Compared to historical controls, wherein the CNS relapse rates exceeded 20%, relapse rates of 9% and 3% in each of these two consecutive trials represented significant treatment advances.[134]

Developmental and neuropsychological evaluation of long-term survivors from these recent CCG trials have demonstrated mean scores on standardized cognitive and motor tests in the average range, with a normal distribution of scores by comparison with population-based standards.[141,142] These findings suggest a positive early developmental outcome for these children and represent a substantial improvement over the neurocognitive potential of previously treated infants.

To date, no other long-term clinical complications in patients, now followed for up to 8 years after successful completion of therapy, have emerged. Effective strategies to prevent CNS relapse while eliminating the potential for adverse neuro-cognitive and neuro-developmental sequelae are crucial to current future clinical trials investigating the optimal management of ALL in infants.

### *Acute Myelogenous Leukemia*

The outcome for infants with AML is not significantly different from that for older children (see Chapter 20).[53,143] However, an excess of myelomonocytic and monoblastic subtypes, which are associated with a less favorable prognosis, has been observed in infants. Infants with AML are more often found to have hyperleukocytosis, CNS leukemia at diagnosis, skin infiltration, and 11q23 abnormalities compared with older children.[53,143,144] The same therapeutic strategy is applied to infants and older children with AML. Despite the marked differences in these clinical and laboratory features, no differences in complete remission rate or survival have been observed between infants and children older than 2 years of age.

### *Retinoblastoma*

The incidence of retinoblastoma is 29 cases per million infants per year in the United States, representing approximately 13% of all cancers in infants (see Chapter 28).[2] Retinoblastoma is usually considered hereditary or nonhereditary (sporadic). Hereditary retinoblastoma represents approximately 40% of all cases, usually presents at a younger age (median, 13 months), and occurs with bilateral disease.[145,146] Only 10% of hereditary cases have a family history of retinoblastoma.[12] Susceptibility to retinoblastoma is inherited by deletions in the gene on chromosome 13q14, the retinoblastoma gene.[147] Sporadic cases are thought to be caused by acquired somatic mutations of this gene.

Infants with retinoblastoma most commonly present with leukocoria.[116] Strabismus, proptosis, blindness, an orbital mass, or other signs and symptoms of distal metastases can also be the initial finding.[116] Up to 70% of infants with retinoblastoma present with bilateral disease. Depending on the stage of disease, therapeutic options for infants with retinoblastoma include enucleation, irradiation, cryotherapy, and photocoagulation. Chemotherapy has limited effectiveness and is reserved for patients with metastatic disease.[148]

The prognosis for survival and salvation of vision for infants with retinoblastoma depends on the extent of disease at diagnosis. Overall, the survival rate for infants is high (85%).[145,146] In contrast, the mortality rate for retinoblastoma with distant metastasis or local extension at diagnosis is poor. Infants with hereditary retinoblastoma have a worse prognosis for long-term survival because of their increased risk of developing a second malignancy, most often osteosarcoma, later in life.[149]

### *Renal Tumors*

Renal tumors account for 11% of cancer in infants (see Chapter 30).[2] Although 16% of patients entered on the NWTS-II were infants, infantile congeners of Wilms' tumor are the more common renal neoplasms in newborns and infants (Table 15-6).[19] The most common is the congenital mesoblastic nephroma.[150] In the past, this growth was confused with Wilms' tumor, which may account for the more favorable reported prognosis of Wilms' tumor in infants. Mesoblastic nephroma (also known as *mesenchymal hamartoma of the kidney*) is not encapsulated and infiltrates into normal renal parenchyma. Complete surgical excision, with meticulous nephrectomy, is required. Local recurrences follow inadequate resection, and close follow-up is recommended. Only sparse reports of metastatic spread exist.[151]

| Renal neoplasm | Histologic and clinical characteristics |
|---|---|
| Congenital mesoblastic nephroma | Fibromyomatoid tumor; usually benign; often congenital; most common in infants <6 mo |
| Well-differentiated epithelial nephroblastoma | Closely packed, well-differentiated tubules; usually benign |
| Polycystic nephroblastoma or multilocular cystic nephroma | Macrocysts lined by flattened epithelium and fibrous septae; usually benign |
| Fetal rhabdomyomatous nephroblastoma | Predominantly in skeletal muscle; one-third bilateral; usually benign |
| Nodular renal blastema/ nephroblastomatosis complex | Nodular or confluent subcortical masses of hamartoid, hyperplastic epithelium; precursor of Wilms' tumor, particularly bilateral, hereditary type |

**TABLE 15-6. INFANTILE CONGENERS OF WILMS' TUMOR**

A potentially aggressive variant of mesoblastic nephroma is identified by foci of hemorrhage and necrosis, involvement of adjacent structures, and high cellularity and mitotic index. It is associated with invasion of adjacent structures or organs, multiple recurrences, and metastases. [152] This lesion probably represents an intermediate form between congenital mesoblastic nephroma and clear cell sarcoma of the kidney in the spectrum of infantile renal mesenchymal tumors originating from the premetanephric stromagenic stage of renal blastema. [153]

The clinical presentation of Wilms' tumor and its management in infants are not different from the experience of older children. However, toxic deaths were reported for 6% of infants with group I or II disease in NWTS-II, presumably related to excessive hematologic toxicity. [71] Modifications in therapy for infants, consisting of a 50% reduction in the dosage of all chemotherapeutic agents, were subsequently implemented and resulted in significant reduction in the severity and frequency of toxic effects and no deaths. Reduction in dosage did not jeopardize the therapeutic efficacy of adjuvant therapy. [52] Similar management has produced no excess toxicity or relapse in those infants in the NWTS-III study.

***Rhabdomyosarcoma***

Soft tissue sarcomas are relatively rare in infants, and this age group accounts for only 5% of patients in the Intergroup Rhabdomyosarcoma Studies. [154] No differences in sex ratio or clinical groupings (i.e., stage) were observed. The significant differences in clinical presentation, histopathology, and response are shown in Table 15-7. Unlike neuroblastoma and Wilms' tumor, rhabdomyosarcoma occurring before 1 year of age is not associated with a more favorable outcome. Before a study-wide amendment recommending a 50% reduction in chemotherapy doses for infants, excessive toxicity-related fatalities were observed.

| Characteristic | Children (n = 78) | Infants >1 y of age (n = 1,483) |
|---|---|---|
| Histology | | |
| Undifferentiated sarcoma | 18% | 7% ($p < .0005$) |
| Botryoid | 10% | 4% ($p < .005$) |
| Primary site | | |
| Bladder, prostate, or vagina | 26% | 10% ($p < .05$) |
| Clinical group III outcome | | |
| 3-yr survival | 41% | 62% ($p = .0002$) |
| Local recurrence rate | 29% | 11% ($p = .02$) |

**TABLE 15-7. INTERGROUP RHABDOMYOSARCOMA STUDIES I AND II: CLINICAL FEATURES AND OUTCOME OF INFANTS AND OLDER CHILDREN**

Review of the radiotherapy data for infants with embryonal rhabdomyosarcoma demonstrated an increased risk of local recurrence in those given total doses below 4,000 cGy in an attempt to reduce morbidity. In cases of orbital rhabdomyosarcoma, effective local control was achieved with doses between 3,000 and 4,000 cGy; reduction of radiation doses to less than 3,000 cGy to minimize acute and long-term side effects in infants with soft tissue sarcomas may jeopardize local tumor control. [155] The use of high-dose-rate remote brachytherapy as an alternative to external beam radiation therapy was reported to be safe, well tolerated, and effective in the treatment of a small group of very young children with rhabdomyosarcoma. [156] The efficacy of this treatment option awaits verification.

**Conclusion**

Improved survival for infants with cancer can be achieved with intensive therapy and the awareness of treatment-related toxicity. The most important challenges that remain include continued investigation of the unique etiologic and biologic characteristics of certain tumor types in infants; the pharmacology of chemotherapeutic agents in the infant population, particularly in newborns; and the design of specific therapeutic strategies that provide adequate or increased disease control while lessening potential acute and long-term toxic effects. Meeting these challenges will improve the outcome of infants with cancer.

## CANCER IN ADOLESCENTS AND YOUNG ADULTS

### Epidemiology

Data from the NCI's SEER program indicate that the overall rate of cancer in 15- to 29-year-olds was twice that in younger persons. Among adolescents 15 to 19 years of age, the rate in the United States during the 1990s was 203 new cases per year per million persons in this age group. [157] This rate is approximately 50% higher than the incidence of cancer in children younger than 15 years of age. The incidence of cancer in 15- to 19-year-olds is similar to the incidence of cancer among 0- to 4-year-olds in the United States, is twice that found in 5- to 9-year-olds, and is nearly twice that observed in 10- to 14-year-olds.

This rate is the highest reported since the SEER program began in 1973, with the incidence in 15- to 19-year-olds observed to increase an average of 0.9% per year from 1973 to 1997. Most of the increase occurred during 1973 to 1984 (estimated annual increase of 1.6% per year). During the more recent interval, 1985 to 1997, the rate is estimated to be only 0.1% per year. This pattern of a slowing in the increasing incidence is similar to the change in incidence observed in younger age groups.

The most common cancers among 15- to 19-year-olds in the United States are Hodgkin's disease (16%), germ cell tumors (15%), CNS tumors (10%), non-Hodgkin's lymphoma (NHL) (8%), thyroid cancer (7%), malignant melanoma (7%), and ALL (6%) (Table 15-8). As emphasized by Smith and co-workers,[158] this distribution is strikingly different from the pattern in younger and older persons (see Chapter 1). Many of the common malignancies in children younger than 5 years of age are virtually absent in 15- to 19-year-olds, including the embryonal malignancies of Wilms' tumor, neuroblastoma, medulloblastoma, ependymoma, hepatoblastoma, and retinoblastoma. Similarly, those cancers that predominate in adults, such as carcinomas of the breast and aerodigestive and genitourinary tracts, are distinctly unusual among adolescents. Although rare, many of the cancers of younger and older patients have nonetheless been reported to occur in adolescents (see Chapter 38). [159] [160] [161] and [162]

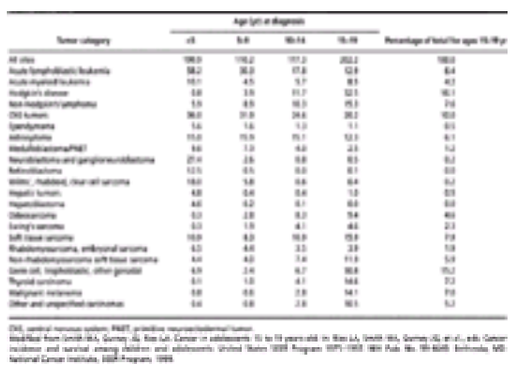

**TABLE 15-8. AGE-SPECIFIC CANCER INCIDENCE RATES PER MILLION AND PERCENTAGE OF TOTAL CASES BY CANCER TYPE AND AGE GROUP, ALL RACES, BOTH SEXES, SURVEILLANCE EPIDEMIOLOGY AND END RESULTS, 1986–1995**

At least six of the common malignancies in 15- to 19-year-olds increased in incidence between 1973 and 1995 ( Table 15-9). NHL and testicular carcinoma underwent the greatest increases over this interval, each averaging more than 2% per year for 24 years. ALL, osteosarcoma, and other germ cell and gonadal tumors showed similar increments (Table 15-9). This pattern is in contradistinction to the increased incidence of cancer in children in whom the increase was restricted to the two most common cancers, ALL and brain tumors.

| Tumor type (ICCC category) | 1975–1979 | 1980–1984 | 1985–1989 | 1990–1995 |
|---|---|---|---|---|
| All sites | 183.0 | 187.7 | 199.3 | 203.8 |
| Acute lymphoblastic leukemia | 10.6 | 13.2 | 12.4 | 13.0 |
| Non-Hodgkin's lymphoma | 10.7 | 14.5 | 14.4 | 16.3 |
| Osteosarcoma | 6.6 | 8.9 | 9.7 | 9.3 |
| Testicular germ cell tumor | 22.1 | 26.7 | 24.9 | 28.4 |
| Ovarian germ cell tumor | 7.9 | 8.3 | 11.8 | 13.3 |
| Gonadal carcinoma | 2.7 | 2.4 | 4.3 | 5.3 |

Modified from Smith MA, Gurney JG, Ries LA. Cancer in adolescents 15 to 19 years old. In: Ries LA, Smith MA, Gurney JG, et al., eds. Cancer incidence and survival among children and adolescents: United States SEER Program 1975–1997. NIH Pub. No. 99-4649. Bethesda, MD: National Cancer Institute, SEER Program, 1999).

**TABLE 15-9. AVERAGE ANNUAL AGE-SPECIFIC INCIDENCE RATES PER MILLION ADOLESCENTS 15 TO 19 YEARS OLD FOR SELECTED TUMORS, ALL RACES, BOTH SEXES, SURVEILLANCE EPIDEMIOLOGY AND END RESULTS, 1975–1995**

Osteosarcoma, Ewing's sarcoma, gonadal germ cell tumors, and Hodgkin's cancers peak in incidence during the adolescent and young adult age interval. The two sarcomas peak during the 15- to 19-year interval, and the latter two cancers peak during the 20- to 29-year age range ( Fig. 15-1). The type of soft tissue sarcoma that occurs in 15- to 19-year-olds is also distinct from that of younger patients. Rhabdomyosarcoma predominates among the sarcomas of childhood, accounting for more that 60% of the soft tissue sarcomas in children younger than 5 years of age. In 15- to 19-year-olds, rhabdomyosarcoma accounts for only 25% of the soft tissue sarcomas. Non-rhabdomyosarcoma soft tissue sarcomas represent 75% of the soft tissue sarcomas. These include synovial sarcoma, liposarcoma, malignant fibrous histiocytoma, and malignant peripheral nerve sheath tumors.

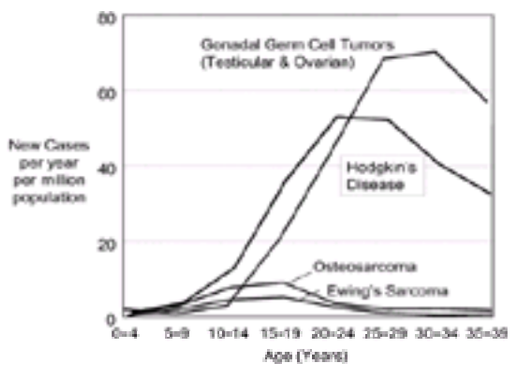

**FIGURE 15-1.** Incidence of four cancers that peak in the adolescent to young adult age range. Data from Surveillance Epidemiology and End Results, 1986–1995. From Ashikari H, Jun MY, Farrow JH, et al. Breast carcinoma in children and adolescents. Clin Bull 1977;7:55–62, with permission.

Leukemias and lymphomas are also distributed differently in older adolescents than in young children. ALL declines steadily with age from the 0- to 5-year age bracket upward, such that by age 15 to 19, ALL accounts for only 6% of the cancers in contrast to the 30% level in children younger than 15 years of age. In 15- to 29-year-olds, NHL is more common than ALL. NHL increases steadily with age (Fig. 15-2), but the subtype distribution changes from a predominance of lymphoblastic and Burkitt's lymphomas during early childhood to a predominance of diffuse large cell lymphoma during adolescence and early adulthood. AML is nearly as common as ALL in 15- to 19-year-olds and more common than ALL in 20- to 29-year-olds. Chronic myelogenous leukemia increases steadily with age from birth on, but is it not as common as either ALL or AML during the 15- to 29-year age range. Juvenile myelomonocytic leukemia is uncommon at all of the four 5-year age groups before age 20, but especially during the 15- to 19-year interval.

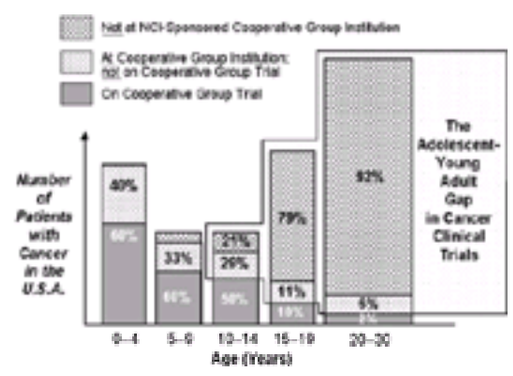

**FIGURE 15-2.** Adolescent and young adult cancer patients on clinical trials. NCI, National Cancer Institute.

Ethnic and racial differences in incidence are particularly apparent among African-American and non-Hispanic white adolescents and young adults. Among 15- to 19-year-olds in the United States, the overall incidence of cancer is 50% higher among whites than blacks. Among specific cancers, melanoma and Ewing's sarcoma are strikingly higher in whites, as is the case during any age range. ALL, germ cell tumors, and thyroid cancer are also more common in whites than in blacks, each by at least twofold. Only soft tissue sarcomas, considered as a group, are more common in blacks than in whites among the common cancers in this age group.

Incidence by gender is also different, with an overall incidence equal among males and females 15 to 19 years of age in contrast to a 20% higher rate in boys younger than 15 years of age. Individual tumor types have unequal sex distributions in the older adolescent populations, however. The most striking difference is in thyroid carcinoma, with females being ten times more likely to get this disease. The next greatest gender difference is ALL, in which males are more than twice as to likely develop this disease. Females are also 50% more likely to be diagnosed with melanoma, and approximately 15% more likely to sustain Hodgkin's disease. [159] Males are nearly twice as likely to have NHL or Ewing's sarcoma, 50% more likely to develop osteosarcoma, and 20% to 30% more likely to have brain tumors or NHL. [159]

**Etiology**

As in younger patients, little is known about the causes of cancer in adolescents and young adults. Very few cancers in adolescents and young adults have been attributed to environmental or inherited factors. Most cases of clear cell adenocarcinoma of the vagina or cervix in adolescent females were found to be caused by diethylstilbestrol (DES) taken prenatally by their mothers in an attempt to prevent spontaneous abortion. [163] Radiation-induced cancer may occur in adolescents and young adults, in most cases when the radiation exposure occurred during early childhood. Many of the adolescent and young adult cancers that have been linked to

etiologic factors are second malignant neoplasms in patients who were treated with chemotherapy or radiotherapy, or both, for a prior cancer. Skin cancer, lymphoma, sarcoma, and hepatic cancers occur at higher frequency in persons with inherited conditions such as neurofibromatosis, ataxia telangiectasia, Li-Fraumeni syndrome, xeroderma pigmentosa, Fanconi pancytopenia, hereditary dysplastic nevus syndrome, nevoid basal cell carcinoma syndrome, multiple endocrine neoplasia syndromes, and Turner syndrome. In the aggregate, however, these cancers account for a small proportion of the cancers that occur during adolescence and early adulthood. The vast majority is unexplained, similar to the state of knowledge of cancer during childhood.

Given that the duration of exposure to potential environmental carcinogens is directly proportional to age, older adolescents and young adults should be more likely to develop tobacco-, sunlight-, or diet-related cancers than younger persons. Nonetheless, there has been little evidence that the cancers in 15- to 29-year-olds are substantively related to these known environmental carcinogens, which of course is not the case for older adults. It appears to take considerably longer than one or two decades in most persons for these environmentally related cancers to become manifest.

## Diagnosis

### *Symptoms and Signs*

With few exceptions, the signs and symptoms of cancer in adolescents are similar to signs and symptoms of the same cancer in younger or older patients. Because of psychological and social factors, patients in this age range may be at higher risk for a delay in diagnosis. Adolescents may present with advanced disease—we have had older adolescents with extraordinarily large masses that they harbored for months—because they were too embarrassed to bring the problem to attention.

### *Pathologic Considerations*

Diagnosis is facilitated by an increased ability of the older patient to describe and localize the symptoms and signs caused by the malignancy, and the greater ease with which biopsies can be obtained.

## Management

### *Surgery*

In general, surgery is more readily performed in the larger patient, and anesthesia is easier to administer. That young adults are generally healthier than older patients is an advantage. The main disadvantage young adults have relative to children is that the fully grown patient generally has fewer compensatory mechanisms to overcome deficits and disabilities rendered by surgical resection of large tumors.

### *Radiation Therapy*

Adolescents and young adults are spared the vulnerabilities of developing tissues to the adverse effects of ionizing radiation. This is particularly true for the CNS, the cardiovascular system, connective tissue, and the musculoskeletal system, each of which may be irradiated to higher doses or larger volumes, or both, with less long-term morbidity in the older patient.

### *Chemotherapy*

For the same chemotherapeutic agents, acute and chronic toxicities are generally similar in children, adolescents, and young adults. Exceptions for the older patients in this age range may be a greater degree of anticipatory vomiting, a somewhat less rapid recovery from myeloablative agents, and fewer stem cells in the peripheral blood available for autologous rescue. Adherence to therapy regimens, particularly oral chemotherapy, is much more problematic in teenagers than in younger or older patients.[164,165 and 166]

### *Psychosocial and Supportive Care*

The greatest difference in the management of adolescents and young adult patients is in supportive care, particularly psychosocial care. These patients have special needs that are not only unique to their age group but also broader in scope and more intense that at any other time in life. The challenges include autonomy and independence, peer pressure, education, graduation, social development, sexual maturation, intimacy, marriage, reproduction, fertility, employment, parenting, and insurability.

When cancer threatens during this critical period of life, the patient, family, friends, and care providers are faced with unique challenges. High school students, college students, recent graduates, newlyweds, new employees, and new parents are expected to take on more challenges than at any other time in life. How can they plan and begin their future when they suddenly realize they may not have one? What will happen if they cannot graduate, keep their friends, finish their education, attain a good job, get married, have children, or be whatever they aspired to be? How can they possibly learn to be independent when becoming a patient makes them dependent on many others, the effectiveness of medical therapy, and the help of their families to survive at all, let alone survive the usual obstacles of adolescence and early adulthood?

These questions and many others emphasize the special needs of patients in this age range. Some of the adverse effects of therapy can be devastating to an adolescent's self-image, which is often tenuous under the best of circumstances.[167] Mutilating surgery to the face and extremities, weight gain, alopecia, acne, and stunted growth are examples. Although there is a dearth of publications that address these issues,[168] there are several that provide substantive advice on how to manage these issues.[169,170,171,172,173,174,175,176,177,178,179,180 and 181]

### *Lack of Participation in Clinical Trials*

Generally, 90% to 95% of children younger than 15 years of age with cancer are managed at institutions that are members of an NCI-sponsored clinical trials organization. In contrast, approximately 20% of 15- to 19-year-olds with cancer are seen at one of these institutions, and only approximately 10% of the patients are entered into a clinical trial (Fig. 15-2).[182,183] Among 20- to 29-year-olds, the participation rate is even lower, with fewer than 10% seen at member institutions of the cooperative groups, either pediatric or adult. Approximately 2% of 20- to 25-year-olds are entered into clinical trials of the pediatric or adult cooperative groups. This gap has been observed throughout the United States and spares no geographic region or ethnic group.[183] This dramatic reduction in clinical trials participation in older adolescents may help explain a lower than expected level of progress in older adolescents and young adults (see following section). There is evidence that older adolescents who participate in clinical trials have a more favorable outcome than those who do not.[182,183,184 and 185]

### *Survival*

Table 15-10 shows 5-year relative survival rates overall and for different cancer types for 15- to 19-year-olds. For all patients in the 15- to 19-year-old age group, the 5-year survival rate for the recent reporting period was 77%, which was higher than that for the other 5-year age groups younger than 20 years of age. Comparison of a recent reporting period (1985 to 1994) with that of an earlier time period (1975 to 1984) indicates that substantial survival gains have been made in most cancers of this age group during the past quarter century (Table 15-10) (see Chapter 1). The only cancer to show no gain, thyroid carcinoma, is also the one that has, by far, the highest 5-year survival rate, 99%.

| Tumor category | 1975–1984 (%) | 1985–1994 (%) |
|---|---|---|
| Total | 69 | 77 |
| Acute lymphoblastic leukemia | 35 | 51 |
| Acute myeloid leukemia | 22 | 42 |
| Hodgkin's disease | 88 | 90 |
| Non-Hodgkin's lymphoma | 56 | 69 |
| Astrocytoma | 62 | 75 |
| Medulloblastoma | 63 | 75 |
| Osteosarcoma | 49 | 59 |
| Ewing's sarcoma | 36 | 56 |
| Soft tissue sarcoma | 70 | 63 |
| Rhabdomyosarcoma | 40 | 45 |
| Germ cell tumors | 79 | 90 |
| Thyroid carcinoma | 99 | 99 |
| Melanoma | 84 | 92 |

Modified from Smith MA, Gurney JG, Ries LA. Cancer in adolescents 15 to 19 years old. In: Ries LA, Smith MA, Gurney JG, et al., eds. Cancer incidence and survival among children and adolescents: United States SEER Program 1975–1997. NIH Pub. No. 99-4649. Bethesda, MD: National Cancer Institute, SEER Program, 1999.

**TABLE 15-10. FIVE-YEAR RELATIVE SURVIVAL RATES BY CANCER TYPE AND TIME PERIOD, AGE 15–19, ALL RACES, BOTH SEXES, SURVEILLANCE EPIDEMIOLOGY AND END RESULTS, 1975–1984 AND 1985–1994**

However, improvement in survival in older adolescents has lagged behind the improvement in younger patients. In 1975, the 5-year survival for all patients with cancer was estimated to be 64% for patients 15 to 19 years of age when diagnosed with cancer and 55% for those younger than 15 years of age when diagnosed. In 1990, the 5-year survival increased to 76% for 15- to 19-year-olds and to 75% for younger patients. Thus, the relative improvement in survival was considerably greater in the younger patients than in older adolescents, as illustrated in Figure 15-3 for each 5-year age interval below age 20. By projecting this trend, the 5-year survival should have reached 80% for 15- to 19-year-olds and 85% for younger patients by 2000. If so, a reversal in the survival order will have occurred, from a 10% advantage in 5-year survival for older adolescents diagnosed in 1975 to a 5% disadvantage today.

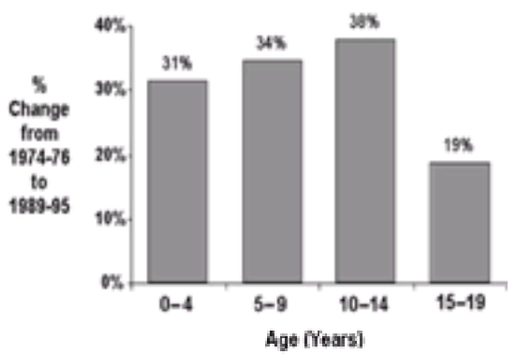

**FIGURE 15-3.** Percent change in 5-year survival rates from 1974 to 1976 and 1989 to 1995, by age. (From Ries LA, Eisner MP, Kosary CL, et al., eds. SEER Cancer Statistics Review, 1973–1997. Bethesda, MD: National Cancer Institute, 2000, with permission.)

The worst outcomes among the common cancers in 15- to 19-year-olds are in AML, ALL, and the sarcomas, particularly rhabdomyosarcoma, Ewing's sarcoma, and osteosarcoma. Each of these has a considerably lower mean 5-year survival rate than the corresponding malignancy in younger patients. With the exceptions of thyroid carcinoma, melanoma, and germ cell tumors, most of the remaining common cancer types in older adolescents have a worse prognosis than the same cancer in younger patients.

The mortality burden is a function of the survival and the incidence rates. More than 80% of the U.S. national cancer mortality burden in 15- to 19-year-olds is due to four malignancy groups: sarcomas, leukemia/lymphomas, CNS tumors, and germ cell tumors. The leukemias are the primary contributor to the cancer mortality burden for cancers developing in 15- to 19-year-olds. Although thyroid carcinoma and melanoma are among the more common cancers in this age group, they contribute little to the overall cancer mortality burden.

## Conclusions

Surviving adolescence and young adulthood is difficult enough, even when all is well and health is not limiting. Adding cancer to this phase of life is extraordinarily more challenging and demanding. There is evidence that progress in diminishing the cancer problem for these patients has lagged behind accomplishments in younger patients. The relative gap in clinical trial participation by older adolescents and young adults with cancer is at least a partial explanation for the relative lack of progress.

Despite a need for adolescent oncology that was recognized years ago, [186] a specific discipline for this special target population is just beginning to evolve. This will help bring the problem in focus and begin to address solutions. Meanwhile, resources should be devoted to educating the public, professionals, insurers, and legislators about the special needs of these patients. [187] The U.S. NCI and the NCI-sponsored pediatric and adult cooperative groups have launched a national initiative to improve the accrual of adolescents and young adults with cancer in clinical trials.

# STEM CELL TRANSPLANTATION IN PEDIATRIC ONCOLOGY

EVA C. GUINAN
ROBERT A. KRANCE
LESLIE E. LEHMANN

## INTRODUCTION

Reconstitution of hematopoiesis via infusion (transplantation) of hematopoietic progenitor or stem cells (SCs) is an established treatment approach for many malignant and nonmalignant diseases that affect the hematopoietic or immune system, or both. In addition, transplantation is also used to support myelosuppression secondary to the dose-limiting toxicity of chemoradiotherapy regardless of the tissue origin of the tumor cell.

The first recorded use of bone marrow (BM) infusion to treat human disease described an empiric decision to infuse blood and BM from a sibling into a patient with marrow failure.[1] The theoretical basis for hematopoietic stem cell transplantation (HSCT) evolved later from observations that mice could withstand an otherwise lethal exposure to whole-body irradiation if the spleen was protected, and similar radiation protection could be provided by an infusion of BM. [2,3 and 4] The first attempts at human BM transplantation (BMT), reported in 1957, were largely unsuccessful but did demonstrate that large amounts of anticoagulated and screened BM could be infused intravenously without ill effects. [5] In 1959, two patients with acute lymphoblastic leukemia (ALL) who received supralethal total-body irradiation (TBI) and infusion of BM from identical twins had successful hematologic recovery, although their leukemia recurred. [6] By the end of the 1960s, several different groups had achieved success in transplanting patients with a variety of immunodeficiency disorders. [7,8,9,10 and 11] Over the next decade, an increasing degree of success was attained using transplantation of BM from matched sibling donors for patients with hematologic malignancies. [7,8,9,10,11,12 and 13]

Both in this early period and subsequently, animal models and clinical trials have jointly contributed to our understanding of transplantation biology. Among the key observations that have contributed to making HSCT a more commonly available treatment modality have been an improved understanding of the critical role of histocompatibility in allogeneic HSCT; the pathophysiology and prophylaxis of graft-versus-host disease (GVHD); the identification, collection, and quantitation of hematopoietic progenitors in BM, peripheral blood (PB), and/or umbilical cord blood (UCB) that are capable of sustaining long-lived human hematopoietic reconstitution; and the identification of essential elements of supportive care during the period of most profound hematopoietic ablation and greatest immune compromise. Indeed, advances in establishing and maintaining long-term vascular access, infectious prophylaxis, treatment of opportunistic infections, transfusion support, nutritional management, and treatment, prophylaxis, and improved management of toxicities due to chemotherapy or TBI preparative regimes, or both, are also improving outcome in HSCT.

By current treatment standards, HSCT should be considered for patients for whom this treatment is physiologically rational and for whom alternative therapeutic options are likely to result in inferior long-term disease-free survival (DFS). The likely benefit of HSCT must outweigh the risks both in terms of acute and chronic complications and, particularly in the case of nonmalignant or more indolent diseases, the potential benefits of other standard or experimental treatments. Potential candidates must have a suitable source of hematopoietic stem cells (HSCs) available at an appropriate time in the course of the disease.

This chapter reviews the current status of HSCT in pediatric oncology and addresses its use in patients with ALL, acute myelogenous leukemia (AML), chronic myelogenous leukemia (CML), myelodysplasia (MDS) or myeloproliferative syndromes, non-Hodgkin's and Hodgkin's lymphoma, and neuroblastoma and other solid tumors. In addition, an overview of HSCT procedures, including conditioning regimens and selection of donor and HSC source, as well as a discussion of common early and late-onset posttransplant complications are provided.

## OVERVIEW

### Hematopoietic Stem Cell Sources

Potential sources of HSCs have increased in recent years and are likely to expand even further. Thus, the pediatric oncologist must consider all the available SCs and their relative merits for each potential patient and disease state.

#### *Autologous Stem Cells*

Autologous HSCs can be harvested from the BM, and more recently the PB, of pediatric patients. With the advent of elective UCB banking, UCB may also become an important source. The most significant limitations to use of autologous HSCs have been the potential for contamination with tumor cells and the risk of post-HSCT MDS. MDS that occurs after autologous HSCT may reflect reinfusion of damaged HSCs and/or failure of the HSCT to eradicate damaged residual HSCs in the BM because allogeneic effects against remaining HSCs are absent. [14,15,16 and 17] It is prudent to screen all patients for cytogenetic abnormalities before proceeding to HSC collection.[18]

Few randomized reports compare the long-term results of autologous BMT versus PBSCT, although there are numerous reports suggesting that the cellular composition, immune potential, and degree of tumor contamination may differ. [14,19,20,21,22 and 23] Studies have demonstrated that PBSCT often results in faster engraftment than BMT, although no long-term benefit has been demonstrated.[24,25] Little or no data directly comparing the use of chemotherapy or cytokine-mobilized BM to the use of similarly stimulated PBSCs is currently available, particularly in pediatrics. The $CD34^+$ content of the HSC product is related to the rapidity of engraftment.[20,26]

#### *Allogeneic Stem Cells*

Conventionally, allogeneic donors have been HLA (histocompatibility locus A)-identical siblings, but improved overall results of HSCT coupled with novel immunosuppressive or graft engineering strategies, or both, have encouraged the expansion of the donor pool to include mismatched family members and HLA-matched and partially matched unrelated donors. In the allogeneic setting, therefore, the decision to perform a transplant involves an additional step of weighing the benefits to the patient against the risks to the healthy donor. In general, BM and PBSC donation are considered safe procedures, although some complications have been reported.[27,28 and 29] In the United States, children are routinely used as donors with parental consent. [30] The legality of giving such consent is not straightforward because laws and their interpretations differ by state and country. Additional ethical and legal issues must be considered when using BM or UCB collected from unrelated donors.[27,31,32,33 and 34]

Volunteer unrelated donors include only healthy persons between 18 and 60 years of age who fulfill health requirements similar to those applied to blood donors. All potential allogeneic donors undergo an extensive medical evaluation; in the case of UCB donation the mother serves as a “surrogate” and the evaluation is adjusted appropriately. The examiner should obtain the same history used for blood product donation. Physical examination and screening laboratory tests with complete blood cell count, biochemistry profile, hepatitis screen, and other testing for transmissible infectious agents, including cytomegalovirus and human immunodeficiency virus, should be completed. Many donor candidates will have preexisting medical problems that require further evaluation. BM donors are usually admitted to the hospital the morning of the harvest. The aspiration procedure is conducted in an operating room under sterile conditions and with appropriate anesthesia. Most BM is harvested only from the posterior iliac crests, but when the recipient is significantly larger than the donor or when large cell volumes are needed, BM may also be harvested from the anterior iliac crests. The total volume of BM usually collected amounts to 10 to 20 mL per kg of recipient weight. These volumes represent realistic target volumes that usually yield sufficient HSCs for engraftment. Evidence suggests that BM from children, especially infants, has a higher concentration of nucleated cells and probably a higher proportion of marrow-repopulating cells than BM from older donors. [35] Accordingly, BM volume may be adjusted downward. Donors of appropriate age may store autologous blood before BM donation to be returned during the procedure; this is generally not indicated unless calculations indicate that the loss in red cell mass presents a significant risk. Most BM donors can be discharged the same day after recovery from anesthesia. Cytokine-mobilized PBSC can be harvested from either related or unrelated adult donors as well as related pediatric donors; this has been successfully accomplished with the placement of antecubital access in both arms, although access issues may present a more significant obstacle with younger and smaller donors. [27,36,37] In general, donors receive recombinant human granulocyte colony-stimulating factor, 10 to 16 µg per kg per day, for 3 to 7 days to mobilize sufficient PBSC for collection. As both the short- and long-term toxicities of this treatment for normals are not well established, the ethical issues around using unrelated adult and related pediatric PBSC donors are considerable.

Since the first such report in 1990, UCB has been collected, cryopreserved, and used as a HSC source. [38,39,40 and 41] UCB is most often collected at the local hospital by trained obstetric personnel and then transferred to a public or private bank for processing and storage. UCB units are tested for infectious agents in accordance with still evolving standards developed by governmental and specialty oversight organizations. The extent of histocompatibility and genetic testing required is still being established.

**Histocompatibility**

Suitability of allogeneic donors is first determined by defining their degree of histocompatibility with the recipient. Currently, matching is generally confined to the major class I and II loci, which constitute the human major histocompatibility complex (MHC). The MHC consists of closely linked genetic loci inherited as a genetic unit or haplotype.[42] These genes are mapped within the HLA region located on the short arm of chromosome 6. However, it is becoming increasingly appreciated that there are minor histocompatibility antigens that likely also play important roles in the outcome of allogenic HSCT. [43,44 and 45] T lymphocytes from one person recognize allelic differences in non-self MHC antigens, resulting in an immune or alloreactive response. MHC antigens can be divided into two groups. The class I molecules HLA-A, HLA-B, and HLA-C are generally regarded as endogenous peptide-presenting cell surface molecules. The class I region also contains additional structurally related class I genes, of which HLA-E, HLA-F, and HLA-G are potentially functional. Class I molecules are composed of an a chain and b $_2$ microglobulin, are highly polymorphic, and are expressed on most nucleated somatic cells and on platelets. The class II molecules, HLA-DR, HLA-DQ, and HLA-DP, are involved in exogenous antigen processing and peptide transport. The HLA class II molecules are heterodimers consisting of two HLA-encoded polypeptide chains a and b.

HLA terminology is designated by the World Health Organization Nomenclature Committee for Factors of the HLA system and is updated at regular intervals. [46] The nomenclature distinguishes the technique used to determine the HLA type and its level of resolution. The broadest designation is based on serologic typing whereas the highest resolution is based on actual DNA sequence. For example, “HLA DR 6” designates a specific class II serotype (i.e., determined by reactivity to serologic reagents); antigens (“HLA DR 6”) recognized by these reagents can be subdivided into DR 13 and 14 by additional serologic reagents or by low-resolution molecular techniques. In turn, DR 13 can be further classified by intermediate or high-resolution molecular analysis of the b chain itself. This is incorporated into the nomenclature, resulting in a report of the allele as DRB1 1301 through 1336 (i.e., the number determined by the polymorphisms described to date). The type of assay used and its sensitivity and specificity are important considerations in determining potential histocompatibility, particularly for mismatched family or for any unrelated donor HSCT.

The genetic unit of HLA class I and II regions on one chromosome is referred to as an *HLA haplotype*, and the two HLA haplotypes in one person are called the *HLA genotype*. Class I and class II antigens are codominant and are transmitted as dominantly inherited mendelian traits. Each child expresses one set of paternal and one set of maternal HLA antigens corresponding to the HLA genes inherited as one paternal and one maternal HLA haplotype. The probability that a child will inherit any one of the four possible HLA genotypes is .25. When, by chance, an individual inherits a phenotypically identical HLA allele from each parent, the result is a person homozygous for that locus; a person may be homozygous for one allele at a single HLA locus or for the entire haplotype. The HLA genes can be separated by genetic recombination. Recombination or crossover between class I genes is rare. Genetic recombination between HLA class I and II regions also occurs infrequently. Thus, although a careful examination of family haplotypes is essential to determining donor suitability, the HLA complex can generally be considered as a single genetic unit that is most often inherited as a block. Some haplotypes exist in strong linkage disequilibrium, which are particularly likely to persist without mutation. For example, the haplotype HLA-A1, HLA-B8, HLA-DRB1 1701 is particularly frequent in the northern European white population and has become one of the most common haplotypes in African-Americans, Hispanics, and Native Americans.

**Conditioning Regimens and General Procedure**

The preparative or “conditioning” regimen has traditionally been seen as having three major roles: providing “empty” hematopoietic space for the infused HSCs, providing sufficient host immunosuppression (in the case of allogeneic HSCT) such that donor cells are not rejected and, last, eliminating residual tumor burden. The relative roles of these three goals have shifted somewhat over time and differ greatly by disease process and type of HSCT. It has become increasingly clear that immunologic events (“allogeneic effects”) play key roles in recipient hematopoietic ablation and subsequent disease elimination. In consequence, the potential of allogeneic T cells to facilitate engraftment by eradication of host hematopoiesis, and potentially by other mechanisms, is being incorporated into current approaches to conditioning. Conversely, the association of T-cell depletion (TCD) as a method of GVHD prophylaxis with subsequent graft failure or with an increased degree of residual host hematopoiesis after HSCT, or both, often referred to as *mixed chimerism*, has spurred the addition of further agents to conventional HSCT conditioning regimens.[47,48,49,50,51,52,53 and 54] More recently, these observations have also provided the rationale to explore donor lymphocyte infusions (DLIs) with or without HSC support as a primary part of the conditioning regimen in so-called nonmyeloablative HSCT. [55,56,57,58,59 and 60] In addition, there is increased recognition of the role of allogeneic T cells in eradicating recipient tumor burden as exemplified both by the decreased relapse rate of patients with GVHD and the efficacy of DLI in patients relapsing after HSCT for CML.[61,62,63,64,65 and 66] The mechanisms by which these immune effects can be harnessed more directly in the preparation of the patient for HSCT and their management thereafter are important topics of current research likely to significantly impact HSCT in the next decade. [59,60]

Nonetheless, the current mainstay of conditioning for HSCT remains combination myeloablative therapy, most commonly built on a base of ablative doses of either TBI or busulfan (BU). Despite the observation that donor engraftment was only transient and relapse common, the first allogeneic HSCT were carried out using TBI and established this preparative approach. [6] The use of single-agent cyclophosphamide (CY) produced similar results [67] whereas combination therapy (CY/TBI) was rapidly shown to be more effective. As HSCT neared its first decade, BU was developed as an additional ablative agent that did not require the construction of costly radiation facilities. [68] More varied and somewhat more cytotoxic regimens with or without TBI were piloted in patients undergoing autologous HSCT. In this setting, freedom from post-HSCT GVHD prophylaxis (i.e., methotrexate) as well as the absence of GVHD-mediated cytotoxicity permitted somewhat more intensive treatment.[69] The specific regimens currently in use for patients with various disorders vary significantly and are reviewed by disease entity in the following sections where pertinent.

Allogeneic BM or PBSCs are most often infused intravenously directly into the recipient. Autologous BM, PB, or UCB from any donor is collected before the preparative regimen, cryopreserved until the regimen has been completed, and then infused immediately after thawing. Several techniques have been developed for

special *ex vivo* treatment of SCs before infusion or cryopreservation. These include red cell depletion in the setting of major ABO incompatibility, TCD of allogeneic donor cells to decrease the risk of GVHD, and so-called purging of autologous HSCs to remove contaminating malignant cells. Approaches used for purging vary widely and include positive selection of HSCs or depletion of selected (tumor) cells by various techniques. The duration of neutropenia after HSC infusion varies widely depending on the regimen and SC source. During this period, supportive care is critical. Patients are at risk for bacterial, fungal, viral, and protozoal infections.[70,71 and 72] Infectious morbidity is most commonly associated with allogeneic HSCT; however, the move toward increased intensity of both prior treatment and conditioning for patients undergoing autologous HSCT appears to be increasing opportunistic infections in this population.[73] Accordingly, infectious prophylaxis as well as aggressive management of fever in these neutropenic, immunosuppressed hosts is extremely important.[72] Patients require attentive management of transfusions with attention to adequate irradiation to prevent engraftment of GVHD from cellular constituents and, in the allogeneic setting, to any ABO differences.[74,75,76 and 77] Nutritional support is extremely important, although the best mechanism and intensity are as yet not established.[78,79,80,81 and 82] Prophylaxis of regimen-related toxicities is in its infancy but likely to evolve over the next decade.[83,84,85 and 86]

## TRANSPLANTATION FOR HEMATOLOGIC MALIGNANCY

From its inception, HSCT has been an important treatment option for patients with relapsed leukemia and a matched family donor. The improved identification of patients likely to fail primary therapy as well as expansion of the potential donor pool has made HSCT an option available to additional children. Thus, the role of HSCT in children with hematologic malignancies must continually be reconsidered and re-evaluated, particularly as improvements in patient management have measurably improved the outcome of HSCT since the time that most patients currently being reported were actually treated.[87]

### Hematopoietic Stem Cell Transplantation for Acute Lymphoblastic Leukemia

Historically, the relatively good outcomes of patients with ALL treated with standard chemotherapy limited the contribution of HSCT to the treatment of recurrent disease. For patients newly diagnosed with ALL, HSCT has had more limited application. However, it has become clear that certain patient subsets of ALL do not respond as well to these same approaches and that HSCT may be useful as primary therapy for such patients ( Table 16-1). A retrospective study of children with Philadelphia chromosome-positive ($Ph^+$) ALL treated with chemotherapy found a DFS of only 25%.[88] BMT from HLA-identical related donors significantly improved DFS (65%) and overall survival (72%). The advantage of HSCT became more apparent over time because, in contrast to transplant recipients, the risk for relapse persisted for chemotherapy-treated patients beyond the second year of remission. The benefit of HSCT was not seen for patients transplanted from alternative donors largely due to treatment-related deaths. Reflecting the superior results often reported by a single center or limited centers, a study of HSCT for $Ph^+$ ALL conducted at two institutions reported 65% DFS and 12% relapse rate. Data from the International Bone Marrow Transplant Registry (IBMTR), which combined children and adults with $Ph^+$ ALL, showed 38% DFS and 34% relapse rate for patients in first complete remission (CR1).[89] Because of its poor prognosis, the use of alternative donors has been actively pursued in $Ph^+$ ALL, with DFS of 37% and 68%[90] reported in two studies using TCD. However, children with advanced disease and those who received SCs from less than a full match by current HLA allele–specific typing had reduced DFS due in part to increased regimen-related toxicity. Clearly, the use of alternative donors can be curative and is an appropriate option for newly diagnosed children and adolescents with $Ph^+$ ALL.

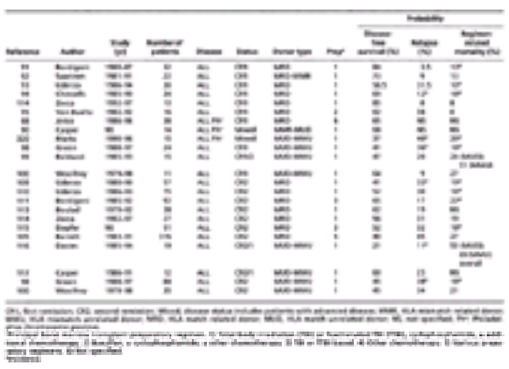

**TABLE 16-1. HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR ACUTE LYMPHOBLASTIC LEUKEMIA (ALL)**

Except for $Ph^+$ ALL, no consensus exists regarding the indications for HSCT for children with ALL in CR1. High initial white cell count, infant ALL, 11q23 rearrangement, T-cell lineage, poor response to prednisone, induction failure, and an unfavorable diagnostic risk index have been considered indications to perform HSCT. With such indications, DFS between 58% and 85% and relapse rates from 3.5% to 31.5% have been reported.[91,92,93,94 and 95] Thus, children whose curability with intensive chemotherapy is less than 50% with contemporary front-line chemotherapy may benefit from early allogeneic HSCT.[96] It is interesting that for children, in contrast to adults, the outcome after alternative donor HSCT has compared favorably to the outcome of HSCT from HLA identical related donors in some studies.[96,97] DFS reported from single institution studies range from 41% to 64% and relapse rates from 9% to 29%.[97,98,99 and 100] Although it is unknown whether improved supportive care will alter this statistic, deaths in remission remain a major obstacle and are responsible for a significant portion of the mortality after HSCT. The major causes of death varied between reports and were related to the specific institutional treatments. Until the optimal approach is determined, HSCT from alternative donors for children with ALL CR1 will remain controversial.

Originally, HSCT primarily addressed the plight of children with ALL no longer considered curable by conventional therapies. Salvage therapy after relapse or induction failure remains the principal indication for HSCT for children. Some contemporary intensive chemotherapy regimens are also able to provide prolonged disease control for selected children with recurrent ALL, but extended follow-up will be needed to assess the durability of these chemotherapy responses.[101,102] Chemotherapy for relapse has been most effective for children with a long CR1 duration and for extramedullary relapse. BM relapse, especially during the first 12 to 18 months of treatment,[103,104 and 105] or early central nervous system (CNS) or testicular relapse all have poor outcome when treated with chemotherapy alone.[101,106] The relative improvement in outcome if HSCT is used in this setting is unclear, and any comparison of chemotherapy and HSCT must address potential biases such as patient selection and time delay between relapse and HSCT.

In studies reported to date of HSCT from matched related donors (MRDs), children with ALL second complete remission (CR2) have reported DFS rates between 32% and 65%.[105,107,108,109,110,111,112,113,114 and 115] Studies that compare DFS between HSCT and chemotherapy find an advantage to HSCT, although the differences have not always been significant; alternatively, the advantage has been limited to certain patients such as those with early BM relapse.[105,109,113,115] Data from two large cooperative groups report superior DFS (or event-free survival) regardless of the duration of CR1, but in one report this difference did not become significant until 4 years post-relapse.[103,105] Among children with early BM relapse, HSCT has consistently provided superior DFS.[101,103,104 and 105,109,113] It is less clear whether HSCT improved the DFS for children whose relapse occurred off therapy.[105,113,115] The probability of relapse has been uniformly lower after HSCT (13% to 45%) compared to chemotherapy, but this advantage has been partially mitigated by the higher numbers of deaths in remission (10% to 20%). The outcome for children in CR2 undergoing alternative donor HSCT has been very similar to that of matched sibling HSCT.[97,103] Although in one study DFS was only 21% for children with ALL in CR1 and CR2 most studies reported DFS greater than 40% (DFS: 42% to 60%).[98,99,116,117 and 118] Because the precision with which degree of match between donor and recipient can be ascertained has improved and as other elements of donor selection become more refined, the results of alternative donor HSCT are likely to ever more closely approximate the matched family setting.[98,119,120]

Children in remission beyond CR2 may also benefit from HSCT. Allogeneic HSCT from MRDs and unrelated donors have resulted in extended DFS ranging between 10% and 42%.[98,99,111,116,117 and 118,121] In contrast, the salvage rate for children with ALL in relapse at the time of transplant remains dismal at less than 10%, and a transplant should probably not be performed except in the context of a clinical investigation.

Even with the expanding number of potential unrelated donors, not every child needing a transplant will have a donor. Furthermore, the time required to establish a suitable donor may be prohibitive under certain circumstances. Some studies have explored the use of mismatched or haploidentical family donors, but no substantial disease-specific data have been established. More disease-specific data are available for the results of cord blood HSCT. Data from the Eurocord cooperative group found 39% DFS after related (the majority HLA identical) and 30% DFS after UCB (the majority HLA mismatched) transplantation for acute leukemia (no difference

between ALL and AML).[122,123] Patients in CR1/2 fared better, with a DFS of 49%. If allogeneic HSCT is neither a practical nor a desired option, autologous transplantation provides another option. For CR1 patients, DFS approached 50% in some studies, but more aggressive and effective chemotherapy treatment has matched these results. As salvage therapy for children whose initial BM remission exceeded 24 months, autologous HSCT has resulted in DFS between 53% and 60%.[124,125] Likewise, for children with isolated extramedullary relapse, autologous HSCT has provided effective disease control. [126] However, a review of the Medical Research Council United Kingdom ALL data found no significant difference in outcome between children receiving either autologous HSCT or chemotherapy after relapse.[103] Similar findings have been reported by other centers.[109,127]

The practical advantage of autologous HSCT has been the low regimen-related mortality (RRM), 10% or less, whereas the most obvious disadvantage has been an unacceptably high relapse rate of up to 72%.[93] Contamination of autologous BM by residual leukemic cells has been recognized as a source leading to relapse in AML[128] although this issue has not been directly explored in ALL. Purging harvested BM with monoclonal antibodies or chemotherapeutic agents has been incorporated into a number of trials, but at present there is no absolute evidence that any of these manipulations provide an advantage to children with ALL undergoing autologous HSCT.[124,129,130] Any future efforts to develop autologous HSCT will likely focus on methods to purify HSC (positive selection) rather than removal of leukemic cells (negative selection) by purging techniques. However, both techniques could be used for additive effect.

Regardless of the source of HSC or the disease status of the patient at the time of HSCT, the majority of posttransplantation failures are due to disease relapse. There are no studies to suggest a consistent difference in outcome by preparative regimen. The alternate strategy of inducing an antileukemia immune esponse post-HSCT has been explored through the use of DLI administered to relapsed patients. Although DLI has not been as effective for patients with ALL when compared to patients with CML, it has demonstrated some activity.[131,132] However, DLI may be followed by severe acute GVHD or pancytopenia, or both. More effective and less toxic measures are needed. Measurements of residual leukemia pretransplant have been correlated with relapse posttransplantation. [133,134] In some studies, persistent recipient chimerism present within selected hematopoietic compartments and assayed by polymerase chain reaction (PCR)–based quantification of HLA alleles has been correlated with relapse.[135] Using assays such as these, it may be possible to define patients for whom adjuvant therapy is appropriate. Those children may be candidates for novel treatments, including posttransplant immune modulation, such as administration of cytokines, antitumor vaccines, and/or leukemia-specific cytotoxic cells.

## Hematopoietic Stem Cell Transplantation for Acute Myeloid Leukemia

### *Allogeneic Hematopoietic Stem Cell Transplantation*

Substantial improvements in the treatment of AML have altered the indications for HSCT ( Table 16-2). Cooperative groups report up to 60% DFS for children with favorable AML subtypes as defined by epidemiologic or cytogenetic characteristics. [136,137] Cytogenetic findings are the most important indicator of AML prognosis. The AML subtypes most consistently reported to be associated with good outcome after chemotherapy include FAB M2 with translocation t(8;21), FAB M3 with translocation t(15;17), and FAB M4 with inv(16), and for these patients, HSCT may not be necessary as primary therapy. In contrast, poor response to chemotherapy and poor DFS has accompanied cytogenetic findings of monosomy 5 and monosomy 7. Some 30% to 40% of pediatric AML cannot be classified as favorable or unfavorable according to cytogenetic findings. The role and timing of HSCT for these latter patients remains a subject of ongoing investigation. Transplantation from MRD produced superior DFS for adults with AML and favorable cytogenetics compared to patients treated with autologous HSCT or chemotherapy, but the data are less clear as to whether transplantation improves the DFS for patients with unfavorable cytogenetics. [138,139] In addition, other poor risk groups, such as infants younger than 2 years of age, have been particularly difficult to treat with standard chemotherapies. The role of HSCT in this population remains unclear as well. In a trial limited to such infants, 38% survived without relapse.[140] Future clinical trials will need to define treatment options and therapeutic outcome for poor-prognosis patients. At present, HSCT studies for childhood AML have not addressed this issue prospectively.

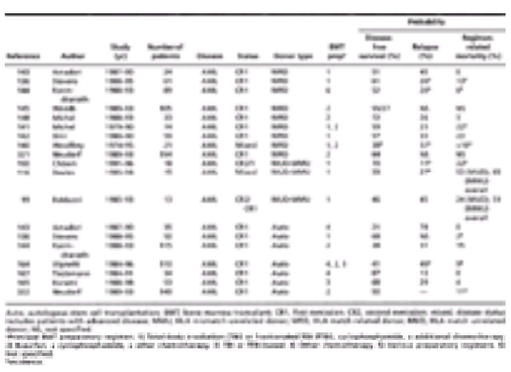

**TABLE 16-2. HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR ACUTE MYELOID LEUKEMIA (AML)**

Single-arm studies of MRD transplantation for children with AML in CR1 reported DFS similar to studies in which patients were assigned to either HSCT or chemotherapy based on donor availability. [141,142] These latter comparative studies, conducted by several cooperative groups, attempted to determine whether allogeneic transplantation from MRDs improves the DFS over that achieved after chemotherapy or autologous HSCT for patients with AML in CR1. In those studies that report DFS, allogeneic HSCT was statistically superior (DFS range, 51% to 52%) to the alternative therapies (DFS: autologous, 21% to 38%; chemotherapy, 27% to 36%).[143,144,145,146] and [147] Using survival as the measure of outcome, one study found no difference between the three options (survival: allogeneic, 69%; autologous, 73%; chemotherapy, 66%).[136] In each trial, children were allocated to allogeneic transplantation if a suitable MRD was available; the remaining patients were randomized to chemotherapy or autologous transplantation. Most of these studies analyzed patients on the basis of intention to treat; patients who refused randomization were excluded from the comparisons. All patients with an available donor were analyzed as part of the allogeneic transplant cohort regardless of whether the patients actually underwent transplantation; likewise for patients randomized to autologous transplantation or chemotherapy. The timing of transplantation varied between two, three, or four courses of chemotherapy administered before transplantation. Thus, comparisons between these studies are difficult, particularly with a view toward understanding the impact of HSCT on cure of AML. One other study compared MRD transplantation and chemotherapy and found statistically superior DFS for the HSCT recipients: 72% and 48%, respectively. [148] This study, like the others, found that allogeneic transplantation patients experienced fewer relapses (probability of relapse: 26% MRD transplantation; 47% chemotherapy). The decline in RRM noted in that study, and subsequently observed by others, will be an important part of reassessing the future role of allogeneic transplantation. [87,143,149]

Experience is limited using alternative donor transplantation for children with AML in CR1. Nevertheless, reported DFS of 33% to 70% appears comparable to that achieved with MRD.[99,116,150] The higher RRM that accompanied the use of unrelated or mismatched donors in the past, 65% in one study, has decreased markedly; similarly, the improved outlook for selected patients treated with chemotherapy in some studies has limited the use of this strategy. [116,151]

Approximately 40% of children relapse after contemporary treatment for AML, and with further treatment one-half of these attain a second remission. [152,153] HSCT remains the most important and successful modality for patients beyond CR1. For HSCT from MRDs performed from 1991 to 1997, the IBMTR data found that 50% of atients who were in CR2 and younger than 20 years old survived 3 years after allogeneic transplantation. If all age groups were included, the survival was 35% for autologous transplantation and 40% for allogeneic transplantation. [154] Other registry data show similar DFS of approximately 40% after allogeneic or autologous transplantation.[155,156] Several single-institution studies report DFS after alternative donor transplantation equivalent to MRD transplantation. [97,150] Factors that determine which relapsed patients are the best candidates for DFS after HSCT include length of CR1, achievement of CR2, and, perhaps, absence of extramedullary disease.[152,153,156,157] Survival for patients transplanted beyond CR2 has been poor in most studies.

Alterations to the conditioning regimen, particularly via the use of antibody therapy targeted to myeloid or stem/progenitor cells, or both, may impact significantly on DFS.[158] Preliminary studies have been encouraging. Adjuvant therapy posttransplantation may also be a useful adjunct in preventing relapse and improving treatment outcome. Quantifiable PCR-based assays have demonstrated persistence of leukemia fusion genes in BM and PB of some patients in clinical remission after HSCT. In some, but not all, instances, this observation has preceded overt relapse. [159] Withdrawal of immunosuppression or administration of DLI has led to clearing of the

leukemic fusion gene.[159,160 and 161] More clinical experience will delineate the role of pre- and post-HSCT modalities in patient management.

### *Autologous Hematopoietic Stem Cell Transplantation*

For children with AML who relapse after conventional chemotherapy, and have no suitably matched allogeneic donor, autologous HSCT is an option if cryopreserved autologous marrow obtained during remission is available. In some reports, the DFS after autologous transplantation in CR2 has been comparable to that achieved for patients receiving autologous transplantation during CR1 or allogeneic transplantation in CR2. [155,162,163] Outcome data from prospective cooperative group trials have been conflicting as to the advantage of autologous HSCT over chemotherapy. In two separate trials conducted by the Associazione Italiana di Ematologia ed Oncologia Pediatrica (AIEOP) and the Pediatric Oncology Group (POG), DFS was equivalent between groups of children randomized to chemotherapy or autologous HSCT (AIEOP DFS: autologous, 21%; chemotherapy, 27%) (POG event-free survival: autologous, 38%; chemotherapy, 36%). [143,144] The Medical Research Council trial found that DFS was superior for children undergoing autologous HSCT (68%) compared to children receiving chemotherapy (46%); however, overall survival was equivalent.[136] Finally, data from the Children's Cancer Group noted an advantage to chemotherapy over autologous HSCT. [146] These studies differ in important ways, and comparison has been problematic. Retrospective data from pediatric registries find that DFS rates ranged from 41% to 68%. Single-institution trials have reported DFS up to 87%.[155,164,165,166 and 167] As with allogeneic transplantation, patients with favorable cytogenetics have improved outcome. [168]

Leukemic contamination of harvested marrow has been demonstrated to contribute to relapse after autologous HSCT. [128] From its inception, various methods have been used to purge BM of residual leukemia cells, generally by treating the BM with chemotherapy or antibodies against myeloid cells. [162] No method has yet been proven to improve DFS, and some purging methods have delayed engraftment and thereby increased transplant morbidity.

## MYELODYSPLASTIC SYNDROME

In addition to the adult subtypes of MDS, children may also present with juvenile myelomonocytic leukemia (JMML) and a variety of other and often unique myeloproliferative syndromes. Aggressive chemotherapy rarely results in prolonged remission, and chemotherapy before HSCT has not been shown to improve DFS.[169,170 and 171] Currently, allogeneic SCT remains the only curative modality. DFS rates between 36% and 87% have been reported for children with primary MDS undergoing allogeneic transplantation from MRDs or alternative donors ( Table 16-3). [169,171,172,173,174,175 and 176] Because of higher relapse rates, patients with JMML and RAEB-T generally fared worse than patients with the other MDS types.[172,173 and 174] As might be expected, patients with MRDs had improved DFS compared to patients transplanted from alternative donors, although, as in CML, the difference in time to donor ascertainment may contribute to this difference in outcome.

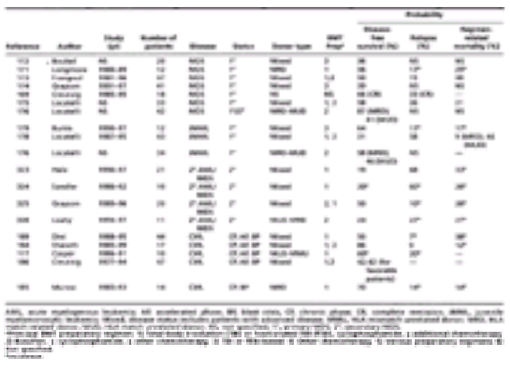

**TABLE 16-3. HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR MYELODYSPLASTIC SYNDROME (MDS), AND SECONDARY MDS AND CHRONIC MYELOGENOUS LEUKEMIA (CML)**

JMML is a myeloproliferative disorder unique to children and is characterized by hepatosplenomegaly, monocytosis, thrombocytopenia, and elevated hemoglobin F. The clinical course of a small proportion of patients with JMML may be indolent, with extended survival reported. For most children, however, progression has usually been inevitable, and allogeneic transplantation has been the only curative option. Aggressive chemotherapy has been effective in some reports but ineffective in others; 13-*cis*-retinoic acid has induced clinical remission for some patients. The reported outcome after transplantation for JMML has been poor, with overall DFS less than 40%.[177,178] Inability to eradicate the disease, resulting in relapse, has been the principal problem. More recent trials have reported improved DFS up to 68%, particularly when BU is used in the preparatory regimen. [176,179]

## CHRONIC MYELOGENOUS LEUKEMIA

As $Ph^+$ CML is uncommon in children, much of current practice is derived from adult clinical trials. Virtually all patients are in chronic phase at presentation. This chronic phase has a variable and an unpredictable duration, but without allogeneic HSCT, $Ph^+$ CML is ultimately fatal. Although interventions such as administration of a-interferon appear to prolong the stable phase and thus prolong survival, they are not curative. The novel tyrosine kinase inhibitor STI 571 has significant hematologic activity in stable phase CML, although its ultimate impact and risk benefit profile in pediatric patients is completely unknown. [180]

In adult trials, delay in transplant beyond a year from diagnosis has been associated with poorer DFS, and thus it has been recommended that transplantation not be unduly delayed.[181] The outcome is also inferior if HSCT is undertaken after the first chronic phase. More recently, it has been noted that treatment with a-interferon before HSCT may influence outcome for some patients. For patients needing transplantation from alternative donors, a-interferon administered for 6 months was associated with increased incidence of severe GVHD.[182] Data from the IBMTR indicated an increased risk of graft failure after transplantation from MRDs but a lower risk of relapse and ultimately no difference in DFS.[183] These observations must be confirmed, but for now caution is warranted regarding a-interferon administration to children before allogeneic HSCT.

In a single-institution study, more than 70% of adults younger than 50 years old who were transplanted within the first year after diagnosis are alive 5 years posttransplantation. There is less experience in children, but results appear comparable to those achieved in adults ( Table 16-3). Children with $Ph^+$ CML transplanted early in the disease have DFS rates between 70% and 86%.[184,185] Predictably, with longer time to transplant or inclusion of children beyond the first chronic phase, DFS rates decline to 42% to 62%.[117,186] The outcome was similar between MRDs and MUDs,[187] although registry data have reported lower survival rates for MRDs versus MUDs (67% versus 50%).[154,186,188,189] The early experience in “mini-transplant” for CML is very encouraging and likely to be successfully applicable to children. The resulting decrease in regimen-related toxicity should further improve the already impressive outcome for allogeneic transplant and will need to be carefully considered when triaging new therapeutic approaches.

## SOLID TUMORS

HSCT has been used for a variety of solid tumors occurring in children. However, in many cases the largest reported experience is contained within mixed adult and pediatric series, making the pediatric experience somewhat difficult to assess. Table 16-4 summarizes representative trials of HSCT for solid tumors.

| Center/reference | Number of patients | Disease and status | Disease-free survival (%) |
|---|---|---|---|
| MSK[191] | 23 | Medulloblastoma/recurrent | 34 |
| Duke[192] | 48 | Primary brain/poor prognosis or recurrent | 15 |
| MSK[193] | 28 | Primary brain/recurrent | 50 |
| MSK[197] | 16 | Pontine glioma/resistant | 0 |
| UCSF[194] | 379 | Neuroblastoma/post-induction without progressive disease | 43 |
| DFCI[195] | 39 | Neuroblastoma/post-induction without progressive disease | 58 |
| EBMT[196] | 63 | Ewing's/first or second remission | 29 |
| European collective[a] | 52 | Rhabdomyosarcoma/post-induction without progressive disease | 30 |
| EBMT[198] | 25 | Wilms'/poor prognosis/recurrent | 50 |

**TABLE 16-4. OUTCOME OF AUTOLOGOUS STEM CELL TRANSPLANTATION IN PATIENTS WITH SOLID TUMORS**

### Brain Tumors

CNS tumors comprise the second largest group of pediatric cancers. The prognosis is dismal for those children failing surgery, radiation therapy, and/or conventional chemotherapy. Attempts were limited by myelosuppression, particularly in those patients who had received prior spinal irradiation leading to the use of autologous SC rescue after high-dose chemotherapy. Most preparative regimens have used thiotepa and etoposide with or without carboplatin, as these agents are known to cross the blood–brain barrier and are dose-limited by myelosuppression. The results for patients with primitive neuroectodermal tumor or medulloblastoma and high-grade gliomas outside of the brainstem are variable, although durable DFS appears achievable for some patients. [190] Outcome is closely correlated with tumor burden at the time of HSCT, ranging from less than 10% in children with bulky disease to 50% for those with minimal or no disease. [191,192,193] and [194] HSCT has also been used with encouraging preliminary results in infants and young children to avoid or reduce neuroaxis radiation. [194,195] However, good outcome depended on the ability of surgery or chemotherapy, or both, to produce a state of minimal disease before HSCT. [196] Patients with brainstem gliomas show no improvement in either survival or DFS with HSCT, presumably related to the refractory nature of these tumors to pre-HSCT conventional dose chemotherapy. [197]

### Neuroblastoma

Conventional treatment of children with high-risk neuroblastoma has generally resulted in a DFS of less than 20%. Efforts to improve outcome have focused on intensifying induction therapy in addition to using high-dose therapy with autologous SC support for consolidation. Newly diagnosed high-risk patients treated with regimens culminating in HSCT have been reported to have a 3-year DFS of 43% after conditioning with myeloablative chemotherapy and TBI. [198] Purged BM was used as the SC source. Post-HSCT therapy with oral *cis*-retinoic acid, which decreases proliferation and induces differentiation in neuroblastoma cells, [199] further improved survival in this cohort. However, relapse remained a significant problem. Further intensification of treatment, using PBSC to hasten engraftment, has since been explored in sequential transplants using non–cross-resistant agents and $CD34^+$ selected PBSC for rescue. It appears that closely spaced transplants (4 to 6 weeks apart) using both chemotherapy and TBI may increase DFS without unacceptable incremental toxicity. [200] A randomized study is planned to assess the advantage of single versus double HSCT as well as the role of oral differentiating agents. Although HSCT has thus been effective in newly diagnosed, chemoresponsive patients, those with relapsed or refractory disease have continued to fare poorly. Recent approaches to such patients have included use of cryopreserved SC to circumvent the dose-limiting hematologic toxicity of iodine-131–metaiodobenzylguanidine, a targeted radiotherapeutic agent that is able to induce a response in some of these highest risk patients. [201]

### Sarcomas and Other Solid Tumors

Although most children with Ewing's sarcoma and rhabdomyosarcoma can be cured with conventional therapy, the survival of high-risk patients remains poor. The results of autologous HSCT for such patients, including those with metastatic disease at presentation or those with recurrent disease, have been discouraging. [202] For Ewing's sarcoma, the most common myeloablative agent has been high-dose melphalan, either alone or in combination with TBI. Although most patients demonstrate responsive disease, few have a durable remission. The European BMT Solid Tumor Registry, incorporating data from 21 transplant centers, reports an event-free survival of 21% at 5 years for new patients with metastatic disease and 32% for those transplanted in CR2. [203] The results of HSCT for advanced stage or recurrent rhabdomyosarcoma are even less favorable than for Ewing's. HSCT after conditioning regimens based on high-dose alkylator therapy has been well tolerated, but there has been no improvement in DFS. [204,205] Smaller cohorts of patients with better results have been reported. [202,206,207]

Although children with metastatic Wilms' tumor have a high likelihood of cure with conventional therapy, as do those who relapse if their histology is favorable, there remains a small group of patients with adverse features who are rarely cured. The European BMT Solid Tumor Registry reported the outcome of 25 children with Wilms' who were treated with HSCT. [208] Most received melphalan in the conditioning regimen. There was appreciable morbidity and mortality. Those in CR at the time of HSCT had a 50% DFS, although no improvement in outcome was seen for those transplanted with measurable tumor. Gonadal germ cell tumors (GCTs) are particularly uncommon in children, and most can be cured with surgery and conventional chemotherapy. Although there is a significant autologous HSCT experience for adults with GCT, this approach is only applicable to children with poor-risk features at diagnosis, cisplatin-resistant disease, or relapsed disease. Small studies have shown improvement in DFS for these patients using two cycles of high-dose therapy with SC support. Randomized trials are on-going to assess whether the increase in DFS can be replicated in a multi-institutional setting. [209] Relapsed or cisplatin-refractory extragonadal GCTs have a very poor prognosis; although HSCT can result in remissions, the responses have not been durable. [210]

In conclusion, curing children with recurrent or refractory solid tumors remains difficult. [211] It appears that high-dose therapy with HSCT offers improved outcome for some subset of these patients, especially those in CR or with minimal disease at the time of HSCT. Further exploration of rapidly sequenced tandem HSCT using non–cross-reactive agents, the manipulation of SC to reduce tumor contamination, and novel strategies to eliminate minimal residual disease post-HSCT is under way. [200,212]

### Hodgkin's Disease and Non-Hodgkin's Lymphoma

With the exception of Hodgkin's disease (HD) patients who received minimal previous therapy or patients relapsing years after therapy, [213,214] pediatric patients with lymphoma who do not enter remission or who subsequently relapse are rarely cured using therapy at conventional doses. [215,216] and [217] Autologous HSCT has been used to allow dose escalation of a broad range of active agents. Conditioning regimens are alkylator based, with or without the addition of TBI. [218] Among frequently reported regimens are CBV (CY, carmustine, and etoposide), BEAM (carmustine, etoposide, cytosine arabinoside, and melphalan), and BEAC (carmustine, etoposide, cytarabine, and CY). [216] The role of local radiation therapy either before or after HSCT is unclear. [219,220]

Most reports of autologous HSCT for both non-Hodgkin's lymphoma and HD include both adult and pediatric patients. Although overall DFS of 50% is consistently reported, predictive factors related to disease burden and responsiveness to chemotherapy have been identified. Lymphoma patients with favorable characteristics have a DFS of up to 60% after HSCT, whereas less than 20% of poor-risk patients achieve durable remissions. [215,216,219,220] In non-Hodgkin's lymphoma, progressive disease or lack of response to salvage chemotherapy before HSCT is a negative prognostic factor associated with DFS of less than 10%. [219,221] For patients with relapsed HD, bulky disease at the time of HSCT adversely affects outcome [222,223]; response to prior chemotherapy has been shown to impact DFS in some [224,225] and [226] but not all studies. [227] In fact, there is a suggestion that patients who proceed to HSCT in untreated relapse of HD fare best, although the reasons are unclear. [215,228] Patients with HD who are classified as having induction failure or primary progressive disease may be cured by HSCT even in the setting of minimal response to salvage chemotherapy. [229] Whether this represents a response to dose intensification or whether chest x-ray and CT overestimate residual HD is unknown.

Virtually all autologous HSCT for lymphoma now use mobilized PB instead of BM as a hematopoietic SC source. Most reports demonstrate that the time to neutrophil engraftment is shortened and costs reduced, although it has been difficult to show an impact on survival. [25,230,231] Which SC source is preferable in terms of lymphomatous contamination is a complex issue, likely affected by many factors, including the natural history of BM involvement with disease, the degree of BM involvement, and the mechanism by which PBSCs are mobilized. [25,232] No pediatric studies using sensitive techniques, such as PCR, address quantitative differences

in contamination or possible impact on relapse rate. One report found an increased incidence of post-HSCT MDS when PBSCs were used as compared to BM, but this has not been assessed in prospective comparative trials.[233] Overall, the reported risk of developing secondary leukemia and MDS varies greatly, but it is difficult to ascertain the degree to which autologous HSCT increases this risk beyond that conferred by prior exposure to leukemogenic therapy. Some single-institution studies show an actuarial incidence of up to 20% at 10 years post-HSCT with no evidence of a plateau.[16,17,234] The European BMT Lymphoma registry, reporting on 5,000 patients, found an incidence of 4%, similar to that seen after conventional therapy.[235]

The role of allogeneic HSCT has also been investigated, although never in a randomized manner. Most studies use matched sibling donors and suggest a decreased incidence of relapse. This is presumably due to graft-versus-leukemia effect or use of a noncontaminated SC source, or both. There has been no improvement in DFS due to an increased toxic death rate.[227,236,237,238] and [239]

## COMPLICATIONS AFTER STEM CELL TRANSPLANTATION

### Infections

Susceptibility to infection remains a major problem in the management of patients undergoing HSCT. A complete review of the pathophysiology of infectious predisposition in transplant patients, the prophylaxis and treatment of infections associated with HSCT, and post-HSCT immunodeficiency are beyond the scope of this chapter, and only basic principles of infectious management are reviewed here.

Conditioning regimens cause profound myelosuppression, placing patients at risk for bacterial and fungal infections. Mucosal integrity is disturbed and virtually all patients have indwelling catheters, which further increase the risk of bacteremia. Methodologies, such as reverse precautions, hepafiltration, laminar airflow, and handwashing, have all been used to minimize contact of these compromised hosts with infectious agents. The relative contribution of any or all of these maneuvers is unclear. Historically, gram-negative bacteria, known to be virulent pathogens in neutropenic patients, were responsible for much of the morbidity and mortality seen in HSCT. In recent years, gram-positive organisms have emerged as the most common bacterial pathogens.[240] Use of broad-spectrum antibiotics as well as the widespread use of indwelling central venous lines are likely contributors to this change in epidemiology. Fungal infections have also become increasingly problematic. Although HSCT patients should be considered for antifungal prophylaxis, the relative value of prophylaxis versus the risk of generating resistant organisms has not been completely elucidated.[241] Patients also demonstrate deficits in cell-mediated immunity relatively rapidly after the completion of the conditioning regimen. Thus, reactivation of viruses, such as herpes simplex virus I and II and, subsequently, cytomegalovirus, is quite common. The risk for such reactivation is generally defined by recipient seropositivity, and seropositive patients may receive prophylactic antiviral therapy based on institutional practice.

Even after neutrophil recovery and repair of epithelial barriers have taken place, patients appear to remain at significant risk for infection. This risk is particularly marked in patients undergoing allogeneic HSCT in whom depressed cellular and humoral immunity persist for protracted periods. The degree to which host immunity is impaired is influenced by many factors, including patient and donor age, conditioning regimen used, degree of HLA disparity between recipient and donor, presence of acute or chronic GVHD, and type of post-HSCT immunosuppression. Due to this persistent delay in immune recovery, the majority of allogeneic HSCT patients is maintained on prophylaxis against *Pneumocystis carinii* for at least 1 year post-HSCT. Autologous HSCT recipients most often receive prophylaxis for a shorter interval, generally 6 months. The most common post-HSCT infection may be varicella-zoster, although visceral dissemination or mortality in children is rare.[242] Prophylaxis with acyclovir during the months after HSCT may be useful for some patients, although the overall value of this approach has yet to be established. Immune recovery appears to occur more quickly and more completely in children than in adults. This advantage is believed to derive from greater residual thymic function and perhaps to the relatively higher likelihood of young donor age.

### Veno-Occlusive Disease of the Liver

Veno-occlusive disease (VOD) is a clinical diagnosis characterized by painful enlargement of the liver, fluid retention, and jaundice.[243,244] It is the most common serious manifestation of regimen-related toxicity occurring somewhat more frequently after allogeneic than autologous HSCT. The incidence of significant VOD in adults is reported to be between 10% and 20%, with pediatric patients less often affected.[245] The differential diagnosis is broad and includes infection, drug toxicity, and acute GVHD as well as VOD. Ultrasound examination with Doppler flow studies can detect hepatomegaly, ascites, and reversal of blood flow in the portal vein, which are consistent with but not diagnostic of VOD. Damage to the centrilobular area of the liver by high-dose therapy produces a characteristic pathologic appearance, and liver biopsy can provide a definitive diagnosis based on concentric narrowing or fibrous obliteration of terminal hepatic venules and necrosis of centrilobular hepatocytes. In addition to providing tissue, liver biopsy allows the measurement of wedged hepatic venous wedge pressure. An elevated pressure (greater than 10 mm) has approximately 90% specificity and positive predictive value for VOD.[246] For many patients, however, especially those with refractory thrombocytopenia or coagulopathy, or both, this procedure may carry excess risk and treatment is often initiated based on clinical criteria alone. The cornerstone of management is supportive, with meticulous attention to preserving intravascular volume in the face of capillary leak, third-spacing, and hepato-renal physiology. Most patients with mild or moderate VOD will recover, but those with severe VOD have an almost uniformly fatal course.[247] Attempts to prevent VOD have been unsuccessful to date. Although early studies suggested a beneficial effect of ursodeoxycholic acid in high-risk patients[248] a larger multi-institutional study failed to corroborate these findings.[249] The role of vitamin E, an antioxidant, remains speculative at this time.[250] Another approach to decreasing the incidence of VOD involves monitoring levels of potentially hepatotoxic drugs. This has been successfully used with BU, where higher area under the curve of concentration versus time has been associated with an increase in VOD. Measuring BU levels and subsequent dose reduction in patients with elevated area under the curve have resulted in a reduced incidence of VOD.[251] Based on the microthrombi found in hepatic venules on pathologic examination and a physiology consistent with venous outflow obstruction, therapeutic strategies for established VOD aimed at fibrinolysis and anticoagulation have been evaluated. Agents such as tissue plasminogen activator have shown efficacy but have been associated with excessive morbidity from complications related to bleeding.[252] Defibrotide, a single-stranded polydeoxyribonucleotide that decreases thrombin generation and increases fibrinolysis without causing systemic anticoagulation, has been used. No serious hemorrhage occurred, and response rates were encouraging.[253] The role of this agent must be established in additional studies.

### Acute Graft-Versus-Host Disease

Acute GVHD is a clinicopathologic syndrome of enteritis, hepatitis, and dermatitis that develops within 100 days of allogeneic HSCT. The effector cells are thought to be donor T lymphocytes that recognize antigenic disparities between donor and recipient. In addition, the altered host milieu promotes the activation and proliferation of inflammatory cells with resulting dysregulated production of inflammatory cytokines secreted by many cell types in addition to T cells.[254] This cytokine network may be the final common pathway for the tissue damage associated with GVHD, and this entire cascade has been described as a “cytokine storm.”[255,256]

GVHD is staged by the degree of organ involvement, and these stages are summed into an overall grade ( Table 16-5, Table 16-6, and Table 16-7). Several conventions for grading are currently in use. The skin is the organ most frequently involved. Skin GVHD classically manifests as a maculopapular rash that is pink to deep red in color and may be painful. The most severe form of dermal GVHD produces bullae and extensive epidermal separation that resembles toxic epidermal necrolysis. The differential diagnosis of skin rash in this setting is extensive and includes drug allergy, viral exanthem, or reaction to the conditioning regimen, particularly TBI. Differential sensitivity of skin biopsy is not high and is negatively affected by temporal proximity to the conditioning regimen.[257] Histologically, GVHD is associated with basal cell vacuolar degeneration with apoptosis (single-cell necrosis) of epidermal cells and, in severe cases, separation of the dermal/epidermal junction.

| Stage | Skin | Liver | Gut |
|---|---|---|---|
| + | Maculopapular rash: <25% body surface | Bilirubin, 2–3 mg/dL | Diarrhea, <1,000 mL/d<br>Nausea and vomiting |
| ++ | Maculopapular rash: 25–50% body surface | Bilirubin, 3–6 mg/dL | Diarrhea, 1,000–1,500 mL/d<br>Nausea and vomiting |
| +++ | Generalized erythroderma | Bilirubin, 6–15 mg/dL | Diarrhea, >1,500 mL/d<br>Nausea and vomiting |
| ++++ | Desquamation and bullae formation | Bilirubin, >15 mg/dL | Pain or ileus |

**TABLE 16-7. OVERALL CLINICAL GRADING OF ACUTE GRAFT-VERSUS-HOST DISEASE (INTERNATIONAL BONE MARROW TRANSPLANT REGISTRY)[a]**

Hepatic GVHD usually presents as a cholestatic process with elevation in bilirubin and alkaline phosphatase. Definitive diagnosis is often difficult due to the many possible causes of liver dysfunction in these patients (e.g., infection, drug toxicity, and biliary sludging). On pathologic examination, portal triaditis with bile duct damage is found.[258] GVHD of the lower gastrointestinal tract presents as diarrhea, which can be voluminous. It is often bloody and may be associated with crampy abdominal pain. Edema and mucosal sloughing are seen endoscopically and histology reveals single cell necrosis and, if severe, complete loss of crypts. Allogeneic transplant patients receive prophylaxis to prevent the development of GVHD, either through pre-HSCT graft manipulation, such as TCD, or through administration of post-HSCT immunosuppression. Most studies have demonstrated that the combination of cyclosporine and methotrexate is superior to either agent alone. [259] Optimal drug combinations are the subjects of current studies. TCD has proven an effective mechanism by which to decrease acute GVHD, but associated graft failure, relapse, and post-HSCT lymphoproliferative disorders have made it difficult to demonstrate any impact on overall survival. [260],[261] and [262] Other approaches to GVHD prevention, such as the use of augmented SC dose with exhaustive TCD or induction of host tolerance in the donor, are being explored in clinical trials. [263],[264] If GVHD occurs despite prophylaxis, further immunosuppression is necessary. Addition of or increased doses of steroid is the most common and effective approach. [265] The treatment of steroid refractory GVHD remains problematic despite aggressive interventions, and most patients succumb to infection or organ dysfunction.

### Graft Failure

Graft failure is relatively uncommon after allogeneic HSCT for hematologic malignancies, occurring in approximately 1% of patients receiving SCs from genotypically identical donors[266] and increasing to 5% to 10% if the donor and patient are mismatched. Other risk factors for graft failure include TCD, low marrow nucleated cell dose, and a positive pretransplant crossmatch for antidonor lymphocytotoxic antibodies. [267],[268] The exact mechanism of rejection is not known, but the utility of increased donor cell number or increasing recipient immunosuppression, or both, in the setting of TCD suggest both host and donor elements may be contributory. Once graft failure occurs, treatment with growth factors[269] or re-infusion of donor cells may be successful in a small number of patients. However, mortality remains high due to prolonged neutropenia and consequent infections.

### Late Complications and Sequelae of Stem Cell Transplantation

The type and severity of delayed complications arising after HSCT are related to the underlying disease for which HSCT was performed, the conditioning regimen and SC source used, and the age of the patient at the time of HSCT. Because these late effects are protean and can occur months to years after HSCT, it is important that this group of patients receive lifelong follow-up either at or in concert with a transplant center. As more patients survive HSCT, there is increasing attention being devoted to obviating or ameliorating long-term sequelae. Although these complications can be problematic or even life-threatening for a subset of HSCT survivors, one study assessing a cohort of adult and pediatric patients 5 years after HSCT found that 90% were in good health and had returned to work or school in a full-time capacity.[270]

#### *Chronic Graft-Versus-Host Disease*

Chronic GVHD (CGVHD) is a potential complication of allogeneic HSCT that ranges in impact from trivial to devastating. Major risk factors for the development of CGVHD are prior acute GVHD, donor-recipient HLA disparity, and increasing patient age. [271],[272] and [273] The decreasing incidence of CGVHD in the 1990s reflects more sophisticated HLA matching of unrelated donors as well as more effective strategies for preventing acute GVHD. In the past, CGVHD was significantly less likely to occur with a matched sibling versus an unrelated donor.[274] More recent data show that in the pediatric population there may be little to no significant difference in severe CGVHD rates between sibling and matched unrelated donors.[97] CGVHD primarily affects the same organ systems involved by acute GVHD—skin, liver, and gastrointestinal tract—but may affect others as well. In the skin, manifestations range from dry patches or areas of variegated pigmentation to extensive dermal scarring that produces thickened atrophic skin and joint contractures. Hair follicles can be involved, with consequent alopecia over part or all of the scalp as well as loss of hair on the arms and legs. Other skin appendages may also be lost, leading to dry skin and limited ability to sweat. Changes in the upper and lower gastrointestinal tract may be observed. Patients may have depapillation of the tongue and scarring of the buccal mucosa. The lips may develop variegated coloration and blurring of the vermilion border. Sclerodermatous changes of the mucous membranes and salivary glands can produce xerostomia. In addition to causing patient discomfort, these conditions have consequences that include increased risk of dental caries and gingival injury. [275] Patients with CGVHD are often underweight. This can be a result of anorexia, esophageal webs, or strictures that make swallowing difficult or chronic diarrhea with malabsorption. A careful history can narrow the differential diagnosis, but endoscopy with appropriate biopsies may be necessary. CGVHD of the liver usually presents as a cholestatic process with elevation in alkaline phosphatase. Elevation in bilirubin and liver enzymes can also occur with findings that can progress to a syndrome similar to primary biliary cirrhosis. Pulmonary dysfunction can also occur in the setting of CGVHD. The most frequent clinical presentations of pulmonary disease are nonproductive cough, wheezing, and dyspnea, although children with significant defects can also be completely asymptomatic. Pulmonary function tests should be obtained regularly post-HSCT, particularly in patients with CGVHD or in the presence of persistent pulmonary symptoms. Most patients have obstructive defects with interstitial fibrosis and bronchiolar changes seen on biopsy. This complication may occur more frequently in children, with one study reporting an incidence of 26%. [276] Restrictive defects, though less common, can occur as well.[277]

The most effective therapy for CGVHD is unknown.[278] As the effector mechanisms of CGVHD are poorly understood, current modalities are directed at immunosuppression of donor T lymphocytes, the effector cells of acute GVHD. Initial therapy usually includes steroids, calcineurin inhibitors, such as cyclosporin and FK 506, and/or antithymocyte globulin.[279] Newer modalities include monoclonal antibodies directed against activated T cells [280] as well as alternative immunosuppressants such as mycophenolate.[281,282] Children with CGVHD are profoundly immunocompromised, both by their underlying immune dysregulation and its pharmacologic management, and require continuing prophylaxis against opportunistic infections and aggressive evaluation of fever. Infectious death is common, often from encapsulated organisms. A proportion of patients are functionally asplenic. [283] Antibacterial prophylaxis is indicated. Despite advances in supportive care, CGVHD remains a major cause of morbidity and mortality for children undergoing allogeneic HSCT.

### *Secondary Malignancies*

After HSCT, patients are at risk for a variety of secondary neoplasms. Secondary MDS/leukemia, presumed to arise from prior exposure of SCs to chemotherapeutic agents or irradiation, or both, is a significant problem after autologous HSCT. Risk factors include prior therapy with topoisomerase II inhibitors or high cumulative doses of alkylating agents, older age at HSCT, and poor BM function before transplant. [284] The incidence of therapy-induced MDS has been reported to range from 4% to 20% at 5 to 6 years after autologous HSCT.[16,285] Posttransplantation lymphoproliferative disease (PTLD) is another significant source of malignancy after HSCT. The use of either TCD or antithymocyte globulin for prevention or treatment of GVHD is associated with PTLD [286] presumably because of the greater degree of ensuing immunologic dysfunction. Patients receiving transplants from mismatched donors, those with CGVHD, and those transplanted for congenital immunodeficiencies are also at increased risk.[287,288] PTLD is usually but not always Epstein-Barr virus (EBV)–positive and can present as an infectious mononucleosis syndrome, as a localized process, or as a fulminant lymphoma. The abnormal cells may be polyclonal, oligoclonal, or monoclonal, with some suggestion that response to therapy is inversely related to the degree of clonality. [289] The treatment depends on the extent of disease and may include decreasing immunosuppression, treatment with interferon, or chemotherapy. Other strategies have involved prophylactic or therapeutic infusions of EBV-specific autologous or allogeneic donor T lymphocytes.[290,291] This therapy has been effective, but requires purified and expanded donor cells to be available and can carry a significant risk of GVHD. In addition, not all donors are EBV seropositive, limiting the ability to derive EBV-specific lines or clones. More recently, the use of monoclonal anti-CD20 antibody IDEC-C2B8 (rituximab) has been successfully employed.[292]

Last, patients post-HSCT may develop solid tumors. Those receiving TBI in the conditioning regimen appear to be most vulnerable. Tumors include skin and soft tissue cancers, with a preponderance of tumors localized to brain, thyroid, and salivary glands. The majority of skin neoplasms are basal cell or squamous cell carcinomas, although melanoma can also occur.[293] Bone tumors may develop and can be benign (osteochondromas)[294] or malignant (osteosarcoma). In contrast to PTLD, which generally presents within the first 6 months after transplantation, solid tumors occur later, at a median of 4 years post-HSCT. The overall incidence of malignant neoplasms is approximately 2%, which is eight times greater than expected in an age-matched cohort. [293] However, a recent report found a much higher incidence in children undergoing allogeneic HSCT for acute leukemia. [288] The cumulative risk of solid tumors was 11% at 15 years post-HSCT. Children younger than 5 years of age at the time of HSCT were at greatest risk. Prior cranial radiation therapy for CNS prophylaxis was associated with a particular increase in the incidence of brain or thyroid cancer. HD is also more frequent after allogeneic HSCT, occurring at a median of 4 years post-HSCT. [295] Reported patients all had acute or CGVHD, or both, implicating immune dysregulation as a potentiating factor.

### *Endocrine Complications*

Endocrine disturbances after HSCT are myriad. Primary gonadal failure has been described in approximately three-fourths of post-pubertal females after treatment with TBI-containing conditioning regimens, but can also occur after BU/CY or other chemotherapy-only conditioning. [296,297 and 298] Less longitudinal data are available for girls who were pre-pubertal at the time of HSCT, but it appears that the majority has experienced complete ovarian failure. [299,300 and 301] Whether this will be true for patients receiving fractionated or hyperfractionated TBI, or both, or other novel preparatory regimens remains to be established. Regular follow-up is essential so that puberty can be chemically induced and the ill effects of low estrogen production, such as osteoporosis, avoided by appropriate supplementation. Although Leydig cell function and testosterone production are usually unimpaired, [298,300,302] virtually all male patients appear to be infertile after the use of TBI or myeloablative chemotherapy. Sperm banking should be addressed with all eligible males before conditioning, and the transplant community should remain alert to advances in sperm and oocyte collection and preservation techniques. Patients have occasionally preserved their reproductive function, particularly those who are pre-pubertal at the time of HSCT, so subsequent evaluation is important. For women who do conceive after HSCT, there is an increased chance of having an infant with low birth weight and an increased rate of spontaneous abortion for those who have received TBI. There does not appear to be any increased risk of congenital anomalies in children born to survivors of HSCT.[296]

Thyroid dysfunction is well documented after HSCT and is most prevalent after regimens containing TBI [298] but can occur after chemotherapy-only conditioning regimens as well.[303] The use of fractionated TBI has decreased the incidence of hypothyroidism from more than 30% to 10%. [302,304] Thyroid function tests should be checked annually, as it may take many years for thyroid abnormalities to present. Treatment of thyroid hormone deficiencies allows for optimum growth as well as decreases the risk of thyroid malignancy.

### *Growth and Development Complications*

Children undergoing HSCT are at risk for growth failure. Patients who receive TBI after prior cranial irradiation are at greatest risk. [305] Reports on the linear growth of children after BU-based conditioning are conflicting. Some studies show no adverse effect on final height, [305,306] whereas some show effects comparable to TBI-based regimens.[307] Prolonged steroid use post-HSCT can further contribute to decreased growth rate. [307] Cognitive outcome for children after HSCT has not been systematically and extensively investigated, but children older than 6 years old at HSCT appear to have minimal risk of neurocognitive sequelae. Younger children, in particular those younger than 3 years old, show some small risk of cognitive decline when tested 1 year post-HSCT. [308] This decline does not seem to be progressive, as cognitive ability stabilized on follow-up evaluations. [309]

### *Other Late Complications*

A substantial risk of cataract development exists for patients receiving TBI. Fractionation of the TBI dose decreases the risk from 60% to 10% to 30%. [310,311] As cataracts typically develop years after HSCT, annual ophthalmologic evaluation is indicated. Patients may also have decreased lacrimation secondary to chronic GVHD or chemoradiotherapy that can result in keratopathy. The most important bony complication of HSCT is avascular necrosis. [312] Patients may develop findings of renal disturbance similar to classic hemolytic-uremic syndrome. The disorder usually presents as moderate hemolysis and renal insufficiency beginning 4 to 9 months after HSCT. The mechanism appears to be radiation-induced damage to renal arterioles and capillaries with secondary effects on glomeruli and tubules. Most cases resolve spontaneously over time with resolution of clinically apparent hemolysis, although subtle deficiencies in renal function may be more persistent. [313] Hemolysis post-HSCT can also be a result of ABO incompatibility between donor and patient because inheritance of blood group antigens is independent of the HLA gene complex.[314] This does not usually present a clinical problem. Red cell depletion of the infused BM prevents significant acute hemolysis. A short delay in reconstitution of the red cell compartment occurs, but prolonged red cell aplasia, although reported, is uncommon. [315] Autoimmune hemolytic anemia may also result as a consequence of HSCT-associated immune dysregulation.[316,317] Immune-mediated cytopenias have been reported to involve the other cell lines as well. [318,319] These cytopenias can occur months to years after allogeneic HSCT and are most often reported in the setting of TCD or with the use of alternative donors, but can be seen even after autologous HSCT. This can be a pernicious problem that may require prolonged periods of immunosuppression with frequent relapses and can be fatal.

# GENE TRANSFER AND THE TREATMENT OF PEDIATRIC MALIGNANCY

MALCOLM K. BRENNER

## INTRODUCTION

It has been asserted that every century has its revolution in medicine—public health in the eighteenth century, surgery in the nineteenth century, and antibiotics in the twentieth century—and that the ability to transfer and express new genes in cells will fulfill this role in the new millennium. Others counter by pointing out that because genetic disorders account for less than 2% of all human disease, even fully evolved forms of gene therapy can have only a limited impact on human health. The truth, as always, lies somewhere in between. Although only a few diseases are caused by single gene defects, a far larger proportion of human ills, including cancer, can be attributed to the interaction of multiple genes and gene defects. More important, however, is that the correction of genetic defects is only one of many potential clinical applications of gene transfer. Of greater probable importance will be the use of gene transfer to act as a form of drug delivery system, as a means to modify the behavior of cells, by ablating normal characteristics or adding new ones, and as a way to mark cells so their behavior and fate can be monitored *in vivo*. When one considers these possibilities, it becomes evident that gene transfer may have a role in most human disease. Achieving these goals will require substantial improvements in current gene transfer technologies, however. For example, many applications require genes to be transferred with high efficiency and precise targeting. Targeting does not end with the penetration of the cell membrane, because the transferred genetic material must be targeted to the nucleus. If long-term expression is needed, the transferred DNA usually has to integrate, ideally in a specific site in the DNA. Finally, the transferred genes should respond to appropriate cellular regulatory mechanisms so the gene product will be produced in correct quantities and at appropriate times. We are currently a long way from achieving any of these aims with current methods of gene transfer. To date, therefore, the practice of human gene therapy has largely been governed by a need to match the desires of the investigator with the capabilities of the available transfer technology. These limitations notwithstanding, more than 100 clinical protocols for gene transfer in cancer have already been approved. Early clinical results have often been of both scientific and clinical value and have indicated the considerable potential of the approach.

They have also demonstrated, however, that the highest standards of clinical practice have not always been adhered to. As with any new field, regulatory and public scrutiny of gene therapy studies has been intense and has revealed a need for improved training of investigators and superior record keeping. The ensuing tumult has undoubtedly slowed progress toward gene therapy trials as institutions begin to remedy the deficits in their regulatory and data handling infrastructure. Longer term, however, it is likely that the presence of chastened but more experienced clinical investigators implementing better designed and better run studies will prove of benefit not just to gene therapy but to clinical investigation as a whole.

This chapter reviews the successes, limitations, and long-term potential of gene transfer techniques for therapy of pediatric malignancy, and reviews the accomplishments in the field as well as the impediments to progress. Most important, this chapter gives an idea of the incremental way in which gene transfer technologies will supplement, long before they supplant, current therapeutic approaches to these cancers.

There are four major approaches to incorporating gene transfer into therapy for childhood cancer. [1] The tumor cell itself is modified, either by “repairing” one or more of the genetic defects associated with the malignant process, by introducing a gene that triggers an antitumor immune response, or by delivering a prodrug-metabolizing enzyme that renders the tumor sensitive to the corresponding cytotoxic agent. [2] The immune response to the tumor is modified by altering the specificity or effector function of immune system cells.[3] The drug sensitivity of normal host tissues is decreased by delivering cytotoxic drug-resistance genes to marrow precursor cells, thereby increasing the therapeutic index of chemotherapy. [4] Finally, it is possible to mark normal or malignant cells so that the efficacy of conventional therapies can be monitored more closely. These efforts must all be tempered by the limitations of current vectors, which invariably lack the efficiency and targeting capacity that are required for optimum results.

## CURRENT VECTORS

Because no single vector has all the characteristics desired for effective gene transfer, the choice of a gene transfer agent requires the demands of the specific application to be matched as closely as possible with the characteristics of the vector. This section outlines the structure and function of the most widely used gene transfer methodologies currently in clinical practice: retroviruses, [1,2] and [3] adenoviruses,[4,5] adeno-associated virus (AAV),[6] and liposomes.[7]

### Retroviruses

Figure 17-1A shows the structure of a classic retroviral vector.[8] The structural and replicative genes (gag, pol, and env) of a murine retrovirus are replaced by one or more genes of interest, driven either by the retroviral promoter in the 5' long terminal repeat or by an internal promoter. The retroviral constructs are made in cell lines in which the missing retroviral genes are present *in trans* and thus reproduce and package a vector that is not replication competent. Retroviral vectors have a wide target cell range, and the genetic information they convey is integrated into the host cell DNA. Thus, the transferred gene not only survives for the entire life-span of the transduced cell, but is also present in that cell's progeny. Hence, these vectors are ideal for transferring genes into rapidly dividing cell populations, such as hemopoietic stem cells or lymphocytes. Provided that replication-competent virus is absent, the vector preparations appear to be nontoxic. However, retroviral vectors have several disadvantages. Because expression of the transferred gene requires viral integration of the genome, and hence a population of dividing cells, the efficiency of transfer to many types of cell may be low.[3] It is possible to increase efficiency by bringing vector particle and target cell into close physical apposition, for example, by performing transduction on substances like fibronectin, but even then, overall levels of transfer leave much to be desired. Furthermore, because the integration events themselves occur largely at random in the host cell DNA, regulatory genes could conceivably be damaged, contributing to oncogenesis. [9] Finally, retroviral vectors are not well suited for use *in vivo*,[10] because they are generally unstable in primates, and, as yet, they cannot be targeted to specific cell types. The development of pseudotyped particles, in which a retroviral vector genome is incorporated into an envelope derived all or in part from a different virus, may improve the *in vivo* stability of retroviral vectors and alter their target cell range.

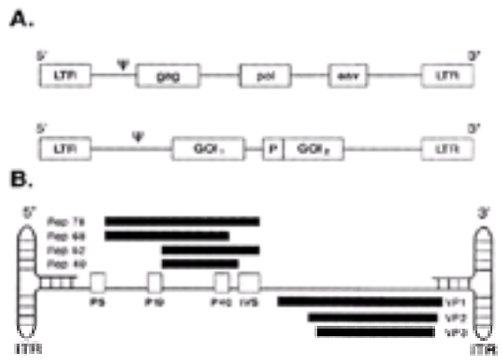

**FIGURE 17-1. A:** Retrovirus and retrovirus vector. The reverse transcriptase (gag), polymerase (pol), and envelope (env) coding sequences are removed and are supplied *in trans* by a producer cell. One or more genes of interest (GO1) are inserted, driven from the viral long terminal repeat (LTR) promoter or from an internal promoter (P). The viral packaging signal (y) remains in the vector, so it is appropriately packaged by the producer cell. **B:** Structure of adeno-associated virus (AAV). The AAV genome is a linear single-stranded DNA molecule. The viral genome is transcribed in three overlapping regions producing seven primary transcripts. The transcripts obtained from each gene are shown as black lines. The virus has two palindromic inverted terminal repeats (ITR) that, in combination with products of the rep region, are responsible for site-specific integration. The rep products are also required for replication during coinfection with adenovirus. VP1 to VP3 encode the viral capsid proteins. Promoter regions for these genes are boxed (p5, p19, p40, IVS).

### Adenoviruses

First generation adenoviral vectors are E1 (early protein) deletion mutants and therefore are not replication competent. [4,5] These vectors infect a wide range of cell types and, unlike retroviruses, can transfer genes into nondividing cells. The vectors are reasonably stable *in vivo* and can be used to infect cells *in situ*. Examples include gene transfer into respiratory epithelium (the CFTR gene in cystic fibrosis [4]) or liver (genes encoding factor VIII and factor IX in hemophilia A or B [11]). Adenoviral vectors are generally nonintegrating, however, so that the gene products are expressed from episomal DNA. [12] The episome is often lost after cell division and can be inactivated or lost even in a nondividing cell. [11] Thus, adenoviral vectors are unsuited for any application that requires long-term expression in a rapidly turning-over cell population or transfer into a stem cell and expression in that cell's progeny. A more important limitation is that most adenoviral vectors are immunogenic. Immune responses are generated against the vector proteins themselves (often preventing readministration of the vector), as well as against low levels of adenoviral proteins, expressed even when cells are transduced by defective viruses. [11] Moreover, concurrent expression of adenoviral genes appears to increase the probability of developing an immune response to the transgene product. The mechanism for this effect is unclear, but it is likely related to the ability of adenoviral entry into many cell types to trigger the release of cytokines, such as interleukins (ILs) 6 and 8, which also induce a potentially highly destructive local inflammatory response.[13] Finally, adenoviral damage to vascular endothelium and to other organ systems may cause a potentially lethal disseminated intravascular coagulopathy, or a more chronic hepatocyte hypertrophy and hepatic fibrosis. [14,15] As deletion of the E1 region alone does not prevent these toxicities, subsequent generations of adenovectors have been prepared that lack more than one set of adenoviral genes (e.g., *E1* and *E4*,[16] *E2a*[17] and *E4*,[18] or *E1* and *E3*[19,20]) (reviewed in Hitt et al.[21]). Although showing less immunogenicity and toxicity and more durable transgene expression in some studies, such modified vectors produced little or no benefit in others.[16,17,18,19 and 20] Indeed, administration of an *E1*/*E4*-deleted vector has been linked to a human death. [22]

The quintessential attenuated adenovector is the so-called helper-dependent or “gutless” vector, in which virtually all of the adenoviral genes have been removed and replaced with the gene of interest and its promoter, together with irrelevant DNA to allow packaging in the viral envelope. [23] These vectors can only be made with the assistance of a helper adenovector, which must then be separated from the deleted vector. [24] Helper-dependent vectors have shown a much higher therapeutic index than conventional adenovectors in several different models. [21,23,25,26 and 27] Importantly, they also seem to be much less immunogenic, so that transduced postmitotic cells (e.g., muscle or liver) may secrete vector-derived proteins over many months, [16,28] a prime consideration in the treatment of many deficiency disorders.

### Adeno-Associated Vector

AAV[6] (Fig. 17-1B) is a “dependovirus” that can replicate only when an AAV-infected cell is coinfected with adenovirus or herpesvirus. Structurally, AAV is a DNA parvovirus, containing two palindromic inverted terminal repeats. When linked with two gene products from the rep gene region, these repeats favor site-specific integration of chromosome 19[29] by the AAV. Thus, AAV, like retroviruses, should persist for the entire life of the host cell and its progeny. Because genomic integration by AAV is relatively site specific, the risk of oncogenesis is low. Although, in contrast to retroviruses, AAV may integrate the genomes of nondividing cells and become permanently expressed even in resting or postmitotic cells, this and other putative advantages have proved hard to exploit in clinical practice. For example, the rep gene products that contribute to site-specific integration are toxic to virus-producing cells and are usually deleted from vectors. However, rep-deficient vectors appear to lose almost all of their ability to integrate genomes, regardless of site. [6] Finally, it has proved difficult to develop high-titer producer cell lines, free of contaminating helper adenoviruses. Although the introduction of AAV into clinical use has therefore been delayed, preliminary studies in which AAV vectors encoding factor IX are injected into postmitotic tissues, such as muscle, are already producing encouraging results. [30]

### Liposomes and Other Physical Methods

Clinical experience with the available physical methods of gene transfer has primarily involved cationic liposome/DNA complexes, [7,31,32] which fuse with the cell membrane and enter the endosomal uptake pathway. DNA released from these endosomes may then pass through the nuclear membrane and be expressed. The main advantage of liposomes is that they are nontoxic and can be given repeatedly. In some cell types, high levels of gene transfer have been obtained by this method.[7] Liposomes are rather unstable *in vivo*, but liposomal transfer by local injection of human melanoma cells *in situ* has resulted in the expression of a new gene (HLA-B7).[7] However, the DNA transferred by liposomes does not integrate the genome, and despite the incorporation of a variety of ligands into the liposome-DNA complex[32] the ability to target these vectors is still quite limited. More recently, successful gene transfer *in vivo* has been reported with use of a bio-ballistic (“gene gun”) technique in which DNA coated onto colloidal gold particles is driven at high velocity by gas pressure into the cell. It is not yet clear whether this approach can be used to transduce normal or malignant hemopoietic progenitor cells with sufficient efficiency to allow therapeutic application. Localized electroporation of plasmid DNA using microelectrodes has also proved to be highly effective for the transduction of muscle and skin and can be followed by significant transgene expression.

### Other Vectors

Other vectors, including herpesviruses[33] and lentiviruses,[34] have been proposed as high-efficiency transducers of many cell types, and herpesviruses have recently entered clinical trials. However, although these viruses may become future substitutes for currently available vector systems, most investigators now accept that no naturally occurring virus and no simple physical vector will ever prove suitable for all gene therapy purposes. Ultimately, therefore, entirely new synthetic or semisynthetic vectors will have to be developed.[35] Possibilities include the generation of hybrid viral vectors, which may combine, for example, the *in vivo* stability of adenoviruses and the integrating capacity of retroviruses. Alternative, fully synthetic vectors will be developed by combining components from multiple different vectors, allowing safe, efficient, and specific gene transfer and regulation. In the meantime, gene therapy protocols for immunodeficiency and for cancer will require investigators to circumvent the limitations of current vectors and to choose their agents on the basis of the most important feature required. For example, a requirement for long-term gene expression by the progeny of hemopoietic stem cells dictates a retroviral vector, whereas a protocol specifying transient expression of differentiated malignant cells and their transduction *in vivo* would favor adenoviral vectors.

## IMPROVING VECTOR SYSTEMS

### Targeting

To target viral vectors to specific cells or organ systems, it is usually necessary not only to add a targeting ligand to provide the new specificity, but also to disrupt preexisting ligands so that the new specificity replaces, rather than adds to, the old. Moreover, the new ligands should allow the virus to enter the cells by membrane fusion or active transport, through the same intracellular pathway as the native vector. For adenoviruses in particular, retargeting may also be an important means of

limiting virus-induced toxicity to vulnerable organs. Adenoviruses bind to at least two molecules on their target cells—the *Coxsackie* adenovirus receptor and cell surface integrins (usually av3 or av5).[21,36,37 and 38] Binding is mediated by domains on the adenoviral knob protein. Because the sequence and crystal structure of this protein is known, one can identify new ligand sequences and incorporate them into positions that disrupt preexisting patterns of binding and establish new ones. However, the complexity of the process has hampered efforts to effectively retarget viral vectors. Retargeting may be much simpler with liposomal vectors, whose intrinsic targeting capabilities are limited, so that simple addition of a ligand could secure the desired effect. Despite the appeal of these retargeting strategies, the only success reported to date has been infection of liver cells through directed binding to the asialoglycoprotein receptor.[39]

### Regulation of Transgene Expression

Most effective gene therapies require regulation of the transgene. Two approaches are available. The first relies on endogenous regulatory elements by replacing the defective sequence with an inserted wild type sequence—the process of homologous recombination. One promising technique for achieving this effect is the so-called chimeroplast technology,[37,38] which utilizes a partial sequence of the gene of interest, incorporating the corrected base pair attached by hairpin structures at each end to RNA complementary to the complementary DNA strand sequence.[40] An additional short DNA sequence is included at the mid-point of the RNA. This chimeric molecule is resistant for 48 hours to intracellular exonucleases or ribonucleases. These chimeroplasts appear particularly effective for repairing single nucleotide defects, but may be less effective whenever more lengthy sequences are abnormal or absent. Nonetheless, in animal models of several diseases (e.g., Crigler-Najjar disease or uridine diphosphate-glucoronysyl transferase deficiency,[32] or $a_1$-antitrypsin inhibitor deficiency and the factor IX deficiency of hemophilia B[41]), as many as 40% of the hepatic cells can be repaired *in vivo*, and clinical trials of this approach are imminent.

For most disorders, regulatory elements may need to be introduced with the transgene. Thus, several regulatory structures are being developed with the intention of using orally absorbed small molecules to control transgene expression. The three systems closest to clinical use are regulated by rapamycin or tetracycline and their analogues,[42] or by the antiprogestin agent RU486.[43] By modifying the DNA-binding domains, it is possible to alter the target sequence that is bound, allowing a repressor and an inducer to be present in the same cell. Similarly, by modifying the receptor for the small molecule, it is possible to use two different oral agents, one to upregulate and one to downregulate production. This provides a lower background than an inducible system alone and a higher level of maximum expression than a repressor alone. Alternatively, the system could be used to turn on two separate genes.

## APPROACHES TO GENE TRANSFER IN PEDIATRIC MALIGNANCY

### Modification of the Tumor

#### *Tumor Correction*

There is an attractive elegance to the strategy of introducing genetic material into a pediatric malignancy to correct the specific genetic defects contributing to the neoplastic phenotype. A number of mutant oncogenes and fusion transcripts have been identified in childhood cancers that are certainly specific to the malignant clone and frequently form a critical component of the malignant process. This approach is technologically demanding, however, as all malignancies result from a multiplicity of genetic abnormalities. Unless correction of a single defect is subsequently lethal to the malignant cell, transfer of an individual corrective gene to a patient with $10^{11}$ or $10^{12}$ tumor blasts will leave a multiplicity of premalignant cells, with a high risk of later transformation. Present methods of gene transfer are also inefficient.[3,44,45 and 46] Even if it were possible to transfer genes to 90% or more of malignant cells *in vivo*—a feat currently beyond any available vector[47]—it would be insufficient to produce more than transient clinical benefit in most pediatric malignancies. Moreover, many relevant gene defects produce molecules with "transdominant" effects that continue to produce a malignant phenotype, even if a wild-type gene is introduced.

Transdominant malignant genes could be neutralized only by ribozymes, by antisense RNA, by intracellular antibody genes (intrabodies), or by homologous recombination with a wild-type gene.[48,49] These "subtractive" approaches to gene transfer are designed to destroy the function of an expressed gene rather than to add a new activity. Ribozymes are RNA structures that are able to cleave specific sequences in the targeted messenger RNA molecules. For clinical use, ribozymes that form hairpin or hammerhead structures are preferred because of their stability, even in the absence of substrate, and their activity under physiologic conditions. The original function of these molecules in viruses and other microorganisms is probably to autocatalyze their own cleavage into functional RNA, and perhaps also to destroy the RNA of invading organisms. For applications in gene transfer, ribozymes may be used to destroy transcripts originating from the unwanted host cell DNA sequence while leaving intact the messenger RNA originating from the transgene. If necessary, the sequences for these ribozymes could be delivered in the same vector as the corrective transgene. Alternatively, chemically modified ribozymes may be administered as drugs. Antisense RNA molecules consist of sequences that bind the sense transcript of interest and prevent translation. These molecules are usually stabilized by the addition of residues that prevent their degradation by host cell ribonucleases, and are usually delivered directly or packaged in liposomes. Although both approaches have the attraction of extreme specificity, in practice it has proved difficult to ensure that expression of ribosomal or antisense genes will be adequate to overcome transdominant effects. There also have been instances in which the specificity of the approach has been less than expected. The "intrabody" strategy is based on the ability to genetically manipulate genes encoding antibodies, so that the antigen-binding domain is expressed intracellularly.[50] Such intrabodies may block protein-protein interactions, alter protein function, or divert proteins from their normal cellular compartment. For example, the a unit of the IL-2 receptor, which is overexpressed in some T-cell leukemias, can be blocked in this fashion *in vivo*.[51] Finally, homologous recombination attempts to replace the defective sequence within the gene with a normal sequence. Until recently, the efficiency of this strategy was far too low to permit its application to human disease. Claims that hybrid RNA-DNA molecules joined by a hinge region may be much more effective at producing recombination, at least over short stretches of DNA, has led to renewed interest in the approach. Plans are well advanced for the treatment of abnormalities such as Crigler-Najjar syndrome,[52] and application to treatment of sickle cell disease[40] and perhaps pediatric malignancy may follow.

The preceding limitations notwithstanding, several tumor correction protocols have been proposed. In spite of the polygenic origins of cancer, it is hoped that certain individual genetic abnormalities will be both pivotal to the malignant process and amenable to correction. For example, efforts are being made to neutralize fusion transcripts such as *BCR-ABL* or activated oncogenes such as *MYB* (in chronic myeloid leukemia), using ribozymes, antisense RNA, or wild-type genes.[53,54 and 55] These efforts have been lent support by success using specific small molecule inhibitors of the enzymes produced by such mutations. Similarly, nonfunctional antioncogenes such as p53 may be replaced by wild-type genes in patients with acute myeloid leukemia or myelodysplasia.[56] Interest is also increasing in targeting the gene pathways involved in regulating apoptosis. Experimental models suggest that even minor perturbations in these pathways can greatly modify the sensitivity of cancer cells to chemotherapy. Finally, it has been suggested that tumor correction may best be used in a preventive manner for patients in whom known single gene defects predispose to subsequent mutagenesis and cancer.

#### *Prodrug-Metabolizing Enzymes*

Efforts have also been made to insert genes that will encode enzymes able to convert harmless prodrugs into lethal cytotoxins. More than a dozen prodrug metabolizing enzyme (PDME) systems have been described. Of these, the thymidine kinase gene (phosphorylates acyclovir/valacyclovir/ganciclovir to toxic nucleoside) has been the most widely used. Other systems in various stages of clinical development include cytosine deaminase,[57,58] which converts 5-fluorocytosine to 5-fluorouracil, the P450-2BI system (converts cyclophosphamide to 4-hydroperoxycyclophosphamide),[59] and the bacterial nitroreductase system[60] (reduces CB 1954 to the more active 4-hydroxylamine). For the PDME approach to be selective for a given leukemia, either the vector or the prodrug product must be targeted to the malignant cell. The first clinical studies to test this novel strategy have aimed for both types of selectivity by introducing a thymidine kinase gene into a tumor cell with use of a retroviral vector.[61,62] On exposure to ganciclovir, the transduced cells phosphorylate the drug. If the cell then divides, the product is incorporated into DNA with lethal consequences, whereas nondividing cells are unaffected. Initial therapeutic study of thymidine kinase gene transfer was made in patients with primary or secondary brain tumors; in this context, there is a particularly clear distinction between tumor cells (which divide and are destined to be killed by the ganciclovir) and normal neurons (which do not divide and should escape unharmed). Retroviral vectors offer additional tumor specificity in this system because they function only in dividing cells, and therefore do not transduce normal neurons.

Transfer of prodrug-metabolizing genes may not require all the tumor cells to be transduced for benefit to be seen. One of the most puzzling features of the original thymidine kinase-retrovirus system was that it worked so well in many preclinical tumor models. Even when fewer than 10% of tumor cells were transduced, ganciclovir destroyed nearly 100% of the tumor cell population.[61,63] This advantage over the tumor correction protocols described earlier appears due to a "bystander" effect. That is, cells that lack the PDME gene can be killed if they are adjacent to transduced cells. The bystander effect is most evident in tumor cells that have gap junctions, so it likely represents the transfer of a toxic metabolite or an apoptotic signal.[63,64] The potency of this effect will likely be much lower among the "gapless" cells of hematologic malignancies. However, an immunologic bystander effect might also occur *in vivo*: Once the tumor cell is killed by the toxic metabolite and is processed and presented by antigen-presenting cells, the host may be immunized against tumor development[35,36] (see following section). At present, retinoblastoma

is the only pediatric malignancy to be treated by this approach. [127]

### *Generation of Tumor Vaccines*

In an attempt to enhance immune recognition of poorly immunogenic tumors, investigators have evaluated the effect of transducing tumor cells with lymphotactic chemokines,[65] cytokine genes,[66] allogeneic major histocompatibility complex (MHC) molecules,[7] or costimulatory molecules such as B7.1 or CD40 ligand[47,67] that activate cytotoxic T cells after engaging their surface ligands or counter receptors.

In murine model systems, the transfection of tumor cell lines with these molecules has augmented immunogenicity. Injection of neoplastic cells in doses that would normally establish a tumor instead recruits immune system effector cells and eradicates injected tumor cells. Often, the animal is then resistant to challenges by further local injections of nontransduced parental tumor. The transduced tumor has therefore acted like a vaccine. In some models, established, nontransduced, parental malignant cells are also eradicated.

There are two major problems in translating these approaches to pediatric malignancies. The primary malignant cells of many pediatric malignancies are highly resistant to transduction by many currently available vectors. This problem may be overcome *ex vivo* by using herpes viruses[33] or modified adenoviral vectors.[68] If adequate transduction of tumor cells cannot be obtained, nontransduced primary tumor cells may be combined with transduced fibroblasts expressing the immunostimulatory genes of interest. Although this approach has proved effective in animal models, it has not yet been validated clinically. A more fundamental concern about the tumor vaccine approach is that neoplastic cells show considerable phenotypic heterogeneity. Moreover, malignant “stem cells” may be phenotypically and functionally distinct from the bulk tumor population,[128] so that a vaccine made from a small proportion of these cells obtained from one site may not express the full array of antigens present in the patient as a whole.

As of this writing, tumor vaccines were being evaluated in more than 200 different clinical trials. Relatively few studies included pediatric patients. Preliminary results in melanoma, renal cell carcinoma, and neuroblastoma suggest that tumor cells transduced with the *IL-2*, *GM-CSF,* or *HLA-B7* gene can be given safely and will frequently produce immunomodulatory effects, including peripheral blood eosinophilia, a rise in natural killer (NK) and activated killer (AK) cell number and activity, and an increase in tumor-specific cytotoxic T-lymphocyte precursor frequency.[69,70,71,72,73] and [74] There have been reports of clinical responses in distal tumor sites, although other metastases have continued to grow (perhaps because their phenotypic heterogeneity allowed them to evade the immune system, as described earlier in this section). There has also been concern that the immune response itself can produce adverse hypersensitivity reaction. and certainly no patients have yet been cured of their disease.[75]

As more information is gained about the safety and efficiency of tumor vaccines, the approach has been altered. Vaccines are beginning to be used as adjuvants to prevent relapse in patients with presumed minimal residual disease, and several different immunostimulatory genes are being introduced in combination into the tumor. The immune response has at least four distinct components: (a) processing of antigen, (b) attraction of lymphocytes to the site of antigen presentation, (c) costimulation of cells that have engaged their antigen-specific receptor and of costimulator molecules, and (d) amplification of the attracted, stimulated cells by growth factors. Immunotherapy that combines two or more of these separate classes of stimulatory agents will likely prove more effective than treatment based on single immunogens. For example, in murine studies, combinations of the T-cell–attracting chemokine lymphotactin, and the T-cell growth factor IL-2 caused regression of preestablished leukemia and neuroblastoma when either agent alone was inadequate.[65]

Studies using combinations of, for example, IL-2 and lymphotactin and of IL-2 and CD40 ligand expressing neuroblastoma and acute leukemia cells have begun, and the increasing availability of vectors able to transduce primary human leukemic cells with high efficiency should simplify exploration of this combinatorial approach.

## Modification of Host Immune System

### *Gene-Modified Cytotoxic T Cells*

A considerable body of evidence indicates that the immune system has the potential to eradicate leukemia and perhaps lymphoma and certain pediatric solid tumors as well.[76,77] and [78] This effect is clearest in patients who have received bone marrow allografts for the treatment of a hematologic malignancy. In those cases, the presence of graft-versus-host disease (GVHD) lowers the risk of subsequent relapse, whereas measures that prevent GVHD, such as T-cell depletion or the use of an identical twin allograft, are associated with an increased risk of disease recurrence. This so-called graft-versus-tumor effect may simply be another manifestation of GVHD in which both normal and malignant host cells share the same host-specific polymorphisms, which serve as targets for alloreactive T lymphocytes. However, it is also possible that some of the host's normal T cells are able to detect discrete antigens on tumor cells. Cytotoxic T lymphocytes (CTLs) recognize processed intracellular proteins presented as short peptide fragments together with MHC molecules on the cell surface. Hence, internal proteins unique to the malignant clone may act as tumor-specific antigens for CTLs. Several human malignancies contain novel proteins, such as mutated oncogenes or fusion proteins generated by chromosomal translocations.[79,80] Even normal proteins can elicit CTL responses if they are expressed in higher-than-usual quantities; tyrosinase and the MAGE series of proteins in melanoma cells are two good examples.[81] If tumor cells are able to process and present these tumor-specific peptides, then it is possible that a malignancy-specific response could be generated in the absence of any other host reactivity. Exploration of this possibility and of the effector mechanisms involved is easiest when the target antigens have been identified and characterized. Once this has been done, gene transfer affords an attractive mechanism for enhancing or amplifying particular effector functions.

Epstein-Barr virus (EBV) infection provides an excellent model system to examine genetic enhancement of immune effector function. EBV is a latent herpesvirus that infects more than 90% of the population. Primary EBV infection is usually a self-limited process followed by a life-long latency in oral epithelial cells and in B cells. The virus is also associated with a range of malignant diseases, not only of B and epithelial cells, but also of T cells, NK cells, and muscle. [82] All EBV-positive tumors reflect the latent life cycle of the virus. That is, with any given type of EBV-related malignancy, only a small proportion of the viral genome is expressed, and the differential regulation of these genes is one of many strategies the virus uses to evade the immune response.

### Lymphoproliferative Disease

Latent EBV infection can become active and induce lymphoproliferative disease (LPD) in children who have received solid organ or allogeneic stem cell transplants or who are receiving immunosuppressive therapy, or who lack an efficient CTL response for any other reason. The reported incidence of EBV-LPD among persons undergoing solid organ transplantation ranges from 1% to 10%, with the highest risk in seronegative recipients and patients receiving higher doses of immunosuppressive agents. Risk factors include *in vitro* T-cell depletion of donor marrow, use of a mismatched family donor or closely matched unrelated donor, and intensive immunosuppression.[5]

The onset of EBV-LPD is usually preceded by a large increase in viral load in recipients of either solid organ [83,84] or stem cell transplants.[85,86] The majority of these cases are B cell lymphomas or histologically high-grade non-Hodgkin's lymphoma of the immunoblastic or undifferentiated large cell type, [87] which respond poorly to cytotoxic therapy. The malignant cells express latent cycle virus-encoded antigens (EBNA1, 2, 3A, 3B, and 3C and LMP1, 2a, and 2b), most of which are targets for virus-specific immune activity.[88] The immunogenicity of these antigens has been exploited to treat posttransplantation EBV-LPD with unmanipulated donor T cells. Sloan-Kettering investigators reported responses to donor T cells in 20 of 22 patients undergoing stem cell transplantation. [89] Others have also had success with this strategy but have shown lower response rates and a significant risk of GVHD.[90] EBV-specific CTLs can be used as either prophylaxis or treatment for this disease. By genetically marking these cells using retroviral vectors, it is possible to track their behavior and survival *in vivo*.

***Prophylaxis with Cytotoxic T Lymphocytes*** Thirty-nine patients were treated with infusions of CTLs after transplantation of T-cell–depleted stem cells. None developed LPD, compared with 11.5% of a comparable untreated historical control group.[91,92] and [93] Gene-marked EBV-specific CTLs persisted in the patients for as long as 60 months, reconstituted immune responses to EBV, and reduced the high virus load seen in approximately 15% of patients. A study from Sweden recently confirmed the efficacy of EBV-specific CTLs in reducing the viral load in patients with high EBV-DNA levels posttransplantation. [86]

***Treatment with Cytotoxic T Lymphocytes*** Immunotherapy with antigen-specific CTLs can also be used to treat patients who develop overt lymphoma. In one study, two of three patients with this complication responded well to CTL infusion. One had a biopsy-proven accumulation of gene-marked CTLs at the disease site, [93] but there was a marked inflammatory reaction during the therapeutic response, underscoring the benefits of a prophylactic approach. The third patient did not respond and died of progressive disease 24 days after CTL therapy. This failure was traced to a deletion in the EBNA3B gene in tumor cells that removed immunodominant

epitopes, thereby inducing resistance to killing by CTLs.[94] Such escape mutants can compromise results, even when polyclonal CTL lines are used, and present a particular problem in patients with a large tumor load. Because production of EBV-specific CTL may be laborious, efforts have been made to use nonspecific T cells that are transduced with the thymidine kinase gene, allowing their destruction by ganciclovir should they produce adverse effects such as GVHD. Bonini et al.[95] used this approach to treat patients with posttransplant leukemic relapse or EBV-associated lymphoma. The transduced cells provoked GVHD in three patients, which resolved in two after treatment with ganciclovir. Several other patients developed immune responses to the transgenes, which may have reduced the longevity of the transferred cells, limiting their benefits.

***Hodgkin's Disease*** In North America, 50% of Hodgkin's tumors are EBV positive, expressing limited viral antigens in a type 2 latency pattern. In one study, EBV-specific CTLs were prepared from eight patients with advanced relapsed disease, gene marked, and reinfused as antitumor therapy.[96] Follow-up analyses showed *in vivo* expansion and long-term persistence of CTLs specific for LMP2, one of the Hodgkin's-expressed EBV antigens. There was also a reduction of EBV load and evidence for penetration and selective accumulation and expansion of CTLs at tumor sites. Despite resolution of type B symptoms and stabilization of disease, none of the patients had a complete response and all subsequently progressed.[96] Gene transfer may have an important role to play in improving this outcome. In one strategy, based on the use of CTLs specific for the subdominant antigens expressed in this disease, dendritic cells are transduced with an adenoviral vector encoding a full-length LMP2 gene. The CTLs recovered after exposure to these gene-modified cells are highly biased toward recognition of the LMP2 antigen. Another approach centers on the mechanisms by which Hodgkin's cells evade immune surveillance. Such cells secrete a number of T helper cell 2 (Th2) cytokines and chemokines, such as thymus and activation-regulated chemokine (TARC) and IL-10, that can inhibit to CTL immune responses. TARC recruits Th2 cells, which secrete IL-4 and thus contribute to the pro-Th2 and anti-Th1 environment already induced by the secretion of IL-10. To overcome this inhibition, CTLs can be transduced with the CCR4 gene, which encodes the chemokine receptor for TARC. It is hoped that TARC-expressing, LMP2 specific CTLs will be recruited to tumor tissues.

***Chimeric T-Cell Receptors for the Targeting of Hematologic Malignancies***

Tumor-specific T lymphocytes can also be produced by genetically modifying human T cells to express tumor antigen-specific chimeric immune receptors ("T-bodies").[97] This tactic is based on the observation that engagement of a single T cell or Fc receptor chain suffices to induce cellular activation.[98] One can generate chimeric receptors by joining the heavy- and light-chain variable regions of a monoclonal antibody, expressed as a single-chain Fv molecule, to the TCR-z ( Fig. 17-1), or Fc-g immune receptor domain. To promote functional recognition of its target antigen, the single-chain Fv is disengaged from the plasma membrane, usually by insertion of an immunoglobulin hinge-like domain. Antigen stimulation of the extracellular component of the chimeric receptor results in tyrosine phosphorylation of immune-receptor activation motifs present in the cytoplasmic domain, initiating T-cell signaling to the nucleus. Human T lymphocytes genetically engineered to express the recombinant receptor genes were capable of specific lysis and cytokine secretion on exposure to tumor cells expressing the relevant target antigens.[98] Adoptively transferred chimeric receptor–transduced cells were protective in murine tumor models.[98]

T cells with chimeric receptors have numerous advantages over immunotherapies based on monoclonal antibodies or T lymphocytes alone. They can be directed toward any native tumor- or viral-associated antigen for which a monoclonal antibody exists, making this strategy applicable to a wide variety of malignancies and viral diseases. In contrast to the lengthy process of CTL selection by standard methods, characterization and expansion of lymphocytes with native specificity for target antigens allows one to generate large populations of antigen-redirected T lymphocytes in a matter of weeks. Because chimeric T-cell receptors provide T-cell activation in a non–MHC-restricted manner, they permit cells to evade the major mechanisms by which tumors avoid T-cell recognition, such as downregulation of HLA class I molecules and defects in antigen processing. The absence of MHC restriction may also allow a "universal" cytotoxic T cell to be generated, although immune recognition of such foreign cells may reduce their clinical value. T-body–mediated effector functions are more likely to eradicate tumor cells than humoral immune responses alone, in that cytokine secretion upon T-cell activation recruits additional components of the immune system, amplifying the antitumor viral immune response. Finally, unlike intact antibodies, T cells can migrate through microvascular walls and penetrate the cores of solid tumors to exert their cytolytic activity.

Ensuring long-term persistence of transferred T cells in the host is a major challenge in adoptive immunotherapy. Rapid clearance of modified T-effector cells may be partly overcome by humanization of currently available hybridoma antibodies or by the generation of fully human single-chain antibodies by phage display technology. T lymphocytes may be locally lysed by factors secreted by tumor cells, and the surviving modified T lymphocytes may lose their antitumor viral reactivity by returning to a resting state. Although T-cell activation was not a prerequisite for efficient signaling through the chimeric receptor *in vitro*,[99] the functional capabilities of T cells with chimeric receptors in situations in which costimulation is limiting remain to be determined. To avoid the functional inactivation of T lymphocytes expressing chimeric receptors *in vivo*, it may be necessary in future designs to engage relevant co-receptor molecules.

The specific properties of the antibody used for antigen recognition may also be crucial for effective receptor stimulation. Signaling through native TCRs requires low-affinity binding to allow for serial triggering of a large number of these receptors,[61,100] yet the majority of antitumor antibodies used in the clinic bind with high affinity. Whether such binding is optimal for the efficient lysis of tumor cells by T bodies remains to be determined. Similarly, the target antigen for chimeric receptor–mediated immunotherapy should be carefully chosen, as receptor binding by shed tumor antigens or downregulation of the target antigen represents potential mechanisms of immune system evasion by tumor cells. Ideally, the targets of chimeric receptors constitute part of the tumor cell phenotyping.

Thus far, chimeric receptors have been developed for a variety of antigens associated with solid tumors, including neu/HER2,[101] folate-binding protein, carcinoembryonic antigen,[102] tumor-associated glycoprotein-72,[103] renal tumor-associated antigen, CD30,[104] and CD33.[105] For pediatric malignancies, studies are planned for patients with neuroblastoma and Ewing's sarcoma.

**Modification of Host Cytotoxic Drug Sensitivity**

An increased understanding of cytotoxic drug resistance has suggested gene therapy approaches to protect normal host tissues from the toxicity of chemotherapy. If, for example, hemopoietic stem cells could be rendered resistant to one or more cytotoxic drugs, it might enable them to resist the myelosuppressive effects of cytotoxic drugs during cancer therapy, allowing longer or more intensive therapy that could cure additional patients.[106]

The *MDRI* gene has been the most widely considered for human therapy. Its product, P-glycoprotein, functions as a drug efflux pump and confers resistance to many chemotherapeutic agents.[107] The feasibility of using *MDRI* to protect hemopoietic cells has been demonstrated by murine experiments, and retroviral transfer of *MDRI* to murine clonogenic progenitors conferred drug resistance both *in vitro* and *in vivo*.[108] These experiments with MDR1-containing vectors prove the principle that drug resistance genes can be used to attenuate drug-induced myelosuppression. It is likely that other drug resistance genes could function analogously. DNA-methylguanine methyltransferases (MGMTs) are enzymes that repair DNA damage induced by the nitrosoureas, a class of alkylating agents used widely in cancer chemotherapy. Preliminary data suggest that retrovirally mediated gene transfer of the human *MGMT* gene to mouse bone marrow cells results in protection of murine progenitors from toxicity produced by carmustine.[109] Other drug resistance genes, including those for dihydrofolate reductase[110] and topoisomerase 11, are also under consideration for clinical testing.

The clinical application of drug-resistance gene transfer has several potential pitfalls. The low efficiency of stem cell transduction and poor gene expression observed in the earliest clinical protocols resulted in no selection of gene-modified cells and hence no *in vivo* protection.[111,112] Improved transduction technologies using fibronectin and altered combinations of growth factors are beginning to result in *in vivo* selection, albeit not yet to clinically useful levels.[113] There remains the risk of transferring the genes to neoplastic cells that contaminate the hematopoietic stem cell (HSC) graft and produce drug-resistant relapse. Finally, toxicity to nonprotected organs, including gut, heart, and lungs, may rapidly supervene when marrow resistance allows intensification of cytotoxic drug dosages. The approach will only come to full fruition once it becomes possible to target normal tissues *in vivo* and transduce them with high efficiency.

**Gene Marking of Hemopoietic Progenitor Cells**

Not all of the applications of gene transfer to patients with malignant disease are directly therapeutic in intent. Gene marking of hemopoietic cells provides no immediate benefit to patients, but the information from these studies can be used to improve therapies that incorporate autologous HSC transplantation as a means of eradicating hematologic malignancies.[114]

Autologous HSC rescue has shown promise as effective treatment for leukemias and lymphomas (and perhaps for some solid tumors)[115,116,117,118] and[119] although disease recurrence continues to be the major cause of treatment failure. When the tumor originates from or involves the marrow, relapse could originate from malignant cells persisting in the patient, in the rescuing HSCs, or in both. Concern that the HSCs may contain residual malignant cells has led to extensive evaluation of techniques for purging these cells.[116,120,121] However, no method has been unequivocally shown to reduce the risk of relapse in naturally occurring disease, and

purging techniques usually slow engraftment due to damage to normal progenitor cells.

In the gene marking studies conducted to date, gene transfer has been used to address biologic questions about clinical issues related to bone marrow transplantation (BMT). More specifically, gene transfer has been used after autologous BMT to determine the source of relapse and to learn more about the biology of normal marrow reconstitution and how best to accelerate this process.

### *Source of Relapse after Autologous Bone Marrow Transplantation*

Although autologous BMT appears to improve survival in many pediatric malignancies, it does not eliminate relapse as the major cause of treatment failure. The possibility that reinfused malignant cells may contribute to disease recurrence has led to extensive evaluation of techniques for purging marrow to eliminate residual malignant cells, although it has been unclear whether such precautions are necessary. In one study, attempts were made to resolve this issue by marking the marrow at the time of harvest with a retroviral vector, and then determining if the marker gene was present in malignant cells at the time of relapse. [2] Among 12 patients with acute myeloid leukemia who were studied in this manner, four relapsed, two with cells that contained the marker gene. [2] Similar results have been obtained in patients with neuroblastoma and with chronic myelogenous leukemia.[122] These data show definitively that marrow harvested from patients in apparent clinical remission may contain residual tumorigenic cells and that these cells can contribute to disease recurrence. The implication is that effective purging will be one requirement for improving the outcome of autologous BMT.

### *Gene Transfer to Normal Cells*

The efficiency of gene transfer to normal marrow progenitor cells can also be determined from marker studies. By phenotypic (neomycin resistance) and genotypic (polymerase chain reaction amplification), analysis, the *neo* gene was present in approximately 15% of hematopoietic progenitor cells after autologous BMT in children.[3] Somewhat lower levels were found in adults.[44,123] The marker gene continued to be detected and expressed for up to 7 years in the mature progeny of marrow precursor cells, including peripheral blood T and B cells and neutrophils. These results suggest that true stem cells, and not simply lineage-committed progenitors, were transduced by this method.[3] Overall, the results are encouraging, as the levels of gene transfer in children were higher than one would predict from animal models. This gain can be attributed to the fact that marrow was harvested during its regeneration after intensive chemotherapy, when a higher-than-normal proportion of stem cells are in cycle. Second-generation studies of marrow marking have begun. In one effort, two distinguishable gene markers in two related retroviral vectors are being used to ascertain whether marrow purging is superior to no purging, as well as the relative efficacy of two different purging techniques within a single patient.[124]

### Ex Vivo *Expansion Studies*

Double gene marking is also being used to determine directly which *ex vivo* or *in vivo* combination of cytokines will increase the proportion of long-lived marrow-repopulating cells that enter the cell cycle, thereby reducing the period of marrow hypoplasia and immunodeficiency that follows autologous stem cell transplantation. In humans, it certainly appears possible to use growth factors to increase by ten- to 50-fold the numbers of hematopoietic progenitor cells, as well as the efficiency of gene transfer to levels as high as 50%. However, such *ex vivo* data are not always reflected by results *in vivo*. In primate and human studies, transplantation of marrow treated *ex vivo* with growth factor combinations that greatly augment both progenitor numbers and gene transfer rates can yield disconcertingly low levels of long-term gene expression *in vivo*.[44] The likeliest explanation for this seeming paradox is that many of the growth factors intended only to induce cycling in marrow stem cells also induce their differentiation and the loss of their self-renewal capacity. More recent efforts, using modified growth factors combined with fibronectin or the recombinant fibronectin fragment retronectin have resulted in greatly improved levels of gene transfer and detection *in vivo*.[113,125]

It is possible to use the marker gene technique to evaluate whether any increase in progenitor cell numbers and transducibility produced by growth factor combinations and cell culture devices *ex vivo* has an effect *in vivo*. Once again, the use of two distinguishable vectors to mark each patient's marrow allows comparison of treatment regimens within a single patient, so that very small patient samples can be used to answer difficult study questions. This technique is also being used to compare peripheral blood- and marrow-derived progenitor cells for their relative ability to reconstitute hematopoiesis after BMT or other marrow ablative treatments.

### Safety of Gene Transfer in Pediatric Malignancy

Because most studies of pediatric malignancy have involved *ex vivo* gene transfer, concerns about direct vector-mediated toxicity are not as acute as in protocols in which vast numbers of vector particles are administered parenterally. To date, more than 200 patients have received genetically modified cells in clinical trials in pediatric disease, including more than 60 who have received genetically modified hemopoietic progenitor cells. With a maximum follow-up of 9 years, and a total patient follow-up of more than 250 patient years, no adverse events attributable to the gene transfer process have been identified. In particular, there has been no evidence of lymphoproliferative disorders. Of potential concern, however, are reports showing a cellular immune response directed against transferred gene products.[126] Clearly, if an immune response is regularly generated against the product of any transferred gene, the value of gene therapy would greatly diminish. Prolonged follow-up of patients receiving genetically modified cells is essential at this early stage of technology development.

## CONCLUSION

We have far to go before the extraordinary potential of gene transfer for therapy of pediatric malignancies can be fully exploited. However, it is important to remember that most advances in medicine proceed incrementally, and that gene transfer is already being used successfully to complement conventional therapies for malignant hematologic disorders. The benefits of this new technology can only increase as current limitations are progressively—albeit slowly—surmounted.

# CANCER CLINICAL TRIALS: DESIGN, CONDUCT, ANALYSIS, AND REPORTING

RICHARD S. UNGERLEIDER
SUSAN S. ELLENBERG
STACEY L. BERG

## INTRODUCTION

The major concern of pediatric oncologists is the cure of children with malignant diseases. The past four decades have witnessed a remarkable improvement in the life expectancy of children diagnosed with cancer, the cumulative result of many modest advances. Demonstration of the benefit of these advances relies on the systematic use of therapeutic clinical trials.

A clinical trial is an experiment that attempts to answer a medical question, most often about the effect of a therapeutic intervention on the outcome of a disease. The experiment is carried out under conditions determined in advance by the investigator, who uses a specified methodology to test a hypothesis. A valuable experiment is one that addresses a nontrivial question in a way that provides unambiguous, reliable, and easily interpreted results. This chapter discusses the requirements of a valuable clinical trial in terms of design, analysis, and subsequent reporting, with attention to the particular problems in applying clinical trial methodology to the study of pediatric cancer. Our intention is to provide information useful in mounting clinical trials and in reviewing the published efforts of other investigators.

The rationale for conducting clinical trials in pediatric oncology goes beyond the demonstrated utility of the therapeutic approach. It is based on the need to reach accurate conclusions about the benefit of toxic and expensive therapies. Nonexperimental research, in which reasoning rather than observation is used to reach conclusions, or flawed experimental research, in which the therapeutic intervention is inconsistent or uncontrolled, can severely restrict progress toward the cure of childhood cancer by erroneously supporting the value of what is actually useless or harmful treatment.

Cancer clinical trials are conventionally categorized into three types, derived from usage adopted by the National Cancer Institute (NCI) drug development program. [1] A phase I trial investigates the toxicities associated with a particular agent and determines the maximum tolerated dose (MTD) or the appropriate dose with a given schedule and route of administration for use during subsequent efficacy studies. [2] A phase II trial estimates the activity of the agent against individual tumor types. [3] A phase III trial assesses the activity of the agent in a comparative fashion, with reference to standard therapy or, in some cases, the natural history of the disease. [4] The application of these concepts now extends beyond new drug development to include the evaluation of any new therapeutic approach, but the progression (from assessment of toxicity through estimation of efficacy and establishment of superiority, equivalence, or inferiority through direct comparison) remains constant. When clinical trials are used to evaluate a treatment regimen rather than an individual agent, phases I and II are sometimes combined. These trials are referred to as *pilot studies*.[5]

## PLANNING A CLINICAL TRIAL

The process of planning a clinical trial culminates in the generation of a protocol, which is a written guide to the experiment to be conducted. As a procedural guide, the protocol helps to ensure that the investigation is carried out uniformly. An equally vital role is to encourage investigators to develop a precise, well-justified, and practical approach to the study. Adherence to the organizational requirements of a well-constructed protocol should guide the investigator through the planning process, so the resulting clinical trial is significant, feasible, and likely to provide a definitive answer to an important question.

An essential step in the design of the clinical trial is the approach to regulatory affairs. In the narrowest sense, this means attention to documentation of compliance with study requirements such as eligibility criteria, drug administration, laboratory and clinical follow-up, and response and toxicity measurement for each individual subject entered onto the trial. In a broader sense, regulatory affairs encompass the sponsors' and investigators' obligations to ensure that the conduct of the study falls within legal and ethical guidelines set forth by the relevant agencies [e.g., in the Good Clinical Practices Guidance document adopted by the U.S. Food and Drug Administration (FDA) as well as regulatory agencies in other countries]. [6] Although some regulatory activities, such as obtaining informed consent from subjects, do not take place until the clinical trial is activated, careful consideration of the requirements starting early in the trial design process may circumvent many difficulties and prevent frustrating delays in the initiation of the study.

The sponsor of a clinical trial may be the investigator initiating the trial, a pharmaceutical company, or an entity such as the NCI's Division of Cancer Treatment and Diagnosis. The sponsor is legally responsible for the overall conduct of the trial. Early in the design of the study, the sponsor must consider whether there are special regulatory requirements for the particular type of research in question. For example, if the trial involves an investigational agent, the sponsor must submit to the FDA an Investigational New Drug application. The Investigational New Drug application details the preclinical pharmacology and toxicology experience, the relevant manufacturing information, and details of the proposed clinical trial. The sponsor must allow 30 days after the Investigational New Drug application is submitted for the FDA to complete its safety review before initiating the clinical trial.

The sponsor of a protocol involving an investigational agent is also responsible for ensuring that individual investigators and participating institutions fulfill their regulatory responsibilities. All participating investigators must complete FDA Form 1572 documenting their qualifications as well as their agreement to conduct the study according to federal regulations. In addition, at each institution the investigators must obtain appropriate review of the protocol by an Institutional Review Board (IRB). The IRB's duty is to ensure that human subjects participating in clinical trials are protected from research-related risks. The philosophy behind such protection is stated in the Nuremberg Code, the Declaration of Helsinki, and the Belmont Report, and codified in the United States in federal law. [7,8,9,10,11] and [12] Central to the protection of human subjects is the concept of informed consent, which is discussed in detail in Chapter 48. In addition, the potential risks and benefits of the research

must be shared fairly among the general population (justice), the risks to the individual must be minimized and the benefits maximized (beneficence), and the rights of the individual to decide whether to assume research risks must be observed (respect for persons). Furthermore, because children are considered a highly vulnerable population, they are afforded additional protections, such as a requirement in most instances that they stand to have individual benefit from participating in research that exposes them to more than minimal risks. It is important to note that good scientific design of the clinical trial is an absolute requirement for protection of human subjects, not only because potential benefits will be maximized and risks minimized in a good trial but also because a poorly designed study that is unable to answer the research question cannot offer patients or society any benefit to offset the potential risk of participation.

Once the study is open, the sponsor and investigators are responsible for strict adherence to the principles of good study conduct. Both individual patient data, submitted on case report forms developed during the protocol design process, and periodic study summaries that review the overall status of the protocol are required. At a minimum, yearly review must be conducted by the IRBs at each participating institution. The sponsor must ensure that there has been compliance with the protocol requirements, that the data reported are accurate, and that all study procedures have been followed. For every subject entered on the trial, there must be documentation that diagnostic and eligibility criteria were met, study treatment was correctly administered, required observations were performed, appropriate endpoints were documented, adverse events were appropriately reported, and so forth. In particular, adverse event reporting to the appropriate regulatory bodies is an important part of every investigator's obligations, and the procedures for such reporting should be carefully outlined in the study protocol. The accuracy of data submitted on the case report forms for each subject is usually verified using audits of the medical records of some or all participating patients. Finally, compliance with study procedures ensures that appropriate IRB approvals, individual subjects' informed consent, and study drug accountability are all correctly documented. [13,14] Unavoidably, a certain tension exists between a clinical investigator's role as caregiver and as scientist, and between the study participant's role as patient and as research subject. Similarly, there is tension within our society between the desire to further scientific and medical understanding for the good of all, and the need to protect each individual's safety and autonomy above all else. Although it is unlikely that these tensions can be completely resolved, they can be minimized by scrupulous attention to regulatory requirements that are designed to promote responsible clinical research while protecting individual subjects from undue risk.

The components of a typical protocol are listed in Table 18-1. The eventual success of any clinical trial depends heavily on the care and skill devoted to the consideration of each of these items. Given the substantial time, effort, and expense required of collaborators and patients during the trial and the potential damage associated with an incorrect result, the responsibility of critical protocol development cannot be overemphasized. Proper attention to these requirements helps to maximize the value of the experiment and its probability of impacting the medical community.

**TABLE 18-1. TYPICAL PROTOCOL SECTIONS**

### Objectives

The first protocol requirement is a statement of objectives. This statement should be limited to the actual research question, such as, “in stage I Wilms' tumor, to determine whether 6 months of postoperative treatment with vincristine and dactinomycin (actinomycin D) results in event-free survival inferior to that observed with 15 months of vincristine and dactinomycin.” Less exact versions, such as, “to reduce the vicissitudes of treatment of Wilms' tumor,” should be avoided. The inability to set down a sharply defined objective is indicative of a poorly developed research plan, as is commonly seen when a patient management guide masquerades as a research protocol. A precise statement of the objective focuses the investigator on the conditions required to conduct the chosen experiment and allows him or her to assess the feasibility of the trial in terms of the available resources.

Of particular importance in pediatric clinical trials is the limiting of the number of study objectives, because the available patient population is not large enough to provide reliable answers to many experimental questions. The objectives should reflect the most important hypotheses that require evaluation, although this goal is not always possible to achieve. The restrictions imposed by limited numbers of patients often necessitate multi-institutional collaborations. Although such arrangements do increase patient availability, they often cause difficulty in arriving at a common research plan because of the multiplicity of opinions.

Investigators should select objectives that can provide useful information regardless of whether the study results are positive or negative. This end is possible when a biologic hypothesis is tested in a carefully controlled manner. [15]

### Background

The background section provides the underpinnings for the entire protocol by presenting the arguments for conducting the clinical trial and for selecting the specific experimental conditions enumerated in subsequent sections. As a crystallization of the thoughts that led to the proposal's existence, the background section should provide adequate justification for mounting what will be a difficult, time-consuming, and costly exercise. This section offers a review of the pertinent medical literature, presented in such a way as to convince the reader that the question is compelling, has not previously been answered, and can feasibly be addressed with existing resources. The plausibility of the hypothesis must be supported through documentation of its biologic or experimental basis. Information on prognostic factors pertinent to patient selection should be reviewed, and material relevant to design considerations should be included. Discussion of the significance of the proposed trial should be within the perspective provided by previous clinical trials. Background information for phase I protocols should include preclinical ( *in vitro* and animal) data and results of human trials with the experimental agent. The rationale for using the agent in children should be presented with justifications for the chosen schedule and starting dose.

Phase II protocols additionally should include a summary of available data on toxicity in adults and children and a justification of the choice of malignant diseases against which the agent will be assessed. Phase III protocols require extensive background sections that establish the basis and significance of the protocol within the framework of previously ascertained results.

### Patient Eligibility Criteria

The protocol should define the characteristics of the patient population to be studied, including factors such as diagnosis, extent of disease (stage), age restrictions, allowable prior therapy, physiologic and performance status, and any other conditions the investigator wishes to specify, such as the expression of particular biologic markers by malignant cells. In the United States, informed consent must be obtained from patients or parents (depending on patient age) to establish eligibility (see Chapter 48). The population defined by these criteria is the one to which the study results apply; thus, patient criteria must be carefully chosen and precisely defined.

Although the investigator may wish to restrict study entry to a homogeneous patient population, the realities of biologic variability preclude this possibility; until all factors affecting prognosis are elucidated, study populations will consist of mixtures of patient groups, each of which may behave differently under the conditions of the experiment. The relatively small number of pediatric patients available for clinical trials presents further problems, because overly restrictive criteria can yield insufficient entries to answer the study question. Frequently, determining the optimal balance is difficult.

Homogeneity of patients is more important in phase I and phase II studies, in which information about biologic activity is sought. Phase I protocols generally specify patients in whom conventional therapy has failed yet who have sufficiently intact organ function for accurate assessment of toxicity. Enough time (usually 2 to 4 weeks) should have elapsed since the most recent antitumor therapy to ensure that the short-term effects of that treatment have subsided. Patients with solid tumors

should not have bone marrow dysfunction, so toxic effects on normally functioning marrow can be assessed. This criterion does not apply to patients with leukemia. Patients with any histologic type of cancer are usually eligible for phase I studies, although patients with solid tumors and leukemia must be evaluated separately to determine the MTD.[2] Patients with leukemia commonly tolerate higher doses of myelosuppressive agents; moreover, marrow suppression is sought in leukemia patients but is avoided in patients with solid tumors.[4,16] Regardless of tumor type, life expectancy sufficient to permit assessment of drug-related effects should be specified.

Phase II studies are ideally conducted with previously untreated patients to avoid the problems of acquired drug resistance and diminished tolerance associated with prior treatment. Because most childhood cancers are potentially curable at diagnosis with conventional therapies, however, phase II studies in children generally specify that standard therapy must have failed in these patients. Phase II evaluation has been used increasingly before definitive therapy [17] (“experimental window,” “upfront phase II window”) for certain clinical situations, such as metastatic osteosarcoma, [18] unresectable rhabdomyosarcoma,[19] or disseminated neuroblastoma in children older than 1 year[20] in whom the outcome of conventional therapy has been unsatisfactory. Although the value of this approach in establishing reliable estimates of activity in high-risk situations is promising, [18] a clear concern is that delay in starting definitive therapy may compromise patient outcome if the agent used in the upfront window is inactive.[21,22] and [23] Proponents of the method counter that responses during phase III therapy in patients randomized to receive initial phase II therapy with an agent subsequently found to be inactive are similar to those seen in patients randomized to phase III therapy only.[20,24] Nevertheless, as the data cited by proponents are not definitive, consideration should be given to the possibility that patient outcome can be compromised if agents or combinations of agents are used in the upfront window in the absence of strong preclinical or clinical rationale for such evaluation. A meeting of clinicians, clinical researchers, patient advocates, and bioethicists in 1997 discussed these issues. Participants affirmed the need to ensure that patients and their parents are fully informed about the role and optional nature of upfront window research in the patient's overall treatment plan.[25]

Phase II protocols additionally specify histologic diagnoses acceptable for entry because the end point often depends on tumor type. Patients are also generally required to have measurable disease, so antitumor response can be reliably assessed.

In phase III studies, the issue of generalizability of results obtained in the study population to the affected population as a whole becomes more important. Despite (or perhaps because of) the rarity of cancer in children, NCI-supported pediatric clinical trials cooperative groups annually accrue more than one-half the eligible patient population, including those in racial and ethnic minorities. Because this large patient sample is representative of the affected population, the fundamental principle is to select patients with reasonable potential to show benefit, whether due to decreased toxicity or improved survival, from the experimental therapy. Patients whose prognosis is so good that therapy is unlikely to have an observable positive effect during the course of the study should be excluded. It is also appropriate to exclude patients with contraindications to any of the study treatments or those who have other serious conditions that may interfere with administration of therapy.

## Design

The design section of the protocol provides a brief overview of the study's structure and describes the methods by which the objectives are to be met. The minimum requirements for this section include the plans for patient allocation and the criteria by which the experimental effect is to be evaluated (i.e., study end points). In our previous example of a phase III clinical trial in stage I Wilms' tumor, in which the goal is to evaluate event-free survival, the design would specify that after surgical removal of the tumor and 6 months of adjuvant chemotherapy with vincristine and dactinomycin, patients would be randomly allocated to no further therapy or to an additional 9 months of chemotherapy, with tabulation of event-free survival times on both regimens.

### *Phase I Trials: Specific Designs*

A consensus guideline on the conduct of pediatric phase I trials has recently been published.[26] Phase I studies using children typically use a standardized design in which cohorts of three patients are treated with identical doses of the experimental agent and are then observed for acute toxicity. If none of the three patients experiences dose-limiting toxicity (DLT), the dose is escalated. At any dose level, when DLT is observed in one patient, the cohort is expanded to six patients. The MTD is defined as the dose level immediately below that at which two patients (in a cohort of three to six) experience DLT, and is usually also the recommended starting dose for phase II trials. If myelosuppression is the DLT, consideration is often given to enrolling patients with limited prior therapy onto the study, because an inappropriately low MTD may be defined if only heavily pretreated patients, who may tolerate therapy less well, are enrolled in the phase I trial.[27] Similarly, separate phase I trials of the same agent are usually conducted in patients with leukemia and with solid tumors, because more prolonged myelosuppression is acceptable in the treatment of hematologic compared with nonhematologic malignancies.

The starting dose for adult phase I trials is based on animal toxicology studies and generally is one-tenth the dose lethal to 10% of a cohort of mice, expressed in mg per $m^2$ (0.1 MELD10).[28] Stepwise dose increases are specified in the protocol. Often, a modified Fibonacci scheme is used to determine the escalations for successive cohorts.[29] The starting dose is increased by 100% in the first escalation, and subsequent doses are increased by adding 67%, 50%, 40%, and 33% of the dose established by the preceding cohort. The diminution of the escalations reflects increasing caution as one becomes farther removed from the starting dose. An alternate version of this scheme is to double the dose until “biologic activity,” such as mild myelosuppression, is observed, then to institute the diminishing escalations of the Fibonacci series.[30]

If data from phase I trials in adults are available, an efficient method is to start children's trials at 80% of the adult phase II dose, or at 80% of the dose at which biologic activity was observed in adults, bypassing levels that are presumably safe in children but are unlikely to be of benefit. In the absence of DLT, dose escalation should continue in children beyond the phase II dose established for adults, because children often display greater tolerance to chemotherapy, and the goal is to deliver the highest safe dose of a new agent in efficacy trials.[31] Starting doses derived from the adult MTD are presumably close to the childhood MTD, and escalation should proceed cautiously, using 30% increases over the preceding dose level.[31]

An alternative method for selecting the entry dose level and rate of escalation in phase I trials has been proposed by Collins and colleagues,[29,32] who advocate pharmacologic guidance based on preclinical toxicology in place of the empiric Fibonacci system. Although this method has been used by some investigators in phase I studies of new agents in adult patients, the value of this procedure in efficiently determining safe phase II doses for children remains to be determined.[33,34]

O'Quigley and colleagues[35,36] and [37] proposed a new approach to phase I studies in cancer aimed at moving to the MTD more quickly and thereby increasing both the efficiency of this early phase of development and the likelihood that patients treated in phase I will receive potentially beneficial treatment. This approach, the continual reassessment method, targets the dose to an “acceptable” toxicity level selected by the investigators. Bayesian methods are used to continually update the expected probability of toxicity based on the experience observed up to that point in the study. The continual reassessment method has been criticized on the grounds that it may lead too frequently to treatment at unacceptably toxic levels and may in many cases lead to longer phase I trials.[38,39] Modifications of the method that address these difficulties have been proposed.[39,40]

The current explosion in information about the molecular mechanisms underlying many malignancies is likely to result in an ever-increasing number of specifically targeted agents being brought into the clinic. Because most pediatric tumors are biologically distinct from adult tumors, some agents will be designed only for the treatment of pediatric cancers so that phase I trials of those agents in children must be conducted without prior information from adult studies. Furthermore, the appropriate phase I end point for such agents may be the determination of the dose that produces the optimal desired host response (the optimal biologic dose), rather than the MTD, for use in phase II studies of the agent.[41] Thus, the requirement for innovative strategies in pediatric phase I trial design is likely to increase as biologically targeted therapy becomes more common.

### *Phase II Trials: Specific Designs*

The conventional objective of phase II trials is to determine whether a new agent or treatment strategy appears sufficiently active to warrant further study. Activity is usually defined by objective tumor responses, although laboratory end points, such as immune parameters and cytogenetic normalization, are of increasing interest because of the advances in understanding of the malignant process. It is generally desirable to limit phase II studies to small numbers of patients to permit testing of the maximum number of agents or programs that require evaluation. Sample sizes for phase II studies have traditionally been set at 25 to 40 patients, but these numbers do not permit accurate estimation of tumor response rate. For example, if five responses are observed in 25 patients, the 90% confidence interval around the observed rate of 20% is [10%, 36%]. With 40 patients and eight responses, the 90% confidence interval around the same observed rate of 20% is [11%, 31%], narrower but still too wide to permit reliable distinction between uninteresting and moderate levels of activity. Thus, typical designs have been geared toward

identifying regimens whose response rates appear consistent with interesting levels of activity, rather than obtaining accurate estimates of response rates.

The simplest and perhaps most widely used phase II design was suggested by Gehan in 1961.[42] Gehan proposed a two-stage design, with the sample size in the first stage dependent on the minimum response rate of interest and the total sample size dependent on the expected variability of the estimate of the response rate (i.e., standard error). A sample size of 25 patients produces an estimate of response rate with a standard error no greater than 10%. The purpose of the two-stage design is to permit early termination if the activity level observed is clearly inconsistent with the minimum level of interest. For example, in a disease for which many agents are reasonably active, a new agent may be of interest only if it is associated with a true response rate of 25% or more. If this agent is given to 11 consecutive patients without a response, one would probably want to discontinue its use because a drug with a "true" 25% response rate would produce such a negative result less than 5% of the time. In a clinical situation for which few active agents have been identified, the threshold response rate of interest may be as low as 15% or even 10%. Table 18-2 shows the required first-stage sample size for different response rates. The total sample size should be at least 25, and larger samples are needed if small response rates are of interest.

| Minimal response rate of interest (%) | First-stage sample size[a] |
|---|---|
| 5 | 59 |
| 10 | 29 |
| 15 | 19 |
| 20 | 14 |
| 25 | 11 |
| 30 | 9 |
| 40 | 6 |
| 50 | 5 |

[a]If no responses are observed in these patients, the trial may be terminated with the conclusion that the true response rate is unlikely to be at or above the specified minimal level. If any responses are observed, additional patients are accrued.

**TABLE 18-2. FIRST-STAGE SAMPLE SIZES FOR GEHAN PHASE II TRIAL DESIGN**

Multistage phase II designs have been proposed as a means to improve the efficiency of phase II studies and to minimize the number of patients treated with inactive therapy. The Fleming design uses two or more stages and allows termination at any stage when the activity level appears too low or is sufficiently high to support moving to Phase III.[43] Chang and associates[44] and Simon[45] developed optimization strategies for the multistage Fleming-type designs in which sample size is minimized under specific conditions. Ensign and colleagues [46] provided a modification of Simon's approach for optimal designs by incorporating an initial stage after which the study would be terminated if no responses were observed, a feature of Gehan's original design for phase II studies. Zee and co-workers [47] developed a multi-stage procedure that considers early disease progression in addition to response as a primary end point and basis for decision making.

Other approaches to phase II trials have been described. Herson's design incorporates prior information about therapeutic efficacy into the decision rules. [48] Thall and Simon's[49] proposed Bayesian approach to phase II trials similarly incorporates prior information and continually updates the probability of response based on the accumulating observations. In this approach, sample size is not fixed; the trial continues until the probability of response is either high enough or low enough to warrant a decision regarding the desirability for further study of the agent or until a prespecified maximum study size is obtained. Sylvester and Staquet [50] and Sylvester[51] took a decision-theoretical approach, incorporating financial and ethical costs associated with making incorrect decisions about treatment efficacy and information available from earlier studies. Lee and co-workers [52] proposed a design that allows an inconclusive result as well as "positive" and "negative" outcomes.

If patient accrual is expected to be rapid and if multiple new agents are available for study, a randomized phase II design, as discussed by Simon and associates, [53] has some advantages over the sequential study of one treatment arm at a time. A randomized phase II study is simply the simultaneous implementation of two or more phase II studies with randomized assignment to the investigational agents. It does not permit formal statistical comparisons among the arms because sample sizes are too small for such comparisons to be done reliably. The randomization does ensure that no systematic bias is operating in the selection of study patients to receive each treatment, however. Thus, results from a randomized phase II study can be more reliably ordered in setting priorities for future studies than can results from sequentially conducted studies, in which patient selection patterns may have differed.

### *Phase III Trials*

#### Eligibility and Choice of Controls

Phase III trials compare the efficacy of an experimental therapy with that of a standard or control therapy. Because these trials are intended to determine definitively whether a new therapeutic strategy should be adopted, the design must be precise enough to avoid false-positive and false-negative results. In the study of pediatric cancer, phase III trials are usually feasible only in cooperative group or multicenter settings because of the relative scarcity of patients.

Investigators have debated issues relating to acceptable control groups for phase III studies. The optimal approach is a two-arm study, in which one group of patients receives standard therapy and the other receives experimental therapy. Alternatively, all patients can be treated with the experimental therapy, with results eventually compared with those achieved with a previous group of patients given what is currently considered standard therapy. This use of historical controls appeals to many physicians because it sharply reduces the number of patients required for study and because a nonrandomized study in which all patients receive the same therapy is easier to explain to potential subjects. These studies are inherently unreliable, however, because they have no protection against the possibility that different types of patients are treated with the two therapies.

As an example, suppose standard therapy for a particular category of patients is purely palliative, and a new, potentially curative therapy is being tried for these patients. The investigators elect to treat a series of patients with the new therapy and then compare the survival of these patients with that of a historical series treated with the palliative therapy. Several clear sources of potential bias exist in this situation. First, eligibility criteria are established for patients receiving the new therapy. Patients who appear close to death, who show evidence of organ dysfunction, who have received intensive prior therapy, or who refuse consent may not be treated with the new therapy. The historical series may not have been constructed with these (or any) eligibility criteria and thus may include some patients with an extremely poor prognosis who are not comparable with any patients treated with the new therapy. (Even if the same eligibility criteria are applied, changes in diagnostic techniques may affect patient selection.) Second, some patients considered for the new therapy meet the eligibility criteria but, for one reason or another, are not entered on the study. Perhaps these patients appear to be in worse condition than the required tests indicate; perhaps investigators are reluctant to enter infants, although these patients are technically eligible; perhaps the new therapy is expensive (e.g., bone marrow transplant), and only affluent patients are ultimately entered. Certain types of patients may then appear in different proportions in the historical and the experimental series. The comparison of survival or other outcome between these two series of patients is likely to be heavily biased if such patient characteristics are correlated with prognosis. Third, changes in supportive care procedures may improve survival apart from any fundamental population differences, and there is no way to adjust for this type of effect.

Thus, if differences in outcome are found [e.g., if the average survival with the experimental therapy is substantially longer than with the palliative (historical control) therapy] investigators will find it difficult to know how much of the difference to attribute to the new treatment and how much to attribute to fundamental variations in the patient populations or to changes in diagnostic techniques or supportive care. Although the statistical methods to "adjust" comparisons for some of these differences have been developed and are useful in many situations, one cannot measure and record all patient characteristics that affect prognosis. Many such characteristics undoubtedly remain to be identified. Thus, observed differences in outcome in historically controlled studies are always potentially attributable, to some extent, to causes that are not related to treatment and are always suspect. Such concerns are even more severe for comparisons made from databases in which patients were never treated on any protocol but received a regimen decided on by their physicians and themselves.

The most reliable way to generate unbiased comparisons between treatments is to allocate patients to treatment arms by randomization. A randomized trial is unquestionably the procedure of choice for the definitive evaluation of an experimental therapy. Large randomized studies do not always seem feasible, but they can sometimes be made feasible if investigators pool their efforts and develop a cooperative trial. Occasionally, even the multicenter approach is unsuitable. For example, relatively few cases of nonmetastatic medulloblastoma are diagnosed in toddlers each year, and a randomized trial using this patient population is probably

unrealistic. In these patients, a carefully done historically controlled trial, however imperfect, may be the only way to evaluate a new therapy.

### Sample Size

The required sample size for a randomized phase III study depends on (a) the minimum difference in outcome considered important to detect, (b) the levels of type I and type II errors considered acceptable, and (c) the expected outcome with standard therapy. Type I (a) error is the conclusion that the new treatment is better than the standard treatment when in fact it is not. The probability of a type I error is the significance level ( *p*) of the experiment and is denoted by a. Type II (b) error is the failure to conclude that the new treatment is superior to the standard when it actually is. The probability of a type II error is denoted by b; its complement (1-b) is called the *power* of the experiment.

The interpretation of the type I error depends on whether the test performed is “one-sided” or “two-sided.” A one-sided test considers differences in only one direction. For example, if treatments A and B are compared, a one-sided test will permit only two conclusions: A is better than B, or A is not better than B. A two-sided test permits a third conclusion: A is worse than B. Because a two-sided test allows for type I errors in both directions, a larger sample size is required to restrict the overall type I error to the desired level. Defining situations in which one-sided tests are appropriate is controversial. Some researchers maintain that such tests should not be used unless a difference in one direction is actually impossible; other researchers use one-sided tests whenever the expectation is clearly in one direction. Therefore, the investigators must specify *p* values as one-sided or two-sided, so readers can make their own interpretations of the degree of significance.

The specifics of the sample size calculation also depend on the type of end point of primary interest. A complete discussion of sample size determination for binary end points (e.g., yes or no variables, such as response) and extensive tabulations of sample size requirements according to the foregoing parameters were published by Fleiss.[54] Sample size considerations for time variables (e.g., survival time and remission duration) are discussed by George and Desu [55] and by Rubinstein and colleagues.[56] Both reports deal with the problem of “censored data”—survival times for patients who remain alive at the time of study reporting. These methods assume that the risk of an adverse event, such as death or relapse, is constant over time for any given patient, however. In many instances, particularly with pediatric tumors, a substantial cure rate can be anticipated, so the risk of recurrence should essentially disappear once a patient has been event-free for a certain period. Sposto and Sather developed methods for determining sample sizes in this situation. [57] Detailed expositions of general issues in sample size determination are given by Lachin,[58] Lachin and Foulkes,[59] Donner,[60] and Ellenberg.[61]

Conventionally, the type I error for testing results from phase III studies is set at 5%, and the type II error is set between 10% and 20%. This is done because incorrectly abandoning a standard treatment, with which investigators may have extensive experience, is considered a more serious error than failing to identify an experimental treatment that affords a moderate advantage. In general, the relative seriousness of the two types of error depends in part on characteristics of the treatments other than efficacy. A small a relative to b is appropriate if the experimental therapy is highly toxic, logistically difficult (e.g., requiring extensive hospitalization or multiple clinic visits), or very costly, whereas the standard therapy is relatively benign, simple, and inexpensive. In other circumstances, it may be more appropriate to set a and b more nearly equal. For example, if the new therapy is less intensive than the standard, the new therapy should be adopted only if it has not led to a worse outcome on average. In this case, one would worry as much if not more about failing to detect reduced efficacy than about falsely concluding that the standard, more intensive therapy was superior.

The size of the difference one is interested in detecting must be carefully considered, because the required sample size is extremely sensitive to this difference. For example, if one wanted to be 80% certain of observing a statistically significant ( $p < .05$) difference in event rates associated with two therapies when the true event rates were 20% and 40%, 91 patients per arm would be required. For event rates of 20% and 30%, however, the required sample size would be 313 per arm, and for rates of 20% and 25%, 1,134 per arm. Thus, detection of small differences, although possibly desirable, is not an achievable goal for most pediatric studies. On the other hand, the specified difference must be small enough so that a study resulting in “no statistically significant difference” is convincingly negative. If a study enters only enough patients to detect large differences reliably, smaller differences that may be clinically meaningful are unlikely to produce statistically significant results.

As an example, consider the hypothetical data in Table 18-3. The difference in complete response rates appears impressive: 50% versus 30%. The *p* value for this difference is .147, however, meaning that the probability of observing a difference at least this great if the two treatments were truly equivalent is 14.7%, which is suggestive but far from conventional significance. These data would be considered inconclusive. The observed difference is too large to conclude comfortably that the two drugs are equivalent, but the numbers are too small to exclude chance as the basis for the difference.

| | Treatment | |
|---|---|---|
| Complete response | Drug A | Drug B |
| Yes | 15 (50%) | 9 (30%) |
| No | 15 | 21 |
| Total patients | 30 | 30 |

**TABLE 18-3. HYPOTHETIC PHASE III TRIAL DATA**

## *Specialized Designs for Randomized Clinical Trials*

### Sequential Designs

A sequential design is one in which the total sample size is not fixed at the beginning but depends instead on the data accumulated as the trial progresses. Historically, the motivation for the use of sequential designs was the desire for efficiency, achieved by terminating an experiment as soon as the answer is “known.” In the context of clinical trials, the motivation is primarily ethical. If early results indicate that one treatment is producing substantially improved outcomes, it becomes difficult to justify the continued randomization of patients to the study. The application of simple monitoring plans, such as stopping the study as soon as the *p* value reaches .05, however, has been shown to lead to a far greater frequency of type I errors (false-positives) than the nominal .05 level would indicate. For example, McPherson[62] points out that if the data are reviewed ten times during the course of a study in which the true efficacies of the treatments are identical, the probability of observing a *p* value of .05 or less at least once is approximately 20%. Thus, the true type I error in this context is actually 0.20, not 0.05. The type I error increases with more frequent interim monitoring.

To deal with the problem of inflating type I errors by frequent evaluation of study results, several different approaches have been developed. All require the use of more stringent significance criteria than the usual 0.05 level. The most practical of these approaches are called *group sequential designs* because they are based on analysis of data at regular intervals, often semiannually, as groups of data are accumulated. The basis for these designs is that one must try to compensate for the extra opportunities to declare significance (and possibly make a type I error) by reducing the significance level of each test so, over the entire course of the trial, the probability of type I error remains at 5%. The most widely used design was proposed by O'Brien and Fleming. [63] Their method uses a sequence of *p* values for successive analyses: the first is exceptionally small, with the remainder gradually increasing so the final *p* value is close to the conventional level (typically .05). Other approaches are described by Pocock,[64,65] and Fleming and co-workers.[66]

Lan and DeMets[67] showed that the O'Brien-Fleming approach could be made more flexible by introducing a “use function” that specifies how rapidly the type I error may be used up, but it does not require prior specification of the total number of monitoring times or the intervals between these times. More recent work by these authors indicates that when the pattern of interim review changes as a direct result of the observed data, the overall type I error is affected, but the effect is small. [68] Jennison and Turnbull[69,70] and [71] developed a sequential design based on repeated confidence intervals. This approach is appealing because it provides more

information about the possible treatment effect than does a simple *p* value.

These designs allow for the possibility of early termination only if one treatment appears markedly superior to the other. It is frequently the case, however, that as the data accumulate, the experimental treatment appears no better (or perhaps even somewhat worse) than the standard. Just as an intuitive but nonrigorous approach to early termination because of large differences inflates the type I error, [69,70] and [71] such an approach in the face of small or no differences can inflate the type II error. Some designs allow early termination of apparently negative trials while maintaining high power to detect reasonable differences if they do exist. DeMets and Ware [72] proposed an asymmetric design that allows early trial termination not only when the experimental therapy offers large advantages but also when the new therapy appears equivalent to or worse than the standard. Whitehead and Stratton [73] developed a design based on similar considerations. Ellenberg and Eisenberger [74] showed that a two-stage design in which the study is terminated with a negative conclusion if the experimental therapy is producing outcomes equivalent to or worse than the standard therapy at the end of the first stage affects power only minimally. This type of design was further studied by Wieand and Therneau, [75] who determined the sample sizes required to maintain power at the nominal levels, and by Thall and co-workers, [76] who investigated optimal relative sizes for the two stages.

Sequential designs are desirable because they permit valid interpretation of significance levels even though a trial does not complete its full accrual. Their impact may differ depending on the particular clinical trial situations. When observation of the end point may be substantially delayed (e.g., survival time is the outcome of interest and average survival time is a year or more from study entry), a sequential design may not affect patient accrual, which may be almost complete by the time sufficient events have been observed to justify an interim analysis. Nevertheless, a sequential approach may permit earlier dissemination of study results, which may affect treatment decisions for others. For trials studying varying durations of therapy, earlier availability of results may also affect the treatment of patients in the trial itself.

### Factorial Designs

In a factorial design, two or more questions are addressed in the same cohort of patients by multiple randomization. For example, if a surgical question and an adjuvant chemotherapy question are of interest in a given population, a double randomization allocates the patients to treatment as shown in Table 18-4.

| Adjuvant therapy | Surgical technique A | Surgical technique B | |
|---|---|---|---|
| Therapy A | n/4 | n/4 | n/2 |
| Therapy B | n/4 | n/4 | n/2 |
| Total | n/2 | n/2 | n |

**TABLE 18-4. FACTORIAL DESIGN FOR RANDOMIZED CLINICAL TRIAL**

In Table 18-4, n is the total number of patients to be studied. If the effect of each factor can be considered to operate independently of the other (i.e., the difference in efficacy of the adjuvant therapy regimens does not depend on which surgical technique is used and vice versa), each question can be evaluated by collapsing over the categories of the other question. Thus, the n patients accrued may be used to evaluate two maneuvers rather than one. Factorial designs can improve the efficiency of clinical trials in situations in which the assumption of independent effects is reasonable. This assumption must be carefully considered; if the data cast doubt on its validity, categories are not collapsible, and the power of the study to detect differences is drastically reduced. If one of the maneuvers to be tested affects the administration of the other (e.g., if both questions involve cytotoxic drugs, and the doses may vary among the four possible combinations), the assumption of independence is clearly violated, and a factorial design is not appropriate. An example of factorial design is the National Wilms' Tumor Study III, in which early stage patients were randomized between postoperative radiotherapy and no postoperative radiotherapy and also between two different chemotherapy regimens. [77] Another example is a study of adjuvant therapy for colon cancer, in which patients were randomized to receive or not receive chemotherapy and to receive or not receive immunotherapy.[78] Various aspects of factorial designs are discussed by Byar and Piantadosi [79] and by Brittain and Wittes. [80]

### Equivalence Trials

An equivalence trial (sometimes called a *noninferiority trial*) is a phase III trial whose purpose is to demonstrate that a new treatment is no less efficacious than a standard treatment. This is important if the new treatment is clearly more desirable than the standard in some other way (e.g., less toxic, less invasive, less expensive, or more convenient). In such a case, one would prefer the new treatment as long as efficacy was not reduced.

The essential difference between an equivalence study and other clinical trials is that in an equivalence study, one is hoping to conclude that the two treatments are equally efficacious, but in the typical clinical trial, one is hoping to show that one treatment is more efficacious than the other. Enough patients must be entered into an equivalence study to demonstrate that a negative result is convincingly negative. A result of “no significant difference” is not sufficient, because one can easily assure such a result by designing a study too small to detect a credible potential effect. In general, for these types of studies, the preferred design is one in which the minimal difference of interest (usually denoted as d) is specified as the drug effect under the null hypothesis, and the alternative hypothesis is that there is no difference. Thus, the treatments cannot be accepted as equivalent unless one can rule out with high probability that the difference in effect is no greater than d. Sample sizes for equivalence trials are usually larger than those in difference-seeking trials to protect against adopting new approaches that are less efficacious than current practices. In circumstances in which a positive effect has not been documented for either treatment, or effects are not consistently seen or vary widely in size, an equivalence study will usually not be informative. [81,82] and [83] Sample size considerations for equivalence studies are discussed by Makuch and Simon [84] and Blackwelder.[85]

### Treatment Plan

The treatments to be delivered on protocol should be precisely and thoroughly defined to promote uniformity of conditions throughout the experiment. Variations in therapeutic intervention can reduce or destroy the interpretability of the results. All aspects of therapy should be set forth, including surgical procedures to be used and supportive care guidelines. Provisions for treatment modifications in the event of toxicity should be specified. In complex protocols, a scheme that shows the temporal relationships of chemotherapy and other treatment modalities from study entry through various treatment phases (e.g., induction, consolidation, or maintenance) to discontinuation of therapy is particularly useful. Schematics quickly convey information to medical personnel not directly involved in the development of the protocol. For the patient's safety, however, schematics must accurately and unambiguously describe medication prescriptions to those individuals actually delivering patient care.

### Drug Information

The drug information section serves as a reference for participants by supplying specifics about the mechanism of action, animal and human toxicology data, and pharmaceutical information for each of the drugs used in the clinical trial. This information is included to ensure consistency of preparation and administration of drugs by the various house staff, nurses, and pharmacists who are responsible for these activities, and it is an important quality control and safety measure. The protocol is often the only source of information for investigational drugs, which are not included in standard pharmaceutical references.

### Criteria for Evaluating Treatment Effect

The parameters for assessing the effects of treatment on individual patients are generally referred to as *end points*. An end point is a medical event that may represent benefit (e.g., complete remission) or harm (e.g., relapse, death). The results of the clinical trial are based on analyses of the accumulation of end point assessments, the criteria for which were predetermined by the investigator. A well-constructed protocol incorporates end points that are objective, practical, and

relevant to the clinical situation under study. By defining end points, the researcher indicates precisely which measures of treatment outcome reliably meet the objectives of the protocol. These objectives assist in clarifying what clinical and laboratory data need to be obtained during the trial and provide the basis for statistical analysis.

In phase I trials of classic cytotoxic agents, the end points are the degree and duration of changes in organ function after exposure to the experimental agent. It is useful to include in this section of the protocol a table that defines increasing degrees of toxicity for various organ systems and indicates the level of toxicity that is deemed unacceptable. In the interest of standardized reporting as well as accuracy, precision, and completeness, the NCI Common Toxicity Criteria version 2.0 should be used.[86] Phase I trials of newer anticancer agents that are intended to modulate or inhibit a specific cellular target associated with the malignant state may not require escalation to DLT, as the optimally effective dose may be significantly lower than the MTD for normal tissues. For these trials, end points are related to assessment of the specific modulation or inhibition being sought.

Phase II end points (and subsidiary phase I end points) are concerned with the evidence for and duration of response to the investigational agent. Complete response has been widely defined as the total disappearance of all clinically detectable malignant disease for at least 4 weeks, and partial response as a 50% or greater decrease in the sum of the products of the longest perpendicular diameters of all measurable lesions, with no increase in size of any lesions and no appearance of new lesions. Progressive disease denotes appearance of new lesions or enlargement of existing ones. [87] It has been suggested that response assessment might be derived from unidimensional tumor measurements instead of the conventional bidimensional method. [88] This concept has been incorporated into the new Response Evaluation Criteria in Solid Tumors guidelines in an attempt to simplify and standardize phase II methodology. [89]

In phase III trials, in which an untoward event (e.g., death, progression, or relapse) is the end point of interest, investigators generally find it useful not only to tabulate how many patients experienced that event but also to measure the time elapsed from entry to end point. This calculation provides a more sensitive basis for comparing the therapies because additional information is incorporated into the analysis. [90]

Because untreated malignancies are almost always fatal, the ultimate merit of a therapy resides in its ability to prevent the patient's death. Thus, a variable of unarguable interest is survival time; this end point, however, is often an impractical basis for evaluating treatment because death from disease may be considerably removed from the onset of therapy, and results of the trial may be correspondingly influenced by intervening events. Alternative end points are often chosen that are presumed to be early signals of long-term survival, such as the disappearance of detectable tumor or the absence of metastases at 3 years. These alternative end points may not always reflect survival, however, as when salvage therapies are effective despite prior treatment failure; the influence of an adverse outcome during the first treatment is abrogated by the successful second treatment. Demonstration of patient benefit in terms of survival is hampered not only by the logistics of follow-up but also by problems in analysis introduced when subsequent therapies are not uniform.

Because of the problems alluded to in the preceding paragraph, an end point widely used in trials of childhood malignancies is event-free survival. An *event* is defined by Mastrangelo and associates[91] as “the first occurrence of the major events that represent initial treatment failure: failure to achieve remission (i.e., death in the induction period or nonresponse), relapse at any site after achieving remission, and death in remission without preceding relapse.” This end point, also called *failure-free survival* or *time to first event*, is meaningful for studies in any disease population, but it is especially appropriate for trials in which most patients achieve remission and many achieve long-term survival. Mastrangelo and co-workers[91] urged that event-free survival always be evaluated in studies of pediatric acute lymphoblastic leukemia, along with any other end points believed to be of interest, to enhance the comparability of study results in this population.

Ancillary end points may pertain to quality of life; these are frequently highly subjective and are not easily quantified. An excellent review of methodologic issues in assessing these end points is given by Aaronson, [92] Testa and Simonson,[93] and, from a statistical perspective, by Cox and colleagues[94]; an overview of issues in the specific context of cancer trials is presented by Aaronson.[95] Increasingly important in studies of children are end points regarding adverse effects of treatment, such as the occurrence of second malignancies, growth disturbances, and neuropsychologic impairment attributed to therapy. [96,97,98 and 99]

**Clinical and Laboratory Data to Be Accessioned**

The data set required for determination of eligibility and evaluation of treatment effect must be presented in the protocol. This set includes pretreatment, on-treatment, and posttreatment evaluations, indicating specific clinical and laboratory assessments and their timing. These schedules are often presented in tabular form. In comparative trials, the frequency and nature of these assessments must be identical for the regimens being compared to avoid an unbalanced increase in the likelihood of detecting real or chance differences resulting from disparities in medical surveillance.

Clinical trials are also used to provide systematic information about the natural history of the disease independent of therapeutic intervention. [90] For example, patient characteristics are recorded at presentation and are subsequently correlated with outcome. The details of acquiring such data should be included in this section of the protocol.

**Statistical Considerations**

Statistical considerations for each objective of the study are included in the protocol. The estimated number of patients required for assessment of the primary and secondary end points, the anticipated rate of patient accrual, and the expected duration of the trial (including follow-up) are given along with the description of the proposed analysis of outcome data. In planning the study, the availability of patients should be documented whenever possible to determine whether study objectives are realistic. Documentation may be based on accruals to previous protocols for a similar patient population or on data from surveys of collaborating institutions that established the frequency of the required patient characteristics. Conducting a study that accrues too few patients and thereby provides uninterpretable results is a major waste of resources and is inappropriate from the perspective of a patient who agrees to participate on the understanding that the study will provide useful information. Similarly, accruing more patients than are necessary to provide accurate results may lead to patients being subjected unnecessarily to procedures not part of normal care and is also clearly a waste of resources. The central nature of these considerations necessitates close collaboration with experienced biomedical statisticians from the outset.[100]

**Informed Consent**

All research projects that involve human subjects and are conducted or supported in part or entirely by the U.S. Department of Health and Human Services are subject to regulations regarding the protection of those subjects (see Chapter 48).[10] The Office for Human Subjects Protection, formerly the Office for Protection from Research Risk, is the government agency charged with ensuring that all research is conducted according to these regulations.

Documentation that research subjects have given prior informed consent to participate is an absolute requirement of cancer clinical trials supported by federal funds. The federally required elements of informed consent are presented in Table 18-5 in the checklist format used by NCI staff to evaluate these documents.[13] In addition, templates containing these elements are available at the NCI's CancerTrials website. [101,102]

**TABLE 18-5. INFORMED CONSENT CHECKLIST: REQUIRED ELEMENTS**

Every clinical trial should include a sample informed consent document, which can be reviewed by the NCI or other appropriate agency for completeness and also can be used by individual sites in a multicenter trial to construct the consent document to be used at that institution. The local version of the consent should not differ substantially from the sample document and must contain all federally required elements.

Federal law prescribes additional protections specifically for children who are subjects of clinical research. [103] Children are defined as persons who have not reached the legal age of consent to treatments or procedures involved in the research; legal age is determined by the applicable law of the jurisdiction in which the research is conducted. Informed consent must be obtained from the parent or guardian before research procedures can begin. The informed consent of one parent is usually adequate if the child is being enrolled onto a study from which he or she may receive direct benefit from the research, such as in a therapeutic trial. In addition to the informed consent of the parent, investigators wishing to enroll children onto clinical trials must obtain assent from the child in a manner appropriate for the child's age. Although the process of obtaining informed consent can be difficult and time consuming, it is critical to the ethical conduct of clinical research.

## MANAGING THE CLINICAL TRIAL

### Registration

Every study patient should be formally registered as a study participant before receiving any protocol-directed intervention. Registration for a nonrandomized study simply refers to the entry of a patient's name or hospital number into a paper or computer log. Pretreatment registration ensures that all patients who begin treatment can be identified for reporting purposes at the end of the study. In addition, the process of registration can be used to verify that the patient meets the eligibility criteria. Registration is important, even in studies conducted within a single institution, as a quality control measure to prevent the inadvertent loss of “problem patients” (e.g., early deaths and disease progressions or refusals of further treatment after minimal therapy) from the reporting process. In randomized studies, the process of randomization usually ensures the recording of all patients entering the study. Studies in which randomization follows an interval during which all patients are treated uniformly (e.g., a study of maintenance therapy in which all patients receive the same induction therapy) should require registration before the initial treatment interval to identify any selection patterns that may affect the generalizability of trial results.

### Randomization

The purpose of randomization is to avoid systematic bias in the allocation of patients to treatment in comparative trials. A *bias* is the effect on a study result of some systematic aspect of study design, data collection, or analysis that is unrelated to the actual effect of the treatment under study. For example, a comparison of a medical treatment with a surgical procedure in which treatment assignment depends on a patient's health status (e.g., patients who receive medical treatment are those whose poor condition precludes surgical procedures) is biased. The surgically treated patients are in better shape from the beginning; if their outcomes are better, one has no way to know how much of this superiority is attributable to treatment. This may seem an extreme and obvious example of bias that can be avoided by randomizing patients to treatment. Bias can find its way into even the most meticulously randomized trial, however.

Bias will almost surely be introduced if an investigator knows the next treatment assignment before deciding whether to offer participation in the study to the next available patient. It is important, then, to select a method of randomization that does not permit prediction of treatment assignments. Ad hoc methods, such as assigning alternate patients to each of two treatment groups or assigning patients on the basis of birth date (e.g., odd numbers assigned to one group, even numbers to the other), do not provide adequate protection against predictability and should be avoided. [104]

Perhaps the most widely used mechanism is the random number table in published form or generated by a computer program. In using a published table, one begins at some “randomly chosen” entry in the table and uses the sequence of numbers beginning with that entry to determine successive treatment assignments. For example, in the case of two treatment groups, the parity of the number (odd or even) can determine the associated treatment assignments. Alternatively, computer programs that generate series of random numbers may be used to generate treatment assignment lists, which must not be accessible to physicians participating in the trial. (Computer-generated random numbers cannot be said to be truly random, because they eventually repeat. The number of patients on any given trial is small compared with the cycle of repetition, however, making computer-generated numbers acceptably random for practical purposes.)

When subgroups of patients with identifiably different prognoses are studied in the same trial, a stratified randomization plan may be considered. The purpose of stratification is to ensure that patients with a better or worse prognosis are not overrepresented in a particular treatment group. The simplest way to stratify at randomization is to generate a separate allocation list for each subgroup. Thus, if three factors, each with two possible levels, are used for stratification, one needs eight separate lists, one for each possible combination of factor levels. An alternative method involves determining for each new patient the treatment allocation that will result in the best overall “balance” of factors of interest. Patients are directly assigned to a treatment (deterministic method) or are assigned to treatment by a random mechanism that yields a high probability (but not 100%) that they will be allocated to the treatment resulting in the best balance (random method). Detailed calculations are required to determine the balance for each possible allocation; a computer program is the only practical method when more than two or three stratification factors are used. This method of treatment assignment, usually referred to as *adaptive allocation*, has become popular in multicenter trials despite its complexity. Adaptive allocation methods have been described in several reports. [105,106,107 and 108] Deterministic adaptive allocation is not actually a form of randomization because the allocation is determined by the distribution of prognostic factors for the new patient and for the series of patients already entered. Nevertheless, the allocation is, for all practical purposes, not predictable because of the complexity of the required calculations, and it may generally be considered an unbiased allocation, even though it is not strictly random.

To protect the validity of randomization, investigators must establish procedures that are not susceptible to “tampering.” Envelope randomization is less desirable than telephone randomization, for example, because envelopes can be opened and resealed, and the decision to randomize or not to randomize a patient may depend on the contents of the envelope. A randomization list, monitored by a central data manager or a randomization clerk and accessible only in response to a request to randomize a specifically named patient, provides greater security.

The timing of randomization is important. Patients should generally be randomized as close in time as possible to the point at which the treatment programs to be compared actually begin. When a substantial interval occurs between randomization and initiation of the treatment to which the patient was randomized, some patients do not receive the assigned treatment. Some change their minds; some experience changes in status, making the treatment no longer appropriate; and some die. If these patients are included in the analysis, the comparison will be diluted because some patients will not receive the assigned treatment. Their exclusion, however, can introduce bias if the nondelivery of treatment is related to the treatment assigned. For example, patients with poorer prognoses may be more likely to refuse or to become unable to tolerate the more intensive treatment. This issue is especially problematic in studies of maintenance therapy, in which all patients receive the same induction therapy; the induction interval may be as long as 4 months, and many patients may never enter the maintenance phase because they die, their disease progresses, or some other circumstance intervenes. To avoid serious problems in analyzing and interpreting the study data, the preferred procedure is to register patients before induction therapy and to explain that randomization to maintenance therapy will occur in the future. Informed consent, followed by randomization, takes place only after successful completion of induction. Some patients may refuse randomization at this time, but the analysis of all who do agree to participate is unaffected by the problems delineated earlier.

The randomized consent design proposed by Zelen [109,110 and 111] provides for randomization before informed consent, so patients approached to participate in a trial are told what their treatment assignment is. Patients who refuse the allocated treatment are still followed and analyzed as part of that treatment arm. This design was motivated by the belief that providing the treatment assignment as part of the informed consent procedure would make physicians and patients more comfortable and would enhance participation in trials. Early experience with this design, however, has not generally resulted in improved efficiency in completing trials, and ethical concerns about the changed nature of the informed consent process have been raised. [112,113]

### Data Collection

The design of data forms is not a trivial task. It requires the input of a clinician, statistician, data manager, and computer programmer. All data items necessary to meet the objectives of the protocol must be included, and those unlikely to be of interest should be eliminated. The designers must ensure that items are unambiguously presented, coding procedures are consistent and straightforward, the form is structured for maximal efficiency in entering and keying the data, and the format of the data allows efficient analysis.

Determining the required data items is not always simple. One must go through the protocol step by step and carefully consider what information must be collected to answer the questions addressed. It is important to be selective. The collection and computer entry of excessive, nonessential data waste valuable hours.

Composing a perfect data form on the first attempt is almost impossible. Ideally, the forms should be “piloted,” perhaps on patients who are not participants in the study, before they are used to collect study data. Only by actually using the forms can errors and ambiguities be discovered. Instructions should be contained within the form to the extent possible. For complicated forms, a special coding manual may be required. Institutions or cooperative groups often develop general instructional manuals for completing data forms that are used in a variety of studies. The advantage of shortening the form by removing instructional material must be balanced against the advantage of having the instructions immediately available.

Forms should be designed with ease of completion as a primary consideration. Errors are more likely to be made when the form is filled out than at any other point in the data management process. Ease of data entry is also important, and experienced data managers and data entry personnel should be consulted when new forms are designed. The efficiency of forms with regard to computer programming and data analysis is also important, but it is secondary to the previous considerations.

A schedule for collection of data forms should be established, publicized to the investigators, and enforced by the data management offices. Delay in completing the data forms increases the potential for errors and for missing data that may become irretrievable. Because data managers are often nurses with clinical and administrative responsibilities, sufficient time must be allotted for them to complete and submit forms on the required schedule. Proper monitoring of a study cannot be reliably accomplished without a continually current database.

Advances in computer technology have radically changed data management practices. Almost all clinical trial data are now entered into computer databases for further analysis. Data may be collected on paper forms and sent to a central site for processing, or may be entered directly into electronic forms on disks or via an Internet or other remote application. Remote data entry has the potential to drastically decrease the amount of paper consumed during the conduct of clinical trials, but implementation has proved challenging to investigators comfortable with paper-based systems. Nevertheless, electronic submission of data appears to be inevitable as long as the quality of the data submitted is maintained or improved.

**Quality Control**

*Quality control* refers to all the checks and reviews of data over the course of the study that are designed to make sure the protocol is appropriately followed and the data submitted are accurate. Quality control considerations should affect every step of the protocol, from patient entry through final follow-up. Much of the responsibility for quality control during the course of the study falls to the central data management personnel.

Checklists should be used at the time of patient registration or randomization to ensure that the patient actually is eligible and willing to participate before he or she is formally entered on the study. Data entry procedures should be developed to minimize errors in transposing data from the form to the computer file. Many data centers require two independent keyings of every form, with software designed to catch discrepancies. Many centers have also developed software to simulate the data form on the computer screen, with the cursor moving automatically from one field to the next, to increase the efficiency of entry and to control the error rate. Computer programs must be written (and thoroughly pretested) to detect errors and missing information in the data entered. A system must be devised to notify physicians or data managers about errors, to request corrected or updated information, and to flag persistent errors. For multicenter studies or single-institution studies with multiple participants, it is worthwhile to conduct training sessions for staff who are responsible for completing data forms and for submitting the forms to a central office. Complex protocols often require initial training sessions for surgeons, radiotherapists, pathologists, and others who may need more instruction in the experimental procedures than can be reliably transmitted in the written protocol.

Many aspects of the protocol must be subject to medical review. For example, when radiotherapy is an important part of an experimental treatment program, a centralized quality assurance review of the port films is mandatory to ensure that the treatments are administered according to the protocol. Review must be prompt, especially at the beginning of a study, so problems can be corrected before they affect a large proportion of the study population. Pathology and surgical reports must be reviewed for final determination of patient eligibility. Again, these reviews must be performed promptly because a high ineligibility rate signals the need for modification of the patient entry procedures. Reports of responses, relapses, or other events of interest may also require review. The responsibility for data reviews is usually shared among the study chairperson, data management staff, and treatment specialists.

A series of papers on quality control issues in cancer trials provide some useful insights and examples. [114,115,116,117] and [118] Neaton and colleagues[119] looked at training and data verification procedures as part of the overall quality assurance effort. Peduzzi and co-workers [120] and Miller and associates[121] looked at costs and benefits of central laboratories in multicenter trials. More recently, a position paper on quality assurance in multicenter trials was published by a special committee of the Society for Clinical Trials. [122] The paper addresses a variety of issues in assuring high-quality clinical trials data and is one of the few published sources of recommendations in this important area.

**Follow-Up**

For patients entered on phase I and phase II trials, follow-up is typically limited to the period during which the end points of primary interest (e.g., acute toxicity and tumor response or progression) may be seen. Phase III studies, with the goal of defining optimal treatment strategies, require more extensive follow-up. Ideally, all patients enrolled in phase III clinical trials of cancer treatment should be followed throughout the remainder of their lives, although this is not always feasible due to limited resources. Extended follow-up has two major purposes. The first is to maintain a check on the treatment comparisons by detecting any late crossing of survival curves and obtaining better estimates of possible cure rates. The second is to detect late adverse effects of the treatment that may not be evident when trial results are initially reported. In pediatric trials, late adverse affects include second malignancies, sterility, and cognitive dysfunction. Although data to demonstrate that these effects are sequelae of radiotherapy or chemotherapy rather than the disease process itself are often lacking, a strong biologic basis frequently exists for attributing these effects to cytotoxic therapy. Follow-up forms should specifically request information about known or suspected adverse effects of the therapies used and the disease studied and information about all other adverse effects noted, regardless of whether an association between the effect and prior treatment appears plausible.

The desirable frequency of follow-up reporting varies with the time since study entry. Patients should be assessed frequently, preferably three or four times a year, as long as the study is in an active stage (i.e., before reporting of results). Without frequent follow-up, one cannot monitor study results reliably. For example, extreme differences observed early in a study might lead to consideration of early termination. Without current follow-up on all patients, one cannot know to what extent the observed difference may be an artifact of delayed reporting.

After study results have been reported, a large proportion of surviving patients may be expected to be long-term survivors. It may then be reasonable to request follow-up reporting only on a semiannual or yearly basis, with the understanding that any deaths, relapses, or adverse effects should be reported immediately.

**Data Monitoring and Interim Analysis**

The data from clinical trials must be regularly monitored to check for problems in implementing study procedures, for unexpectedly severe toxicity that may require modification of doses/schedules or even termination of the study, or for early evidence related to treatment effects that may also require early termination. Phase III studies should use sequential designs, as discussed in the section on sequential design, to account for the possibility of early termination because of strong early results. NCI-supported clinical trials cooperative groups have implemented formal data monitoring committees to evaluate interim phase III results on a regular basis and to make recommendations to the group chairperson regarding the conduct of ongoing studies. [123] The voting members of these committees are generally clinicians and statisticians with no direct involvement in the leadership of the trial under consideration, to avoid potential financial or professional conflict of interest during decision making. A majority of the voting members of the committee is not affiliated with the group; laypersons such as cancer survivors or patient advocates are generally included, but all members are expected to see themselves as representing the patients' interests. The committee reviews the accumulating data on a schedule related to the trial design and may recommend modifications to the study design (including early termination) based on the interim results. Knowledge of the interim data is restricted to the committee and is considered confidential, because when all trial participants have access to the accumulating results, nondefinitive trends in the data may engender reluctance in some physicians to continue entering patients on the trial. [124] Discussion of a variety of practical issues in data monitoring can be found in published proceedings of an international workshop on this topic. [125]

A statistical monitoring procedure known as *stochastically curtailed testing* evaluates the probability of reversing the currently observed result. [126,127] and [128] For example,

if most of the required number of patients have been entered onto a trial, and if the results of the arms have been similar, one may be able to show that, under a range of reasonable assumptions about what will happen in the remaining patients to be accrued, the probability that one treatment will be shown statistically superior to the other is negligible. This calculation may provide the basis for terminating the study early, even when a sequential design is not established initially.

General issues in study monitoring and interim analysis are discussed by DeMets, [129] Fleming and DeMets,[130] Green and colleagues,[124] Geller and Pocock,[131] Fleming,[132] and Souhami and Whitehead.[133]

## ANALYSIS

The most efficient, most sophisticated statistical analysis cannot compensate for major errors in the design or conduct of a clinical trial. This does not, however, diminish the importance of proper selection and use of analytic procedures. Before discussing specific procedures useful in cancer clinical trials, one should consider some general issues relevant to the analysis of clinical trial data.

### Avoidance of Bias

The most common cause of bias at the analysis stage of clinical trials is the improper exclusion of patients from analysis. This exclusion can affect not only comparisons of treatments but also estimates of the effect of a single regimen. A good rule is that patients who meet the eligibility criteria, who are entered on the study, and who begin treatment should be included in the analysis of study data. This approach is known as *intention-to-treat*, because analysis includes all patients intended to receive the assigned treatment, whether or not it was ultimately fully administered. [134]

An unbiased estimate of the probability of response to a treatment regimen in a given patient population requires the inclusion of all patients in that population who have been treated with the regimen. Problem patients, such as those who die or who refuse further therapy after only one or two doses of drug, are representative of some fraction of the overall population who may be eligible for this regimen but who will not benefit from it because their disease is too far advanced or because they find the treatment intolerable. When such patients are classified as “inevaluable” and are excluded from study analysis, the resulting response rate will overestimate the proportion of patients in the target population who would actually show tumor regression if treated with the regimen. A response rate has a clear meaning only if the numerator is the number of patients who respond and the denominator is the total number treated. The proportion of responders among patients who receive “adequate” treatment (as defined by each investigator) may have some secondary interest but is not readily interpretable by the medical community at large.

In a randomized study, improper exclusions can clearly bias the treatment comparison. Consider a population of children who have achieved complete response to induction therapy and are then randomized to receive either maintenance therapy or no further treatment. The protocol requires that maintenance therapy begin within 14 days of completion of induction therapy. For some patients, initiation of maintenance therapy is delayed; several other patients become sicker or die in this interval; and a few patients refuse maintenance therapy despite their prior agreement. Some investigators exclude such patients from analysis on the basis that the maintenance therapy may be ineffective if delayed too long (and certainly cannot be effective if not given). It may also be true, however, that patients with poorer prognoses are more likely to present these kinds of problems. Moreover, patients randomized to “no further therapy” are not excluded on the basis of treatment delay or inadequate courses of therapy. Thus, the exclusions may bias the comparison in favor of the maintenance treatment. Additional discussion of this topic is provided by Gail.[135]

### Multiple Comparisons and Subsets

If a box contains 19 black balls and one red ball, the probability of selecting the red ball on any single draw is 1 in 20 or .05. The probability of selecting the red ball at least once is .23 if one draws five times (replacing the ball each time) and .40 if one draws ten times, however. In a clinical trial with the data subjected to multiple tests of hypothesis, the probability of at least one spuriously positive result increases rapidly beyond the nominal .05 level of each individual significance test. No totally satisfactory way around this dilemma exists. It does not seem realistic to limit the exploration of data obtained at great expense, nor does it seem reasonable to require that all tests be done at strict significance levels to ensure that the overall significance level be protected at the cost of severely reducing the power to detect important effects. An intermediate approach may be to consider all questions other than the primary focus of the trial as exploratory questions. Tests can be done at the usual .05 or .01 level, but a significant result may be interpreted as a suggestive observation requiring confirmation rather than a definitive result. This approach has been suggested by several investigators. [136],[137] and [138]

An important example of the multiple comparisons problem in clinical trials is the analysis of data within patient subsets. To speculate that treatment effects may be limited to or more pronounced in some subgroups of patients is reasonable, but confirming this speculation is difficult without extraordinarily large sample sizes. The more subsets considered, the greater the chances that either a uniformly ineffective therapy will appear effective in one or more subsets or a uniformly effective therapy will appear ineffective in one or more subsets. In randomized studies, one can test for the significance of interactions between treatment and covariates (i.e., differential effects in subsets beyond what is expected by chance). However, the power for detecting interactions in a clinical trial of moderate size is low. “Qualitative interactions” (i.e., beneficial effect in one subset, harmful effect in the other) are of special concern, but even these are difficult to detect reliably. Thus, when apparent differences in subset-specific treatment effects are observed in a clinical trial, one cannot (except for extreme differences) determine with confidence whether they are real or spurious.[139] The most sensible approach seems to be to base conclusions on the overall result. The overall result is the most stable, and the study population presumably is defined on the basis of an expected homogeneity of treatment effect. Differences in subset-specific treatment effects, if suggestively large, should be independently confirmed before they are accepted. Problems in interpreting data from trial subsets are discussed in more detail by Yusuf and associates [140] and by Assmann and co-workers.[141]

### Phase II Studies

Phase II studies generally are concerned with response rates. The observed response rate (i.e., number of responders per number of patients treated) is usually the statistic of primary interest. Although this is our best estimate of the true response rate—the proportion of patients who would demonstrate response in an infinite patient population—one cannot assume on the basis of findings from 30 to 40 patients that the estimate is precise. To evaluate how close the estimate is likely to be to the true response rate, a confidence interval is constructed around the estimate. A confidence interval can be defined as the set of possible rates that includes, with specified probability, the true response rate.

The most widely used method to calculate a confidence interval for a proportion p observed in a sample of size n is based on the normal approximation to the binomial distribution. The formula for calculating the upper and lower limit of the confidence interval for p is given in Table 18-6A. The point on the tail of the standard normal curve (i.e., centered at 0, standard deviation of 1) beyond which only a (specified) small portion of the distribution lies is z. A few commonly used z values are given in Table 18-6B, and an example of the actual calculation of confidence limits is given in Table 18-6C. Although this method is simple, it is based on an approximation that is reasonably accurate only when p is in the middle range ($0.3 < p < 0.7$) and when n is approximately 30 or more. For smaller sample sizes, or when proportions closer to 0 or 1 are estimated, one can use a better approximation that is only slightly more complicated to calculate ( Table 18-6D).[142]

(A) Approximation to upper and lower confidence limits

$$p \pm z\sqrt{p(1-p)/n}$$

(B) Commonly used $z$ values

| Confidence interval | $z$ |
|---|---|
| 99 | 2.58 |
| 95 | 1.96 |
| 90 | 1.645 |

(C) Example of calculating confidence interval

Number of patients (n) = 30
Observed responses = 9
Observed response rate (p) = 9/30 = 30%
For a 90% confidence interval, $z = 1.645$.
Confidence limits are calculated as follows:
$= 0.30 \pm 1.645\sqrt{(0.30 \times 0.70)/30}$
$= 0.30 \pm 0.14$
$= (0.16, 0.44)$

(D) Better approximation to confidence limits

$$p + A/2 \pm z\sqrt{p(1-p)/n + A/4n}/(1 + A)$$

where $A = z^2/n$.

**TABLE 18-6. CALCULATING CONFIDENCE LIMITS FOR PROPORTIONS**

The estimation of survival time parameters is more complex. If all patients have died, so that all survival times are known exactly, one can directly calculate the median survival and the proportion surviving at various times. The median of the observed survival times is the halfway point in an ordered listing of all survival times. It is preferable to the mean as a central measure for this type of data because the mean can be drawn away from the center of the distribution by one or two large observations, as can be seen in Table 18-7. This example also demonstrates that the central measure, whether median or mean, is often insufficient to summarize the data adequately. For the data in the table, the range of values is essential to a useful description.

| |
|---|
| Observed survival times 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 3, 3, 3, 4, 5, 5, 5, 20, 30 |
| Mean survival time 5.5 |
| Median survival time 2 |

**TABLE 18-7. CENTRALITY ESTIMATES FOR SURVIVAL TIMES (MONTHS)**

When data are censored (i.e., some patients are still alive, so their survival times are known only to be longer than the current follow-up time), estimation of survival parameters is more difficult. Some parameters can still be measured directly. For example, if more than 1 year has elapsed since patient entry was terminated and if follow-up is current on all patients, the proportion of patients surviving for 1 year can be directly estimated by dividing the number of patients who survived for 1 year by the number of patients who entered the study. If the censored survival times are all in the upper half of the distribution when the times are ordered, the median is still the central observation.

When some data are censored at early points in the study, however, we can no longer estimate median or year-by-year survival rates by ordering the observations and counting. In these situations, life-table methods are required to provide valid and maximally informative estimates. The Kaplan-Meier method, which provides probabilities of survival at each point in time at which a death occurs, is probably the most commonly used in cancer studies and should always be used when the number of deaths is small.[143] The other type of procedure, often referred to as the *actuarial method*, calculates probabilities at fixed points in time (e.g., 6-month intervals).[144] With this procedure, some information is lost, because the ordering of deaths within any given interval is ignored. If the number of deaths is large, however, and the size of the interval is chosen sensibly, the loss of information is not serious. This procedure requires less calculation, but with the availability of computer programs to perform these procedures, complexity of calculation has become less of an issue.

Life-table survival probabilities are frequently presented graphically as survival curves. Figure 18-1 shows the Kaplan-Meier plot of survival probabilities for the data set shown in Table 18-8. These hypothetical data represent a clinical situation in which 30 patients were entered on a study over a period of 300 days, with follow-up continuing until day 365. The plot steps down at each point in time at which a death was observed. The tick marks on the plot correspond to the survival times with a plus sign in Table 18-8, indicating data censoring at those points. For example, the survival time for patient 5 in Table 18-8 is given as 326+ days. The experience of this patient is represented by the far right tick mark on the survival plot. The estimated median survival and probabilities of survival at particular points may be approximated from the plot or, more easily, from the table that produced the plot (Table 18-9). In this case, the median survival is 145 days; the probabilities of 3-, 6-, and 9-month survival are 63%, 45%, and 21%, respectively. The actual calculation of Kaplan-Meier life-table probabilities is well described by Peto and colleagues [145]; both procedures are described by Lee.[146] Methods for calculating confidence intervals for survival parameters are discussed by Simon. [142]

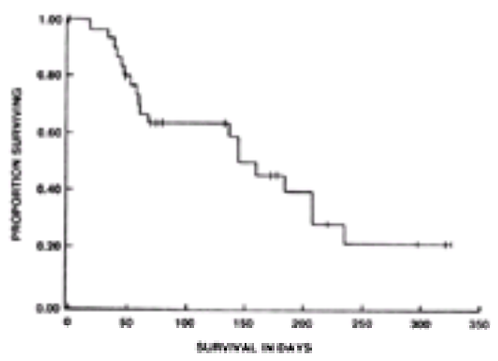

**FIGURE 18-1.** Plot of life-table probabilities. Tick marks indicate censored observations.

| Patient | Day of entry | Status at day 365 | Survival time* |
|---|---|---|---|
| 1 | 11 | Dead | 53 |
| 2 | 23 | Dead | 41 |
| 3 | 35 | Dead | 208 |
| 4 | 37 | Dead | 208 |
| 5 | 39 | Alive | 326+ |
| 6 | 44 | Alive | 321+ |
| 7 | 55 | Dead | 60 |
| 8 | 68 | Alive | 297+ |
| 9 | 79 | Dead | 137 |
| 10 | 85 | Dead | 188 |
| 11 | 86 | Dead | 160 |
| 12 | 91 | Dead | 335 |
| 13 | 94 | Dead | 48 |
| 14 | 104 | Dead | 145 |
| 15 | 139 | Dead | 145 |
| 16 | 144 | Alive | 221+ |
| 17 | 188 | Alive | 181+ |
| 18 | 191 | Dead | 58 |
| 19 | 193 | Alive | 172+ |
| 20 | 205 | Dead | 61 |
| 21 | 208 | Dead | 68 |
| 22 | 217 | Dead | 34 |
| 23 | 232 | Alive | 133+ |
| 24 | 248 | Dead | 45 |
| 25 | 261 | Dead | 18 |
| 26 | 282 | Dead | 39 |
| 27 | 285 | Alive | 80+ |
| 28 | 290 | Alive | 75+ |
| 29 | 295 | Alive | 70+ |
| 30 | 297 | Alive | 68+ |

*Plus sign (+) indicates a censored survival time.

**TABLE 18-8. PATIENT ENTRY AND SURVIVAL TIMES**

| Days from study entry | Proportion surviving |
|---|---|
| 18 | 0.967 |
| 34 | 0.933 |
| 39 | 0.900 |
| 41 | 0.867 |
| 45 | 0.833 |
| 48 | 0.800 |
| 53 | 0.767 |
| 58 | 0.733 |
| 60 | 0.700 |
| 61 | 0.667 |
| 68 | 0.633 |
| 137 | 0.588 |
| 145 | 0.543 |
| 145 | 0.498 |
| 160 | 0.452 |
| 184 | 0.396 |
| 208 | 0.339 |
| 208 | 0.283 |
| 295 | 0.212 |

**TABLE 18-9. KAPLAN-MEIER LIFE-TABLE PROBABILITIES**

Evaluating the effect of therapy on patient survival is difficult in the context of a phase II study. Objective tumor shrinkage is generally accepted as attributable to the treatment administered because the frequency of spontaneous tumor regression in untreated patients is thought to be low. Without a control group, however, one cannot demonstrate, except in dramatic circumstances, that survival benefit is attributable to a particular treatment. Although investigators can reasonably assume that a tumor response would not have occurred in an untreated patient, one cannot so readily assume that a patient who survives for a given number of months after treatment would have survived for a shorter period without treatment. (The exception is the dramatic circumstance of a substantial proportion of patients who achieve long-term survival and who have a disease that previously was uniformly fatal within a short interval.) Investigators reporting results of phase II studies have commonly compared the survival experience of responders with that of nonresponders and have viewed a prolonged survival of the responders as evidence of survival benefit attributable to the treatment. The fallacious reasoning behind this type of analysis has been widely discussed. [147,148 and 149] The fundamental problem is that an association between response and survival cannot be assumed to be causal. Patients show variable survival times whether they are treated or not; patients who are destined to survive longer because of more favorable baseline characteristics may be those who exhibit tumor shrinkage when treated with anticancer therapies. Thus, effects of treatment on survival may be reliably demonstrated only with the use of appropriate control groups.

## Phase III Studies

Most of the methods discussed in this section are directed at the comparison of treatment effects, which is the major objective of phase III trials. Other analyses are considered, however, such as the identification of prognostic factors. Estimates of survival and response parameters are obtained using the methodology described in the previous section. The larger sample sizes available in phase III trials permit more reliable estimates of these parameters.

The general approach in statistical testing is to consider a null hypothesis (no difference in treatment effect) against an alternative hypothesis (unequal effects). When the data demonstrate a sufficiently large difference in patient outcome, the null hypothesis may be rejected. The *p* value associated with the statistical test of the null hypothesis can be interpreted as follows. If the null hypothesis were true (i.e., if there were truly no difference in treatment effect), the probability of an observed difference as large or larger than this one would be equal to *p*. Thus, if *p* is small, the observed data may be considered sufficiently inconsistent with the null hypothesis to warrant its rejection. Failure to reject the null hypothesis does not demonstrate that the null hypothesis is true. If the sample sizes are large enough, however, failure to reject this hypothesis may indicate inconsistency with a true treatment difference that is of clinical importance.

### *Comparison of Proportions*

When the end point is binomial (i.e., only two outcome possibilities exist), the data can be represented in a 2 by 2 table, as depicted in Table 18-10A. Unless an unbalanced randomization scheme is used, a + b and c + d each approximately equal n/2. If no association exists between treatment group and the likelihood of a success, then a/(a + b) and c/(c + d) should be approximately equal.

(A) Representation of data

| | Treatment | | |
|---|---|---|---|
| Outcome | A | B | Total |
| Success | a | c | a + c |
| Failure | b | d | b + d |
| Total | a + b | c + d | a + b + c + d (= n) |

(B) $\chi$-square statistic with correction for continuity

$$\chi^2 = \frac{n(|ab - bc| - n/2)^2}{(a+b)(c+d)(a+c)(b+d)}$$

(C) Significance levels for the $\chi$-square statistic

| *p* value | $\chi^2$ |
|---|---|
| .10 | 2.71 |
| .05 | 3.84 |
| .025 | 5.02 |
| .01 | 6.63 |
| .005 | 7.83 |
| .001 | 10.83 |

**TABLE 18-10. c-SQUARE TEST FOR COMPARISON OF PROPORTIONS**

The most commonly used test of the null hypothesis of no association is the c-square test. This test approximates the distribution of the binomial outcome variable with a normal distribution (bell-shaped curve) and therefore should be used only when the sample size is large and the proportions of successes are neither extremely low nor extremely high. A good rule of thumb in the case of equal numbers in the two treatment groups is that the c-square test is appropriate when the total number of successes (a + c) is no less than 10 and no more than n – 10. The formula for the c-square statistic is given in Table 18-10B. The value n/2, subtracted inside the squared term in the numerator, provides an adjustment ("correction") to account for the application of normal distribution theory to binomial data. When the value of c-square is large, the null hypothesis may be rejected at a significance level that depends on the magnitude of the statistic. Some commonly used values are given in Table 18-10C; more extensive tables can be found in many standard textbooks.[150,151]

When the data are such that the c-square test may be inappropriate, the Fisher-Irwin test (Fisher's exact test) may be performed. This test requires more extensive computation, but it is available in many statistical software packages. Alternatively, extensive tables for use with this test have been published. [152] The calculations required to perform the Fisher-Irwin test are described by Fleiss. [54]

### *Comparison of Survival Times*

In many, if not most, phase III trials in cancer, the primary end point is survival. In comparing survival (or similar end points, such as event-free survival), the use of proportions is not entirely satisfactory. The construction of a table, as described in the previous section, using "alive/dead" as the outcome variable can be misleading if follow-up reporting is delayed longer on one treatment arm than on the other, such as occurs when one treatment requires more frequent contact with the clinic. If we standardize follow-up by modifying the outcome variable to "alive/dead at 3 years after study entry," we lose information on patients who entered the study fewer than 3 years before the analysis, and we gain no information from deaths after the 3-year point.

To improve the efficiency of survival comparisons, methods have been developed that use all the information available for every patient and allow comparison of the overall distributions of survival time, rather than focusing on a particular point in time. These methods also accommodate censored data. Two methods that can be recommended in most situations are the log-rank test and the test based on the Cox proportional hazards model. They are most safely implemented with a well-validated computer program. (Programs for these procedures are available in most large statistical software packages for mainframe computers and in many packages for microcomputers.) An excellent discussion of the actual mechanics of the log-rank test is given by Peto and colleagues [145]; Lee[146] discusses these and other methods for survival analysis in nontechnical terms and provides many excellent examples to illustrate the calculations. [146]

The often-used term *proportional hazards* means that the relative superiority (with respect to prolonging survival) of one treatment over another remains constant over time. The assumption of proportional hazards is the basis of the Cox procedure, and although it is not formally required by the log-rank test, marked nonproportionality of hazards severely limits interpretability of test results. Under many circumstances, hazards are not necessarily expected to be proportional. One example is the comparison of a highly toxic regimen with one that is less toxic. The more toxic regimen may result in more treatment-related deaths early in the study, but it may provide a better chance for long-term survival, even with the excess of early deaths taken into account. In these circumstances, an overall test of survival may obscure the appropriate interpretation of the data. In many instances, particularly with pediatric patients, treatment to improve the chance of long-term survival may be the appropriate strategy, even though the risk of early death resulting from acute toxicity may be greater. The additional early deaths may prevent the more toxic regimen from demonstrating a statistically superior survival advantage overall, however. An excellent discussion of this problem and suggested analyses to demonstrate the

nonproportionality of hazards is provided by Stablein and co-workers. [153]

### *Identification of Prognostic Factors*

The statistical literature concerning the identification of baseline factors associated with eventual patient outcome is extensive. The methodology most suited to determining which of a set of factors is important in predicting outcome is the regression model. These models are used to develop prediction equations for outcome, based on the values of the known factors. Because the outcome of interest in cancer studies is usually binary (e.g., response-nonresponse) or a time variable that may be censored, specialized models must be chosen that accommodate such outcomes. With a binary outcome, one is essentially trying to calculate the probability of the outcome of interest; with a time-interval outcome, one is trying to predict the length of survival or event-free survival. For binary outcomes, the procedure of logistic regression is probably the most appropriate technique for evaluating the relative importance of baseline factors. The Cox regression model is widely used for outcomes such as survival time, in which some of the data may be censored.

In building either type of model, parameters reflecting the contribution of each factor to the accurate prediction of the outcome are estimated. When these parameters differ significantly from zero, one can infer that the factors have some prognostic value. Of course, when many factors are evaluated, the probability that at least one will differ significantly from zero, even if none has any effect on outcome (i.e., the multiple-comparisons problem), is not negligible. Therefore, the results of these analyses must be interpreted cautiously. The multiplicity problem also extends to the selection of “cutpoints,” which are values of covariates used to divide the population for purposes of stratification and analysis, as noted by Altman and colleagues. [154] The significance levels resulting from these analyses depend on the sample size. Weak associations may attain significance when large data sets are analyzed; conversely, strong associations may not be demonstrated at conventional levels of significance in small samples. The identification of several “significant” prognostic factors is therefore no guarantee of a highly predictive model. Simon and Altman[155] discuss the many pitfalls in the evaluation of prognostic factors and propose a hierarchy of prognostic factor studies similar to that for clinical trials. Phase I studies are the initial exploratory studies that identify new factors possibly associated with outcomes of interest. Phase II studies focus on categorizing patients according to risk levels, and phase III studies pre-specify and test hypotheses regarding treatment benefit in patient subsets. This paper provides detailed guidance for the evaluation of prognostic factors in cancer.

### *Adjustment for Covariates*

Randomization ensures that no systematic bias affects the treatment comparison, but it cannot ensure that the two treatment groups will be identical with regard to prognosis. It may happen by chance that more of the patients with a poor prognosis are assigned to one of the treatments. To prevent this type of imbalance from influencing the treatment comparison, one can perform an analysis that accounts for the effects of important prognostic factors, or covariates.

The most common method of adjustment is to perform a separate analysis for each level of the covariate (or for each possible combination of levels when multiple covariates are considered simultaneously) and statistically aggregate the results. For example, in a clinical trial of childhood acute lymphoblastic leukemia, one may want to adjust for age by considering outcomes separately for infants (<1 year), children between the ages of 1 and 10 years, and those older than 10 years because these groups have different prognoses. Even when no imbalances exist, this type of adjusted, or stratified, analysis is more efficient than an unadjusted analysis; by comparing outcomes within homogeneous subgroups, the variability of the overall result is slightly reduced. [156] Both adjusted and unadjusted analyses should be performed and reported whenever important prognostic factors have been identified for the patient population under study. A more complete discussion of the rationale and methodology for adjustment of comparative analyses can be found in the text by Friedman and colleagues [157] and in articles by Simon.[158] For studies intended to provide definitive evaluations, decisions about adjusting for particular covariates should be made before any data analysis to avoid the possibility that the selection of the adjustment strategy may have been influenced by the conclusions that would result. [159]

### *Meta-Analysis*

*Meta-analysis* is defined as a quantitative summary of research in a particular area. What differentiates a meta-analysis from the more familiar review of the literature is the construction of an overall summary result obtained by statistically aggregating the results of the reviewed studies. Formal meta-analysis, also referred to as an *overview*, is becoming more common in medical research and has been widely used in the social sciences for many years.

An extensive literature concerning the application of these techniques to clinical trial results is rapidly developing. [160,161,162,163,164,165,166,167,168,169,170] and [171] Many scientists believe that meta-analysis is proving to be a useful, perhaps even essential, tool in reaching reliable conclusions from the mixed assortment of studies that may have addressed the same research question.[172] Other scientists have expressed concerns about the validity of combining data from separate investigations and about whether the questions that can be properly addressed by these methods are of sufficient interest to warrant the effort they entail. [173] The Cochrane Collaboration, an international initiative to develop and maintain ongoing meta-analyses addressing important questions in medical research, has been highly influential in encouraging the performance of high-quality meta-analyses.[174]

A number of methodologic issues in the performance of meta-analyses have been raised. One concern is “publication bias”: whether meta-analyses that include only studies that have been published substantially overestimate treatment effects because negative studies are less likely to be published than positive studies. [175] Although publication bias is widely acknowledged to be a real concern, combining peer-reviewed reports with those that have not undergone peer review generates other concerns.[176] Another important issue centers on the “combinability” of studies. The question of which studies are sufficiently similar with regard to treatment, patient population, and methods of determining end points must be dealt with in planning any meta-analysis. Selection criteria should be determined in advance of reviewing potential studies: to avoid bias, it is optimal that studies be assessed for inclusion by reviewers who are blinded to the results of the study.

Meta-analysis of data from randomized trials will be unlikely to play a major role in pediatric cancer research because rarely do multiple studies compare similar regimens in the same disease population. The aggregation of nonrandomized studies may be more feasible in terms of patient numbers, but meta-analysis of nonrandomized studies is even more problematic because the selection biases that inevitably arise in uncontrolled studies may be multiplied if the results of such studies are formally combined.

## REPORTING RESULTS OF CLINICAL TRIALS

Ineffective reporting seriously compromises the value of well-conceived and expertly conducted clinical trials. These complex, time-consuming, and expensive investigations are conducted to increase the therapeutic information available to a medical community that relies on the published literature. Meaningful communication is therefore a critical component of the clinical trials process; without it, much of the investment in clinical trials is lost. Indeed, the publication of ambiguous or misleading results can be medically harmful and scientifically counterproductive.

The need for systematic investigation to identify advances in cancer treatment is widely accepted, and sophistication about issues of design and analysis in clinical trials has increased, but the methodology of reporting these trials has not always received the attention it merits. With the recognition that reliable comparisons among results of clinical trials can be made only in the presence of standardized reporting procedures, the World Health Organization in 1979 published recommendations for uniform approaches to assessment and reporting. These recommendations were developed and endorsed by an international assemblage of representatives of cancer clinical trials organizations. [87,177] Although these recommendations provide a useful starting point, they proved ineffective in circumventing the methodologic deficiencies increasingly observed in the clinical trials literature. [147,178,179,180] and [181] Various suggestions have been directed to medical journal contributors and editors in an effort to enhance the utility of reported results. [182,183,184,185] and [186] A useful development is the adoption by the editorial board of the *Journal of the National Cancer Institute* of a set of methodologic guidelines for reporting clinical trials. [187] These guidelines have been endorsed by editors of the *Journal of Clinical Oncology*[188] and *Cancer*.[189] Other articles providing useful guidance have been published by Zelen [190] and Bailar and Mosteller.[191] A checklist of information to be included in clinical trials reports, proposed by the Working Group on Recommendations for Reporting of Clinical Trials in the Biomedical Literature [192] has been superseded by the Consolidated Standards of Reporting Trials statement, [193] which advocates use of both a checklist and a flow diagram to assist editors and reviewers of randomized controlled trials. The Consolidated Standards of Reporting Trials approach has been adopted by *JAMA*[194] and *Lancet*.[195]

The value of any clinical trials publication is obviously related to the value of the experiment it reports. A useful publication is accurate, medically informative, and convincing to the reader. Accuracy is largely predetermined by the validity of the experimental design, the quality of its execution, and the legitimacy of its statistical analysis. The degree to which a paper is medically informative depends on the importance of the study question and the appropriateness of the experimental conditions. The ability to persuade the reader, however, relates largely to the information the researcher chooses to communicate. Although the general structure of

research papers (i.e., background, methods, results, and conclusions) is widely known, the detail presented is often insufficient to persuade a critical readership of the validity or applicability of the conclusions. Even when the design and conduct of the study and the analysis of results are impeccable, an inadequate description of these features prevents meaningful interpretation by the experienced audience for whom it is intended. This deficiency may delay the acceptance of an important advance or, more commonly, as in small studies with limited power, may suggest the acceptance or rejection of a concept based on what is an equivocal result that requires further investigation.[178]

To be maximally effective, the author of a clinical trials report should write from the perspective of a critical reader. In evaluating the manuscript, a reader initially wants to know the scientific motivation for the study, particularly the specific hypotheses addressed and the reasons for their plausibility and pertinence. The investigator must list all the hypotheses addressed in the study, not only the ones for which the results were statistically significant, to permit the reader to assess multiplicity issues. It may happen that the investigator has performed many comparisons, relating to secondary end points, strength of prognostic factors, treatment effect in subgroups, and so forth, but the report includes only those comparisons that result in a significant *p* value. The reader will interpret a report of a single positive test differently from a report of 40 tests with a single positive result.

A detailed methods section permits an assessment of the strengths of the design and provides an opportunity to replicate the effort, if warranted. This section should clearly describe the experimental conditions, including the specifics of patient registration procedures, inclusion and exclusion criteria, the target patient population, the details of the treatment regimen and any modifications, the schedule of follow-up evaluations, the procedures used to assess major end points (including whether the person making the end point evaluation was “blinded” to the treatment assignment), and, in comparative trials, the nature of the control group and the specific methods used for treatment assignment. The report should state whether the treatment allocation was by randomization. A description of the specific methods used to guarantee random treatment assignment and their timing relative to patient entry on study should be provided.[196] A brief description of quality control procedures can ensure the reader that the information reported is complete and accurate. Finally, a discussion of the statistical procedures used to analyze the data allows the reader to assess the reliability of the reported results. This description includes identification of analytic procedures used and explanatory material for techniques likely to be unfamiliar to the journal readership. References to articles or books describing all but the simplest and most standard techniques should be provided.

The results section presents the outcome of the experiment; clear and detailed exposition is crucial. A complete description of the patients entered on the study, including age, disease characteristics, nature and amount of prior therapy, and other items considered important in determining eligibility or establishing prognosis, should be reported. Toxicity and compliance information should be included, and outcomes for all patients entered should be reported. Confining information to patients deemed evaluable prevents accurate comparisons across studies whose policies regarding evaluability may differ.[187,190] If feasible, as with small studies, lists of individual end point determinations are useful.

Investigators must define end points carefully in reports of clinical trials. Common phrases such as “disease-free survival” are not necessarily defined in the same way by all investigators. The adoption of standard definitions and analyses, as proposed by Mastrangelo and colleagues[91] for pediatric leukemia studies and by the proponents of the Response Evaluation Criteria in Solid Tumors guidelines for solid tumors,[89] would facilitate the interpretation of study results and the comparison of results across studies.

Reports of clinical trials usually conclude with the author's interpretations of the study results. If the data have been analyzed appropriately, the conclusions are usually self-evident. Potential sources of bias, the need for independent confirmation, and any other warnings should be included in the discussion. Claims of patient benefit should be circumspect and based on the demonstrated difference in outcome between experimental and control groups, whose characteristics have been accurately described. Claims of no benefit should be accompanied by a confidence interval around the observed difference; a calculated probability (i.e., power) that a clinically important difference would have been detected with the sample size used may also be of interest.[197] Generalizations to a wider population should be made cautiously.

# ACUTE LYMPHOBLASTIC LEUKEMIA

JUDITH F. MARGOLIN
CHARLES PHILIP STEUBER
DAVID G. POPLACK

## INTRODUCTION

The progress made in the treatment of acute lymphoblastic leukemia (ALL) of childhood is one of the true success stories of modern medicine ( Fig. 19-1). Incremental advances in treatment success span a 50-year period, during which ALL has gone from a uniformly fatal disease to one with an overall cure rate greater than 75%.[1,2,3,4 and 5] This extraordinary therapeutic progress is the result of treatment advances that began with the identification of effective single-agent chemotherapy in the late 1940s, followed by the development of combination chemotherapy and maintenance chemotherapy in the 1950s and early 1960s and the implementation of effective central nervous system (CNS) preventive therapy in the 1960s and 1970s. Continued, gradual improvement occurred through the 1990s. Additional information regarding cytogenetic, immunophenotypic, molecular characterization, and early treatment response help refine risk group categorization. This led to more appropriate “tailoring” of therapy, allowing a better defined “high” risk group to receive increasingly intensified therapy, whereas therapy for lower risk patients was successfully modified to reduce the risks of toxicity without compromising therapeutic efficacy. With the improving cure rate, the focus of future studies can move toward decreasing long-term side effects as well as examining short-term convenience and economic issues (i.e., outpatient versus inpatient delivery of the therapies). As the new century begins, the prospects for future progress fueled by advances in genomic research is bright.

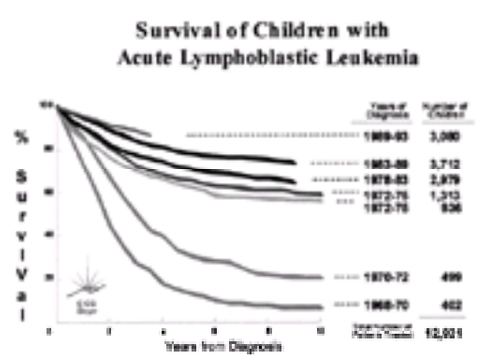

**FIGURE 19-1.** Improvement in survival of children with acute lymphoblastic leukemia. Curves represent survival outcomes for patients treated on successive Children's Cancer Group (CCG) clinical trials conducted over the 1968 to 1997 period. (A. Bleyer, H. Sather, *personal communication*, 2001.)

This chapter reviews the pathophysiology and biology of ALL, including new findings in the molecular biology of ALL, the applications of the new genome and molecular sciences in the initial diagnosis, minimal residual disease (MRD) detection, refinements in risk group stratification, and current treatment principles for ALL. Although the history of therapeutic approaches is briefly reviewed, the focus remains on current therapeutic strategies and on the unresolved treatment and etiology issues that represent the most significant current medical and scientific challenges.

## EPIDEMIOLOGY

Although the overall incidence of ALL has remained constant over the past three decades, new information concerning subgroups continues to be uncovered. [6,7 and 8] ALL is the most common malignancy in children. It accounts for one-fourth of all childhood cancers and approximately 75% of all cases of childhood leukemia. [5] Approximately 2,500 to 3,500 children are diagnosed with ALL each year in the United States, with an incidence of 3 to 4 cases per 100,000 white children. [9,10] The peak incidence of ALL occurs between age 2 and 5 years (Fig. 19-2) and may be trending downward in both the United States and Great Britain.[11,12] This young age peak historically has appeared at different times in different countries. It occurred initially in Great Britain in the 1920s, in the United States in the 1940s, and in Japan in the 1960s.[13] The appearance of these peaks corresponds to major periods of industrialization in these countries, suggesting that they may reflect different periods of exposure to new environmental leukemogens.[8,14]

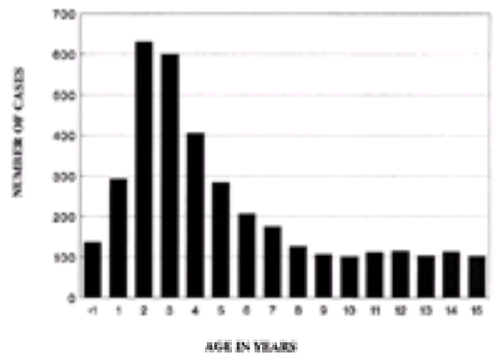

**FIGURE 19-2.** Age distribution of 3,620 children with acute lymphoblastic leukemia. (Data from the Children's Cancer Group, courtesy of H. Sather).

In the United States, ALL is more common among white children than black children. This may be due to the early surge in ALL incidence that occurs in whites. [3,15] This phenomenon may reflect a difference in susceptibility or in exposure to whatever environmental influences may be responsible for the early age peak in whites. Considerable controversy exists concerning whether outcomes differ between white and black children. [3,11,16] Reports from the 1960s and 1970s indicated that black children fared significantly worse compared with white children. [17] The observed differences had been postulated to be due to socioeconomic factors. In the late 1980s and early 1990s, several reports showed equivalent outcomes when the patients were carefully stratified according to risk group. [17] More recent studies, which account for most of the current significant prognostic variables, have shown statistically significant poorer outcomes for black compared to white children. These differences now appear to reflect the fact that a predominance of black patients fit into the higher risk categories, and that there may be specific pharmacogenetic differences between racial groups that result in disparities in outcomes.[3,16,18]

The incidence of ALL is higher among boys than girls, and this difference is greatest among pubertal children. [19] The male preponderance is particularly evident in cases of T-cell ALL.[20] Despite speculation about a possible role for sex hormones in leukemogenesis, none has been definitely established. One recent study in a population with relative genetic homogeneity (the French population of Quebec) demonstrated an increased risk for children with a particular set of glutathione S-transferase (GST) and cytochrome P-450 alleles.[21] A protective effect for girls was associated with the presence of a specific P-450 allele. [21] Other work has suggested an association between a certain HLA-DR haplotype (HLA-DRB4*01) and a particular mutation (C282Y) in the HFE gene (associated with hereditary hemochromatosis) and an increased risk for boys developing ALL.[22,23] These results need to be confirmed in studies of larger and genetically more heterogeneous populations. In addition, as the complexity of the genome is uncovered, it is likely that more complex environmental and genomic interactions are responsible for observed differences in ALL incidence.

It has been known for a long time that the general risk of ALL may be associated with specific environmental exposures (see the section Pathogenesis), as well as with specific but unknown enzymatic genotypes. As discussed later, polymorphisms of the GSTs and similar genes involved in the task of detoxification of drugs and xenobiotics have also recently been found to be important in determining response, side effects, and even the risk of relapse after completion of therapy. [24,25,26 and 27]

There also appear to be geographic differences in the frequency and age distribution of ALL. For example, ALL is relatively rare in North Africa and the Middle East, and non-Hodgkin's lymphoma is the most common childhood malignancy in those regions. In India and China, ALL is somewhat more common, but its incidence is still considerably lower than that in the industrialized West. [15] This geographic variation may reflect, in part, the distribution of different immunologic ALL subtypes. There appears to be a lower incidence of common ALL in developing countries and a higher incidence of T-cell ALL in the more industrialized countries. Although this may reflect an underdiagnosis of common ALL in developing countries, it is also possible that children in industrialized countries are more likely to be exposed to leukemogens that cause ALL.[28]

Several studies have suggested a link between maternal reproductive history and the risk of ALL. [29,30] Higher risk has been associated with a history of fetal loss. It is unclear whether this reflects genetic predisposition, an abnormal intrauterine environment, or a common environmental exposure. Increasing maternal age has been associated with an increased risk of ALL in the offspring. An association also has been posited between fetal loss and homozygosity at the same HLA-DR regions HLA-DRB4*01 (see above), which has been associated with increased ALL risk for males. [23] Higher birth weights appear to be associated with a greater risk of ALL, but the reason is unknown and may simply be related to the fact that birth weights tend to increase with maternal age. [29,31] Paternal chemical exposure (pesticides and fungicides) also has been associated with a higher incidence of childhood ALL. [32]

Numerous reports speak of the occurrence of leukemic clusters, which are observations of a greater than expected number of leukemia cases within a given period or geographic area (see Chapter 1). Under careful scrutiny, however, most purported clusters have not been substantiated. [15]

## GENETICS

Genetic factors are presumed to play a significant role in the cause of acute leukemias, including ALL (see Chapter 2 and Chapter 3). Evidence for this is based on several observations, including the association between various constitutional chromosomal abnormalities and childhood ALL ( Table 19-1), the occurrence of familial leukemia, and the molecular epidemiologic evidence of the importance of various alleles of specific genes (see above).

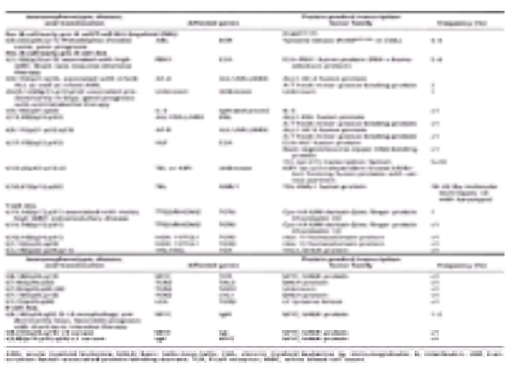

**TABLE 19-1. NONRANDOM CHROMOSOMAL TRANSLOCATIONS ASSOCIATED WITH SPECIFIC IMMUNOPHENOTYPES AND FUSION PROTEIN PRODUCTS IN CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA (ALL)**

Constitutional chromosomal abnormalities are associated with childhood leukemia. Children with trisomy 21 (i.e., Down syndrome) are up to 15 times more likely to develop leukemia than are normal children.[33] Although both ALL and acute myeloid leukemia (AML) are observed, ALL predominates in all but the neonatal age group.[34]

Other less common preexisting chromosomal abnormalities have been linked to leukemia.[35] Included among these are children with Klinefelter's syndrome and the trisomy G syndromes.[36] Children with neurofibromatosis and those with Schwachman syndrome are also reported to have an increased risk of leukemia.[37,38] As noted above, a higher risk of childhood leukemia has been associated with increasing maternal age. This may reflect the increased incidence of subtle karyotypic abnormalities in infants born to older mothers.[39]

The incidence of acute leukemia among those with Bloom syndrome and Fanconi's anemia is well documented.[40] These rare, autosomal recessive disorders are characterized by increased chromosomal fragility. Although AML is more common in those with Bloom syndrome, ALL also occurs.[41,42] There is some evidence that the development of leukemia in these patients is a consequence of genetic recombination of somatic cell chromosomes.[41] Defective replication and repair of DNA appears to play a significant role in both disorders.[43,44] Fanconi's anemia is most frequently associated with the development of acute myelomonocytic leukemia rather than with ALL.[45]

Lymphoid malignancies, with a predominance of T-ALL, have been reported in patients with ataxia-telangiectasia (AT), an autosomal recessive disorder characterized by increased chromosomal fragility.[46] B-cell and pre–B-cell ALL also have been reported occasionally in AT patients.[47] The gene responsible for AT (ATM) has been cloned, but the mechanism by which this increases patients' risk for cancer has not yet been uncovered.[48]

The importance of *in utero* genetic events has been suspected for many years due to concordance studies on twins with leukemia.[49,50 nd 51] The suggestion that leukemogenesis begins *in utero* also has been explored in studies that have found leukemogenic translocations [i.e., t(4;11) and t(12;21)] and markers of clonality that match that of the later leukemic blasts in heelstick blood samples (Guthrie cards) from newborns who later developed ALL.[52,53,54 and 55] Although these studies providing tantalizing clues that the process of developing leukemia may begin *in utero*, the questions of whether these genetic changes are the “accelerating,” permissive, or merely incidental genetic changes in patients who later developed leukemia remain unresolved. Crucial work remains to be done concerning whether the specificity of the leukemogenic mechanism will match the sensitivity of the polymerase chain reaction (PCR) methods used to test for small amounts of presumed leukemic cells. In the neonatal heelstick studies mentioned above, these patients were found to have 1/100 to 1/10,000 of the cells with DNA changes at birth, which contained one genetic alteration found months to years later in their leukemic blasts. It is not clear whether many more “normal” individuals (who never clinically present as leukemics) may show similar chromosomal breakpoints or evidence of clonal rearrangements in their white cells at birth.

Multiple cases of leukemia within families have been reported, including aggregates among siblings and groups within the same generation or in several generations.[56,57] The frequency of leukemia is higher than expected in families of leukemia patients.[58] Siblings of children with leukemia, including ALL, have an approximately twofold to fourfold greater risk of developing the disease than do unrelated children in the general population.[35,59] Although the occurrence of leukemia in identical twins has been used to support the role of genetic factors in the disease, the extent to which this association implicates a genetic susceptibility is ambiguous.[35] The concordance of acute leukemia in monozygotic twins is estimated to be as high as 25%. The risk for concordance among twins (both mono- and dizygotic) is highest in infancy; this risk diminishes with age, and after age 7 years, the risk to the unaffected twin is similar to that for persons within the general population.[35,57] Although the high concordance rate among younger twins suggests a genetic predisposition or *in utero* transfer of the leukemic cells, it may also be the result of simultaneous exposure to a common prenatal or postnatal leukemogenic event.

## PATHOGENESIS

In addition to genetics, environmental factors, viral infection, and immunodeficiency may predispose children to leukemia.

### Environmental Factors

Exposure to ionizing radiation and certain toxic chemicals can facilitate the development of acute leukemia. The high incidence of leukemia in survivors of the atomic bomb explosions in Japan during World War II is well documented.[60,61] The risk of leukemia was greatest for those closest to the explosion.[62] For persons who received exposure doses greater than 100 cGy, the dose-response relation for the production of leukemia was linear.[63] The type of leukemia observed was related to the age at exposure. ALL was seen more frequently in children, and AML was more common in adults.

Among survivors of the atomic bomb, there was no increase in the incidence of leukemia in children exposed to radiation *in utero*. This experience contrasts with other reports of an increased risk of leukemia in children exposed to diagnostic irradiation antenatally, particularly during the first trimester.[64] In a study by the National Academy of Sciences, a fivefold increased risk of all childhood cancers was found for children exposed to diagnostic radiation during the first trimester. When exposure occurred during the second and third trimesters, the risk was 1.5 times normal. Leukemias comprised approximately one-half of the cancers in that study; the increased risk for leukemia extended through age 12 years.[64] A significant leukemogenic effect has been reported in children exposed *in utero* to doses of 0.3 to 0.8 cGy.[65] Prenatal x-ray exposure, however, probably accounts for a very small portion of childhood ALL cases.[20]

The risk of developing leukemia from *ex utero* diagnostic irradiation is difficult to determine. One study suggested that approximately 1% of all cases of adult leukemia can be assumed to be a result of exposure to diagnostic radiography.[66] Therapeutic irradiation has been associated with a higher risk of acute leukemia in patients with ankylosing spondylitis treated with relatively high-dose radiation and in neonates administered thymic irradiation (which was once used to treat enlargement of the thymus).[67,68] An increased leukemic mortality rate was also observed in one study for children who received scalp irradiation for treatment of tinea capitis.[69]

Although the potential of ionizing radiation for causing leukemia is acknowledged, the actual percentage of leukemia cases directly attributable to radiation is presumed to be small. Controversy persists about the risks from exposure to ionizing radiation from routine emissions from nuclear power plants or as a result of fallout from atmospheric nuclear testing. Controversy also surrounds the possibility that exposure to electromagnetic fields (EMF) may be causally related to the development of childhood ALL. Conflicting studies exist in the literature. A case-control evaluation of a population of children in Denver suggested a twofold to threefold higher incidence of childhood cancers, including ALL, among children living in proximity to high-voltage power lines.[70] Similar studies from Sweden have shown increased risk from high-voltage power lines and from low-dose irradiation from ground current sources.[71,72] In contrast, studies of children living in Rhode Island and in Yorkshire showed no association between EMF and childhood ALL.[73,74] Later reviews, including large meta-analyses of multiple studies, present conflicting results.[75,76] Laboratory studies suggesting that EMF exposure might cause cancer by increasing cellular levels of the *myc* oncogene have been questioned by the failure of several groups to replicate the original work.[77,78] The most recent large case-control studies all have concluded that EMF exposure does not cause childhood ALL.[79,80]

Chronic chemical exposure (e.g., to benzene) has been associated with the development of AML in adults.[81] Direct evidence linking exposure to the development of childhood ALL does not exist. However, recent work with NAD(P)H:quinone oxidoreductase 1, one of the enzymes responsible for benzene and other quinone metabolism, has a mutation with decreased enzymatic activity that has been linked with the development of both AML and ALL in adults.[82] Patients with low NAD(P)H:quinone oxidoreductase 1 activity are less able to respond to oxidative stress, have evidence of increased numbers of chromosomal translocations, and have a general increase in the risk of developing leukemia. The GSTs represent another set of xenobiotic detoxifying enzymes with a known series of polymorphic mutations that effect function.[83] It has been suggested that GST null mutations may be associated with the development of infant and other subtypes of ALL.[84,85] There is substantial evidence that chemotherapy itself, particularly with alkylating agents, has leukemogenic potential. In a study of more than 9,000 2-year survivors of childhood cancer, a 14-fold excess of leukemia was observed, primarily attributable to therapy with alkylating agents.[86] Most of these cases, however, were AML. Other factors studied for possible association with ALL include parental cigarette smoking; herbicide and pesticide exposure; paternal military experience (particularly with service in Vietnam or Cambodia, in which servicemen were exposed to Agent Orange and other chemicals); maternal use of alcohol, contraceptives, and diethylstilbestrol; household radon exposure; and chemical contamination of ground water.[29,32,87,88,89,90 and 91] Definitive causal relationships between these factors and

childhood ALL have not been demonstrated.

### Viral Infection

There has been intense interest in the possible role played by viral infection in the pathogenesis of human leukemia. [92,93] and [94] This has been due in part to the fact that the young age of onset distribution of ALL corresponds with a time when the immune system is developing and is perhaps more vulnerable to the oncogenic effects of particular viruses. Some reports have suggested an increased risk for ALL in children born to mothers recently infected with influenza, varicella, or other viruses, but no definitive link between prenatal viral exposure and leukemic risk has been confirmed. No direct association between childhood or maternal viral infections and the occurrence of ALL has been documented, and those that have been investigated have not been shown to be clearly causative. [20,95] A possible inverse association with hepatitis A virus (as a measure of general hygiene) has been shown. [96] On the basis of this association, it has been hypothesized that the greater increase in ALL incidence in United States and Japanese populations compared to that in the less developed countries may simply be that children in the developed world are more "immunologically naive." Thus, they may be more susceptible to infectious/oncogenic agents acquired either *in utero* or early in life. Both the possible existence of a rare leukemogenic virus and the hypothesis that ALL represents a "rare response to a common infection" have stimulated continued investigation of a viral etiology. [94] Possible causal associations between human ALL and feline and bovine leukemia viruses and the polyomaviruses JC, BK, or simian virus 40 have never been confirmed.[95,98]

The Epstein-Barr virus (EBV) has been linked to cases of endemic Burkitt's lymphoma, the L3 morphologic subtype of ALL, and some cases of Hodgkin's disease. The EBV association is discussed further in the section on molecular genetics and in Chapter 24. The human lymphotropic viruses I and II are retroviruses that are implicated in some cases of adult T-cell and hairy cell leukemia. Cases of childhood malignancies have been linked to human immunodeficiency virus (HIV) infection, but the spectrum of histologies is different from those seen in adult acquired immunodeficiency syndrome patients. Pediatric acquired immunodeficiency syndrome patients have an increased incidence of non-Hodgkin's lymphoma (usually of B-cell origin; see Chapter 24), mucosa-associated lymphoid tumors (so-called MALT lymphomas), cystic tumors of the thymus, leiomyomas, leiomyosarcomas, and angiosarcomas.[99,100,101] and [102] Whether HIV or the immunodeficiency state that it induces is responsible for the increased rate of malignancies is unknown.

### Immunodeficiency

Children with various congenital immunodeficiency diseases, including Wiskott-Aldrich syndrome, congenital hypogammaglobulinemia, and AT (see the sections on epidemiology and genetics), have an increased risk of developing lymphoid malignancies, as do patients receiving chronic treatment with immunosuppressive drugs. These are usually lymphomas with mature B-cell phenotypes. Although ALL may occur in these circumstances, it is uncommon. Individuals with AT and Fanconi's anemia have increased chromosomal fragility and frequent abnormalities of chromosomes 14 and 7, suggesting that genetic mechanisms are important in these disorders.[103]

Abnormalities of the immune system are occasionally observed in newly diagnosed patients with ALL. [104] Abnormally low serum immunoglobulin levels have been observed in as many as 30% of these patients. Whether such abnormalities precede the development of leukemia or are a consequence of the disease is unclear. Similarly, abnormalities of the immune system may persist after therapy, although the effects of therapy versus those of the leukemia may be difficult to discern. [105] In addition to possibly contributing to the etiology of ALL, altered immune status may effect susceptibility to relapse or the development of second malignancies after completion of therapy (see the section Late Effects of Treatment; see also Chapter 14 and Chapter 17).

### Clonal Pathogenesis

ALL, similar to other lymphoid malignancies, is believed to develop as a consequence of malignant transformation of a single abnormal progenitor cell that has the capability to expand (into a so-called clone of similar progeny cells) by indefinite self-renewal. It is not entirely clear where in the normal course of differentiation the leukemic "clonal event" occurs, and it may actually be highly variable. In pediatric ALL there is evidence that these events occur in committed lymphoid precursors, whereas in AML and Philadelphia chromosome–positive ($Ph^+$; see the section Cytogenetics) ALL, it appears that they may occur earlier because there is evidence of mutation in multiple cell lineages. [106,107] The events that lead to the process of malignant transformation are complex and multifactorial. It has been proposed that ALL results from spontaneous mutation(s), which may occur in lymphoid cells of B- or T-cell lineage or in their precursor cell(s). [54,108] As noted previously, there is emerging evidence that the causative mutations may occur years before the presence of clinical leukemia. During normal lymphoid development, lymphocyte precursors may be at higher risk for spontaneous mutation because of the intrinsic, regulated, mutagenic activity occurring during the process of gene rearrangement and the high rate of proliferation in these cells. Many of the described molecular mutations bear evidence of immunoglobulin VDJ and T-cell receptor (TCR) recombinase activity. [109]

Greaves[108] theorized that one or, more likely, two sequential mutations spontaneously occurring in important regulatory genes in a lymphoid cell population undergoing significant proliferative stress could account for most ALL cases. Elaborating on this hypothesis, Greaves [108] suggested a model, analogous to that proposed in Knudson's two-hit hypothesis for the origin of embryonal malignancy, in which two distinct genetic events, one initiational and the other promotional, are involved in leukemogenesis. This hypothesis, which is a particularly attractive explanation for the development of B-cell precursor ALL, requires further confirmation. The recent *in utero* mutational findings discussed above may indeed localize the timing (if not the mechanism) of the initiational events.

Other support for the clonal expansion theory comes from classic studies of glucose-6-phosphate dehydrogenase isotypes, and cytogenetic and molecular studies. [110] Rearrangement of immunoglobulin and TCR genes also has been studied as a marker of clonality in ALL of pre-B lineage. [109,111] In most cases, identical patterns of immunoglobulin and TCR gene rearrangement are observed in leukemic cells obtained at diagnosis and relapse. [107,111,112] Infrequently, clonal variations occur in serial samples, suggesting polyclonal disease, or clonal progression. In most of these cases, however, the leukemia cells share at least one identical immunoglobulin gene rearrangement, implying a common clonal origin.[112]

For many years, it has been assumed that cure of ALL implied the killing of all leukemic cells. This may not be true, because multiple MRD technologies (see the section Minimal Residual Disease) are occasionally reported to show evidence of viable leukemic cells late and even off-therapy in patients who do not clinically relapse. Whether these cells truly represent clonal cells identical to those at leukemic diagnosis (versus a vestige of a preleukemic clone) is the subject of intense scrutiny. Another hypothesis would accept these cells as being those of the original clone; however, the patient's own immune system may have learned to control their proliferation.[111]

### Molecular Pathogenesis

The identification of chromosomal translocations in leukemic blasts led to the eventual identification and cloning of the individual genes disrupted by these events (see the section Cytogenetics and Table 19-1). Many of these cytogenetic changes occur at the location of immunoglobulin, TCR, and various transcription factor genes. In addition to chromosomal translocations, there are a variety of genetic events that appear to be leukemogenic but are undetectable with classic cytogenetic methods. These include small deletions, mutations, or chemical alteration (i.e., methylation) of DNA that can inactivate tumor suppressor genes or activate oncogenes. Point mutations can result in missense, nonsense, or frame shift mutations. These molecular lesions are discussed in greater detail in Chapter 4.

DNA mutations or alterations in the protein expression of p53, MDM2, p16, or p15, the interferon genes located on 9p, WT1 (i.e., the Wilms' tumor gene located at 11p13), the TEL and KIP1 loci on 12p12-p13, and others have all been described in fresh ALL samples and ALL-derived cell lines. [113,114,115,116,117,118] and [119] Although the abnormalities detected in most of these genes may not be as definitively leukemogenic as the bcr-abl and other fusion gene mutations described later (Table 19-1), they are commonly observed in pediatric ALL and appear to contribute both to the development of leukemia and (in some cases) to the response to specific chemotherapeutic agents.[120]

p53 is the gene most frequently found to be altered in human cancers (see also the discussion of p53 in Chapter 3).[121] Studies of p53 sequence, structure, and function in pediatric ALL have revealed a low rate of the same types of missense mutations and loss of heterozygosity of the wild-type allele as that found in solid tumors.[114,122,123] These changes are associated with the production of a mutated p53 protein. A number of cases of pediatric ALL have had deletions and large chromosomal rearrangements that resulted in the total loss of p53 protein. [114] The p53 mutations are predominantly found in T-cell leukemias. [124,125] and [126] Because p53 abnormalities are more commonly observed at relapse and occur at a relatively high rate (greater than 60%) in T-cell lines derived from relapsed patients, some investigators believe that they may not be directly causative in these leukemias. Alternatively, it has been hypothesized that p53 mutations may function as progression factors involved in the biologic events that lead to relapse or disease that is refractory to treatment. [120] In support of this hypothesis, several studies have

shown p53 mutations or overexpression of MDM2 (a protein that binds and causes p53 inactivation) in the blasts of patients who were refractory to treatment or had early relapse.[113,127] The exact role of p53 mutations in different types of ALL is unknown. Mutations have been identified in cases involving virtually every level of ALL differentiation.[128]

Another potential mechanism in the development of ALL involves mutational events that prevent apoptosis (programmed cell death). Originally cloned from the oncologic translocation breakpoint, t(14;18)(q21;q32), common in adult follicular and diffuse B-cell lymphomas, the Bcl-2 protein is able to prevent apoptosis and immortalize cells in tissue culture and transgenic murine models.[129,130] In transgenic murine models it not only prevents the normal apoptosis seen in developing lymphoid cells but also causes an expanded lymphoid compartment and leads to a high rate of lymphoid malignancies.[131] Several groups have noticed that increased Bcl-2 levels in leukemic blasts correlate both with their ability to grow in tissue culture and with poorer prognosis in ALL and AML.[131,132] and[133] However, there is an innate redundancy in the apoptotic pathways, such that apoptosis mediated by Fas or even wild-type p53 may be able to overcome a lack of Bcl-2 in some ALL blasts.[134]

## PATHOBIOLOGY

Morphologic, immunologic, cytogenetic, biochemical, and molecular genetic characterizations of leukemic lymphoblasts have confirmed that ALL is a biologically heterogeneous disorder. This heterogeneity reflects the fact that the leukemia may develop at any point during the multiple stages of normal lymphoid differentiation.

### Morphologic Classification

There have been several attempts to classify ALL cells morphologically using criteria such as cell size, nuclear to cytoplasmic ratio, nuclear shape, number and prominence of nucleoli, nature and intensity of cytoplasmic staining with a variety of staining agents, presence of cytoplasmic granules, prominence of cytoplasmic vacuoles, and the character of nuclear chromatin (Table 19-2 and Table 19-3).[135,136] Most of these efforts were unsuccessful because they were technically difficult to reproduce or lacked meaningful clinical correlations.[137,138] One system, however, proposed by the French-American-British (FAB) Cooperative Working Group has become generally accepted.[139,140] The FAB system (Fig. 19-3 and Table 19-2) defines three categories of lymphoblasts. L1 lymphoblasts are usually smaller, with scant cytoplasm and inconspicuous nucleoli. Cells of the L2 variety are larger, and they demonstrate considerable heterogeneity in size, prominent nucleoli, and more abundant cytoplasm. Lymphoblasts of the L3 type, notable for their deep cytoplasmic basophilia, are large, frequently display prominent cytoplasmic vacuolation, and are morphologically identical to Burkitt's lymphoma cells.

| Cytologic Features | L1 | L2 | L3 |
|---|---|---|---|
| Cell size | Small cells predominate | Large, heterogeneous in size | Large homogeneous |
| Nuclear chromatin | Homogeneous in very one case | Variable; heterogeneous in any one case | Finely stippled and homogeneous |
| Nuclear shape | Not visible or small and inconspicuous; none vesicular | Irregular clefting and indentation common | Regular—oval to round |
| Nucleoli | Regular; occasional clefting or indenting | One or more present; often large | Prominent; one or more |
| Amount of cytoplasm | Scanty | Variable; often moderately abundant | Moderately abundant |
| Basophilia of cytoplasm | Slight or moderate; rarely intense | Variable; deep in some | Very deep |
| Cytoplasmic vacuolation | Variable | Variable | Often prominent |

**TABLE 19-2. FRENCH-AMERICAN-BRITISH CLASSIFICATION OF LYMPHOBLASTIC LEUKEMIA**

| | Acute lymphoblastic leukemia | Acute myeloid leukemia |
|---|---|---|
| **Characteristic** | | |
| Nuclear/cytoplasmic ratio | High | Low |
| Nuclear chromatin | Clumped | Spongy |
| Nucleoli | 0–2 | 2–5 |
| Granules | – | + |
| Auer rods | – | + |
| Cytoplasm | Blue | Blue-gray |

| Naphthyl ASD chloracetate esterase | – | + |
| α-Naphthyl acetate esterase | – | + |
| α-Naphthyl butyrate esterase | – | – |
| Terminal deoxynucleotidyl transferase | +* | – |

+, cytochemical stain positive; +/–, cytochemical stain equivocal; –, cytochemical stain negative.
Note: Table provides information on characteristics that may be useful in differentiating acute lymphoblastic leukemia from acute myeloid leukemia. Wide variation in morphology is encountered in both disease categories. Diagnostic evaluation should use other studies, including immunophenotyping and cytogenetics.
*Terminal deoxynucleotidyl transferase is usually negative in typical French-American-British L3 acute lymphoblastic leukemia.

**TABLE 19-3. MORPHOLOGIC, CYTOCHEMICAL, AND BIOCHEMICAL CHARACTERISTICS HELPFUL IN DIFFERENTIATING ACUTE LYMPHOBLASTIC LEUKEMIA FROM ACUTE MYELOID LEUKEMIA**

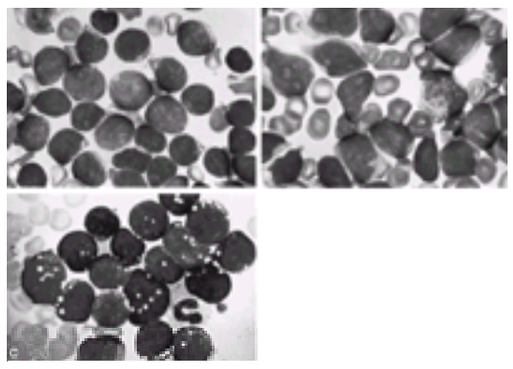

**FIGURE 19-3.** Morphologic appearance of acute lymphoblastic leukemia cells classified according to the French-American-British system. **A:** L1 morphology. **B:** L2 morphology. **C:** L3 morphology.

Approximately 85% of children with ALL have predominant L1 morphology, 14% have L2, and 1% have L3.[141] The L2 subtype is more common in adults.[142] Lymphoblasts of the L3 type possess cell surface immunoglobulin and other characteristic B-cell markers. There is, however, no apparent correlation between the FAB L1 and L2 morphologic types and immunologic cell surface markers.[143,144] Concordance among investigators using the FAB system is relatively high.[141,145,146] Since its original description, refinements of the FAB system have been proposed.[147,148] Although the existence of different approaches to FAB classification can confound interstudy comparisons, a variety of individual studies have demonstrated that the FAB classification has prognostic value.[147,149,150]

L1 morphology has been associated with a higher remission induction rate and better event-free survival (EFS) than L2 morphology, which appears to convey poor prognosis.[147,150] In early studies, L2 morphology appeared to be an independent prognostic variable indicative of poor outcome.[148] In more recent studies, however, it sometimes loses its predictive value when the patients are stratified for age, sex, and diagnostic white count.[136] Patients with the L3 morphology have the worst overall prognosis.[151,152] Although the FAB classification system appears to have value as a prognostic indicator, no biologic basis for the morphologic differences

delineated by this system has been identified. Generally, the most important morphologic distinctions are those between ALL and AML ( Table 19-3). Routine Wright's and cytochemical stains are usually adequate for this task, but fluorescent antibody cell sorting (FACS) and chromosomal analysis can be helpful in equivocal cases.

An unusual morphologic variant of ALL is the so-called hand mirror–cell variant in which leukemic cells are characterized by a hand mirror shape caused by a handle-shaped uropod.[153,154] Approximately, 5% to 23% of pediatric ALL cases are said to have this morphology.[136,155] The data concerning the prognostic implications of hand mirror morphology have been mixed.[136,155,156] The suggestion that the hand mirror–cell variant is associated with the development of CNS disease has not been confirmed.[157,158] In adult ALL the hand mirror morphology has been associated with a subset of female patients whose leukemic blasts display myeloid and lymphoid antigens (i.e., mixed phenotype) and whose clinical course is relatively indolent despite the fact that they rarely enter complete remission. [159,160]

Cytochemical stains have been studied with respect to their ability to differentiate between various clinical and immunologic subsets of ALL. The periodic acid–Schiff, acid phosphatase, b-glucuronidase, and acid a-naphthyl acetate esterase reactions have been evaluated. [161,162,163,164] and [165] Although some correlations appear strong (e.g., strong focal paranuclear acid phosphatase activity appears to be more common in T-cell disease), the practical use of this type of information is limited and has been supplanted by more sophisticated immunologic techniques, such as immunophenotyping with FACS. In rare cases of acute leukemia that cannot be definitively classified by current immunologic or molecular methods, ultrastructural detection of platelet peroxidase or myeloperoxidase may be helpful in identifying the megakaryocytic or myeloid nature of the disease.[166]

**Immunobiology**

Studies of the immunobiology of ALL have confirmed that leukemic transformation and clonal expansion can occur at different stages of maturation in the process of lymphoid differentiation (Fig. 19-4 and Fig. 19-5). In the early 1970s, when the first surface markers were used to characterize ALL in terms of cell origin and stage of differentiation, three immunologic subsets were delineated: T-cells, B-cells, and non–T/non–B-cells. Using receptors for sheep erythrocytes, approximately 20% of pediatric patients with ALL were found to have T lymphoblasts. [167] Cell surface immunoglobulin and complement receptors identified ALL of B-cell origin in 1% to 2% of patients. With these older immunologic methods of characterization, the remaining patients with ALL had no detectable cell surface markers on their blasts and thus were considered to have non-T, non–B-cell or so-called null cell leukemia. [168] The development of heterologous antisera and monoclonal antibodies directed against human leukemia–associated antigens indicated that approximately 80% of patients formerly presumed to have had non-T, non–B-cell ALL had a common ALL antigen (CALLA), CD10, on their cell surface.[169,170] and [171] This leukemic subset is now referred to as *CALLA+*, *CD10+*, or *common ALL*.

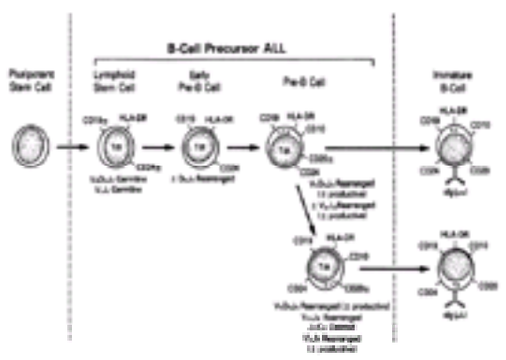

**FIGURE 19-4.** Schematic representation of stages of lymphoid differentiation found in B-cell precursor acute lymphoblastic leukemia (ALL) of childhood. Stages are delineated on the basis of reactivity with commonly used monoclonal antibodies, immunoglobulin and T-cell receptor gene rearrangement, terminal deoxynucleotidyl transferase activity, and presence or absence of cytoplasmic or cell surface immunoglobulins. (From Felix CA, Poplack DG. Characterization of acute lymphoblastic leukemia of childhood by immunoglobulin and T-cell receptor gene patterns. Leukemia 1991;5:1015–1025, with permission.)

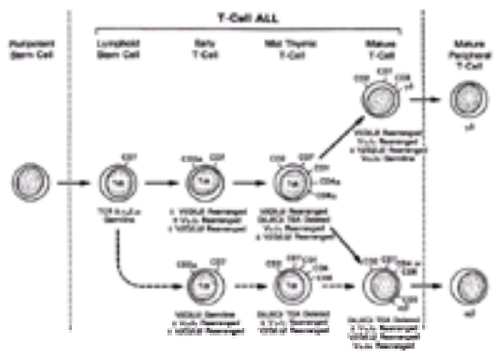

**FIGURE 19-5.** Schematic representation of stages of lymphoid differentiation found in T-cell acute lymphoblastic leukemia (ALL) of childhood. Stages are delineated on the basis of reactivity with commonly used monoclonal antibodies, immunoglobulin and T-cell receptor gene rearrangement, and terminal deoxynucleotidyl transferase activity. (From Felix CA, Poplack DG. Characterization of acute lymphoblastic leukemia of childhood by immunoglobulin and T-cell receptor gene patterns. Leukemia 1991;5:1015–1025, with permission.)

Most leukemias previously determined to be of the non-T, non-B type are actually of early B-cell lineage. The demonstration of intracytoplasmic immunoglobulin in some of these cells, their reactivity with monoclonal antibodies specific for B-cell associated antigens, and their ability to differentiate *in vitro* into cells with mature B-cell markers confirmed that approximately 80% to 85% of childhood ALL cases develop as a result of the monoclonal proliferation of B-cell precursors. [172,173] The presence of cytoplasmic immunoglobulin (cIg) has been a useful marker to determine the level of differentiation of leukemic cells of B-cell lineage. [146,174] cIg exists in approximately 20% to 30% of cases of B-cell precursor ALL.

The use of monoclonal antibodies, improvements in the enzymatic and fluorescent tagging of these antibodies, and the development of the multiparameter FACS machine have revolutionized pathologic classifications of many diseases, including ALL. [175] More than 200 different monoclonal antibodies are commercially available that can detect antigens associated with the different hematopoietic lineages. Those most helpful in the immunologic classification of ALL are shown in Table 19-4. Using a panel of monoclonal antibodies associated with various stages of B-cell differentiation along with information on the presence or absence of cytoplasmic and surface immunoglobulin, investigators have classified B-lineage ALL into discrete stages according to the degree of differentiation or maturation ( Fig. 19-4).[141,143,176] However, none of the monoclonal antibodies used in routine clinical immunophenotyping is absolutely lineage specific. [177,178] *Lineage associated* is the preferred terminology. To accurately immunophenotype most cases requires use of a panel of multiple antibodies. The choice of the diagnostic panel may vary among institutions and laboratories, but for the characterization of lymphoid leukemias antibodies for several T-cell antigens (i.e., CD3, 5, or 7) and early-B lineage, antigens CD10, 19, and 22 are generally used.

| CD* | Predominant reactivity |
|---|---|
| **T Cell** | |
| CD1 | Thymocytes |

**TABLE 19-4. MONOCLONAL ANTIBODIES COMMONLY USED TO IMMUNOPHENOTYPE LEUKEMIA**

There are some prognostic differences between the various precursor B-lineage ALL subgroups. Mature B-cell ALL has a poorer prognosis than earlier B-lineage subgroups. The distinction between patients with pre–B-cell (cIg+) ALL and those with early pre-B ALL (cIg–), however, does not seem to be prognostically relevant as long as the patients are stratified by risk group criteria and treated accordingly (see the section Treatment).[5,146,179] Patients with B-cell precursor ALL whose lymphoblasts manifest CALLA (CD10) have a more favorable prognosis.[145,146] Expression of the stem cell antigen CD34, present on approximately two-thirds of B-cell precursor ALL, also appears to be associated with a good prognosis.[180,181 and 182]

Identification of immunoglobulin gene rearrangement is helpful in confirming the B-cell precursor lineage of ALL cells otherwise devoid of other B-cell or pre–B-cell markers.[145,146] There is a hierarchy of immunoglobulin gene rearrangements in B-cell precursor ALL that mirrors different stages of normal B-cell differentiation ( Fig. 19-4).[146,183] Heavy-chain rearrangement precedes k light-chain rearrangement, which precedes l light-chain rearrangement. [143,183,184 and 185] As shown in Figure 19-4, it is possible to relate the pattern of immunoglobulin gene rearrangement to the discrete stages of lymphoid differentiation.

Although many cases fit the hypothesis that ALL is a disorder characterized by the clonal expansion of cells representing a specific stage of normal differentiation, it is evident that many B-cell–lineage leukemias exhibit a differentiation antigen pattern or immunoglobulin gene rearrangement profile that is not synchronous with any of the normal stages of differentiation.[186,187] In addition to this asynchrony of antigen expression, leukemic cells from some patients manifest characteristics of more than one lineage. The significance of such “lineage infidelity” in the display of immunophenotypic markers is controversial. [177,188]

Heavy-chain immunoglobin gene rearrangement has been observed in approximately 10% to 15% of T-cell ALL cases. [176,189,190 and 191] This phenomenon of “lineage spillover” indicates that heavy-chain rearrangement alone is an insufficient basis for assigning B-cell lineage. [190,192] TCR gene rearrangement also occurs with relatively high frequency in B-cell precursor ALL.[192,193] B-cell precursor ALL devoid of immunoglobulin (or TCR) rearrangement has been described. This germline configuration appears to be a characteristic of some cases of B-cell precursor ALL of infancy. [190]

T-cell ALL has distinctive immunobiologic as well as clinical features (see the section on prognostic factors). Molecular genetic analysis of the genes encoding the TCR provides a useful molecular marker of T-cell lineage commitment and the stage of T-cell differentiation. Study of the d, g, b, and a TCR gene rearrangement in T-cell ALL reveals a hierarchy of sequential TCR activation events that can be roughly correlated with the sequence of T-cell surface antigen expression in a fashion analogous to the hierarchy of immunoglobulin gene rearrangement found in B-cell precursor ALL ( Fig. 19-5).[176,194] Although molecular genotyping can provide insight into the developmental state of T-cell ALL, use of molecular markers alone to designate T- or B-cell lineage is inappropriate. As discussed above, immunoglobulin gene rearrangements may occur in T-cell ALL, and TCR gene rearrangements are observed even more frequently in B-cell precursor ALL. [176,195] Such lineage spillover may represent leukemias derived from cells at an early stage of lymphoid development, when TCR and immunoglobulin genes are accessible to a common recombinase enzyme. Cases of T-cell ALL putatively derived from the earliest stages of differentiation have neither immunoglobulin nor TCR rearrangements.

T-cell ALL has been subclassified using monoclonal antibodies, which detect surface antigens present at discrete stages in the process of normal T-cell differentiation or maturation.[168,196] Three stages of normal intrathymic differentiation have been proposed: early (stage I), intermediate (stage II), and late (stage III; Fig. 19-5). T-cell maturation involves a continuum of phenotypic changes, and T cells can be identified that are presumably derived from each of these different stages of differentiation.[168] Most T-cell leukemias display the antigen pattern of the early thymocyte stage I. In contrast, malignant cells from patients with T-cell lymphoma generally manifest an intermediate or a mature phenotype.[168] As in B-cell precursor ALL, however, numerous reports exist of T-cell ALL cases expressing immunophenotypes not typically representative of the normal stages of T-cell maturation. [186]

As noted previously, not all ALL cases adhere to a specific lineage. Comparisons between normal and leukemic cells using monoclonal antibodies or molecular genotyping have verified that numerous cases occur in which the leukemic cells express characteristics of more than one hematopoietic lineage. [197,198 and 199] In biphenotypic or acute mixed-lineage leukemia, lymphoid and myeloid characteristics are present on the same leukemia cell. Bilineal or biclonal leukemias are those in which there are two distinct populations of cells, one lymphoid and the other myeloid. *Lineage switch* (or *lineage shift*) is the term used to describe a conversion from one phenotype at diagnosis to a different phenotype at relapse.

Confirmation of the existence of mixed-lineage leukemia usually requires the use of immunophenotypic, molecular, karyotypic, and cytochemical information. When initial reports of mixed-lineage leukemias first appeared, it was assumed that dual markers represented an artifact produced by phenotypic markers that lacked specificity. However, numerous well-documented cases exist that meet even the most stringent classification criteria. It is apparent that the simultaneous expression of lymphoid and myeloid markers occurs more commonly than previously believed. In various series of pediatric ALL cases, the incidence of myeloid marker expression has ranged from 7% to 25%.[188,200,201 and 202]

The biologic basis for the appearance of mixed-lineage leukemias is not understood. It has been suggested that they occur as a result of inappropriate or aberrant gene activation and thus do not represent leukemias derived from a corresponding normal stage of hematopoietic development. [198] Alternatively, it has been proposed that mixed-lineage leukemias represent the clonal expansion of normal, bilineage, or multilineage potential precursors, which are difficult to detect in normal bone marrow.[198] Mixed-lineage leukemia is sometimes associated with particular cytogenetic and molecular findings; there is a higher incidence of mixed-lineage phenotype seen in the abnormal 11q23 cases, especially in the t(4;11)(q23;q23) cases, and in leukemias containing Ph, t(9;22). [5,203,204] The 11q23 abnormalities and the t(9;22) cytogenetic abnormalities are independently associated with poor prognosis (see the section on cytogenetics). It is unclear whether expression of one or more myeloid antigens in a subset of these lymphoid leukemias conveys further prognostic significance.

Although in the past, controversy existed over the preferred treatment of mixed-lineage leukemias, most investigators now agree that with modern chemotherapy regimens, there is no difference in outcomes between myeloid antigen–postive and myeloid antigen–negative ALL. Thus therapy should not be altered for this finding.[188,200,201 and 202] Confounding features in these studies have been differences in the actual treatment regimens used, differing definitions of myeloid antigen positivity, and occasionally differences in the source of the antibodies and methodologies used to phenotype the cells. [178]

In addition to immunophenotyping, which is essentially a gene expression study, other gene expression modalities are beginning to be used to characterize leukemias. These include complementary DNA (cDNA) microarray (Fig. 19-6A), real-time and other modifications of reverse transcriptase-PCR (RT-PCR), which examine messenger RNA expression levels, and new mass spectroscopy techniques for proteins (proteomics). [205,206 and 207] These and other new techniques allow researchers to examine large patterns of gene expression at either the RNA or protein level. If specific patterns can be correlated with clinical response, these new characterization methods should allow increased refinement of current prognosis-based stratification systems.

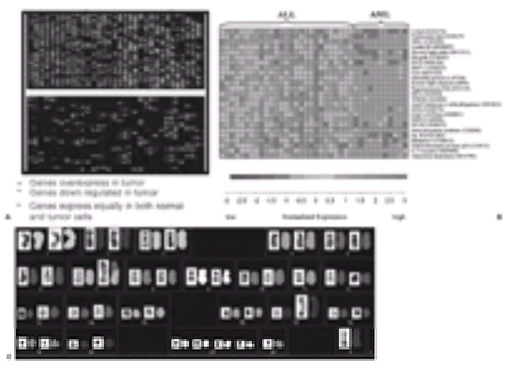

**FIGURE 19-6.** Application of new techniques for the molecular and cytogenetic characterization of acute lymphoblastic leukemia (ALL) blasts. **A:** Complementary DNA/messenger RNA (cDNA/mRNA) microarray. There are several current versions of this technology, including spotted cDNA arrays and oligonucleotide arrays. This example is of a cDNA array undergoing competitive hybridization from two sources of fluorescent-labeled RNA. The relative expression of each of 6,000 genes is measured by quantifying the amount of light emitted at the designated wavelengths at each spot on the array. **B:** Clustering of expression data on 11,000 genes (on an Affymetrix oligonucleotide array) from 38 cases of leukemia, showing that it is possible to use this technology to see differences as well as similarities among disease cases. (From Golub TR, Slonim DK, Tamayo P, et al. Molecular classification of cancer: class discovery and class prediction by gene expression monitoring. Science 1999;286:531–537, with permission.) **C:** Spectral karyotyping (SKY) on leukemic ALL blast cells. This case is remarkable for aneusomy (abnormal number) of chromosomes 21 and 22 as well as several complex marker chromosomes [45, der(X)t(X;17)(p21;q24), –Y, der(7)t(5;7)(a12;p22), and ider(17)(q10)t(X;17)(?q11)]. AML, acute myelogenous leukemia; IL-7, interleukin-7. (SKY results courtesy of X.Y. Lu, C.P. Harris, C.C. Lau, and P.H. Rao, *personal communication*, 2001.) (See Color Figure 19-6.)

Although immunophenotyping and cytogenetic analysis arise from different scientific disciplines, it has now become apparent that specific combinations of antigen expression correlate with the likelihood of detecting specific molecular genetic changes. [208,209,210 and 211] Advances in immunophenotyping reagents and instrumentation are also opening up new avenues of leukemic clone characterization—that is, it may be possible to quantitatively compare and find prognostic significance in the fluorescence intensity of specific antigens. [212] Multicolor/multiparameter FACS, which now permits the detection of as many as five different antigens simultaneously expressed on the same cell, is sensitive enough to determine the clonality of blast populations as well as detect phenotypically abnormal cells with a sensitivity of $10^{-4}$.[111] Current research is evaluating to what extent these newer FACS techniques may provide for accurate correlation with molecular cytogenetic changes and clinical outcomes.

## CYTOGENETICS

The improvement in the technology of cytogenetic analysis has increasingly contributed to the understanding of the biology and treatment of ALL. When combining the newer methods of chromosomal banding and standard fluorescent *in situ* hybridization (FISH) with the molecular genetic techniques of spectral karyotyping (SKY) (Fig. 19-6B) and comparative genomic hybridization (CGH), abnormalities can be recognized in the leukemia cells of virtually 100% of cases of pediatric ALL.[213,214,215,216,217 and 218] The SKY technique uses 24 color chromosomal paints (one specific to each chromosome). These paints allow reliable, genome-wide assignment of the chromosome origin of material in complex translocations that are often below the level of standard Giemsa detection. CGH is particularly suited for detecting losses or gains of material (e.g., deletions, duplications, and amplifications) that can be missed by both SKY and standard cytogenetic techniques. CGH also has the advantage of not requiring metaphase cells or cell culture of the diagnostic material. Both SKY and CGH are currently research techniques, which are used in conjunction with standard cytogenetics. These new methods require specific computer and fluorescent microscopy workstations and a licensed clinical cytogeneticist for proper clinical interpretation and correlation with the diagnostic Giemsa banded karyotype.

The cytogenetic abnormalities reported in ALL involve both chromosomal number (ploidy) and structural rearrangement. [219,220,221 and 222] The following sections discuss the molecular and clinical correlates of specific chromosomal changes in ALL. Their implications for treatment are discussed in the section on treatment.

### Ploidy

Ploidy can be determined directly by the classic method of counting the modal number of chromosomes in a metaphase karyotype preparation, or by an alternative indirect method of measuring DNA content by flow cytometry.[221] The DNA content by flow cytometry is measured in a DNA index (DI), which is a ratio between the normal amount of fluorescence seen in a diploid cell and the fluorescent content of the bone marrow blasts (in $G_0/G_1$) at diagnosis.[223] Normal diploid or pseudodiploid cells (cytogenetically abnormal but have a normal DNA content) have a DI of 1.0. Hyperdiploidy is defined by a DI greater than 1.0 and hypodiploidy by a DI less than 1.0.

Prognostically significant hyperdiploidy is often measured starting at a DI of greater than 1.16, which corresponds to a modal number of 53 chromosomes. [224] Most cases of ALL exhibit diploidy or hyperdiploidy (Table 19-5). The ploidy of B-lineage ALL karyotypes has long been known to be a prognostic determinant. [221,224,225] Although the absolute number of chromosomes chosen as the "cut-point" for analysis may vary slightly between studies, children with higher ploidy (greater than 50 chromosomes) have the best prognosis. Those in the pseudodiploid category (those with a DI of 1.0 or a normal chromosome number but other chromosomal abnormalities, for example, translocations) have a relatively poor prognosis ( Fig. 19-7). Children with diploidy and hyperdiploidy with 47 to 50 chromosomes have a slightly worse prognosis than that of the hyperdiploid group with 51 to 56 chromosomes, and the best prognosis appears to be for the higher-hyperdiploid group with 56 to 67 chromosomes.[226,227 and 228] Patients in the hyperdiploid group usually share a number of the more important good prognostic features (see the section on prognostic factors), including a favorable age, low initial leukocyte count, and a B-cell precursor phenotype often displaying CALLA. [221] An exception to the general rule that hyperdiploid ALL cases have good prognoses is the relatively rare group of hyperdiploid ALL cases with the near-tetraploid subtype (82 to 84 chromosomes), which appear to have a poorer prognosis.[226,229]

| Ploidy group | Frequency (%) |
|---|---|
| Near haploidy | <1.0 |
| Hypodiploidy, 30–40 | <1.0 |
| Hypodiploidy, 41–45 | 6.0 |
| Pseudodiploidy | 41.5 |

**TABLE 19-5. FREQUENCY OF PLOIDY GROUPS IN CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA CASES**

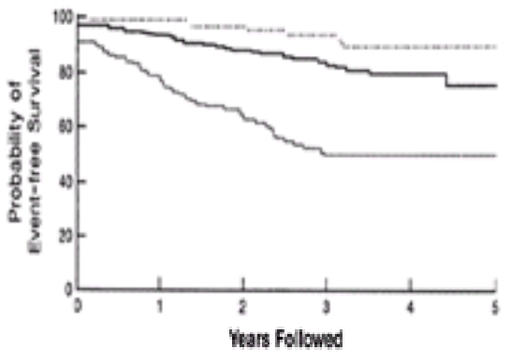

**FIGURE 19-7.** Ploidy is a prognostic determinant. Results are shown for patients with B-precursor acute lymphoblastic leukemia (infants excluded) treated by the Pediatric Oncology Group. Patients (n = 114) with a DNA index greater than 1.16 [i.e., hyperdiploid: (...)] have a better prognosis than those (n = 353) with a DNA index less than or equal to 1.16, white blood cell count (WBC) less than $50 \times 10^9$ per L, and age younger than 11 years; (*bold line*) or a DNA index less than 1.16, WBC less than $50 \times 10^9$ per L, and age older than 11 years (*lowest curve*). (From Trueworthy R, Shuster J, Look T, et al. Ploidy of lymphoblasts is the strongest predictor of treatment outcome in B-progenitor cell acute lymphoblastic leukemia of childhood: a Pediatric Oncology Group study. J Clin Oncol 1992;10:606–613, with permission.)

Hyperdiploidy occurs when there are more than 46 autosomes and two sex chromosomes, so by definition some chromosomes will be present in more than two copies. Trisomy (presence of three copies of a Chromos) is the most common abnormality seen in hyperdiploid ALL. Trisomies of virtually every chromosome have been described in ALL, but the most commonly found include trisomies 4, 6, 10, 14, 17, 18, 21, and X.[228] Trisomies of chromosomes 4 and 10 have been associated with a very low risk of treatment failure in Pediatric Oncology Group studies ( Fig. 19-8).[230] The Children's Cancer Group (CCG) found similar correlations with trisomies of chromosomes 10 and 17 (Fig. 19-9).[228] Trisomy 10 has the larger effect, but in the studies cited, both trisomy 4 and trisomy 17 appear to have independent positive effects on prognosis.[228,230] When the analysis of the combined trisomies 4 and 10 were linked by the Pediatric Oncology Group and combined 10 and 17 by the CCG data, it was found that (in these data sets) the combination of these pairs of trisomies had better outcomes than those with either trisomy alone.[228,230] Trisomy 6 has also been described as a good prognostic karyotypic feature but does not have as strong a positive prognostic correlation as trisomies 4, 10, and 17.[228,231] At least one trisomy, trisomy 5, has been correlated with a slightly worse prognosis in ALL. However, this effect was lost when the T-cell cases were removed from the analysis.[228] It is unclear which genes on any of these trisomic chromosomes may be responsible for the specific biologic behavior and response to individual therapies.

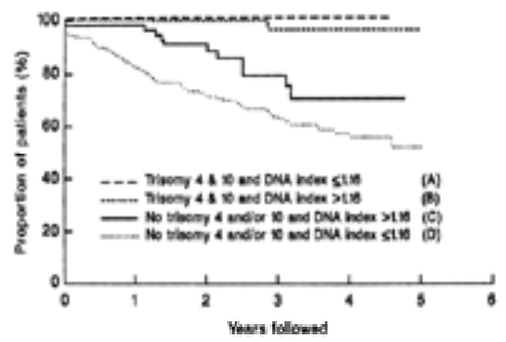

**FIGURE 19-8.** Prognosis of patients with trisomies of chromosomes 4 and 10. Presence of trisomies of chromosomes 4 and 10 are associated with a low risk of treatment failure. Results are shown for patients with B-precursor acute lymphoblastic leukemia (infants excluded) treated by the Pediatric Oncology Group. Patients with these trisomies have a better prognosis than those of patients in the good-risk (DNA index, greater than 1.16) and poor-risk (DNA index, 1.16 or less) groups. (From Harris MB, Shuster JJ, Carroll A, et al. Trisomy of leukemic cell chromosomes 4 and 10 identifies children with B–progenitor cell acute lymphoblastic leukemia with a very low risk of treatment failure: a Pediatric Oncology Group study. Blood 1992;79:3316–3324, with permission.)

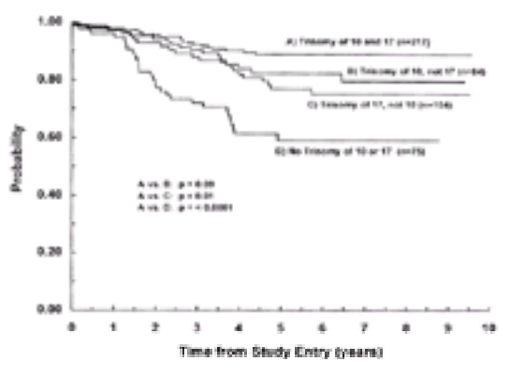

**FIGURE 19-9.** Prognosis of patients with trisomies of chromosomes 10 and 17. Presence of trisomies of chromosomes 10 and 17 are associated with a low risk of treatment failure on Children's Cancer Group protocols. Trisomies of both chromosomes 10 and 17 confer better event-free survival than that for patients with trisomies of each of these chromosomes individually. [From Heerema NA, Sather HN, Sensel MG, et al. Prognostic impact of trisomies of chromosomes 10, 17, and 5 among children with acute lymphoblastic leukemia and high hyperdiploidy (>50 chromosomes). J Clin Oncol 2000;18:1876–1887, with permission.]

Trisomies of chromosomes 8 and 21 are similar to most of the trisomies found in the hyperdiploid category. They are prognostically neutral but warrant some specific comments.[214,232] Trisomy 8, the most common chromosomal numerical abnormality seen in AML, occurs rarely in ALL and is associated with T-cell immunophenotype.[233] When chromosome 8 of leukemic lymphoblasts (i.e., those with trisomies and those without) is examined using FISH, t(8:14)(q24:q32) translocations or duplications of the same 8q24 band may be identified.[232] Region 8q24 is the location of the c-*myc* gene, which is important for cell growth (see Chapter 4 and Chapter 10) and the site of many leukemia-related translocations ( Table 19-1). Thus, the finding of trisomy 8 in leukemic lymphoblasts should prompt a reexamination of the available data to be sure that by morphology, histologic staining, immunophenotype, and karyotype the patient has pre-B ALL and not L3 ALL or AML.

Trisomy 21, as an isolated finding in the leukemic lymphoblasts of non-Down patients, is a neutral prognostic finding.[228] Interestingly, chromosome 21 has been extensively studied and finely mapped, and the sequence was recently published.[234,235] Chromosome 21 contains a large number of known oncogenic transcription and growth factors. AML1, an oncogene from the *runt* family of *Drosophila* transcription factors is encoded on chromosome 21 (21q22). This gene is associated with cytogenetically evident translocations in AML [i.e., the t(8;21) A/ETO fusion] and the t(12;21) TEL/AML1 fusion, which is usually not seen with standard karyotype techniques in ALL (see below) but confers good prognosis.[236,237] and [238]

The worst prognosis (by ploidy) occurs in the rare group of patients with near-haploid ALL (24 to 28 chromosomes), which has an EFS less than 25%.[239,240] Independent of other prognostic factors, ploidy more than or fewer than 45 appears to have important prognostic implications that have not changed with modern therapy (Fig. 19-10).[240,241] Within the fewer than 45 chromosome group, other prognostic factors (i.e., National Cancer Institute standard versus poor risk) still appear

to have some impact (Fig. 19-10).[240]

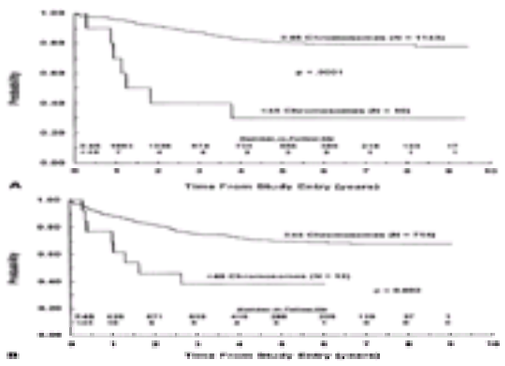

**FIGURE 19-10.** Event-free survival for patients with fewer than 45 chromosomes in their leukemic blasts analyzed by clinical risk grouping. **A:** National Cancer Institute (NCI) standard risk (age 1 to 9 years with leukocyte counts less than 50,000 per µL). **B:** NCI poor risk (age 10 years or older or leukocyte count 50,000 per µL or more). (From Heerema NA, Nachman JB, Sather HN, et al. Hypodiploidy with less than 45 chromosomes confers adverse risk in childhood acute lymphoblastic leukemia: a report from the Children's Cancer Group. Blood 1999;94:4036–4045, with permission.)

### Structural Chromosomal Abnormalities

Structural chromosomal abnormalities also occur in ALL. They are limited to the leukemic cells, a finding consistent with the presumed clonal nature of the disease. Of the structural abnormalities encountered, translocations are the most common. Translocations that are detectable by standard Giemsa banding techniques occur in approximately 40% of cases, but that number is likely to rise with the implementation of the SKY technique described earlier. Multiple recurrent chromosomal translocations have been found in pediatric ALL, which have been linked to rearrangement and altered regulation of cellular oncogenes ( Table 19-1). They are suspected of playing a pivotal role in the leukemogenic process. Translocations are most frequent in the pseudodiploid and hypodiploid groups, occurring with approximately equal frequency in the other abnormal ploidy groups. [213] Translocations were traditionally associated with a poor prognosis. [220,225] The high incidence of translocations in the pseudodiploid and hypodiploid groups may partially explain their relatively poor prognoses. [172] There appears to be an association between certain translocations and immunophenotype (see the section Immunobiology and Table 19-1).

The more common translocations in ALL, the ones linked to prognosis, and known genes in pediatric ALL are listed in Table 19-1. The t(8;14), t(9;22), t(4;11), and t(1;19) translocations are associated with high rates of early treatment failure, but the most common ALL translocation, the t(12;21), appears to have good prognostic implications.

Approximately 5% of ALL patients have visible deletions on standard karyotyping of 12p12-p13 and rearrangements and molecular evidence of loss of heterozygosity involving this region. [238,242,243 and 244] These abnormalities commonly occur in patients with CALLA-positive B-cell precursor disease. [242] The preponderance of reports now indicate that a large percentage of 12p abnormalities in childhood ALL are associated with cryptic t(12;21)(p13;q22) translocations and a good overall prognosis. [244,245] In fact, 22% to 25% of pre-B ALL patients have a cryptic t(12;21)(p13;q22) translocation. This translocation results in the fusion of the coding regions of two transcription factors (i.e., TEL on chromosome 12p13 and AML1 on chromosome 21q22) that are already known to be involved in other hematologic malignancies. [237,244,246]

There is general agreement that the cryptic t(12;21)(p13;q22) confers a favorable initial response to treatment, which extends for at least 3 to 5 years from diagnosis. However, controversy exists concerning the occurrence of late relapses. [247,248,249,250 and 251]

The t(1:19)(q23;p13) translocation, the second most common chromosomal abnormality in childhood ALL, is found in 6.5% of all children with ALL, and is present in 25% of cIg+ pre–B-cell ALL and 1% of cIg early pre–B-cell ALL cases. [213,252,253 and 254] This translocation results in the fusion of the transcriptional activation domain of E2A (a helix-loop-helix transcription factor) on chromosome arm 19p with the DNA-binding homeodomain of PBX1 located on chromosome 1, band q23. [255,256 and 257] The resulting E2A-PBX protein is a transcriptional activator that has been associated with a variety of tumors in different animal models, including T-cell ALL and AML. [258,259] The pre-B ALL cases that have the t(1;19)(q23;p13) and express E2A-PBX1 protein appear to have a poor prognosis. [253,260,261] There appears to be considerable heterogeneity in the location of the E2A and PBX1 breakpoints, however, and in clinical outcome among patients. [253,260,262] For example, patients have been described with a good prognosis who clearly have the t(1;19)(q23;p13) in their leukemic cells but no expression of the E2A-PBX1 fusion protein. It is both the presence of the E2A-PBX1 fusion and its expression in the form of a chimeric messenger RNA and protein that gives the t(1;19) its prognostic influence. [208,263,264] Because the t(1;19) karyotype is often equivocal or falsely negative, molecular techniques such as PCR and FISH have been used effectively to detect E2A-PBX1 fusions. [261,265]

Another fusion partner of the E2A gene on band 19p13 was originally described as a variant of the t(1:19)(q23;p13). [260] The t(17:19)(q22;p13) occurs in 1% of childhood ALL and appears to define a poor-prognosis group of adolescent patients who have an unusual clinical presentation characterized by hypercalcemia, an increased risk of disseminated intravascular coagulation, and a pre-B (cIgM–), low CD10–positivity immunophenotype. [266,267] The E2A fusion partner in this translocation is the hepatic leukemia transcription factor gene (HLF) found on 17q22. The E2A-HLF protein can cause transformation *in vitro*. [268] The known sequence of the E2A-HLF fusion has been incorporated in an RT-PCR system for detecting MRD in patients with this type of disease. [267]

The t(8;14)(q24;q32) can be identified in virtually every case of B-cell ALL (FAB L3). [225,269] In this translocation the c-*myc* proto-oncogene, normally located on chromosome 8, is translocated near a transcriptional enhancer of the immunoglobulin heavy-chain gene on chromosome 14. The resulting dysregulation of c-*myc* expression is believed to be responsible for the uncontrolled proliferation of B cells characteristic of this disorder. In addition to the translocation of c-*myc* coding sequences, mutations sometimes occur in the translocated sequences. [270] Two variant translocations, t(2;8)(p11-p12;q24) and t(8;22)(q24;11), involving the k and l light chains, respectively, are observed less commonly. The similarity in the molecular mechanisms associated with these translocations in B-cell ALL and those that occur in Burkitt's lymphoma supports the presumption that B-cell ALL represents a disseminated form of Burkitt's lymphoma. [219] Patients with B-cell ALL respond quite poorly to conventional ALL treatment but fare somewhat better on therapy similar to that used for Burkitt's lymphoma.

Similar translocations [e.g., t(8;14)(q24;q11)] involving TCR loci and the c-*myc* gene have been described in some cases of T-cell ALL. [271,272 and 273] In these cases, the c-*myc* gene is overexpressed, but the resulting leukemic blasts display T-cell immunophenotype (see the section on T-cell ALL cytogenetics).

There are a number of examples of translocations of transcription factor genes to TCR loci in T-cell ALL ( Table 19-1; see Chapter 4). These translocations may involve the TCRb at 7q34 or the abTCR on 14q11. Rhombotin 1 and 2, TAL1/SCL, TAL2, HOX11, and LYL are the best studied examples of these transcription factor translocations to TCR loci. [274,275,276,277,278 and 279] In most of these translocations, the coding sequences for transcription factor proteins, not normally expressed in T cells, are relocated near the TCR. These translocations cause inappropriate expression of the translocated transcription factors. The mechanisms that lead from the inappropriate expression of these proteins to leukemia presumably vary with the transcription factors involved.

TAL1 (also known as SCL) is translocated to a TCR in approximately 5% of pediatric T-cell ALL cases. A partial TAL1 deletion, which causes overexpression of the TAL1 protein, has been described in approximately 25% of pediatric T-cell ALL cases. [278] TAL1 is not expressed in normal T cells, but it appears to be critical for the formation of the entire hemopoietic system. [280] The mechanism by which TAL1 translocation or partial deletion may cause leukemia is not understood. Translocations involving TAL1, TAL2, LYL, and the TCRs occur in 30% of T-cell ALL ( Table 19-1). [278,281] The genes regulated by these transcription factors are believed to represent a common pathway for the development of T-cell leukemia.

The t(10;14)(q24;q11) and t(7;10)(q35;q24) involve translocations of the transcription factor HOX 11 and TCR loci. HOX genes are known to be important regulators

of hemopoietic development (see Chapter 3 and Chapter 4). Thus, translocations involving different members of this gene family in cases of ALL are not surprising. Despite the heterogeneity of the multiple transcription factor translocations with TCRs in T-cell leukemia, the actual disease associated with these molecular findings is relatively homogenous in clinical and histologic presentation, course, and prognosis. [270,281]

Structural abnormalities, including translocation, deletion, and partial duplication of chromosome band 11q23 are associated with poor prognosis. [282,283] The 11q23 abnormalities are present in 5% to 10% of pediatric and adult ALL, 60% to 70% of infant leukemia (i.e., ALL and AML in patients younger than 1 year), and 85% of secondary leukemias in patients who have received epipodophyllotoxin therapy. [282,284,285,286 and 287] Virtually all of these 11q23 abnormalities have occurred in the same region of a gene variously named MLL (myeloid/lymphoid leukemia gene or mixed lineage leukemia), Htrx1/HRX, and ALL-1. [287,288,289 and 290] The MLL protein is believed to be an important developmental regulator of pluripotent hematopoietic cells. Multiple fusion partner genes have been found for MLL ( Table 19-1 and Fig. 19-11; see also Chapter 3), the most common of which are located on chromosomes 4, 6, 9, and 19.[287,290,291 and 292]

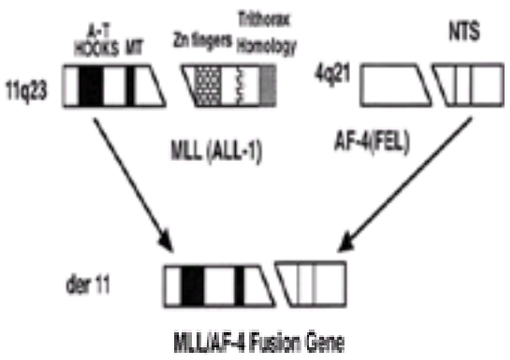

**FIGURE 19-11.** Schematic representation of the MLL/AF-4 fusion protein created by the t(4:11)(q21;q23) found in up to 70% of infant acute lymphoblastic leukemia (ALL) cases. The translocation involves a reciprocal transfer between the ALL-1 gene (located on band 11q23) and the AF-4 gene (located on band 4q21). The resulting der11 product codes for a protein that is thought to be responsible of the development of the 4:11-positive infant ALL. NTS, nuclear translocation signal; MT, methyl transferase activity; Zn, zinc.

ALL patients with rearrangements involving 11q23/MLL have significantly poorer treatment outcomes than do similar patients who do not demonstrate the cytogenetic abnormality (Fig. 19-12).[282,293] The t(4;11)(q21;q23) is the most frequent of these translocations ( Fig. 19-12 and Table 19-1). It has been reported in up to 5% of pediatric ALL cases, is more common in girls, and occurs in more than 60% of infant leukemias of all types. [285,294,295 and 296] The t(4;11)(q21;q23) generally occurs in B-cell precursor ALL and is somewhat more frequently observed in patients with early pre–B-cell disease (cIg+). [285] A large percentage of these cases manifest a characteristic immunophenotype (i.e., CD10–/CD15+/CD19+/CD24+).[285] Leukemic cells from patients with t(4;11) may manifest some cytochemical and ultrastructural features of monocytes and thus have biphenotypic characteristics. Because other translocations involving 11q23 have also been associated with characteristics of mixed lineage [e.g., t(11;19)(q23;p12), t(9;11) (p21;q23)], it has been suggested that leukemias with the 11q23 rearrangement arise from a pluripotent progenitor cell.[213,297]

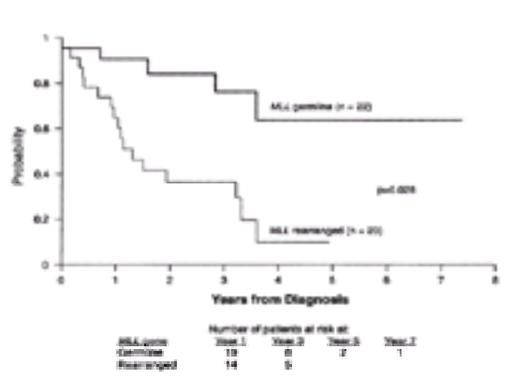

**FIGURE 19-12.** Event-free survival for patients with acute lymphoblastic leukemia, demonstrating the poorer overall prognosis for those with rearrangements involving 11q23/MLL. (From Behm FG, Raimondi SC, Frestedt JL, et al. Rearrangement of the MLL gene confers a poor prognosis in childhood acute lymphoblastic leukemia, regardless of presenting age. Blood 1996;87:2870–2877, with permission.)

The t(9;22)(q34;q11) was one of the first leukemic translocations described and remains the translocation with the worst prognosis in pediatric ALL ( Fig. 19-13).[298,299] The t(9;22) translocation that results in the formation of a small marker chromosome, known as the Ph chromosome, is found in approximately 5% of childhood ALL, and 20% of adult ALL.[270,300] The typical translocation, t(9;22)(q34;q11), is similar to that observed in chronic myeloid leukemia (CML). In the past, it had been suggested that $Ph^+$ ALL represented CML that lacked a chronic phase and presented in blast crisis. Cytogenetic and molecular differences distinguish $Ph^+$ ALL from CML. In $Ph^+$ ALL, unlike in CML, the translocation can usually not be detected in multiple cell lineages. [106,107,301] The Ph chromosome is not detectable during remission in successfully treated $Ph^+$ ALL patients, but it is often present in the remission or chronic phase of CML. [294]

**FIGURE 19-13.** Outcomes for subgroups of pediatric patients with Philadelphia chromosome–positive ALL treated with either chemotherapy alone or bone marrow transplant. **A:** N = 326 patients classified by modified Rome–National Cancer Institute criteria as follows: best prognosis (age 10 years or younger with a leukocyte count less than 50,000 per $mm^3$), intermediate prognosis (intermediate-risk features), and worst prognosis (any age with a leucocyte count greater than 100,000 per $mm^3$). Outcomes analyzed regardless of therapy. **B:** Disease-free survival and overall survival for n = 267 patients treated with either HLA-matched related transplants or chemotherapy alone. (From Arico M, Valsecchi MG, Camitta B, et al. Outcome of treatment in children with Philadelphia chromosome–positive acute lymphoblastic leukemia. N Engl J Med 2000;342:998–1006, with permission.)

The t(9;22)(q34;q11) translocation disrupts the proto-oncogene c- *abl* on chromosome 9 that encodes the tyrosine kinase ABL, which is part of the *ras* signaling

pathway (see Chapter 3). In CML, the c-*abl* gene on chromosome 9 is translocated to a 5.8-kb span of chromosome 22 known as the major breakpoint cluster region (M-bcr).[302] In $Ph^+$ ALL, however, the breakpoints on chromosome 22 usually occur upstream from the M-bcr at a site referred to as the *minor breakpoint cluster region* (m-bcr or bcr-2).[219,303,304] The translocation places the c-*abl* coding sequences under the transcriptional control of breakpoint cluster region (bcr) on chromosome 22. There are also differences between the bcr-abl gene products, expressed in the two diseases. In most cases of $Ph^+$ ALL, a unique p185 bcr-abl protein with tyrosine kinase activity has been observed that is distinct from the typical p210 bcr-abl protein encoded by the chimeric bcr-abl message in CML (see also Chapter 4).[305,306 and 307] However, the p210 bcr-abl protein also has been detected in some cases of $Ph^+$ ALL.[308] Both fusion products have been shown to encode active tyrosine kinases, immortalize cell lines transfected with fusion protein cDNA constructs, and cause leukemias in transgenic mice.[307] In mice, the p185 fusion protein appears to produce more aggressive disease with shorter latencies than those of the p210. This is consistent with differences in the natural history of ALL and CML.

The Ph chromosome has been observed in B-cell precursor ALL and in T-cell ALL. Children with $Ph^+$ ALL tend to be older, have higher initial leukocyte counts, and are more likely to display FAB L2 morphology. Occasionally, leukemic blasts may have the bcr-abl translocation, but they have inadequate cytogenetics, or they do not demonstrate the Ph chromosome. PCR techniques have proven useful in diagnosing bcr-abl–positive, Ph-negative ALL and CML.[309,310] The bcr-abl fusion protein confers the poor prognosis.[311,312] Quantitative PCR and colony assays may also be useful in measuring MRD during the therapy and after bone marrow transplantations (BMTs) for bcr-abl positivity.[309,313]

Clinically, $Ph^+$ ALL patients respond poorly to therapy, having a distinctly lower remission induction rate, a higher frequency of CNS leukemia, and early recurrence of their disease.[314,315] A subgroup of children with $Ph^+$ ALL who also have partial or complete monosomy 7 apparently have an even poorer prognosis.[316] Some cases of $Ph^+$ ALL exhibit mixed-lineage characteristics. It has been suggested that, because of its poor prognosis, children with $Ph^+$ ALL require an alternative to conventional ALL treatment. Early BMT with an HLA-identical sibling, and in some cases with an alternative donor, has been the recommendation of many groups, and the results of BMT appear to have improved over time (see the section on bone marrow transplantation).[315,317,318 and 319] Recently, a subgroup of $Ph^+$ ALL patients has been identified with low-risk presenting features (see the section on prognostic factors) who appear to do well with intensive conventional therapies ( Fig. 19-13).[320,321]

Deletions of chromosomal band 9p21-22 occur in pediatric ALL with a frequency of 10% to 30%.[322,323] The reported incidence of deletions in the 9p21-22 region has increased as the use of Southern blots, PCR, and newer interphase FISH techniques capable of detecting lesions not visible using classic cytogenetic techniques has increased. Two separate regions are the targets of these deletions at 9p22. At one locus, the interferon cluster and interferon-b1 gene are fully or partially deleted. The second locus, at 9p21, is the site of two cyclin D kinase inhibitors, p16 and p15. p16 is a potent tumor suppressor, which has been shown to be important in a variety of adult solid tumors.[323] It is thought that deletion of p16, p15, or both allows cells to progress through the $G_1$ cell cycle check point in an uncontrolled way, ultimately resulting in leukemia (see Chapter 3). Deletions of large portions of 9p (including the 9p21-22 region) are associated with T-cell ALL, but do not (with current therapies) seem to be associated with prognosis.[324]

As previously noted, trisomy 8 and del9p are frequently seen in T-ALL.[324] Other frequently described structural abnormalities in T-ALL include del6q and breakpoints at the known immunoglobin and TCR genes (Table 19-1). The ploidy findings in T-ALL are very different than the ones described above for common pre-B ALL. The majority (86% in one study) of T-ALL are pseudodiploid or normal diploid.[324,325] Despite the description of a series of characteristic cytogenetic features for T-ALL, none of these findings appears to identify patients at greater or lesser risk of relapse. Stratification strategies for T-cell patients generally rely on clinical presentation features, and when they are grouped with pre-B ALL patients with similar findings the clinical results appear to be equivalent.

The reciprocal translocation of the long arms of chromosomes 5 and 14, t(5;14)(q31;q32), has been characterized by a B-lineage phenotype and hypereosinophilia.[326] The immunoglobulin heavy-chain gene and the promotor region of the interleukin-3 (IL-3) gene are joined by this translocation.[213] Overexpression of the IL-3 gene may be involved in the pathogenesis of the hypereosinophilia and leukemia observed in these patients.[327]

Unique translocations, observed in single cases, make up approximately one-half of the chromosomal translocations in ALL.[219] Whether all translocations are intimately involved in the leukemogenic process is unknown. It appears likely that some translocations, through induction of altered gene expression, confer a growth advantage on cells of a particular phenotype.

Chromosomal studies of bone marrow obtained during remission in ALL are karyotypically normal. The presence of aneuploidy during remission usually heralds relapse.[328] At relapse in most patients, the leukemic clone is cytogenetically related to that observed at diagnosis, although evidence of clonal evolution at relapse is common.[213,328] This information is consistent with the suggestion that relapse of ALL signifies the recurrence of original leukemia rather than the development of a new leukemic clone.

### Biochemical Characterization

Various biochemical markers have been studied in ALL. Some have been found to be useful in the diagnosis and classification of the disease; others have been evaluated as potential avenues for selective therapy. Terminal deoxynucleotidyl transferase (TdT) is an unusual DNA-polymerizing enzyme that catalyzes the polymerization of deoxynucleoside monophosphates into a single-strand DNA primer without the need for template instruction.[329] TdT is found in the nucleus and is thought to play a role in immunoglobulin and T-cell antigen receptor rearrangement, influencing the generation of immunologic diversity.[330] Significant TdT activity is not present in normal lymphocytes but is detectable in normal cortical thymocytes and in leukemic lymphoblasts of T-cell and B-cell precursor lineage. TdT activity is usually not present in mature B-cell ALL.[331] Determination of TdT activity may be helpful in the diagnosis of ALL and in differentiating ALL from AML, in which TdT activity rarely occurs.[332] Detection of TdT activity may help identify sanctuary relapses (e.g., testes), particularly in cases in which routine pathologic examination yields equivocal results. Because TdT-positive cells may be present in increased numbers in patients recovering from chemotherapy or BMT, they cannot be used as a sole indicator of bone marrow relapse.[332] Serial measurement of TdT activity in peripheral blood lymphocytes obtained during remission does not permit the earlier detection of bone marrow relapse.[333]

Purine pathway enzymes play an important role in normal lymphocyte function, and this pathway has been extensively studied in ALL.[334] A unique pattern of three enzymes, adenosine deaminase, 5'-nucleotidase, and purine nucleoside phosphorylase, has been observed in ALL.[335,336 and 337] Abnormal lymphocyte function and the absence or reduction in activity of each of these enzymes is a characteristic of certain immunodeficiency disorders. Among the acute leukemias, the activity of adenosine deaminase, which catalyzes the conversion of adenosine to inosine, is highest in ALL. The highest levels are found in T-cell ALL, which is also characterized by decreased 5'-nucleotidase and purine nucleoside phosphorylase activity compared with that of non–T-cell ALL.[329,336,337 and 338] Investigators have attempted to take advantage of the unique biochemical profile of T-cell ALL.[339] A potent inhibitor of adenosine deaminase, 2'-deoxycoformycin, as well as several other purine analogs singly and in combination, have demonstrated activity against a broad spectrum of lymphoid malignancies.[336,340,341 and 342]

Elevated serum levels of lactate dehydrogenase (LDH) have been observed in ALL at diagnosis.[343,344] LDH levels reportedly normalize during remission and increase again at relapse. Abnormalities in lysosomal enzymes also have been observed in ALL.[345] Glucocorticoid receptors have been identified on leukemic lymphoblasts, and the distribution of glucocorticoid receptor number appears to differ significantly among the major immunologic subtypes of ALL. The greatest numbers of receptor sites per cell are seen in early B-lineage ALL. T-cell ALL has significantly lower receptor numbers, and B-cell ALL has the lowest.[346,347] Glucocorticoid receptor content correlates with sensitivity to steroid treatment *in vitro*, and attempts have been made to correlate receptor number with response to therapy *in vivo*. Lower receptor number has been associated with poorer responses to induction therapy and shorter remission durations.[348,349] It is uncertain whether glucocorticoid receptor number is an independent prognostic variable that provides more information than the technically less complex, more conventional prognostic factors.[350] Nevertheless, a poor *in vivo* clinical response to initial corticosteroid therapy has been used by the Berlin-Frankfurt-Munster (BFM) study group to identify patients at particularly high risk for treatment failure.[170,351]

### Pharmacogenetics

In addition to ALL cells having unique biochemical and enzymatic profiles, it is reasonable to assume that individual patients will demonstrate differences in drug metabolism and response, which may have important effects on therapeutic efficacy and toxicity. The field of pharmacogenomics studies the genetic basis for the differences between individual responses to specific drugs.[352,353] Perhaps one of the best examples of pharmacogenomic effects in ALL relates to the isoforms of thiopurine methyltransferase (TPMT). TPMT is a crucial enzyme that metabolizes parent 6-mercaptopurine (6-MP) into an inactive metabolite. Patients homozygous for TPMT null mutations have been shown to have severe 6-MP related toxicity, whereas heterozygote patients appear to have moderate toxicity with 6-MP. Patients

who have two copies of the wild-type TPMT allele show no untoward toxicity when treated with 6-MP.[354,355] Thus, under certain circumstances the toxic effects of a therapeutic drug may be largely dictated by the function of a single gene. However, it is more likely that the pharmokinetic profile of a particular agent in any individual patient is related to a complex interaction between the various alleles of multiple genes and other factors related to therapy (e.g., concomitantly administered drugs, state of hydration). Efforts to control for some of these factors by using rational pharmacokinetic dosing of drugs (see the section Treatment) have shown promise.[356,357]

It appears that some of the biochemical pathways that are implicated in the etiology of the disease (see the discussion of environmental factors in the section Epidemiology) may also be involved in determining the response to and toxicities of various chemotherapeutic agents. The GST genes encode at least four different subfamilies of cytosolic proteins, some of which display known genetic polymorphisms. GST genotypes that confer lower enzyme activities may enhance the efficacy and toxicity of chemotherapy. The enzymatic null genotypes of GST have been associated with a decreased risk of relapse in childhood pre-B ALL and with an increased risk of toxicity and lower overall survival for patients treated for AML.[358] These same GST null mutations have been linked in small series to the development of several adult solid tumors and with pediatric ALL.[25,358]

### Cytokinetics

$^{3}$H-thymidine labeling indices and flow cytometry have been used to evaluate cell kinetics in newly diagnosed patients with ALL.[359,360 and 361] An inverse correlation appears to exist between lymphoblast proliferative capacity and prognosis. Several investigators have shown an association between high proliferative activity and shorter remission duration, suggesting that the kinetic characteristics of leukemic blasts underlie the clinical responsiveness of children with ALL. It has been suggested that the $^{3}$H-labeling index and the percentage of cells in S phase function as independent prognostic variables, but this has not been a consistent finding and awaits further confirmation.[361,362 and 363] Lymphoblast proliferative activity varies with immunophenotype; higher $^{3}$H-thymidine–labeling indices and a greater percentage of cells in the S phase of the cell cycle have been observed in T-cell ALL and B-cell ALL.[360,361] In one study, a poor response to induction treatment correlated with a low RNA content in pretreatment marrow.[363] This finding presumably indicated a greater percentage of nonproliferating cells in these patients.[363,364]

## CLINICAL PRESENTATION

The signs and symptoms of the child presenting with ALL reflect the degree of bone marrow infiltration with leukemic cells and the extent of extramedullary disease spread. The most common symptoms and clinical findings (Table 19-6) are usually manifestations of the underlying anemia, thrombocytopenia, and neutropenia, which reflect the failure of normal hematopoiesis. Pallor, fatigue, bone pain, petechiae, purpura, bleeding, and fever are often present. Lymphadenopathy, hepatomegaly, and splenomegaly are manifestations of extramedullary leukemic spread. Hepatosplenomegaly occurs in approximately two-thirds of the patients and is usually asymptomatic. Lymphadenopathy, usually painless, may be localized or generalized.

| Clinical and laboratory features | Percentage of patients |
|---|---|
| **Symptoms and physical findings** | |
| Fever | 61 |
| Bleeding (e.g., petechiae or purpura) | 48 |
| Bone pain | 23 |
| Lymphadenopathy | 50 |
| Splenomegaly | 63 |
| Hepatosplenomegaly | 68 |
| **Laboratory features** | |
| Leukocyte count (mm$^3$) | |
| <10,000 | 53 |
| 10,000–49,000 | 30 |
| >50,000 | 17 |
| Hemoglobin (g/dL) | |
| <7.0 | 43 |
| 7.0–11.0 | 45 |
| >11.0 | 12 |
| Platelet count (mm$^3$) | |
| <20,000 | 28 |
| 20,000–99,000 | 47 |

| L2 | 15 |
| L3 | 1 |

**TABLE 19-6. CLINICAL AND LABORATORY FEATURES AT DIAGNOSIS IN CHILDREN WITH ACUTE LYMPHOBLASTIC LEUKEMIA**

The duration of symptoms in children presenting with ALL may vary from days to months. Anorexia is common, but significant weight loss is infrequent. Bone pain, particularly affecting the long bones, is common and reflects leukemic involvement of the periosteum and bone. Young children may present with a limp or refusal to walk. Bone tenderness is frequently observed. These symptoms and the presence of arthralgias, which may result from leukemic infiltration of a joint, frequently make the delineation between ALL and nonmalignant disorders, such as juvenile rheumatoid arthritis or osteomyelitis, difficult.

T-cell ALL represents approximately 15% of ALL cases and is noted for its distinctive clinical features. It frequently occurs in older boys who present with high initial leukocyte counts and commonly have a mediastinal mass. Approximately one-half of children with T-cell ALL have mediastinal masses, and one-third to one-half have initial leukocytes counts greater than 100,000 per mm$^3$.[365,366] Patients with T-cell leukemia reportedly have a higher incidence of CNS leukemia.[367]

Signs or symptoms of CNS involvement are rarely observed at the time of the initial diagnosis. A number of presenting clinical features and laboratory findings have prognostic importance. These are elaborated in the sections on prognostic factors and treatment.

The child with ALL typically presents with nonspecific symptoms. Thus, ALL may mimic a variety of other nonmalignant (Table 19-7) as well as malignant conditions. These include infectious mononucleosis, idiopathic thrombocytopenic purpura, acute infectious lymphocytosis, pertussis and parapertussis, and certain viral illnesses (e.g., cytomegalovirus and EBV infections), all of which may have similar clinical features. Childhood ALL must be differentiated from other pediatric malignancies that may present with bone marrow involvement, including neuroblastoma, rhabdomyosarcoma, retinoblastoma, and non-Hodgkin's lymphoma. Under light microscopy, neuroblastoma may be difficult to differentiate morphologically from ALL, especially if typical neuroblastoma pseudorosettes are not present. Additional laboratory and clinical evaluation can differentiate these two disorders.

| |
|---|
| Nonmalignant conditions |
| Juvenile rheumatoid arthritis |
| Infectious mononucleosis |
| Idiopathic thrombocytopenic purpura |
| Pertussis; parapertussis |
| Aplastic anemia |
| Acute infectious lymphocytosis |

| Rhabdomyosarcoma |
| Unusual presentations |
| Hypereosinophilic syndrome |

**TABLE 19-7. DIFFERENTIAL DIAGNOSIS IN CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA**

Clinicians must also consider ALL among the differential diagnosis of the rare patients who present with hypereosinophilia. Cases of ALL occurring in association with symptomatic hypereosinophilia have been reported, and in rare instances, eosinophilia has preceded the diagnosis of ALL by many months.[368] In symptomatic patients with eosinophilia, the classic findings of the hypereosinophilic syndrome (i.e., Löffler's syndrome of hypereosinophilia, pulmonary infiltrates, cardiomegaly, and congestive failure) have been observed. The pathogenesis of ALL occurring with hypereosinophilia is not fully defined, but a characteristic translocation, t(5;14), is associated with this syndrome.[326] ALL presenting with hypereosinophilia must be differentiated from eosinophilic leukemia and from AML presenting with

hypereosinophilia, which also has a characteristic chromosomal abnormality involving structural rearrangements of chromosome 16. [369]

**Leukemia or Lymphoma?**

ALL and childhood non-Hodgkin's lymphoma are closely related disorders, and distinguishing between the two can be difficult. Many patients who present with features characteristic of a lymphoma, such as an anterior mediastinal mass, massive lymphadenopathy, or both, have bone marrow involvement. The malignant T cells of lymphoblastic lymphoma are indistinguishable from those of T-cell ALL, and the malignant B cells of Burkitt's lymphoma are similar to those from children with B-cell ALL. B-cell ALL shares immunologic and molecular features of Burkitt's lymphoma and is considered to be a disseminated form of that disease. Most institutions treat patients with advanced B-cell disorders with similar chemotherapy regimens.

The distinction between T-cell ALL and T-cell lymphoblastic lymphoma is also ill-defined. There is some evidence that these disorders arise from different stages of T-cell differentiation and have immunophenotypes reflecting different stages of T-cell maturation. [168] Because this distinction does not apply in every case, it does not provide a reliable basis for delineating between the two diseases.

In the absence of more refined biologic criteria, the percentage of blasts in the bone marrow is conventionally used to differentiate T-cell ALL and T-cell non-Hodgkin's lymphoma. This arbitrary method is confounded by the fact that different institutions and study groups have used different criteria. For some, more than 25% blast cells in a bone marrow signifies leukemia; for others, any evidence of abnormal bone marrow infiltration, regardless of percentage, is used to define leukemia. Because of these differences, meaningful comparisons of treatment results obtained by different groups are often difficult.

**Hematologic Abnormalities at Presentation**

An elevated leukocyte count (greater than 10,000 per $mm^3$) occurs in approximately one-half of patients with ALL. In approximately 20% of patients, the initial leukocyte count is greater than 50,000 per $mm^3$ (Table 19-6). The degree of leukocyte count elevation at diagnosis is the single most important predictor of prognosis in ALL. Neutropenia (less than 500 granulocytes per $mm^3$) is a common phenomenon and is associated with an increased risk of serious infection. [370] Anemia (hemoglobin less than 10 g per dL) exists in approximately 80% of patients at diagnosis. Even if the anemia is severe, the erythrocytes usually manifest a normocytic, normochromic pattern, and the reticulocyte count is low. Thrombocytopenia occurs in most patients; approximately 75% have fewer than 100,000 platelets per $mm^3$. Isolated thrombocytopenia, however, is a rare event. The severity and the degree of bleeding correlate with the degree of thrombocytopenia. [371] Severe hemorrhage is rare even with platelet counts less than 20,000 per $mm^3$ unless fever and infection, both of which can affect platelet survival and function, are present. [371]

Rarely, ALL may initially manifest with pancytopenia and must be differentiated from aplastic anemia. [372,373] An aplastic presentation may represent a true preleukemic state.[372] Other explanations have been reported, including inhibition of normal hematopoietic progenitors by leukemic cells and evidence of an abnormal cellular reaction during or before the aplasia followed by a definitive diagnosis of ALL. [374,375]

To definitively establish the diagnosis of leukemia, a bone marrow aspirate is necessary. Although leukemia cells may be present in the peripheral blood at diagnosis, attempts to establish the diagnosis on the basis of morphologic assessment of these cells alone may be misleading. Under most circumstances, a bone marrow aspirate provides sufficient material to establish the diagnosis. Occasionally, bone marrow biopsy may be required. Although more than 5% lymphoblasts in the bone marrow is highly suggestive of leukemia, a minimum of 25% blast cells is usually required before the diagnosis is confirmed. Usually, most cells in the marrow aspirate are leukemic lymphoblasts. In some situations (e.g., to differentiate an aplastic presentation of ALL from aplastic anemia) multiple bone marrow aspirates and biopsy specimens may be required.

Until recently, definitive diagnosis of the specific leukemic cell type was made primarily by morphologic assessment of bone marrow aspirate slides stained with Romanovsky's dye and by the use of special histochemical stains (e.g., periodic acid–Schiff, myeloperoxidase, Sudan black B), which are helpful in differentiating ALL from AML (Table 19-3).[376] TdT analysis may also contribute important diagnostic information. However, few centers rely solely on morphologic or cytochemical information to make the diagnosis of ALL. Most routinely use immunophenotyping, using a panel of monoclonal antibodies ( Table 19-4) and cytogenetics. Both traditional karyotyping and the use of molecular technologies such as RT-PCR, and FISH (see the section on cytogenetics) are used for identification of chromosomal features. In difficult diagnostic cases, ultrastructural evaluation (i.e., using electron microscopy) and molecular analysis may be helpful.

**Other Abnormal Laboratory Findings**

A variety of other abnormal laboratory study results frequently are obtained in newly diagnosed patients with ALL. Many of these findings and their degree of abnormality reflect the leukemic cell burden, the extent of extramedullary spread, or the excessive proliferation and destruction of the leukemic cells. Increased serum uric acid levels, most common in patients with a large leukemic cell burden, reflect increased anabolism and catabolism of purines. A major complication of hyperuricemia is uric acid nephropathy and subsequent renal failure. The risk of this complication is greatest immediately after the start of treatment, when leukemic cell lysis releases large quantities of uric acid. Adequate hydration, alkalinization, and the use of the xanthine oxidase inhibitor allopurinol have traditionally been required to prevent this potentially serious complication. Alternatively, the high uric acid level can be ameliorated with hydration and the therapeutic use of urate oxidase (an agent commonly used in many countries that is still considered investigational in the United States). [377,378] The only significant side effect of uricozyme noted thus far is a relatively high [4.5% of patients in a St. Jude Children's Research Hospital (SJCRH) study] of acute hypersensitivity reactions. [378] A recombinant preparation of the enzyme is under development, which may alleviate this problem.

Various metabolic abnormalities may be encountered, including decreased and increased serum levels of calcium and increased levels of potassium and phosphorus. Renal stones, both of the $CaPO_4$ and precipitated uric acid types, may occur and are principally treated with hydration. These abnormalities are more frequent in patients with bulky disease (i.e., extensive lymphadenopathy and hepatosplenomegaly), and high initial leukocyte counts. [379] Kidneys may be infiltrated with leukemic cells and are often enlarged at diagnosis. [380,381] Although kidney infiltration and dysfunction can complicate the initial therapy, it does not usually effect outcome. [382] Hypercalcemia may result from leukemic infiltration of bone, although release of a parathormone-like substance from lymphoblasts has been reported. [383] Elevated serum phosphorus levels can occur as a result of leukemic cell lysis and may induce hypocalcemia. [384]

Hepatic dysfunction resulting from leukemic infiltration of the liver is usually mild. Leukemic cell lysis, ineffective hematopoiesis, and liver involvement are associated with elevation of serum LDH. Approximately 5% to 10% of newly diagnosed patients, usually those with T-cell ALL, have an anterior mediastinal mass detected on chest radiographs. Skeletal radiographic changes, particularly in the long bones, are most frequent and include transverse radiolucent metaphyseal growth arrest lines, periosteal elevation with reactive subperiosteal cortical thickening, osteolytic lesions, and diffuse osteoporosis. [385] Radiologically documented bone changes may be seen in asymptomatic patients. When present, bone pain usually resolves quickly after initiation of antileukemic therapy. Rarely, ALL may masquerade as osteomyelitis.[386] Coagulation abnormalities may occur but are usually not a feature of the disease, and at presentation, disseminated intravascular coagulation is encountered infrequently. [387] When coagulopathies occur at diagnosis or early in therapy, they are usually associated with concomitant infection or with therapy, particularly with the use of L-asparaginase, rather than with the leukemia itself. [388] Both *Escherichia coli* and *Erwinia* L-asparaginase may produce thromboses or hemorrhagic infarction.[389,390]

**Patterns of Spread**

Extramedullary involvement may be readily detectable clinically or demonstrable solely by diagnostic tests and procedures. Extramedullary disease is significant because it may cause morbidity at a localized site, and it often represents a significant percentage of the total body leukemia burden. Many patients have some evidence of extramedullary involvement at diagnosis (Table 19-6). The most common sites of extramedullary spread are the CNS, testes, liver, kidneys, nodes, and spleen. However, virtually any site in the body can become involved either at initial presentation or relapse—skin, ocular anterior chamber, pleural and pericardial spaces, and ovarian involvement have all been described. [97,391,392] From a clinical point of view, the two most important sites of extramedullary involvement are the CNS and the testes.

***Central Nervous System Leukemia***

CNS leukemia is found at diagnosis in fewer than 5% of children with ALL. [393] With the institution of CNS preventive therapy, routine lumbar punctures have become an integral part of ALL treatment protocols. As a consequence, symptomatic CNS disease is observed less frequently, and the diagnosis is most often made in the

asymptomatic patient. Diagnosis of CNS leukemia requires cytologic confirmation of leukemic cells in CSF. CSF obtained by lumbar puncture must be examined after cytocentrifugation, a procedure that concentrates the leukemic cells and increases diagnostic sensitivity. [394,395] Leukemic cells found in the CSF are usually cytogenetically identical to those found in the bone marrow. In symptomatic patients, CSF pressure is usually increased, and elevated CSF protein and hypoglycorrhachia are common. With CNS leukemia now more frequently diagnosed in the asymptomatic patient, CSF pressure may be normal, CSF leukemic cell counts relatively low, and abnormalities in CSF chemistry determinations absent.

If there is no significant pleocytosis, the diagnosis of meningeal leukemia is problematic. [396] Controversy exists about the meaning of blast cells in situations in which the total CSF white blood cell (WBC) count is low, such as fewer than 5 WBCs per µL with blast cells. Three separate studies have documented that this circumstance, identified in as many as 19% of patients at initial presentation, was associated with a significantly higher likelihood of CNS relapse when compared with patients without detectable CSF lymphoblasts.[397,398] Other investigators have not been able to confirm this finding. [399,400] In an effort to evaluate the importance of low WBC count, lymphoblast-positive initial CSF samples, National Cancer Institute–sponsored studies are prospectively gathering data on these patients. [401] The consensus criteria for grading CNS involvement at diagnosis are outlined in Table 19-8.[401] CNS-1 status is defined as no evidence of leukemic lymphoblasts in the CSF. CNS-2 and CNS-3 are respectively defined as fewer than 5 WBCs per µL with blasts and greater than or equal to 5 WBCs per µL with blasts (or with cranial nerve palsy) on CSF cytospin preparations. In suspicious but equivocal cases, TdT determination has been suggested as an additional means of confirming the diagnosis of CNS leukemia.[402] The results of cranial computed tomographic (CT) scans, electroencephalography, plain skull radiographs, and magnetic resonance imaging (MRI) may be abnormal for patients with CNS leukemia, but are often normal. None of these imaging methods has sufficient diagnostic sensitivity to be indicated for routine use, but they should be used as symptoms clinically indicate.

| Status | Cerebrospinal fluid findings |
|---|---|
| CNS-1 | No lymphoblasts |
| CNS-2 | <5 WBCs/µL with definable blasts on cytocentrifuge examination |
| CNS-3 | ≥5 WBCs/µL with blast cells (or cranial nerve palsy) |

WBC, white blood cell.

**TABLE 19-8. DEFINITIONS OF CENTRAL NERVOUS SYSTEM (CNS) DISEASE STATUS AT DIAGNOSIS BASED ON CEREBROSPINAL FINDINGS**

CNS leukemia may result from hematogenous spread of circulating leukemia cells or by direct extension from involved cranial bone marrow. [403] Hematogenous spread may occur by means of migration of circulating leukemia cells through venous endothelium or as a consequence of petechial hemorrhages in cases of severe thrombocytopenia.[404] The choroid plexus, with its abundant capillaries, is often a site of leukemic infiltration. [405] Direct extension of leukemia cells may occur from involved cranial bone marrow through bridging veins to the superficial arachnoid. Eventually, infiltration of the deep arachnoid, the pia-glial membrane, and the brain parenchyma itself may occur. Direct spread from involved cranial bone marrow may also occur along the perineurium.

The signs and symptoms of clinically overt CNS leukemia include headache, nausea and vomiting, lethargy, irritability, nuchal rigidity, papilledema, and other manifestations of increased intracranial pressure. Cranial nerve involvement, most frequently involving the third, fourth, sixth, and seventh cranial nerves, may occur with other symptoms or as an isolated event. Infiltration of the optic nerve can result in visual disturbances. Eighth cranial nerve involvement, manifested by hyperacusis, tinnitus, vertigo, and even deafness, has been observed. A more unusual manifestation of CNS leukemia is the hypothalamic obesity syndrome, in which destruction of the ventromedial nucleus of the hypothalamus, the satiety center, results in hyperphagia, pathologic weight gain, and diabetes insipidus. Leukemic subdural involvement and spinal epidural leukemia with spinal cord compression also have been observed. Intracranial leukemic cell masses occur relatively rarely. The numerous neurologic manifestations of overt CNS leukemia make it obligatory for clinicians to exhaustively investigate any neurologic signs or symptoms in the child with ALL to exclude the possibility of CNS leukemia.

The potential clinical impact of CNS leukemia did not become fully apparent until the late 1950s and early 1960s. With improved systemic therapy and longer survival, the CNS became the most common site of initial relapse.[406] By the early 1970s, the incidence of CNS leukemia in some studies ranged as high as 80% to 85%. [406,407] Initial bone marrow remissions of short duration could be obtained in most patients, but CNS recurrence was common. [408] The significance of this increasing rate of CNS relapse was twofold. First, CNS leukemia itself was difficult to eradicate. Second, CNS relapse was usually followed by the rapid development of bone marrow disease.[409] Most patients who experienced a CNS relapse during the era before CNS preventive therapy died as a consequence of marrow relapse rather than of CNS disease. The recognition of this phenomenon led to the development of effective CNS preventive therapy, a strategy in part responsible for the improved prognosis of children with this disease (see the section Central Nervous System Preventive Therapy).

***Testicular Leukemia***

Demonstrable testicular disease is rarely present at initial diagnosis, but occult testicular disease has been diagnosed in 25% of newly diagnosed boys. [410] The possibility of occult testicular disease, together with the fact that testicular recurrence is frequently followed by systemic relapse, prompted several centers to advocate routine bilateral testicular biopsy at some time during maintenance chemotherapy or immediately before its cessation. This practice has been abandoned by most centers because of studies indicating that testicular biopsies at diagnosis, after induction, during maintenance, or before cessation of chemotherapy are associated with a significant false-negative rate and do not accurately predict for eventual testicular relapse. [411,412 and 413] Routine testicular biopsies for occult disease at the end of therapy are no longer recommended. Noninvasive screening for occult testicular disease using transscrotal ultrasound and MRI has been evaluated; neither technique is sufficiently sensitive. [414]

Clinically, overt testicular involvement usually appears as painless testicular enlargement, most often unilateral. The diagnosis must be established by testicular biopsy. When testicular leukemia is suspected clinically, bilateral biopsies are indicated because disease frequently affects the contralateral testis. [415] Wedge biopsies are the preferred diagnostic technique, because this procedure is less likely to result in sampling error. Histologic interpretation is frequently difficult. The incidence of false-negative results from testicular biopsies obtained during maintenance therapy or before stopping all treatment approaches 10%. [412,416] Although it has been suggested that TdT determination may help discriminate between leukemic lymphoblasts and reactive lymphocytes in equivocal biopsy specimens, the value of TdT determination appears to be limited.[417] Immunophenotyping of testicular biopsy specimens may help confirm leukemia cells, but it has not been demonstrated to improve the overall detection rate.[418]

Before the introduction of effective chemotherapy for ALL, clinically evident testicular relapse was a rare event. [419] Paradoxically, with improved therapy and prolonged survival, the incidence of testicular involvement increased. In the 1970s and 1980s, the incidence of overt testicular relapse was reported to be as high as 16%, although the actual figure is probably less than 10%. [420] In boys who had successfully completed a full course of chemotherapy for their disease, overt testicular recurrence was a principal cause of late relapse. The reported incidence in this setting varies but was approximately 10%. [421,422] With the introduction of more intensive therapies, the incidence of testicular relapse may be declining toward 5% or less. [1,4]

The occurrence of isolated testicular relapse led many investigators to consider the testes to be a sanctuary site for extramedullary disease. It has been suggested that leukemic testes are protected from therapeutic concentrations of systemically administered chemotherapy by the blood-testes barrier. [423] Animal studies, however, have questioned the role of the blood-testes barrier in the development of testicular leukemia. [424] The leukemia often can be demonstrated in the liver, spleen, and abdominal lymph nodes in patients studied by exploratory laparotomy at the time of a presumed isolated testicular relapse. [425] This raises the possibility that “isolated” testicular relapse may be a misnomer. Some evidence indicates that the incidence of testicular relapse may be somewhat lower on treatment regimens using more aggressive therapy.[425,426] Although the use of prophylactic testicular irradiation to prevent testicular disease had been advocated, this approach has not gained wide acceptance because testicular relapse has become less of a problem on current protocols, and testicular irradiation is associated with sterility (see the section Late

Effects of Treatment).[427,428]

In testicular relapse, the disease is usually located within the interstitial spaces; in advanced cases, leukemic infiltration of the tubules may occur. [429] Several factors have been associated with an increased likelihood of developing testicular relapse, including a high initial leukocyte count (greater than 20,000 per $mm^3$), T-cell disease, prominent lymphadenopathy and splenomegaly, or significant thrombocytopenia (less than 30,000 per $mm^3$).[429,430] The time to development of overt testicular relapse ranges from 2 months to several years.[420,431,432]

## PROGNOSTIC FACTORS

Certain clinical and laboratory features exhibited at diagnosis, including early response to induction criteria, have prognostic value. The identification of such factors has become essential in the design and analysis of modern therapeutic trials. It is common practice to assign patients on the basis of prognostic factors into different risk groups and to tailor treatment accordingly. Prognostic characteristics of childhood ALL ( Table 19-9) have included the following: the initial leukocyte count, age at diagnosis, sex, race, degree of organomegaly and lymphadenopathy, presence of a mediastinal mass, initial hemoglobin level, initial platelet count, FAB morphologic classification, cytogenetics, immunophenotype, expression of myeloid antigens on leukemic cells, serum immunoglobulin levels, CNS disease at diagnosis, the length of time to attainment of remission, glucocorticoid receptor levels, and HLA type and nutritional status. [136,433,434,435] and [436] The prognostic implications of many of these are covered in the sections on epidemiology, pathogenesis, and pathobiology.

**TABLE 19-9. FACTORS ASSOCIATED WITH PROGNOSIS FOR PATIENTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA**

Because they are readily available and relatively independent predictors of prognosis, the parameters of initial leukocyte count and age at diagnosis have traditionally provided the most reliable basis for patient stratification. The relative value of other clinical and laboratory features as prognostic indicators varies. To a certain extent, intensity of therapy has become an important prognostic factor. As modern therapy for ALL has become more intensive as well as more successful, many clinical and laboratory features that were once important prognostic features have lost statistical significance with appropriate multivariate analysis. Similarly, differences in treatment approach between large cooperative groups have resulted in differences in published, statistically significant prognostic factors. To facilitate comparisons among the results from different groups, a National Cancer Institute workshop developed a set of consensus prognostic factors outlined in Table 19-10.[401]

| Risk | Definition | 4-year event-free survival (%) | Percentage of B-precursor patients |
|---|---|---|---|
| Standard | WBC count <50,000/μL and age 1.00–9.99 yr | 80.3 | 68 |
| High | WBC count ≥50,000/μL or age ≥10.00 yr | 63.9 | 32 |

WBC, white blood cell.
Note: Table describes the event-free survival and percentages of patients with pediatric B-precursor acute lymphoblastic leukemia treated by the Pediatric Oncology Group (-POG and 1800 series) Protocols by the Uniform Age and WBC Count Criteria.

**TABLE 19-10. UNIFORM AGE AND WHITE BLOOD CELL COUNT CRITERIA FOR B-PRECURSOR ACUTE LYMPHOCYTIC LEUKEMIA STANDARD AND HIGH-RISK COHORTS ADOPTED AT THE CANCER TREATMENT AND EVALUATION PROGRAM/NATIONAL CANCER INSTITUTE WORKSHOP**

### Leukocyte Count and Age

The initial WBC and age are the two factors universally accepted as prognostic factors. In most cases initial leukocyte count retains its importance after adjustment for other criteria. There is a linear relation between the initial leukocyte count and outcome in children with ALL; children with the highest leukocyte counts tend to have a poor prognosis.[437,438] Although there is no sharp dividing line and the data are influenced by the specific therapy given, patients with an initial leukocyte count greater than 50,000 cells per $mm^3$ (approximately 20% of children with ALL) are recognized as having a particularly poor prognosis. [439] The biologic basis for higher initial leukocyte counts is unclear, although there are definite associations between certain biologic features and this pattern of presentation. Patients with T-cell ALL often have a high initial leukocyte count and increased lymphoblast proliferative activity.

There is also a relation between age at diagnosis and outcome. [438] Patients who are young at diagnosis (younger than 2 years) and older patients (older than 10 years) have a relatively poor prognosis compared with children in the intermediate age group. The worst prognosis has traditionally been for infants younger than 1 year at diagnosis (see below).[440] Adolescents with ALL also fare poorly, having a lower remission induction rate and EFS than that of other children, excluding infants.[441] Adolescents tend to have a greater constellation of other poor-risk features including T-cell immunophenotype. [441] In the recently published DFCI 91-01 study, age was the only statistically significant prognosis factor. [442] This study included both high- and standard-risk patients (using traditional age, WBC, and karyotype criteria) and demonstrated an EFS for all patients of 83% ± 2% ( $p = .03$). There were a limited number of infants (n = 7 of which six were evaluable) in this study, but they did remarkably well with 5-year EFS of 71% ± 17%.

Infants (i.e., those younger than 12 months of age) with ALL have historically demonstrated poor prognosis (EFS less than 10% to 20%), worse than virtually any other leukemia patient group.[440,443,444] Infants with ALL have an increased incidence of poor prognostic features, including increased initial leukocyte count, massive organomegaly, thrombocytopenia, CNS leukemia at diagnosis, and failure to achieve complete remission status by day 14 of induction therapy. [440] Although their complete remission rate appears to be no different than that of older children, the EFS and disease-free survival (DFS) for patients in this age group has been extremely poor. This is the consequence of a high incidence of early bone marrow and extramedullary relapse. The CNS relapse rate in infants is particularly high.

ALL of infancy appears to be biologically unique. The leukemic cells appear to arise from a very early stage of commitment to B-cell differentiation. They usually express the HLA-DR antigen, are CALLA (CD10) negative, and do not express mature B-cell antigens. [445] Although there are data regarding the immunoglobulin and TCR gene configuration in these patients that suggest ALL in infancy represents an earlier stage of B-cell development than that found in the B-cell precursor ALL of older children, this finding has not been universal. [446] Infants with ALL also have an increased incidence of chromosomal abnormalities that are associated with a poor prognosis (Fig. 19-11 and Fig. 19-12; see the section on cytogenetics). Structural abnormalities of chromosome 11, particularly rearrangement of band 11q23 within the MLL/ALL-1 gene, are observed frequently.[446,447] The t(4;11) abnormality is particularly common. The leukemic cells from infants with ALL frequently express myeloid markers (e.g., CD15), suggesting that in many infants, the leukemia arises in a multipotent precursor cell. [440,446,448] Infants with rearrangement of 11q23/MLL

have a particularly poor prognosis (Fig. 19-12). Because of their poor prognosis, infants are stratified separately for treatment purposes.

Recently, the EFS for infants has been raised to 50% and higher by using high-dose antimetabolites, rotating pairs of non–cross-resistant chemotherapy, and using maintenance similar to standard leukemia therapy.[449,450 and 451] It has been suggested that there may be chemoresponsive subgroups of infants with ALL that can be determined on the basis of initial prednisone responsiveness. [452]

### Cytogenetic Factors

Cytogenetic abnormalities in chromosomal number and structure are common in pediatric ALL (see the section on pathobiology) and appear to have prognostic significance. One interesting association between cytogenetic status and treatment response involves the metabolism of methotrexate. Hyperdiploid leukemic lymphoblasts accumulate increased amounts of methotrexate and methotrexate polyglutamates, and they have higher basal apoptotic rates compared with leukemic cells with lower ploidy and normal cells.[453,454] These may be factors in the better prognosis observed for patients with hyperdiploid lymphoblasts. The prognostic significance of both ploidy and structural cytogenetic changes are presented with the specific associated cytogenetic findings above and in Figure 19-7, Figure 19-8, Figure 19-9, Figure 19-10, Figure 19-12, and Figure 19-13 and Table 19-1 and Table 19-5.

### Sex

The prognostic importance of sex has been well documented (see also the section Epidemiology) and persists on modern chemotherapy protocols.[455,456] In most studies, girls have a better prognosis than boys. Although this appears to be partially due to the development of testicular relapse and to the higher incidence of T-cell disease in boys, there are likely to be other genetic, metabolic, and endocrine effects that contribute to this difference.

### Immunophenotype

T-cell ALL historically has been characterized by significantly shorter remission duration and decreased overall survival. Recent evidence appears to show that the outcome for T-cell patients on intensive chemotherapy regimens has improved and that it may be possible to adequately treat these patients on intensive, short (e.g., 1-year) protocols.[457,458] Because of the frequent occurrence of T-cell disease in older patients with high initial leukocyte counts, the degree to which the T-cell immunophenotype is a significant independent prognostic variable is unclear. [145,434] Younger (especially younger than 5 years) T-cell patients, especially those who present with lower WBC counts and smaller amounts of bulk disease, have done quite well both on the T-cell–specific and more standard therapies of multiple cooperative groups.[459,460,461 and 462]

Whether myeloid antigens on ALL lymphoblasts may have prognostic importance is controversial. Initial reports indicated that concomitant expression of myeloid antigens on the lymphoblasts of children and adults with ALL was associated with a particularly poor prognosis. [188,199] These results conflict with several large studies of children with ALL treated with intensive therapy that found no differences in the rates of complete remission or the EFS between children whose cells expressed two or more myeloid-associated antigens and those with one or no myeloid-associated antigens. [200,201] The different findings in these and other studies of myeloid antigen expression may reflect differences in the definition of myeloid antigen expression, immunophenotyping techniques, or the type of treatment. [202]

### Race

The effect of race on prognosis has been a controversial topic (see the section Epidemiology). It now appears that blacks with ALL present with a different distribution of clinical and biologic features, including a higher frequency of elevated leukocyte counts, mediastinal masses, and L2 morphology. [3] The common ALL phenotype and hyperdiploidy appear to occur less frequently in black ALL patients. This results in proportionately more black children than white children being stratified on higher risk protocols. Hispanic children have a similar increased rate (relative to white children) of higher risk disease, but the effect does not appear to be as large as with black children.[3] Within the various risk categories, it appears that Hispanic children have equivalent outcomes as those of white children, but black children may be doing slightly worse. This appears to be related to variations in chemotherapeutic response, which may be due to specific differences in pharmacogenetic profiles (see the section Pharmacogenetics).[3]

### Leukemic Cell Burden

Leukemic cell burden can be assessed indirectly by evaluating the extent of extramedullary disease. The degree of hepatosplenomegaly and lymphadenopathy have emerged in most univariate analyses as important prognostic variables. Although in some studies multivariate analyses reveal that some of these features, such as a mediastinal mass, may tend to be dependent variables, other features retain significance even after adjustment for other independent variables, such as the initial leukocyte count. The BFM study group has used a measurement of hepatosplenomegaly with the initial leukocyte count to compute a “risk factor index,” which forms (along with response to glucocorticoids) part of the prognostic basis for subsequent treatment stratification. [463]

### Response to Treatment

Rapidity of response to treatment has emerged as an important (perhaps the most important) indicator of prognosis. It has been known for a long time that patients who do not achieve a complete remission within the usual 4- to 6-week induction period have a high rate of relapse and shortened survival. [464] A number of studies have shown that assessment of initial response at earlier time points yields valid prognostic information. Residual leukemia demonstrable in bone marrow on day 14 of induction is an independent predictor of outcome.[464,465] Patients with residual disease on day 14 have a lower rate of complete remission and a greater likelihood of early (within the first 24 months of therapy) and late relapse.[465] The day 7 marrow status also has been correlated with treatment outcome.[466] One group reported that the failure to clear peripheral leukemic blasts by day 8 of therapy correlates significantly with a poorer 5-year EFS. [467] Patients who have an intermediate response to initial chemotherapy (i.e., M1 by day 14) do less well but have a superior EFS compared with slow responders (i.e., M1 status by day 28). [468] Rapid early responders (i.e., those with an M1 marrow on day 7) have the best EFS (Fig. 19-14). A recent report suggests that early response to induction in infants may not have the same prognostic implications that it does for older patients (Vora et al. ASH 2000 [Abs] 1996).

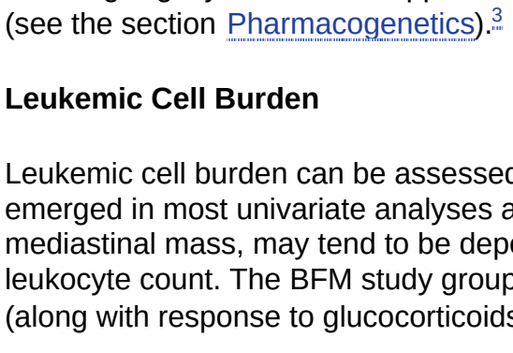

**FIGURE 19-14.** Event-free survival (EFS) and rapidity of cytoreduction during induction treatment. Rapid early responders (RER), those whose bone marrow aspirate was rated M1 by day 7, have the best EFS. Patients who are M2 or M3 on day 7 can be separated by their day 14 marrow results into an intermediate response group (IER) (M1 on day 14) and a slow early response (SER) group. (From Steinherz PG, Gaynon PS, Breneman JC, et al. Cytoreduction and prognosis in acute lymphoblastic leukemia—the importance of early marrow response: report from the Children's Cancer Group. J Clin Oncol 1996;14:389–398, with permission.)

### Nutritional Status

Some studies have suggested that nutritional status is a significant prognostic factor. [469,470 and 471] In one study, undernutrition, defined as both height and weight for

age below two standard deviations, was a significant predictor of treatment failure. [469] In another study, in which weight for age was used to define undernutrition, more than a threefold higher 5-year DFS was observed in well-nourished children. [472] It has also been reported that children who were undernourished have less tolerance for chemotherapy and received suboptimal doses.[473] Additional, confirmatory studies to define the prognostic role of nutritional status are needed.

### Other Prognostic Factors

Low serum levels of IgG have been associated with induction failure. Low levels of all three of the major immunoglobulin subclasses (i.e., IgG, IgM, IgA) have been correlated with a poor chance of EFS; the association with low IgM levels appears to be most significant. [474,475] Most of the immunoglobin findings were detected on earlier series of studies. An association between certain HLA types and prognosis has been suggested but has not been demonstrated in most major studies. The association of specific HLA influences in the development of ALL and the increased incidence of ALL in boys appear to be valid (see the section Epidemiology).[22,23,435,476] The relation between FAB morphologic classification and prognosis was addressed earlier (see the sections on pathobiology and morphologic classification).

### Analyzing Prognostic Factors for Patient Stratification

As therapy has improved, the vast majority of factors, which had prognostic significance on earlier studies, has been rendered insignificant. Until recently, only age, initial WBC count at diagnosis, and a few cytogenetic abnormalities (noted above) appeared to retain their importance. With the newest results of intensive multi-agent chemotherapy, the factors that may retain the greatest prognostic significance appear to be related in large part to therapy itself—that is, early response, MRD at various time points, and the presence of focused cytogenetic (i.e., trisomy 4 and 10) and molecular cytogenetic [t(12;21)] findings in the blasts. [442]

## TREATMENT

The recognition that ALL is a heterogeneous disease and that children can be stratified into various risk groups has profoundly influenced therapy. Although combination chemotherapy remains the primary therapeutic modality, it is no longer considered appropriate, in the context of current biologic knowledge, for all patients with ALL to be treated on a single treatment regimen. The initial evaluation of the patient with ALL requires sophisticated laboratory techniques to derive appropriate cytogenetic, immunologic, or molecular information. As our understanding of the disease has improved, the approach to its treatment has become more complex. This circumstance, coupled with the increased intensity of many current treatment regimens, emphasizes the need for children with ALL to be evaluated and treated by established pediatric cancer centers at which state-of-the-art treatment protocols are available. Although the specific approaches to patients in various risk groups may be somewhat different, modern ALL treatment regimens divide therapy into four main treatment elements: remission induction, CNS preventive therapy, consolidation, and maintenance therapy.

### Induction Therapy

The aim of initial ALL treatment is induction of remission. By definition, patients in remission have no evidence of leukemia when evaluated by physical examination as well as by standard laboratory examination of the blood (e.g., complete blood cell count) and bone marrow with standard cytochemical stains under light microscopy. Peripheral blood values must be within the standard range of normal for age, and the bone marrow must be of normal cellularity, with fewer than 5% lymphoblasts.[477] Complete remission status also assumes the absence of detectable CNS or extramedullary disease by traditional light microscopy on CSF and physical examination findings. [478] Achievement of a traditionally defined remission is a basic premise of antileukemic treatment and a known prerequisite for prolonged survival.[479] In clinically overt ALL, the leukemic cell burden is estimated to be approximately $10^{12}$ leukemic cells (Fig. 19-15).[479,480] To induce a complete remission, chemotherapy must reduce the total number of leukemic cells by 99%, leaving fewer than $10^{10}$ blasts.[481] In reality, most patients who achieve a successful remission induction have their total body leukemia burden reduced even further. [111] As noted above, the rapidity of this response to initial chemotherapy as well as the total reduction in leukemic cell burden are also important factors in determining eventual treatment success (see the sections Prognostic Factors and Minimal Residual Disease).[482,483] Early results with standard risk patients from the CCG, suggest that intervention with intensification of chemotherapy (both in the induction and later consolidation phases) may be able to rescue slow responders so that their EFS is comparable to those with more rapid responses (Stork L.C. ASH 2000 [Abs] 2007).

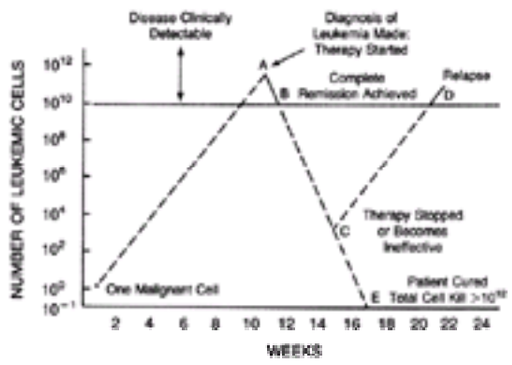

**FIGURE 19-15.** Schematic representation of the results of therapy in a patient with leukemia. (Adapted from Valeriote F, Vietti TJ, Fernback DJ, eds. Clinical pediatric oncology. St. Louis: CV Mosby, 1977:1182.)

Although the basic two-drug combination of vincristine and a glucocorticoid induces remissions in approximately 85% of children with ALL, the addition of L-asparaginase, an anthracycline, or both, improved the remission induction rate to approximately 95%. [484] Prednisone and prednisolone have been the most common glucocorticoids used for this purpose. Recently several cooperative groups have switched to dexamethasone because of laboratory data implying that it is more potent and may have pharmacokinetic advantages (e.g., increased efficiency in crossing the blood–brain barrier) in treating CNS disease. [485,486] However, newer experience suggests that dexamethasone may be associated with higher acute and long-term complication rates, so its use in this setting should remain as part of authorized clinical trials.[487,488] The addition of L-asparaginase to vincristine and a glucocorticoid also significantly prolonged remission duration. [489] Whether the added leukemic cytoreduction theoretically achieved by including a fourth induction (an anthracycline) leads to improvement in remission duration is controversial. The results of one randomized study indicated that adding daunorubicin (daunomycin) to the three-drug combination of vincristine, prednisone and L-asparaginase did not improve remission duration.[490] However, protocols using this four-drug induction combination with intensive consolidation and maintenance therapy uniformly demonstrate improved overall remission duration, even for high-risk patients. [491,492] Because the use of a fourth drug or additional drugs may increase the incidence of toxic effects during induction therapy, many centers reserve the use of drug combinations using four or more agents for patients in the highest risk groups.

Failure of induction therapy is a relatively rare event, occurring in less than 5% of children with ALL treated with most current regimens. [5,493] Induction failure occurs when the patient demonstrates residual leukemia in the end-of-phase bone marrow aspirate (typically performed on day 28 or 36, depending on the regimen), or when there is clear evidence of tumor progression (e.g., rising numbers of leukemic blasts in blood, bone marrow, and extramedullary sites) on chemotherapy. The long-term EFS for induction-failure patients in a recent Dana-Farber Cancer Institute (DFCI) study was 16%. [493] Rarely, a patient has severe aplasia at the end of induction and hence does not meet the criteria for achieving M1. In the DFCI study, prolonged aplasia had a better prognosis than did induction failure and was associated with EFS comparable to that of the patients who were clearly in a standard remission at the end of induction. [493] Patients who have bone marrow aplasia at the end of induction should receive adequate blood product and other supportive measures until the marrow either recovers (M1) or enough blasts can be distinguished (M3) that refractory disease is diagnosed.

There are occasional patients who demonstrate an M2 marrow (greater than 5% but less than 25% leukemic blasts) at the end of a standard induction. Although many of these patients eventually go into remission (either with an extension of the standard induction or with institution of more intensive treatments), this slow response to initial therapy is indicative of poor prognosis (see the section Minimal Residual Disease).[111,494] Improved supportive care has decreased the mortality rate during induction therapy to approximately 3% or less.[5,495]

## Central Nervous System Preventive Therapy

The recognition that CNS recurrence constituted a major obstacle to overall treatment success stimulated efforts to prevent CNS disease. The concept of CNS preventive therapy is based on the premise that the CNS acts as a sanctuary site in which leukemic cells, undetected at diagnosis, reside protected by the blood–brain barrier from therapeutic concentrations of systemically administered antileukemic drugs. According to this view, prevention of CNS relapse is more appropriately called *presymptomatic CNS therapy* than *CNS prophylaxis*, a term that is widely used. The introduction of CNS irradiation as preventive therapy was based on murine studies that demonstrated cures of L1210 leukemia when cranial radiation was added to systemic treatment with cyclophosphamide. [496] The first documentation of the value of CNS preventive therapy evolved from a series of studies performed at SJCRH. Although relatively low doses of craniospinal radiation (500 or 1,200 cGy) demonstrated no preventive effect (studies I–III), the administration of 2,400 cGy cranial irradiation plus five concurrent doses of intrathecal methotrexate or 2,400 cGy of craniospinal irradiation alone (studies V–VII) reduced the incidence of CNS relapse from more than 50% to approximately 10%. [497] Because the spinal component of craniospinal irradiation is associated with excessive myelosuppression and retardation of spinal growth, cranial irradiation (2,400 cGy) plus intrathecal methotrexate became the standard form of CNS preventive therapy.

Although this approach was universally adopted in the 1970s, concerns subsequently developed about the apparent adverse effects of this form of CNS preventive therapy (see the section on late effects of treatment). The identification of brain abnormalities on CT scans, altered intellectual and psychomotor function, and neuroendocrine dysfunction in patients treated with 2,400 cGy of cranial irradiation and intrathecal chemotherapy prompted a reappraisal of CNS preventive therapy strategies and stimulated the search for alternative methods of CNS preventive therapy. [498,499,500,501] and [502] The use of a lower dose of cranial irradiation (1,800 cGy) with intrathecal methotrexate appears to be as effective as 2,400 cGy and is currently used in most CNS preventive therapy regimens that continue to administer cranial irradiation. [394,503]

It is unclear, however, whether the use of 1,800 cGy plus intrathecal methotrexate reduces the incidence of adverse CNS sequelae. There is evidence that 1,800 cGy may have significant negative effects on neurocognitive function. [504,505] One study reported that children with ALL treated with 1,800 cGy of cranial irradiation and intrathecal methotrexate demonstrated greater adverse neuropsychological effects than those treated with intrathecal methotrexate alone. [506] In one German study, the use of 1,200 cGy administered on a protocol that included intermediate-dose methotrexate and systemic reinduction therapy was found to provide as effective CNS preventive therapy as 1,800 cGy in a selected group of standard-risk patients. [507] Although this experience suggests that under some circumstances it may be possible to reduce the cranial irradiation dose even further, additional follow-up, including information about the incidence of adverse CNS sequelae using such an approach, is needed.

A variety of patient characteristics are associated with an increased risk of CNS leukemia, including a high initial leukocyte count, T-cell disease, very young age, thrombocytopenia, lymphadenopathy, hepatomegaly, splenomegaly, and black race. [394] The highest rates of CNS relapse occur in infants and patients with extremely high leukocyte counts or lymphomatous presentations. [394,440] Although no single factor or group of factors can predict with absolute certainty whether an individual patient is at risk for CNS relapse, the recognition that patients differ in their risk for developing CNS leukemia has permitted investigators to successfully modify CNS preventive therapy accordingly. Cranial irradiation is unnecessary for patients with a good prognosis; intrathecal methotrexate alone, given periodically throughout maintenance chemotherapy, provides adequate CNS preventive therapy for these patients. [394] Maintenance intrathecal triple chemotherapy, the combination of intrathecal and moderate-dose intravenous (i.v.) methotrexate, and high-dose i.v. methotrexate alone all appear to provide equivalent protection to that offered by cranial irradiation and intrathecal methotrexate for patients at an intermediate risk of CNS relapse. [508,509]

With current CNS preventive therapy regimens, the incidence of CNS relapse is less than 10% overall and below 5% for good-risk patients. [510,511] and [512] The intensity of systemic chemotherapy appears to influence the efficacy of CNS preventive therapy regimens.

The Associazione Italiana di Ematologia ed Oncologia Pediatrica and the CCG groups have both demonstrated that, provided intensive systemic therapy is used, intrathecal methotrexate alone, administered from the start of treatment throughout maintenance therapy, is equivalent to 1,800 cGy of cranial irradiation in intermediate-risk and even high-risk patients (who were rapid early responders during induction). [513,514] Maintenance intrathecal methotrexate was significantly less effective than 1,800 cGy of cranial irradiation when less intensive systemic chemotherapy was used. [515]

CNS preventive therapy may be associated with acute or subacute neurotoxic sequelae. Intrathecal methotrexate or cranial irradiation alone can produce a wide spectrum of neurotoxicities. [501,516] Intrathecal methotrexate may be associated with an acute arachnoiditis, characterized by headaches, nausea and vomiting, meningism, and other signs of increased intracranial pressure occurring 12 to 24 hours after intrathecal injection. [517,518] These reactions usually are not severe, are self-limited, and have been reduced in frequency by the use of an intrathecal methotrexate dosing schedule based on the relation of age to CNS volume. [519] A subacute form of methotrexate neurotoxicity characterized by varying degrees of encephalopathy, myelopathy, and even paraplegia has been observed more rarely. [520,521] Studies using frequent pulses of intermediate-dose methotrexate together with triple intrathecal therapy reportedly are associated with an increased incidence of neurotoxicity, including seizures and CT scan abnormalities. [522] Between 5 and 7 weeks after cranial irradiation, some patients develop a subacute neurotoxic reaction characterized by somnolence, lethargy, anorexia, fever, and irritability. This “somnolence syndrome,” which may be accompanied by electroencephalographic abnormalities and CSF pleocytosis, usually reverses within 1 to 3 weeks. [523,524] It is unclear whether the somnolence syndrome correlates with the development of other late sequelae seen with CNS preventive therapy using cranial irradiation.

The desirability of avoiding cranial irradiation in CNS preventive therapy regimens results from concerns that radiotherapy is in large part responsible for many of the long-term adverse CNS sequelae observed in patients treated with cranial irradiation and intrathecal chemotherapy. Although patients at low and intermediate risks of CNS relapse may receive equally effective therapy with the alternatives to irradiation previously discussed, many centers continue to administer cranial irradiation plus intrathecal methotrexate to patients at particularly high risk for CNS relapse. Nevertheless, at the present time only approximately 10% to 15% of ALL patients (those in high-risk categories) receive cranial irradiation. This is a marked improvement over the 100% use of this modality in the late 1960s and early 1970s. Additional clinical trials evaluating efficacy and relative toxicity are needed to explore whether cranial radiation can be safely removed from CNS preventive therapy in regimens for high-risk patients.

## Consolidation and Maintenance Therapy

After complete remission has been achieved, subsequent therapy is required. Early studies demonstrated that without additional therapy, most patients relapse within a median of 1 to 2 months. The actual duration of an unmaintained remission varies with the intensity and duration of the induction therapy. [525] As shown in Figure 19-15, patients in complete remission theoretically have a leukemic cell burden in the range of $10^{10}$. Although successful induction may have produced a 99% (two log) or greater reduction in the number of leukemia cells, a significant amount of additional therapy is necessary before the leukemia is totally eradicated.

Using a variety of methods, including cytomorphology, biochemistry, *in vitro* cell culture, cytogenetic analysis, flow cytometry, and molecular biologic approaches such as Southern blot and PCR analysis of immunoglobulin and TCR gene rearrangements, investigators have documented that occult leukemic disease is often present in patients during otherwise apparent remission (see also the section Minimal Residual Disease). [111,526,527,528,529] and [530] At relapse, lymphoblasts usually demonstrate chromosomal and immunoglobulin gene rearrangement patterns identical to those obtained at the time of original diagnosis. [531,532] Several mechanisms have been proposed to explain this persistence of leukemic cells during remission. These include the development of biochemical drug resistance, the residence of leukemic cells in physiologic or pharmacologic sanctuary sites (e.g., CNS, testes), and the maintenance of a population of leukemia cells in a kinetic state ($G_0$) in which they are less vulnerable to chemotherapy.

To effectively prevent relapse, postinduction therapy must suppress leukemic growth and provide continuing leukemic cytoreduction without permitting the emergence of a drug-resistant clone. In early clinical studies, a variety of single agents were evaluated as maintenance agents. [497,533] Drugs particularly effective as induction agents were not useful for maintenance therapy. In contrast, maintenance treatment with methotrexate and 6-MP substantially prolonged remission. [534,535,536] and [537] The combination of methotrexate and 6-MP, administered continuously, has been used most widely and constitutes the principal element in most maintenance therapy regimens. The optimal schedule of administration of these two drugs is different. Methotrexate is more effective administered intermittently, but daily administration of 6-MP appears optimal. Various combinations have been studied in which other agents are added to standard 6-MP and methotrexate regimens. Addition of intermittent pulses of vincristine and prednisone to 6-MP and methotrexate maintenance chemotherapy appears to have prolonged remission duration for some patients, although the value of this approach after intensive induction therapy is unclear. [351,538,539] The choice of appropriate maintenance chemotherapy appears to

differ according to risk group. 6-MP and methotrexate may provide adequate maintenance therapy for certain good-risk patients, but more intensive maintenance therapy appears to be more effective for poor-risk patients.

Consolidation therapy is a period of intensified treatment administered immediately after remission induction, and it is a common component of many therapy protocols, particularly for higher-risk patients. [538,540,541] Several regimens use agents and schedules designed to minimize the development of drug cross-resistance. The evidence that intensification has improved treatment success, even in patients with a poor prognosis, is substantial. [4,542] Intensive postinduction treatment with L-asparaginase and doxorubicin is associated with an improved outcome for high-risk patients with T-cell disease. [543]

The BFM study group, using intensive induction and consolidation plus "reinduction" and "reconsolidation" phases of therapy early in maintenance, reported prolonged EFS for approximately 70% of patients, including those with high-risk features. [4,491] Using a similar approach, the CCG reported an EFS rate of approximately 60% for high-risk patients.[492] The use of high-dose methotrexate pulses also has been reported to be associated with an improved EFS of approximately 73% for children with T-cell leukemia. [468] A protocol known as the *New York regimen*, which incorporated many of the features of the $LSA_2L_2$ lymphoma regimen and used alternating non–cross-resistant combination chemotherapy, has also resulted in an improved outcome for children with high-risk ALL. [542,544,545] An SJCRH study using early reinforcement of induction therapy followed by a rotational combination chemotherapy approach produced an EFS rate of 69% in high-risk patients.[542] Although the use of more intensive treatment regimens has been associated with a modest increase in therapy-associated toxicity, the advantages of such treatment particularly for the patients in the highest risk groups, are established.

Drug dosage is an important factor in maintenance chemotherapy. The correlation between chemotherapy dose and therapeutic response in leukemia was originally documented in animals.[546] Its influence during maintenance was demonstrated in a randomized study in which patients receiving chemotherapy with 6-MP, methotrexate, and cyclophosphamide at full dose had significantly longer remission duration than patients receiving therapy at one-half dose. [478] Subsequent clinical studies have confirmed this finding.[547] One study demonstrated a correlation between cumulative 6-MP dose and prognosis in children with average-risk ALL. [548] A Danish study reported a lower relapse rate among patients who had lower leukocyte counts while receiving maintenance therapy with 6-MP and methotrexate, suggesting that more intensive therapy with these two agents is beneficial. [549] In another study, patients who tolerated only low doses of 6-MP because of neutropenia and those who received higher doses of methotrexate had a lower rate of relapse, indicating that the use of these agents in maximally tolerated doses during maintenance may be associated with improved treatment outcome.[550] The results from several cooperative group trials testing this question (i.e., standard versus dose intensive 6-MP/6-thioguanine/methotrexate) are not yet available

The frequency of drug administration also appears to influence the length of remission. [547] Patients who receive maintenance therapy on a continuous rather than an interrupted schedule have longer remission durations. Studies of the clinical pharmacology of orally administered 6-MP and methotrexate have documented that their bioavailability after oral administration may be limited and highly variable, suggesting a possible explanation for treatment failures that occur during oral maintenance therapy with these agents.[551] Compliance problems also may diminish the efficacy of maintenance therapy. [552] The possible problems associated with oral administration of 6-MP and methotrexate theoretically could be circumvented by parenteral administration. However, data on the relative effectiveness of parenteral or oral maintenance therapy are conflicting. Results of a British Medical Research Council (MRC) leukemia trial (UKALL-VII study) indicated a significantly longer actuarial relapse-free survival rate for patients who received methotrexate intramuscularly compared with those given the drug orally. [444] In another study, which randomized children with non–T-cell ALL to receive methotrexate during maintenance as a single oral dose or as an intramuscular injection, the route of administration appeared to have no real influence on relapse rate. [553]

Some studies indicate that intracellular metabolism of 6-MP and methotrexate may influence treatment outcome. [547,554,555] Higher intracellular levels of 6-thioguanine nucleotides, the major cytotoxic metabolites of 6-MP, have been associated with a lower relapse rate. [554,555] As noted earlier, studies have demonstrated that the lymphoblasts from children with hyperdiploid, low-risk ALL more efficiently accumulate methotrexate intracellular metabolites, indicating that these patients may be more sensitive to methotrexate therapy.[556,557] An association has also been found between high levels of lymphoblast dihydrofolate reductase and shorter remission duration.[558]

***Duration of Treatment***

The optimal length of maintenance chemotherapy has not been established. Most centers treat patients for a total of approximately 2.5 to 3.0 years. Data from several studies support this approach.[559,560,561] and [562] The MRC examined the effect of variation in length of treatment on duration of remission and demonstrated that 19 months of therapy was less effective in preventing relapse than 3 years of treatment. [563]

The optimal duration of treatment for girls may be different than that for boys. Another MRC study demonstrated that 1.5 years of therapy was sufficient or girls but inadequate for boys.[564] The tendency for a greater percentage of males to relapse after cessation of chemotherapy was observed in a long-term follow-up study of patients treated on the Children's Cancer Study Group 141 protocol. In that study, patients in complete continuous remission for 3 years were randomized to discontinue therapy, to receive a 4-week course of reinduction chemotherapy and then discontinue therapy, or to continue therapy for a total of 5 years. No significant difference was found in DFS for the different treatment regimens. However, a higher incidence of late relapse occurred among boys, even after excluding patients with occult testicular disease. This is consistent with other studies that have demonstrated that sex is a significant predictor of late relapse, even when isolated testicular relapse is excluded.[565,566]

Investigators at SJCRH have demonstrated that after successful completion of 2.5 years of therapy, approximately 80% of patients remain free of disease. [566] Most of the 20% of patients who eventually relapsed did so in the first year off therapy. In the second through the fourth year after cessation of chemotherapy, the risk of relapse was only about 2% to 3% per year. Recurrence after 4 years from the cessation of therapy was not encountered. [566] Similar results were observed in a study from Great Britain that concluded that patients alive 6 years after diagnosis without relapse have a high likelihood of prolonged survival and cure. [553]

It is likely that the intensity of therapy has a bearing on the optimal duration of therapy. The current practice of treating patients for 2.5 to 3.0 years of maintenance chemotherapy is derived from studies in which patients were treated with a variety of chemotherapeutic regimens, many of which incorporated fewer agents and were less intensive than those currently in use. For this reason, conclusions about the duration of maintenance based on those studies may not be directly applicable to current treatment programs. It is logical to question whether patients receiving more intensive therapy earlier in their course of treatment may ultimately require a shorter overall duration of therapy. In an attempt to address this question, the BFM study group, which uses an intensive chemotherapy regimen, randomized patients to receive 18 or 24 months of total duration of therapy. A therapeutic advantage was observed for patients who received longer treatment. [351] The MRC UKALL-VIII trial, using less intensive therapy, observed no outcome advantage between patients randomized to receive 3 years and those receiving 2 years of maintenance treatment.[547]

**Supportive Care**

Optimal management of the child with ALL requires appropriate attention to several areas of supportive care, including the rational use of blood component therapy, an aggressive approach to detection and treatment of infectious complications, careful attention to the metabolic and nutritional needs of the patient, and comprehensive, continuous psychosocial support for patient and family. Because these topics are thoroughly addressed in Chapter 39, Chapter 40, Chapter 41, Chapter 42, Chapter 43, Chapter 44, Chapter 45, Chapter 46, Chapter 47, and Chapter 48, they are discussed only briefly here.

The importance of adequate hematologic supportive care cannot be overemphasized. Before the systematic use of platelet transfusions, hemorrhage was the leading cause of death for patients with this disease. The use of prophylactic platelet transfusions and aggressive platelet transfusion support has markedly reduced the incidence of significant bleeding. Recently, the use of 20,000 per $mm^3$ threshold for platelet transfusion in adult leukemia patients (primarily with AML) has been questioned by several researchers. These groups found that the use of 10,000 per $mm^3$ in the absence of fever, trauma, or reason for clotting factor consumption resulted in 20% to 30% less transfusion exposure and cost and no significant increase in serious hemorrhage. [567,568] and [569] However, these studies were done on relatively small numbers of patients that included very few children. The development of recombinant thrombopoietin has raised hope that this stimulator of platelet production may soon play a role in ameliorating chemotherapy-induced thrombocytopenia. Clinical trials of this agent and other cytokines (IL-3 and IL-11) to stimulate postchemotherapy platelet recovery have been initiated. [570,571] and [572]

Erythrocyte transfusions are frequently required to treat anemia, and as with all blood products, they must be appropriately screened to exclude the possibility of

contamination with hepatitis virus or HIV. Modern blood banking and transfusion techniques, including the irradiation of all cellular blood products, WBC depletion, and more comprehensive viral and donor screening has improved the safety and efficacy of transfusion of these children. The granulocytopenia that occurs as a consequence of therapy-induced marrow hypoplasia or with disease progression places patients at risk for potentially life-threatening infections.

Hematopoietic growth factors, including granulocyte colony-stimulating factor (G-CSF), are beginning to play a significant role in reducing the complications of granulocytopenia after cancer chemotherapy. G-CSF has already been shown to ameliorate the leukopenia incurred by chemotherapy for ALL. [573] The long-term benefits of using growth factors during intensive phases of ALL therapy remains controversial. [574,575] Receptors for G-CSF and other known factors (e.g., granulocyte-macrophage colony-stimulating factor, IL-3) have been identified in leukemic lymphoblasts, raising concern that their use might stimulate leukemic cell growth.[576] For these reasons, as well as the significant financial cost, G-CSF and other growth factors are not routinely used in most standard risk ALL regimens, but they are used often in BMT and relapse and occasionally in front-line high-risk protocols that use more intensive chemotherapy. [577]

An aggressive approach to diagnosis and rapid empiric therapeutic intervention are important principles for the successful management of the severely neutropenic (less than 500 granulocytes per $mm^3$) patient (see Chapter 41). The early empiric use of broad-spectrum antibiotics has dramatically reduced overall mortality. Granulocytopenia, chemotherapy-induced immunosuppression, disruption of normal anatomic barriers by invasive procedures, or therapy-induced complications (e.g., mucositis) increase susceptibility to bacterial, fungal, viral, and parasitic infections. Although the risk of bacterial and secondary fungal infections may be greater for patients undergoing intensive induction or reinduction therapy, the child with leukemia is susceptible to various forms of infections while undergoing maintenance chemotherapy as well. *Pneumocystis carinii* pneumonia is an extremely serious, potentially life-threatening complication that commonly affects children undergoing maintenance chemotherapy. The prophylactic use of trimethoprim-sulfamethoxazole, instituted early in therapy, dramatically reduces the incidence of this type of infection and is used routinely in most centers. [578,579] When trimethoprim-sulfamethoxazole cannot be tolerated due to count suppression or allergy, dapsone or pentamidine (i.v. or aerosolized) can be substituted. [580,581]

The leukemic child undergoing treatment is also at risk for disseminated varicella if exposure to an infected person occurs. Administration of zoster immune globulin within 72 to 96 hours to such patients appears to have a protective effect. [582] Immunization of children with ALL with a live, attenuated varicella vaccine has been advocated by some but may not work in many patients because of the immune suppression caused by the disease or chemotherapy. [583,584] The immunization of varicella-susceptible household contacts of patients with ALL who have not had varicella is currently a recommended practice. [585] Other viral infections also place the leukemic child at risk. Measles tends to run a more complicated, atypical course in the leukemic host. [586] Nonimmunized children exposed to the measles virus should be treated with gamma globulin. Because of the risk of dissemination, immunization against measles or the use of any vaccines containing a live virus, except possibly in the case of varicella vaccine, is contraindicated in patients receiving chemotherapy.

Adequate nutrition also is a concern for the patient with leukemia. Multiple studies have suggested that malnutrition is an adverse prognostic factor (see the section on nutritional status and Chapter 42). [469,470,473,587] Severe malnutrition was shown in one study to increase the risk of death 2.5-fold during induction. [471] It has been reported that improving nutrition in undernourished patients during chemotherapy improves prognosis. [587] It may be that this effect is due to the relationship between nutritional status and the ability to tolerate standard maintenance chemotherapy. [588] Undernutrition is common at diagnosis, and it frequently becomes worse during the intensive phases of chemotherapy.[589] In most centers, if normal enteral alimentation is prevented by an unforeseen therapeutic complication, i.v. hyperalimentation is considered.

## TREATMENT OF RELAPSE

Before treating any type of relapse, it is helpful to ascertain whether the cells are indeed from the original leukemia (see also Late Effects of Treatment). Most relapsed leukemias retain their original immunophenotypes and karyotypes, but changes have been observed. [169,173,590] The presence of a different cell lineage at the time of relapse, a so-called lineage switch (e.g., lymphoid to myeloid), is a relatively rare event. Lineage switch may result from chemotherapeutic eradication of one clone and subsequent expansion of a second clone of an originally biclonal leukemia. Alternatively, chemotherapy may induce modulation of antigen expression in a leukemic clone that retains the potential for lymphoid and myeloid differentiation. Lineage switch must be differentiated from the development of a secondary leukemia. Molecular and cytogenetic studies may be helpful in documenting similarity with the original clone. In approximately 30% of relapse cases, the karyotype will have undergone changes visible with standard Giemsa banding. [169] However, there is usually evidence of the original clone within the predominant clone at relapse.[169] Lineage switch usually occurs within months of the initial diagnosis; secondary acute leukemias tend to occur years later. [199] Lineage shift from lymphoid to nonlymphoid disease is more common than the reverse, although both have been described. [191,591] In general, both secondary leukemias and relapse of the original leukemia represent disease that is more resistant to chemotherapy, and relapse protocols (often including at least the consideration of BMT) are more intensive than those used on most de novo cases.

### Bone Marrow Relapse

Bone marrow relapse is the principal form of treatment failure in patients with ALL. The two approaches to the treatment of bone marrow relapse are chemotherapy and BMT. Depending on initial chemotherapy regimen used, second complete remissions can be induced in most patients who experience a marrow relapse. The chemotherapeutic approach to the relapsed patient should include aggressive multidrug reinduction therapy followed by intensive systemic consolidation and maintenance chemotherapy. The combination of vincristine, prednisone, and L-asparaginase produces complete remissions in approximately 70% to 75% of patients treated for an initial bone marrow relapse. The addition of daunorubicin increases the reinduction rate to 80% to 90%. With more intensive regimens, reinduction rates greater than 90% have been reported. [592,593] Administration of an intensive course of cytarabine and teniposide, or high-dose ifosfamide with etoposide induces complete remissions in approximately one-third of patients not achieving complete responses with the four-drug reinduction regimen of L-asparaginase, vincristine, daunorubicin, and prednisone. [594] Wherever possible, new agents (drugs not used in the initial therapy) and new combinations of agents should be introduced to try to overcome any drug resistance the leukemic clone may have acquired during the first treatment course.

At the time of a marrow relapse the CNS must also be checked (with a lumbar puncture) and consideration given to how, if the CNS is not involved, a second course of CNS preventative therapy should be administered. Alternatively, if the CNS is involved at the time of relapse, a plan for active CNS treatment must be developed. The need for a second course of CNS preventive therapy for patients in second remission is well established; without it, almost 50% experience CNS relapse. [595] For patients who received cranial irradiation as part of their initial CNS preventive therapy, intrathecal chemotherapy is usually used as the second form of CNS preventive therapy.[595]

The eventual outcome of children who achieve a second remission is influenced by a variety of factors. Patients relapsing after completion of a previous chemotherapy regimen have a better chance of achieving and maintaining a prolonged second remission than do those relapsing while receiving chemotherapy. [596,597 and 598] The overall survival of patients who relapse off therapy is better than for those who relapse on therapy. The prognosis of patients who relapse off treatment is proportional to the interval from the time of discontinuation of therapy to relapse. In most studies, bone marrow relapse occurring during treatment or within 6 months after cessation of treatment is associated with a very poor long-term survival. [593,599,600] Children whose first relapse occurs later than 6 months after cessation of therapy have significantly longer second remissions. [600,601] One study has suggested that with respect to survival, the primary dividing point was 3 months after discontinuation of therapy.[597] In that analysis, patients who relapsed between 3 and 6 months after cessation of treatment had a relatively good prognosis similar to those who relapsed between 6 and 12 months after therapy, although the best overall survival was observed in patients who relapsed more than 12 months after discontinuation of therapy.

The length of the first remission is a factor with predictive value for remission duration of the second remission. [598,602,603 and 604] Children whose first bone marrow remission was longer than 18 months have a significantly better prognosis than those with shorter first remission durations. A review of 600 children in second remission treated with chemotherapy documented prolonged second remissions in fewer than 5% of children who relapsed within 18 months of achieving first remission. In contrast, sustained second remissions were observed in approximately 25% of children whose relapse occurred after 18 months. [603] Using an intensive reinduction treatment regimen, the BFM study group has observed prolonged second complete remissions in approximately 50% of patients who had prolonged first remissions and who had Ph-negative blasts.[605] For relapsed patients with $Ph^+$ disease, the long-term survival was only 8% in the same study. [605]

Features other than duration of the first remission have been associated with the likelihood of achieving a prolonged second remission, including a low leukocyte count (less than 20,000 per $mm^3$) both at initial diagnosis and relapse, and a favorable age (older than 2 years or younger than 10 years) at initial diagnosis. [602] The nature and intensity of previous therapy appears to be important; patients previously treated with suboptimal primary induction and maintenance therapy have a

higher reinduction rate.[606,607] For patients experiencing multiple relapses, the reinduction rate declines with each successive relapse, presumably a result of the development of drug resistance.[608]

A bone marrow relapse portends a poor prognosis for most patients. With aggressive treatment, however, long-term second remissions are being observed.[596,602,609,610] The results of a number of studies suggest that prolonged second remissions (greater than 2 years) can be obtained with aggressive chemotherapy in approximately 10% to 30% of patients who relapse on therapy and in up to 50% of patients who relapse after elective cessation of therapy.[596,598,603,611,612]

The use of BMT as a therapeutic approach for ALL patients who have bone marrow relapse or are assessed to be at an extremely high risk of relapse (e.g., Ph $^{+}$ at diagnosis) has increased in recent years. This approach, discussed in Chapter 16, involves the administration of intensive cytoreductive therapy, usually using total body irradiation (TBI) combined with high-dose chemotherapy in doses lethal to normal bone marrow, and subsequent hematopoietic "rescue" with i.v.-infused bone marrow obtained from a compatible donor. To some degree, the initial interest in BMT was generated by the unfavorable treatment results obtained in relapsed patients treated with conventional chemotherapy. The earliest experiences with BMT involved multiply relapsed patients refractory to conventional chemotherapy who were usually transplanted in relapse. Results in this group of patients were disappointing; approximately 10% of those receiving marrow from an HLA-matched sibling achieved prolonged DFS.[613,614]

Although these earlier results were discouraging, continual innovation and technological refinements have given BMT an important role in the treatment of childhood ALL. Currently, allogeneic BMT is routinely advocated for patients in second or subsequent remission who have an appropriate HLA-matched sibling donor.[615] In this group of patients, overall DFS ranges from approximately 40% to more than 60%.[616,617] Although it is a matter of some debate (see Chapter 16), some groups are reporting results equivalent to these with matched unrelated donors.[618,619] Other strong indications for BMT (even in first complete remission) include patients with unfavorable cytogenetics [e.g., t(9;22), t(4;11)] or ploidy (haploidy or tetraploidy) of the leukemic blasts, who also have prognostically poor presentation features or who did not respond rapidly to their initial treatment.[620] The value of BMT for infants [with or without the t(4;11) translocation] is controversial and is the subject of ongoing clinical trials. Although non-TBI containing regimens are often chosen for young children, they do not seem to be as effective as the TBI-containing regimens.[617] The optimal preparative regimen for any of the common relapse ALL circumstances (i.e., TBI versus non-TBI containing regimens as well as the choice of chemotherapy agents and doses), alternative donor type, and the issues surrounding the management of graft-versus-host disease (GVHD) and posttransplant care are discussed in detail in Chapter 16.

After a bone marrow relapse, better results are obtained for patients transplanted in second remission than in those transplanted in relapse or partial remission. In most studies patients transplanted in earlier remissions fare significantly better than patients transplanted after multiple relapses.[519,621] The length of first remission and high-risk features at diagnosis are predictive factors.[603,622] Patients with shorter initial remissions and those with high-risk features at diagnosis fare worse when transplanted in second remission. Most studies that have compared the efficacy of allogeneic BMT with chemotherapy for patients who had experienced a previous relapse indicate that transplantation is associated with a superior outcome.[623,624]

A retrospective analysis performed by the International Bone Marrow Transplant Registry compared BMT versus chemotherapy for children with ALL in second remission and concluded that transplantation was superior to chemotherapy in patients whose initial relapse occurred within 18 months of achieving first remission.[603] Allogeneic BMT is considered the treatment or choice for patients in second bone marrow remission who relapsed initially while undergoing chemotherapy (or within 3 months of its completion) and have a histocompatible sibling.[597,603,621] It has been suggested that patients who suffer late relapses (greater than 36 months after achieving first remission or after completing maintenance therapy) or had swift initial response to their initial chemotherapy may do well with intensive chemotherapy regimens without transplant.[320,519] Many centers treat patients whose relapses occur 1 year or more off chemotherapy with chemotherapy alone.[602,624] In such patients, BMT is reserved for subsequent relapse.

Routine allogeneic BMT is limited to the approximately one-fourth of relapsed patients who have an HLA-identical sibling. In an effort to circumvent this problem, several alternative strategies have been studied. One approach is autologous BMT in which pretransplant preparative therapy is followed by infusion of previously harvested remission marrow treated *in vitro* with drugs, immunotoxins, or specific monoclonal antibodies to remove potentially contaminating leukemic cells.[622,625,626] and [627] The results of studies of autologous purged and unpurged BMT used in second or subsequent remission vary, with DFS figures ranging from approximately 13% to 40%.[622,627,628] Whether autologous marrow can be adequately purged is still a matter of debate, but evidence shows that autologous marrow is often contaminated with residual leukemia cells, and that the risk of relapse post-BMT is directly proportional to the number of malignant cells reintroduced in the infused bone marrow.[629] Methods to artificially mark the infused graft have been described and are useful for determining whether the source of a later relapse is from cells that were infused with the graft or cells that survived the BMT preparative regimen.[630,631]

Other alternative donor options for ALL patients who lack a histocompatible sibling include transplantation from a partially matched related donor, a matched or partially mismatched unrelated donor, or an HLA-similar cord blood stem cell donor.[628,632] Techniques such as depleting donor marrow of T cells and the use of better immunosuppressive posttransplant regimens (e.g., low-dose methotrexate, cyclosporine, or FK506; see Chapter 16) to decrease the incidence and severity of GVHD have made these types of transplants feasible. Unfortunately, many of these techniques may also lead to graft rejection and potential decreases in the graft-versus-leukemia effect.[633] The results of these approaches have been encouraging, but they remain in an early stage of clinical development.[628] Alternative donors, autologous purging strategies, better methods to prevent GVHD and other BMT complications, and their possible role in ALL treatment are discussed in more detail in Chapter 16.

The outlook for patients who relapse after BMT is poor. Although complete remission can be obtained in as many as 50% of patients, the duration is usually short.[634]

**Minimal Residual Disease**

Although there may be some changes in immunophenotype and karyotype, in most cases of ALL, relapse represents the reappearance of the original clone.[169,635] Thus researchers have known for a long time that some amount of MRD had to exist below the level of detection. Using light microscopy and routine bone marrow stains it is difficult for even an experienced observer to distinguish less than 5% blasts in a specific bone marrow sample. This is made even more difficult at the end of any intensive treatment (e.g., induction, intensification, consolidation) because the cells in the marrow will be repopulating, and normal hematopoietic precursors (so-called hematogones) will be present in amounts greater than or equal to 5% and can be easily confused with leukemic blasts.[111]

Numerous techniques to detect MRD and predict clinical outcome have been evaluated. The techniques used include various types of quantitative PCR or RT-PCR, cell culture/soft agar cloning techniques, FACS analysis for abnormal immunophenotypes, or combinations of these.[111,635,636] and [637] The earliest approaches had limited success because they lacked both sensitivity and specificity and were relatively cumbersome and expensive to apply.[528,634,638,639] PCR technology greatly enhances the ability to detect residual leukemic cells and is the most sensitive method. Targets for PCR detection include leukemia-specific translocations and clonal antigen receptor or immunoglobulin gene rearrangements that are specific to a particular leukemic clone. The leukemia cell–specific changes can be targeted at the DNA level with PCR or at the level of gene expression with RT-PCR. Using *in vitro* dilution experiments, the PCR approach can detect as few as one cell in $10^5$ to $10^6$ normal bone marrow cells.[636,640,641] When this approach has been practically applied to the clinical evaluation of bone marrow specimens, however, sensitivities of $10^{-4}$ to $10^{-5}$ are more commonly reported.[528,642] The $10^{-4}$ and $10^{-5}$ sensitivity is also within the range of current FACS equipment, which can detect the complex immunophenotype patterns that allow leukemic cells to be clearly distinguished from normal cells. FACS has the added advantage of detecting intact cells, in contrast to PCR and RT-PCR, in which contaminating nucleic acid material from dead cells can complicate interpretation.

Early studies suggested that PCR may be useful in identifying patients likely to relapse when the number of detectable leukemic cells in their marrow seemed to be rising.[528,529] In Ph$^{+}$ ALL, the detection of PCR-positive bcr-abl transcripts after BMT or intensive conventional therapy were the first cases in which increasing amounts of PCR+ cells were found to be associated with a decreased DFS.[643,644] More recently the best use of this technology appears to correlate with what is already known about the prognostic value of rapid response to chemotherapy (see the sections Treatment and Prognostic Factors). It is becoming clearer that the rapid (i.e., within the first 2 to 4 weeks) lowering of MRD levels to below $10^{-4}$ correlates well with relapse-free survival.[111,645,646] Conversely, patients in whom MRD does not clear below this point, or more slowly goes below the same level have a higher risk of relapse.[111]

Multiple issues remain to be clarified in prospective studies, including whether MRD levels below $10^{-5}$ are relevant and the most appropriate times during therapy for

MRD measurements. Once these correlative studies are done, it will hopefully be possible to develop interventions to prevent relapse in patients in whom the MRD analysis predicts are at high risk of recurrence. At this point, clinicians should be aware that MRD analysis and its eventual applicability to the clinic are still under investigation. A PCR-negative result during or at the end of therapy does not necessarily guarantee long-term DFS. Conversely, although it has been demonstrated that many patients who are cured appear to be PCR negative, it is not clear that achievement of a PCR-negative status is necessary for cure in all cases.

## Extramedullary Relapse

### *Central Nervous System Relapse*

Despite the success of CNS preventive therapy in dramatically reducing the incidence of CNS recurrence, CNS relapse remains a significant cause of treatment failure in ALL. CNS recurrence is observed in less than 10% of patients. In the past, the outcome for these patients was generally poor, with most patients suffering subsequent CNS relapses or recurrences at other sites, such as bone marrow and testes. [394,647] CNS relapse may occur as an isolated event, with a bone marrow relapse, or with recurrence at another extramedullary site (e.g., testes). Because periodic lumbar puncture surveillance for CNS leukemia is performed in most ALL treatment protocols, it is relatively infrequent for patients to present with overt CNS symptoms. More commonly, the diagnosis of meningeal recurrence is based on a routine examination of CSF. The criteria for diagnosing a CSF relapse have been modified over the years. [395] The generally accepted criteria has included more than 5 leukocytes per µL, with unequivocal blasts demonstrable in a cytocentrifuge preparation. Although this has been a useful working definition, the significance of blast cells in a cytocentrifuge sample when the CSF leukocyte count is less than or equal to 5 leukocytes per µL is unclear. A study by Odom and colleagues [648] suggested that positive, low cell count CSF samples obtained on surveillance lumbar punctures performed during remission indicate a high likelihood of impending CNS relapse. A CCG study, however, did not confirm these findings.[649]

Intensive treatment plans have recently improved the results for patients with an isolated CNS relapse as high as 70% EFS. [650,651] There is evidence that if both craniospinal irradiation and intrathecal chemotherapy are used as CNS prophylaxis in the context of moderately intensive systemic therapy during the initial treatment regimen, the rate of CNS relapse can be reduced to as low as 1% to 2%. [652] However, the combination of CNS and radiation therapy prophylaxis has worse intellectual and growth long-term effects, so except in specific high risk situations, combined-modality treatment for CNS prophylaxis is reserved for relapse situations. [516,653,654]

The most successful treatment regimens for CNS relapse have used intrathecal chemotherapy for CNS remission induction, followed by consolidation therapy with craniospinal irradiation, and maintenance intrathecal chemotherapy. [651,655] Intrathecal methotrexate alone induces CNS remissions in more than 90% of patients; however, unless followed by maintenance intrathecal therapy or craniospinal irradiation, relapse occurs within 3 to 4 months. [656] Therapy for CNS relapse must also contain vigorous systemic therapy to prevent further relapses of all types. Cranial irradiation alone has little value in the treatment of overt CNS disease because it does not adequately treat sites of disease along the spinal axis. Furthermore, when cranial irradiation is combined with intrathecal methotrexate alone, it appears to increase toxicity and does not appear to prolong remission duration. [409,656] Craniospinal irradiation alone, administered in adequate doses (2,400 cGy to both sites) can induce complete remissions and prolong DFS. Most centers, however, do not use craniospinal irradiation alone. The higher spinal irradiation dose required to achieve equivalent disease control if intrathecal therapy is omitted is associated with prolonged bone marrow suppression, which compromises the ability to deliver adequate systemic chemotherapy. A common approach is first to induce a CSF remission with intrathecal chemotherapy and then to administer craniospinal irradiation at doses of 2,400 to 3,000 cGy to the cranial vault and 1,200 to 1,800 cGy to the spinal axis. [394,657] The main factors determining the success rate for patients with CNS relapse include whether the relapse occurred greater than or equal to or less than 18 months (83% and 46% EFS, respectively; Fig. 19-16) after initiating therapy and whether the patient received CNS-directed radiation therapy in their initial treatment regimen. [650,651]

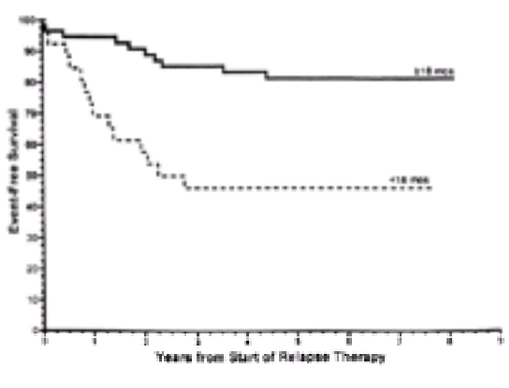

**FIGURE 19-16.** Event-free survival (EFS) for patients who have isolated central nervous system (CNS) relapses greater than or equal to or less than 18 months from initial diagnosis. The 4-year cumulative EFS rate for patients with first remission at greater than or equal to 18 months was 83.3% ± 5.3%, and, for patients with a first remission at less than 18 months, it was 46.2% ± 10.2%. For all patients (n = 83) the EFS after a first isolated CNS relapse was 71.1% ± 5.3%. (From Ritchey AK, Pollock BH, Lauer SJ, et al. Improved survival of children with isolated CNS relapse of acute lymphoblastic leukemia: a pediatric oncology group study. J Clin Oncol 1999;17:3745–3752, with permission.)

The role of craniospinal irradiation to treat CNS recurrence in a patient who originally received cranial irradiation as part of CNS preventive therapy is less certain. Results from the MRC Concord and UKALL-I trials demonstrated a continuous complete remission rate of less than 10% for these patients. [658] Other investigators have demonstrated substantially better results with this approach. [657] However, craniospinal irradiation administered in this setting is known to pose a significantly greater risk of delayed neurotoxicity.[657,659]

Several attempts have been made to improve on the use of single-agent intrathecal methotrexate for CNS relapse. Triple therapy consisting of simultaneously administered intrathecal cytarabine, hydrocortisone, and methotrexate has been advocated, but this produces remission durations similar to those achieved with methotrexate alone.[394] The use of intraventricular chemotherapy, administered by means of an intraventricular subcutaneous reservoir, more completely distributes drug within the CNS, minimizes patient discomfort, and avoids the problems of inadequate delivery of drug into the CSF that may occur with unsuccessful lumbar punctures.[660] Early studies demonstrated longer remission durations and fewer CNS relapses with intraventricular than with intralumbar therapy. [659,661]

Several other treatment approaches have been advocated for controlling meningeal leukemia. High-dose systemic methotrexate infusions induce CSF remissions in most patients.[662] The feasibility or effectiveness of this approach in maintaining CNS remissions is unknown, and its applicability may be limited, particularly in patients receiving CNS irradiation, because of concerns about delayed neurotoxicity. [394,663] Systemic high-dose cytarabine also has produced remissions in patients with overt CNS leukemia.[664,665] The use of high-dose cytarabine is somewhat limited by its attendant myelosuppression and neurotoxic potential. New intrathecal agents are also being developed. Diaziquone, mafosfamide, and topotecan are all being evaluated in separate, ongoing intrathecal phase I or II clinical trials. [660,666] The eventual role of these and other agents in the prevention and treatment of CNS leukemia requires further study.

### *Testicular Relapse*

With the increase in intensity of many protocols, the incidence of testicular relapse appears to be decreasing from the 10% to 15% seen in the 1970s and 1980s to 2% to 5% on more recent trials.[1,4,667,668] Optimal therapy for testicular relapse includes the administration of local radiotherapy and the use of systemic chemotherapy. Radiation dose appears to be a crucial factor in local control. Doses less than 1,200 cGy are generally suboptimal; doses of 2,400 cGy to both testes have been considered adequate.[432,669] Reports of local recurrence in patients treated with 2,400 cGy, however, suggest that higher doses may be better. [670] Bilateral testicular radiotherapy is indicated for all patients; unilateral treatment may be followed by relapse in the contralateral testis. [420]

Radiation therapy adversely affects normal testicular function. Sterility is an expected consequence at the radiation doses used. [432,671,672] Studies also indicate that testicular endocrine function may be impaired at doses of 2,400 cGy. Elevated follicle-stimulating hormone and luteinizing hormone levels, decreased testosterone levels, and delayed sexual maturation have been observed after gonadal irradiation. For this reason, such patients must be carefully followed for signs of delayed

sexual maturation and may require androgen replacement therapy.[673,674]

The impact of a testicular relapse on prognosis depends on whether it was overt (clinically detectable) or occult (detected on routine testicular biopsy), whether the recurrence was an isolated event or accompanied by a simultaneous hematologic relapse, and whether the relapse occurred during or after initial treatment. [420,597,675] Because isolated testicular relapse frequently heralds a systemic relapse, treatment must include intensification of systemic therapy in addition to bilateral testicular irradiation.[429,676] Most centers systemically "reinduce" patients who suffer an overt testicular relapse with intensive systemic chemotherapy. This strategy has dramatically improved the prognosis for patients with testicular relapse. [415,676,677] and [678]

The prognosis is better if the testicular relapse occurs as an isolated event. [420] Isolated testicular relapse is observed more frequently than it is with a concurrent bone marrow relapse, although many patients who present with isolated testicular relapses probably have occult intra-abdominal disease. [425] The outcome for patients with an isolated overt testicular recurrence appears to vary with the time of presentation. An isolated testicular relapse occurring in a patient on treatment is associated with the worst prognosis, although a CCG study suggests that with local irradiation and intensive systemic retreatment, prolonged EFS can be obtained in nearly one-half of such patients.[676] In contrast, a late, isolated, overt testicular relapse that occurs off therapy has an even better prognosis. Prolonged DFS can be obtained for more than two-thirds of such patients.[411,415,675]

The practice of elective testicular biopsy during apparent remission can detect microscopic testicular leukemia in approximately 10% to 15% of boys with ALL. The DFS for patients with occult testicular leukemia treated with testicular irradiation and systemic and CNS chemotherapy is approximately 60% to 70%. The treatment results for occult testicular leukemia and an isolated overt testicular relapse that occurs off therapy are similar. [411] For this reason, documentation of occult disease by performing testicular biopsies in patients on therapy is no longer advocated. [411,679]

### *Other Sites of Relapse*

Leukemia may occasionally recur at other sites (e.g., ovary, eye).[680,681] and [682] If feasible, the appropriate treatment should include local measures for disease control (e.g., radiation therapy) and intensification of systemic chemotherapy.

### Late Effects of Treatment

The improved survival of children with ALL has focused attention on the late effects of antileukemic therapy. A number of adverse sequelae have been identified. These are discussed in more detail in Chapter 49.

CNS sequelae have been particularly concerning. Despite early reports suggesting that CNS preventive therapy with lower dose cranial irradiation and intrathecal chemotherapy was devoid of significant long-term side effects, a large body of evidence indicates that this treatment may produce abnormal CT brain scans (Fig. 19-17), impaired intellectual and psychomotor functions, and neuroendocrine abnormalities. [653,663,683] Four neuropathologically distinct forms of delayed CNS toxicity have been identified in patients with ALL: cortical atrophy, necrotizing leukoencephalopathy, subacute leukoencephalopathy, and mineralizing microangiopathy. [663]

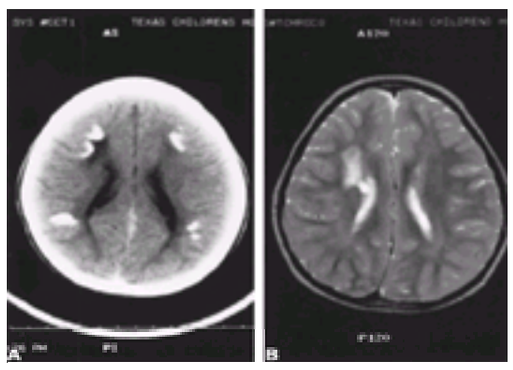

**FIGURE 19-17.** Radiographic measurement of the late effects of chemotherapy and radiotherapy on the central nervous system (CNS). **A:** Computed tomographic image of a patient with acute lymphoblastic leukemia (ALL) and CNS sequelae. Notice the intracerebral calcifications (discrete bright white areas). **B:** Magnetic resonance image of the same patient showing leukoencephalopathy (hypolucent, demyelinated tracts). This patient was originally diagnosed with standard-risk ALL and did not have CNS disease at any time. The patient received standard-risk therapy, which included intrathecal therapy with cytarabine, methotrexate, and hydrocortisone. No radiation therapy was administered. The patient has mild learning and motor disabilities approximately 5 years from diagnosis. Images were obtained several months after completion of therapy.

Cortical atrophy, the most common histopathologic manifestation of CNS treatment, is a well-recognized delayed toxicity of whole brain irradiation. Radiation produces multiple microscopic areas of focal necrosis that eventually cause the loss of cortical tissue and generalized cortical atrophy. [684] Necrotizing leukoencephalopathy, a particularly severe form of delayed neurotoxicity, is relatively uncommon. It occurs most frequently in patients who have received large cumulative doses of cranial irradiation and intrathecal and systemic methotrexate (e.g., for treatment of recurrent meningeal leukemia) but also has been observed in patients who have not received cranial irradiation (Fig. 19-17).[685,686] Leukoencephalopathy is characterized pathologically by multifocal demyelination (Fig. 19-17). Patients with this syndrome may present with a variety of clinical findings, ranging from poor school performance and mild confusion to lethargy, dysarthria, dysphasia, ataxia, spasticity, or progressive dementia.[687,688]

Mineralizing microangiopathy, a degenerative mineralizing disorder of the small vessels, is accompanied by dystrophic calcification of brain tissue, primarily gray matter. It also occurs more frequently in patients who have received greater cumulative doses of cranial irradiation and i.v. methotrexate, particularly in younger children (younger than 6 years). The intracerebral calcifications of mineralizing microangiopathy also can be demonstrated on CT and MRI scans.

The mechanism(s) that underlie the CNS effects associated with cranial irradiation and intrathecal chemotherapy are not entirely clear. Much of the damage may be related to chronic effects on the cerebral vasculature of both CNS irradiation and chemotherapy. [689] Methotrexate and the rises in homocysteine induced by methotrexate have been linked to both acute (seizures) and chronic neurologic toxicity. [689,690]

Numerous studies have demonstrated abnormal CT brain scans in asymptomatic ALL patients who have received CNS preventive therapy, particularly with cranial irradiation and intrathecal chemotherapy. Abnormal CT scan findings identified include ventricular dilatation and widening of the subarachnoid spaces (i.e., cerebral cortical atrophy), decreased attenuation coefficient (i.e., hypodensity of white matter indicating localized edema, demyelination, or both), and intracerebral calcifications (i.e., mineralizing microangiography). [684] The incidence of these abnormalities appears to correlate with the intensity of CNS preventive therapy. [663] Studies have documented a significant association between these abnormalities and neuropsychologic dysfunction. [663,691] The observation that CT scan lesions may first appear as late as 7 to 9 years after initiation of CNS preventive therapy is of concern and emphasizes the importance of long-term follow-up examination. [502,692]

A variety of studies have identified the existence of functional CNS impairment in some survivors of childhood ALL. In addition to significantly impaired academic achievement, problems with poor body image and depression, decreased IQ scores, increased distractibility, and abnormalities in memory and frontal lobe functions have all been documented.[500,663,693,694] Study of interventions for the important psychological and psychosocial consequences of the disease and its treatment for survivors and their families has just begun.[695,696] Careful follow-up with comprehensive neuropsychometric testing may permit early identification of developing deficits and possibly allow therapeutic intervention.

Although new approaches to CNS preventive therapy may offer the possibility of reducing or preventing adverse CNS sequelae, a large number of patients being followed by pediatric oncologists are at risk for developing late CNS toxicity. Diagnostic MRI or CT scans of the brain every 2 to 3 years have been recommended for

patients who have received cranial irradiation. [663,692] Patients who were very young (younger than 8 years) at the time of diagnosis or cranial radiation therapy appear to be at the greatest risk.[663] The finding of an apparent increased incidence of CT and MRI abnormalities in nonirradiated patients treated with intermediate-dose methotrexate and 6-MP indicates the importance of carefully following all patients who have received any form of CNS preventive therapy. [522,697]

Neuroendocrine abnormalities, primarily involving the hypothalamic pituitary axis, also have been documented in children who have received cranial radiotherapy with CNS preventive therapy. The principal finding is decreased growth hormone output measured by response to provocative stimuli or by analysis of basal pulsatile growth hormone secretion.[498,698] The incidence of impaired growth hormone responses to provocative stimuli may be 50% or greater. [699,700] Blunted spontaneous basal pulsatile secretion of growth hormone is a consistent finding in children with ALL who received 2,400 cGy of cranial irradiation and intrathecal methotrexate. [498] Preliminary information suggests that the effect of 1,800 cGy cranial irradiation on pulsatile growth hormone secretion may be less severe. [504] A study found that pulsatile growth hormone output in patients treated with 1,800 cGy, although reduced compared with healthy controls, was not as low as that in patients who had received 2,400 cGy of cranial irradiation. [701]

Short stature occurs in some children with ALL, although there is disagreement about its frequency. [700,702] In many children, “catch-up growth” occurs after discontinuation of therapy; others have persistent short stature. A study of children with ALL treated without cranial irradiation reported that, although an initial decline in height and growth velocity was observed after diagnosis, compensatory increases occur during further treatment. The negative impact of cranial irradiation on growth is well known. Several studies have documented significant reduction in linear growth during and after therapy in patients who received 2,400 cGy or more of cranial irradiation.[703,704] Data demonstrate that the final height of adults who received 2,400 cGy cranial irradiation as children is significantly reduced. [703] Decreases have been reported for patients treated with 1,800 cGy, although this has not been a universal finding. [701,703] The impact of 1,800 cGy on final adult height is reported to be modest, although girls treated with this approach at a young age maybe at risk for significant growth failure. [704,705]

Although abnormal growth hormone output resulting from cranial irradiation may explain the short stature in some children, others have normal hypothalamic-pituitary function, suggesting that growth delay in children with ALL may be multifactorial. [498,706] Effects of therapy on multiple organ systems as well as lung and bone growth itself undoubtedly contribute to the growth problems of some children, both during and after ALL therapy. [707,708 and 709] Nevertheless, the development of short stature after cranial irradiation requires comprehensive endocrine evaluation. If its deficiency is documented, growth hormone replacement may be warranted.

There appears to be a prevalence of obesity among children who have successfully completed therapy for ALL. [706,710] Cranial irradiation is associated with this phenomenon, but it seems likely that corticosteroids and other drugs are contributing factors. One recent study of obesity in ALL patients implicated genetics, finding a substantial number of the patient's mothers were also obese. [711]

Chemotherapy may produce long-term side effects in other organs. Patients receiving maintenance treatment frequently have elevated liver function tests, primarily a reflection of methotrexate hepatotoxicity. After chemotherapy stops, the test results of most patients usually return to normal, and persistent liver function abnormalities are rare.[712] Chronic liver disease is more likely to occur in patients with a history of viral hepatitis and is particularly severe after deltaviral hepatitis infection.[713]

Many current ALL treatment regimens use anthracyclines. Treatment with these agents carries the potential risk of cardiomyopathy, but because the total cumulative doses of these agents in most protocols is considerably lower than 550 mg per $m^2$, clinically significant cardiomyopathy in patients undergoing active treatment has been a relatively rare occurrence. Studies suggest that patients exposed to anthracyclines for treatment of ALL may be at a greater risk for late-onset congestive heart failure than previously appreciated.[714,715 and 716] Exercise or pregnancy may provoke the occurrence of late-onset cardiomyopathy, or it may be spontaneous. In a study from the DFCI, more than one-half of the long-term ALL patients evaluated had evidence of abnormal left ventricular function. [715] Children who are younger at the time of treatment and with a greater cumulative anthracycline dose had a greater incidence of subclinical cardiac damage. This and similar reports have heightened concern about late anthracycline cardiotoxicity and emphasized the importance of careful monitoring and follow-up of children at risk. [714,717] There may be, in fact, no absolutely safe anthracycline dose that will prevent cardiotoxicity. [716,718]

Other chemotherapeutic agents and modalities (i.e., radiation fields that include the cardiac region) may exacerbate anthracycline cardiac toxicity. [719] Studies aimed at reducing and possibly circumventing anthracycline cardiotoxicity by administering these agents by continuous infusion or together with the cardioprotective agent dexrazoxane (Zinecard) are in progress, but follow-up time is too short for analysis (see Chapter 10 and Chapter 49).[720]

Multiple other toxicities are associated with antileukemic agents. Hemorrhagic cystitis and bladder fibrosis from cyclophosphamide treatment, avascular necrosis secondary to steroid treatment, and significant sequelae of L-asparaginase–induced thrombosis and hemorrhagic infarction fortunately are encountered relatively infrequently in patients with ALL. These and other drug-related toxicities are discussed in more detail in Chapter 10 and Chapter 49.

The reproductive capacity and sexual function of patients with ALL treated with prolonged chemotherapy has been studied. [721,722,723 and 724] Primary gonadal damage has been documented in patients of both sexes treated on cyclophosphamide-containing intensive ALL treatment regimens. [725] Cyclophosphamide, ifosfamide, and other alkylating agents continue to be used in the intensification schema and BMT regimens of many groups. Although alkylating agent therapy is known to impair reproductive function, little information exists about the reproductive status of patients treated with other commonly used chemotherapies. In most cases, girls with leukemia retain intact reproductive function. However, the timing of chemotherapy in relation to puberty may be important. [726,727] A study of prepubertal boys who received chemotherapy for ALL, not including cyclophosphamide, also revealed no evidence of significant gonadal dysfunction. [728] Although this evidence is encouraging, additional information on a larger number of patients treated in the periods before, during, and after puberty is required before definitive conclusions about the reproductive capacity of these patients can be drawn.

More information is needed on the outcome of pregnancy after treatment for leukemia. Although our knowledge of the teratogenicity and mutagenicity of antileukemic therapy is incomplete, some data indicate that normal births occur in most cases in which women receive chemotherapy before gestation or after the first trimester. [729] Chemotherapy administered to men close to or before the time of insemination does not appear to result in fetal damage. Although available information suggests reason for cautious optimism, additional long-term follow-up of the offspring of survivors of childhood leukemia is needed.

The risk of second malignant neoplasm (SMN) in children with ALL has been estimated to be between 3% and 12% in the 5 to 24 years after primary diagnosis. [730,731 and 732] This represents a six- to tenfold increase in risk, compared to the general population, for the development of future tumors. The nonhematopoietic SMNs tend to occur 5 to 10 years after the original ALL, and in many cases occur within or in close proximity to the radiation fields used in the original therapy. [733,734] Although a causal relation between the development of secondary brain tumors and cranial irradiation is likely, CNS tumors have also been reported in a small number of patients who have not received cranial irradiation. [735]

Investigators at SJCRH reported an unexpected high incidence of secondary AML among a large group of patients treated with intensive chemotherapy, particularly those with T-cell ALL.[736] These leukemias developed a median of 3 years after the diagnosis of ALL and were predominantly characterized by an 11q23 chromosomal abnormality. The risk of developing secondary AML within 6 years of achieving initial remission in this study was estimated to be 5%. There appears to be a strong relation between exposure to the epipodophyllotoxins and other topoisomerase II inhibitors, anthracyclines, and actinomycin D and the development of secondary AML with 11q23 abnormalities.[736] Similar secondary leukemias have been observed in other cancer patients treated with these drugs. [737,738] Concern over these secondary myeloid leukemias has led to a reappraisal of the role of the epipodophyllotoxins in the treatment of ALL. [739,740]

Despite the degree of increase in risk of SMNs, the risk of other first events (i.e., induction failure, relapse, or death from another cause) remains tenfold higher than the risk of developing a SMN (Fig. 19-18).[733] Most reported SMNs are brain tumors (gliomas of varying histologic grades) in patients who have had radiation therapy and hematopoietic tumors (primarily AML or MDS) in all patients.[732,733] Other reported tumors include thyroid tumors, melanoma, dysgerminoma, ganglioneuroblastoma, leiomyosarcoma, mucoepidermoid carcinoma of the parotid, osteosarcoma, adenocarcinoma of the colon, and testicular carcinoma. [732,733,741,742]

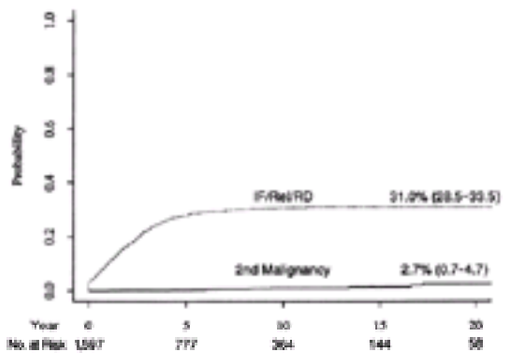

**FIGURE 19-18.** Risk of induction failure (IF), relapse (Rel), and remission death (RD) far exceeds the risk of second malignancies in patients treated for acute lymphoblastic leukemia. (From Kimball Dalton VM, Gelber RD, Li F, et al. Second malignancies in patients treated for childhood acute lymphoblastic leukemia. J Clin Oncol 1998;16:2848–2853, with permission.)

Physicians should be aware of the effects of previous chemotherapy on the immune system of children treated for ALL. Earlier studies suggested that recovery of the immune system occurs within the first year after completion of chemotherapy. More recent studies show that a significant percentage of patients have abnormally low immunoglobulins and other evidence of immune suppression as late as 2 years after completion of treatment.[743] As many as one-third of patients have low antibody titers to clinically significant viruses to which they had been previously immunized.

The psychosocial status of long-term survivors of ALL is an area of considerable concern. Compared with matched groups of controls or with siblings, survivors of ALL are likely to have more behavioral problems, lower levels of life satisfaction, impaired attainment of social skills, and poorer school performance.[488,694,744] Some of these problems may be preventable through modification of treatment (e.g., alternative methods of CNS preventive therapy). Despite the fact that many children with ALL have tolerated their treatment well and may not experience significant late sequelae, the medical community must be aware of the special problems and needs that children with ALL may incur as they are reincorporated into mainstream society. Misapprehension and fears about cancer in general and leukemia in particular are still widespread, and acceptance of patients into normal community activities is not always enthusiastic.

## FUTURE CHALLENGES

Although the scientific and technologic future appears bright and the cure rate for children with ALL continues to climb, the disease continues to present a significant challenge. At present, 20% to 25% of patients are dying from their disease, and significant numbers of the survivors are likely to emerge from current therapies with adverse physical and psychosocial sequelae.

Formidable obstacles remain before cure becomes a reality for all children. Laboratory studies and future clinical trials must focus on resolving a number of critical issues. These include improving therapy for patients at high risk for relapse, developing a better understanding of the biologic causes of ALL, refining methods of identifying patients at risk for relapse, understanding the causes of treatment failure, and overcoming both acute and long-term toxicities of current treatment. In addition, more effective treatment must be found for patients who relapse from conventional chemotherapy.

Improving therapy for patients at high risk for relapse is perhaps the greatest challenge. The recent strategy for approaching such patients has been to significantly intensify treatment. Although this approach has been moderately successful and has improved the cure rate, the associated toxicities are of concern and make further intensification improbable given current supportive care techniques.

Maximal intensification can be achieved through BMT. Indeed, BMT with conventional and alternative donor sources continues to show promise for selected groups of patients. The apparent successes using related, partially matched, and matched unrelated donors has increased the likelihood that the constraints of the HLA barrier may eventually be successfully circumvented, making marrow transplantation an option for an increasing number of high-risk patients. Although the results of autologous transplantation have been disappointing to date, novel antibody and molecular-based purging techniques continue to be studied and a role for autologous transplantation in ALL treatment may eventually prove promising.

Perhaps the most exciting approach to prevention of relapse lies in the use of novel tumor vaccines that are designed to prevent relapse by stimulating the host immune response to leukemia cells.[745,746 and 747] This is being actively studied in several centers.

In the search for effective new treatments, the effort to develop new molecularly targeted therapies is perhaps the most exciting area of research (see below). At present, there are a large number of promising agents in various stages of clinical study (see Chapter 14). These include agents such as tyrosine kinase, farnesyl transferase, purine pathway (e.g., compound 506U), and angiogenesis inhibitors, as well as differentiating agents and other novel biologic compounds.

In the future, the most effective new therapies will evolve from a better understanding of the biology of ALL. The recent sequencing of the human genome now places us in a position to understand leukemia biology at a level heretofore unimagined. Work has already begun to expand and refine our knowledge of leukemia biology using techniques derived from the Human Genome Project and the virtual revolution in computer sciences of the past several years, such as cDNA microarray, SKY, and other recent advances in computational biology. By allowing sophisticated comparisons between previously unimagined amounts of laboratory and clinical data, it is anticipated that the application of these new technologies will improve diagnostic methodologies and refine prognostic stratification.

Ultimately, it is hoped that these technological advances will provide new, more targeted and potentially less toxic treatment approaches. In addition, pharmacogenomics promises to revolutionize chemotherapy by individualizing both the design and dosing of ALL treatment regimens. However, the role of new approaches to therapy will require confirmation in organized, carefully conducted clinical trials. Furthermore, as in the past, childhood ALL may well provide a compelling paradigm for the successful application of the new technologies to cancer treatment.

# ACUTE MYELOGENOUS LEUKEMIA

TODD R. GOLUB
ROBERT J. ARCECI

## INTRODUCTION

Acute myelogenous leukemia (AML) represents a heterogeneous group of hematologic malignancies that arise within bone marrow precursors of the myeloid, monocyte, erythroid, and megakaryocytic cell lineages. Although AML comprises only approximately 15% to 25% of childhood leukemia, it still accounts for greater than 30% of deaths from leukemia.

Despite steady improvement in the treatment of children with AML over the past three decades, event-free survival (EFS) continues to be less than 50% in most large series. The principal reasons for treatment failure include (a) the development of resistance to multiple chemotherapeutic drugs and (b) treatment-related mortality. Resistance to therapy may be present at the time of diagnosis or arise during treatment or at the time of disease relapse. Although many advances have been made in the identification of resistance pathways and in attempts in ongoing clinical trials to circumvent tumor cell resistance to chemotherapeutic agents, it is still not possible to overcome the problem of drug resistance in most patients with AML. Furthermore, the morbidity and mortality associated with currently used chemotherapy significantly limit its success. A major challenge for the future will be to overcome drug resistance of the leukemic blasts while reducing the short- and long-term side effects of treatment. An improved understanding of the molecular heterogeneity of AML should provide important clues to successfully meeting this challenge.

## EPIDEMIOLOGY

Approximately 3,500 children per year develop acute leukemia in the United States. [1] AML represents approximately 15% to 25% of this number for a total of approximately 500 children per year. Although AML remains the most frequently encountered acute leukemia in adults, the ratio of AML to acute lymphocytic leukemia (ALL) in children remains approximately 1:4, except in the neonatal period in which there is a peak in the incidence of AML. [1] The frequency of AML remains stable throughout childhood, but shows a slight increase during adolescence. During adulthood, and particularly beyond age 55 years, there is a dramatic increase in the incidence of AML, much of which is a result of secondary AML and the rise in myelodysplastic syndromes (MDSs). [1] There is no difference in the incidence of AML between males and females. Surveillance, Epidemiology, and End Results Program data from the National Cancer Institute show no significant changes in the incidence of childhood AML over the past two decades. [1]

There is evidence for variation in the incidence of AML among some racial and ethnic groups. For example, black children have an incidence of 5.8 cases per million compared to 4.8 cases per million in white children. [2,3] Children of Hispanic background have the highest incidence. [4,5,6] and [7] Most subtypes of AML are distributed equally in all ethnic and racial groups, with the exception of acute promyelocytic leukemia (APL), which appears to have a higher incidence in the Hispanic and Latin populations. There is a higher incidence of AML in Asia. [4] Of growing concern in the pediatric population is the incidence of secondary leukemia, resulting from chemotherapy and radiation treatment for other malignancies. [8,9,10,11,12] and [13]

## PREDISPOSING FACTORS

### Environmental Risks

Risk factors associated with the development of AML can be either environmental or secondary to inherited or acquired predisposing conditions ( Table 20-1). Significant exposure to ionizing irradiation results in a 10- to 20-fold increase in the incidence of AML. For example, individuals who were exposed to radiation from the atomic bombs dropped on Nagasaki and Hiroshima during World War II developed a 20-fold increase in AML and chronic myelogenous leukemia (CML). [14,15,16] and [17] The incidence peaked between 6 to 8 years after the exposure, but remained significantly higher over the next 20 years when compared to unexposed individuals. [14,15,16] and [17] No increase in leukemia was observed in children exposed prenatally to the ionizing radiation from these atomic bombs. [18] Whether there is an increased incidence of leukemia in children prenatally exposed to diagnostic x-rays remains controversial. [19] There is also no convincing evidence that prenatal or postnatal exposure to ultrasound or the effects of electrical power lines increases the risk of AML. [19,20,21,22,23,24,25] and [26]

**TABLE 20-1. PREDISPOSING CONDITIONS**

The exposure to environmental chemical toxins and increased risk for leukemia has been an area of immense interest concerning the development of AML. Prenatal exposure to maternal cigarette smoking has been associated with an increased risk of developing AML.[3,27,28,29] and [30] Maternal use of marijuana and consequential prenatal exposure has also been linked in some studies to the development of AML in exposed offspring, but subsequent studies have not confirmed this finding.[3,7,31] Maternal alcohol usage also has been reported to be associated with the subsequent development of leukemia in offspring.[28,29] A variety of chemical exposures, including petroleum products, benzene, herbicides, and pesticides, have been closely linked to the development of MDS and AML.[32,33,34] and [35] Although exposure to such chemicals has been eliminated in schools and in many workplaces, the risk to some individuals, such as farmers and migrant workers, continues to be problematic.[36]

A growing area of concern that is, in part, a result of the success of cancer treatments, involves the increased incidence of secondary leukemia after treatment of primary malignant as well as nonmalignant conditions.[10,37] Such exposures take on increased importance for children, adolescents, and young adults who will, by virtue of their age, have prolonged periods of risk. For example, treatment of patients with alkylating agents, such as cyclophosphamide, ifosfamide, nitrogen mustard, chlorambucil, and melphalan, is linked to an increased incidence of MDS and AML, with a peak incidence at 4 to 5 years after initial treatment, but with some cases still occurring 10 to 12 years later.[9,38,39] and [40] The leukemogenic effect of epipodophyllotoxins, such as etoposide (VP-16), is now well established.[39,41] The first reports on the association of prolonged exposure to etoposide for the development of AML came out of clinical trials in children with ALL.[11,13,42] There is no convincing epidemiologic or laboratory data that there is a viral etiology for AML.

## Genetic Risks

Most cases of AML arise in patients for whom no known genetic predisposition is known. Most patients have neither a family history of cancer predisposition nor clinical features, such as developmental abnormalities, that would suggest predisposing inherited risk factors for the development of AML. It remains to be determined, however, whether such “sporadic” cases of AML indeed arise without predisposition, or whether these cases arise in patients with as yet unrecognized, more subtle leukemia-promoting genetic backgrounds. Less commonly, clinically evident genetic risk factors for AML are evident, as detailed in the following sections.

### *Twins*

Several genetic risk factors have been identified that predispose individuals to develop AML. These factors may be inherited or acquired. The increased frequency of leukemia (both AML and ALL) in siblings of patients with leukemia as well as the relatively rare occurrences of familial leukemia strongly suggest an important hereditary contribution in certain instances.[43,44,45] and [46] For nonidentical twins, an estimated two- to fourfold increase for developing leukemia has been made. The risk decreases with age, so that beyond approximately 6 years of age the risk is not significantly greater than that of the general population. The high concordance of AML in identical twins also argues in part for an important hereditary contribution.[47,48] When one identical twin develops leukemia before the age of 6 years, the risk of the other twin developing leukemia is approximately 20% to 25%.[49] A part of the high concordance during the first year of life is due to the transplacental transfer of leukemia cells between twins, in which case, the leukemia usually arises with weeks to a few months in the second twin.[50,51,52] and [53]

### *Down Syndrome*

Although children with Down syndrome (DS) represent the most common inherited condition predisposing to the development of leukemia, it remains unclear what specific gene(s) on chromosome 21 is the cause of this predisposition.[54,55,56] and [57] A number of candidate genes, such as the AML1 gene, have been implicated because of their chromosomal location, but no definitive evidence has been obtained proving mutations of a single gene or true dosage effect contributing to the increased incidence of leukemia in these patients.[57,58] Nevertheless, children with DS have an approximately 14-fold increase over the general population for developing leukemia.[54,55,56] and [57] Of further interest is that although children with DS have a similar frequency of ALL and AML in later childhood, the incidence of AML predominates during the first 3 years of life, and the development of megakaryoblastic leukemia is more common than other subtypes.[59,60] and [61] Patients with DS also have an increased predisposition to develop a transient myeloproliferative disorder (TMD), that, though clinically indistinguishable from congenital leukemia, usually is self-resolving. This syndrome is further discussed later in this chapter. The close association of trisomy 21 with TMD further supports the role that the genes involved in the development of AML in patients with DS are likely to be involved in the control of normal myelopoiesis.

### *DNA Repair and Leukemogenic Risk*

An increased frequency of AML has also been strongly linked to a number of inherited disorders due to defects in genes regulating cell-cycle progression as well as DNA repair.[62,63] For example, patients with Fanconi's anemia, an autosomal inherited disorder, are particularly prone to develop MDS and AML.[64,65] and [66] It has been demonstrated that the incidence of AML in patients with Fanconi's anemia is more than 15,000 times that observed in children in the general population.[65,66] The actuarial risk of MDS or AML has been shown to be approximately 52% by 40 years of age.[67] Although the genetic defect in patients with Fanconi's anemia may represent different genes that functionally are related to one another, the end cellular defect results in alterations in the $G_2$ stage of the cell cycle along with a predisposition for chromosomal instability and a hypersensitivity to DNA damaging agents.[68,69] and [70] Children with Bloom syndrome, another autosomal inherited disorder, show a variety of developmental abnormalities in terms of skeletal and immune function, but also show a profound defect in resolving chromosomal recombination events, leading to a high frequency of abnormal chromosomal exchanges.[68,69] and [70] Bloom syndrome is now known to be due to the inheritance of a defective helicase, BLM, involved in DNA recombination.[71,72] and [73] Patients with ataxia telangiectasia, another autosomal inherited disorder resulting in neuromuscular deterioration and immune deficiency, also show a high frequency of developing leukemia.[72] The mutant gene product, ATM, that causes this syndrome, has been identified and shown to play a role in DNA sensitivity to genotoxic agents.[72,74]

### *Growth and Apoptosis Signaling Pathways*

Patients with neurofibromatosis type 1 (NF-1) represent an alternative inherited molecular pathway leading to a predisposition to develop AML.[75,76] A defective neurofibromin gene product is the cause of this disorder. Neurofibromin is a GTPase that is integrally involved in inactivating the proto-oncogene RAS by converting it from an active deoxyguanosine triphosphate (GTP) state to an inactive guanosine diphosphate (GDP) state.[77] Thus, patients with NF-1 have increased levels of activated RAS, which results in dysregulated cell proliferation and survival, that is clinically manifested by the development of neurofibromas and an increased incidence of AML. Recent data have indicated that patients with severe congenital neutropenia (i.e., Kostmann's syndrome) have an increased risk of developing MDS and AML, and that the risk increases with age.[78,79] The introduction of granulocyte colony-stimulating factor (G-CSF) for the treatment of these patients has clearly allowed more patients to live longer so that it is unclear whether the development of AML is due to the intrinsic disorder or a combination of an inherited predisposition plus G-CSF exposure. The discovery that a significant number of patients with Kostmann's syndrome have functional mutations in the gene encoding elastase has suggested that such proteases may affect other proteins involved in cell growth and apoptosis.[80] In addition, the development of activating mutations of the G-CSF receptor have been observed during the development of AML in these patients, but such mutations appear to be an acquired and relatively later genetic

event.[81,82]

### Acquired Predisposition

Acquired conditions can also predispose to the development of AML. For example, as many as 20% of patients with aplastic anemia treated with immunosuppressive regimens may eventually develop MDS or AML, or both.[83,84] At this time, it remains unclear what the contribution is from an intrinsic genetic alteration of a myeloid precursor or from the immunosuppressive agents. Another acquired disorder of hematopoietic precursors, paroxysmal nocturnal hemoglobinuria, is associated with an increased frequency of AML. The development of MDS should also be considered a predisposing condition for AML. In this context, the acquisition of certain somatic chromosomal abnormalities, often associated with MDS, may predispose individuals to develop AML. [85,86] For example, the development of monosomy 7 in bone marrow precursors, may be associated with an increased frequency of disorders of the myeloid lineage, including MDS and AML. [87,88] The acquisition of a variety of other genetic alterations, most commonly translocations, involving genes that regulate cell growth, differentiation, and apoptosis, also plays a fundamental role in the etiology of AML.[86,89]

Similar to genetic models that have been proposed to explain the development of colon cancer as well as solid tumors associated with inherited defects the retinoblastoma or p53 genes, the development of AML is the result of an accumulation of several genetic abnormalities. [90] The inheritance of predisposing genetic defects is likely to result in the earlier acquisition of other mutated genes involved in cell survival, chromosomal stability, or DNA repair and result in an increased frequency of AML at an earlier age.[89] The accumulation of genetic mutations over the course of a lifetime contributes to the increased frequency of AML during later adulthood. In addition, the types of genetic defects that occur can influence whether the leukemia develops characteristics representative of one of a variety of myeloid lineage phenotypes.

## BIOLOGY AND HIERARCHY OF THE ACUTE MYELOGENOUS LEUKEMIA STEM CELL

AML develops as a result of genetic changes that occur in primitive hematopoietic stem cells, resulting in the expansion of leukemic cells often displaying an incomplete block in normal differentiation. [91,92,93] and [94] Thus, leukemic cells often display many of the features observed in their normal hematopoietic counterparts such as similar morphology, cytoplasmic enzyme synthesis, surface markers, dependence on cytokines for survival, and the ability to generate more mature cells from less mature precursors.[92,95,96] The heterogeneity of these malignant myeloid disorders may arise from the types of genetic changes that have occurred as well as what stage of differentiation the leukemic stem cell becomes transformed. [97]

There is accumulating evidence that the leukemic stem cell in different subtypes of AML and MDS arises at various stages of differentiation as defined by surface marker characteristics as well as *in vitro* leukemic colony assays and *in vivo* leukemia, initiating measurements utilizing transplantation into immunodeficient mice. [91,92] It is generally considered that leukemias with different degrees of differentiation result from oncogenic transformation of hematopoietic progenitors of different states of maturation. That is, it is the cell of transformation that dictates the phenotype of the leukemia. An alternative, equally plausible hypothesis is that all types of AML occur through transformation of very early, stem cell–like hematopoietic cells. In that scenario, it is the transforming oncogene, not the cell of origin, which determines the degree of differentiation observed in the leukemia.

Several strategies have been used to define the molecular changes that are involved in the conversion of a normal hematopoietic progenitor to a malignant phenotype. Cytogenetic analysis with standard, and now more sophisticated methods of fluorescent *in situ* hybridization (FISH), have helped to identify critical chromosomal regions and have been instrumental in the identification of important genes regulating myeloid cell growth, differentiation, apoptosis, and immune recognition, as well as gene products involved in DNA repair and chemotherapeutic resistance. [93]

Initial studies by Fialkow and colleagues using markers on the X-chromosome and the presence of the Philadelphia chromosome demonstrated the heterogeneous involvement of the hematopoietic stem cell and myeloid precursor cell compartments by different forms of myeloid leukemia. [92,98] These studies have been extended by many subsequent investigators to show a complex pattern of involvement of myeloid precursor compartments by AML stem cells. Using flow cytometric analysis and sorting, various precursor cell compartments can be isolated on the basis of specific surface antigen expression patterns. [99] For example, some studies have shown that translocations or chromosomal abnormalities such as t(8;21) or inv(16) are found in the CD33–, CD38–, CD34+, primitive hematopoietic precursor compartment.[91,92,99] Other investigations, using fluorescent activated flow sorting to sort hematopoietic cellular compartments and FISH analysis to detect specific chromosomal abnormalities, have shown that the primary cytogenetic change in many cases of AML is present in the CD34+ primitive stem cell compartment. In contrast, the t(15;17) translocation associated with APL is detected in precursors at a later stage of differentiation than the primitive stem cell. [91,92,99]

These studies have important clinical implications. If the leukemic stem cell arises within a very primitive hematopoietic compartment, then the biologic proximity and similarity to the normal hematopoietic stem cell may be quite high. This would result in possibly fewer biologically important differences to be therapeutically exploited to eradicate the leukemic stem cell while sparing the normal hematopoietic stem cell. If the leukemic stem cell develops in a more differentiated lineage compartment, such as may be the case in promyelocytic leukemia, then therapeutic strategies may be able to exploit a wider range of differences that distinguish leukemic and normal stem cells (Fig. 20-1). In addition, the heterogeneity of AML as a disease may provide the means to direct therapies to different subtypes as defined by a variety of criteria, potentially ranging from morphology to genetic expression patterns. Thus, understanding the different types of AML and their genetic origin is fundamental to the development of more effective therapies.

Colony-forming units (CFUs) are single cells that can form colonies when bone marrow is cultured *in vitro*. BFU-E, bone marrow stem cell assay.

## CLASSIFICATION OF ACUTE MYELOGENOUS LEUKEMIA: AN EVOLVING PROCESS

A good disease classification schema is one that provides a better understanding of the disorder and helps to direct and improve the outcome of treatment as well as serve as the basis for more useful, subsequent classifications. Although the first published cases of leukemia occurred independently in the mid-1800s by Bennett and Virchow, it was not until the latter part of that century, with the further refinement of staining methods, that a distinction between myeloid (derived from bone marrow) and lymphoid (derived from lymphatic tissues) acute leukemias was defined. [100] With increased spread of the microscope and improved histochemical stains, the age of morphologic classification blossomed in the early and middle part of the twentieth century, eventually resulting in a morphologic schema for classifying AML. This effort culminated in the French-American-British (FAB) classification schema first established in 1976 and revised in 1985. [101,102] This system is primarily based on morphologic criteria after staining with Wright, Wright-Giemsa, or May-Grunwald stain, in addition to some histochemical-defined markers ( Table 20-2).

| FAB type | Name | Morphology | Histochemistry |
|---|---|---|---|
| M0 | Acute myeloblastic: no maturation | Undifferentiated; >90% blasts; <10% promyelocytes/monocytes | MPO+; SBB+; PAS- |
| M1 | Acute myeloblastic with maturation | ≥90% and ≤95% blasts; >10% promyelocytes/myelocytes; ≤20% monocytic cells | MPO+; SBB+; PAS- |
| M2 | Acute promyelocytic: hypergranular type | >20% abnormal hypergranular promyelocytes; Auer rods common | MPO+; SBB+; PAS- |
| M2v | Acute promyelocytic: microgranular variant | Fine granularity of cytoplasm in promyelocytes; folded nuclei | MPO+; SBB+; PAS- |
| M4 | Acute myelomonocytic | ≥20% blasts in nonerythroid series; >20% but <80% monocytic cells; blood monocytes >5 × 10⁹/L; lysozyme >3× normal | MPO+; NASDA+ |
| M4Eo | Acute myelomonocytic with eosinophilia | >5% abnormal eosinophils with basophilic granules | MPO+; NASDA+ eosinophils; AAN+ |
| M5a | Acute monocytic | >80% of monocytic cells = monoblasts; rest are promonocytes/monocytes | MPO+; NASDA+ |
| M5b | Acute monocytic with differentiation | <80% of monocytic cells are monoblasts; rest are promonocytes/monocytes | MPO+; NASDA+ |
| M6 | Acute erythroleukemia | >50% of nonerythroid cells are blasts; <90% of marrow are erythroblasts | PAS+; ringed sideroblasts with iron stain |
| M7 | Acute megakaryoblastic | >50% of nonerythroid cells are megakaryoblasts; cytoplasmic blebs; myelofibrosis common | MPO-; SBB-; NASDA+; platelet MPO+ by EM |

EM, electron microscopy; MPO, myeloperoxidase; NASDA, naphthol-AS chloroacetate; NSE, nonspecific esterase; PAS, periodic acid-Schiff; SBB, Sudan black B

**TABLE 20-2. FRENCH-AMERICAN-BRITISH (FAB) CLASSIFICATION OF ACUTE MYELOGENOUS LEUKEMIA**

## Morphologic and Histochemical Classification: The Beginning of Subtypes

The FAB classification system includes seven subtypes (M1 to M7), each characterized by specific morphologic, histochemical, and, more recently, immunophenotypic and cytogenetic features. The M0 subtype has been used to describe acute undifferentiated leukemia. [103] All subtypes are represented in children and adolescents with AML. Although the original classification schema required 30% myeloblasts in the bone marrow for the diagnosis of AML, the new World Health Organization (WHO) classification accepts the presence of 20% or more bone marrow myeloblasts to be sufficient for diagnosis of AML. In addition, the WHO classification proposal defines subsets of AML based on morphologic and cytogenetic characteristics. [104,105,106,107] and [108] However, such numbers may be quite artificial when one considers the pathophysiologic characteristics of AML. Probably more important than an absolute number of blasts is the progression of accumulation of leukemic blasts with replacement of normal bone marrow elements. Additional criteria have been established that define the different subtypes according to the percentage of myeloblasts with specific lineage characteristics, such as monoblasts or promyeloblasts.

Morphologic classification, along with the most commonly used histochemical stains, is usually sufficient to distinguish AML and its subtypes from ALL ( Fig. 20-2). The peroxidase reaction [i.e., staining for myeloperoxidase (MPO) activity] is present in the primary (azurophilic) granules of both myeloid and monocytic precursors. Auer rods are needle-shaped accumulations of primary granules and are commonly observed in the M2, M3, and M5 subtypes of AML. Positive staining with Sudan black B (SBB) detects intracellular lipids that are found in secondary (basophilic) granules of both myeloid and monocytic precursors. Detection of nonspecific esterase (NSE) is quite characteristically observed in monocytic cells, although weak staining can often be observed in myeloid precursors. Staining for the presence of chloroacetate esterase is relatively specific for cells of the granulocytic lineage. NSE staining will usually be able to distinguish M1 to M3 subtypes from M4 or M5. The M5 subtype is always NSE positive, regardless of whether the MPO reaction is positive or negative. M7 AML may also be positive for NSE. The periodic acid-Schiff (PAS) reaction and staining for the enzyme terminal deoxynucleotide transferase are usually negative in AML, except in the case of the erythroleukemic subtype, M6, which is positive for PAS staining. Detection of platelet peroxidase activity is characteristic of megakaryoblastic leukemia or M7 subtype. The judicious use of morphology and histochemical staining can usually distinguish the various subtypes of AML.

## Immunophenotyping: Lineage in Greater Detail

The role of immunophenotyping has taken on an increasingly important role in the diagnosis of leukemia. This approach takes advantage of the development of monoclonal antibodies (MABs) to specific cell surface antigens that are differentially expressed during hematopoietic differentiation. The antigens are usually referred to as *antibody cluster determinants* or *CD* followed by an assigned number, such as CD1, CD2, and so forth. The detection of specific cell surface expression of these lineage- and stage-specific proteins by fluorescence-activated flow cytometry allows a rapid and accurate refinement to the subclassification of the acute leukemias. The specificity and sensitivity of distinguishing AML from ALL by cell surface immunophenotyping are very high. [109,110,111] and [112] In addition, because leukemia cells often display a degree of abnormal expression patterns of specific cell surface antigens, they can be distinguished from normal hematopoietic precursors. [113] For example, aberrant antigen expression has been described to take on one of at least four patterns. These include

1. Coexpression of nonmyeloid antigens
2. Asynchronous expression of antigens such as when an early lineage marker, such as CD34, is coexpressed with a much later antigen, such as CD15
3. Increased expression of a particular antigen significantly above normal levels observed in normal progenitors
4. The absence of myeloid antigens

This abnormal expression pattern can thus be used for the detection of minimal residual disease (MRD) (see under Response to Therapy and Minimal Residual Disease). [113,114] and [115]

Cell surface proteins with particular utility in the diagnosis of AML include CD11b, CD13, CD14, CD15, CD33, CD34, CD41, CD42, and CD61, glycophorin A, class II human leukocyte antigens (HLA-DR), and the stem cell factor receptor, c-Kit. [116,117] During normal hematopoietic maturation, early myeloid precursors are characterized by the expression of CD13, CD33 and CD34. As differentiation proceeds, CD34 expression is lost, CD33 expression decreases, and CD15 becomes expressed. HLA-DR becomes expressed as myeloid differentiation proceeds. When cells differentiate along the monocytic lineage, the expression of such markers as CD14 is often observed, thus making this antigen especially useful in the identification of acute myelomonocytic (M4) and monocytic (M5) leukemia. CD36 and CD64 may also be used to define cells with monocytic differentiation. Progenitors that differentiate along the erythroid lineage express glycophorin A, which helps define acute erythroblastic leukemia (M6). Differentiation along the megakaryocytic lineage is accompanied by expression of platelet-associated proteins, such as CD41, CD42, and CD61, thereby providing a means of identifying acute megakaryocytic leukemia (M7). CD36 is also observed on megakaryocytes. However, it is important to keep in mind that false-positive results have been obtained for cell surface platelet antigens as a result of platelets becoming stuck to the surface of blasts of a non-M7 type of leukemia.[118] When there is any question, the detection of intracytoplasmic platelet proteins, such as platelet peroxidase, should be definitive.

The pattern of expression of such cell surface markers, along with those characteristic of the lymphoid lineage, is informative in terms of distinguishing AML from ALL in greater than 90% of cases (Table 20-3). [109,110,111] and [112] However, leukemia cells, like other types of cancer, may show abnormal expression of proteins not restricted to their own lineage (“lineage infidelity”). For example, proteins, traditionally believed to be expressed on only lymphoid lineage cells, may be expressed on AML blasts in up to 60% of cases. [119,120] Myeloid-associated antigens may also be expressed on ALL blasts. [119,121]

| Marker | M0 | M1 | M2 | M3 | M4 | M5 | M6 | M7 |
|---|---|---|---|---|---|---|---|---|
| **Myeloid** | | | | | | | | |
| CD13 | ++ | + | + | + | ++ | ++ | + | + |

+, minimal expression; ++, moderate expression; +++, high expression; +, variable expression; –, no expression.
[a]CD13 expression has been reported to be present on 100% of M5a but negative on M5b.[11]

**TABLE 20-3. IMMUNOPHENOTYPING OF ACUTE MYELOGENOUS LEUKEMIA**

An important question that arises with such cases is how specific markers are (i.e., does apparent lineage infidelity in fact represent lineage fidelity?). Part of the answer is clearly that what was believed to be lineage restricted simply is not. For example, many markers originally thought to be characteristic of the lymphoid lineage can also be expressed in AML. For example, historically, markers such as CD7 and CD4 were considered to be T-cell–specific antigens, though the former is now known to be expressed on progenitor cells and the latter on monocytes. Not surprisingly, these markers are frequently found in AML. Similarly, markers believed to be B-lineage specific (e.g., CD10, CD19, and CD24) or the natural killer cell marker, CD56, can also be found in AML, more frequently in M4 and M5 subtypes.[122,123 and 124] Myeloid-associated antigens may also be expressed on ALL blasts.[119,121] Furthermore, some expression of CD2 has been found on nearly all of AML M3 subtypes (particularly positive in the microgranular type) and in many cases of M4Eo.[125,126,127 and 128] CD4, originally believed to be characteristic of T-helper lymphocytes, is also expressed on cells of the monocytic lineage and monocytic leukemia.[129] Such examples may suggest that the stage of leukemic cell transformation may be normally represented in extremely low frequency rather than an abnormal phenotype. This possibility may imply that immunophenotyping as a method for detecting MRD is compromised. However, depending on the sensitivity that is required for predicting outcome with MRD, this concern may not be practical in that extremely low frequency events (i.e., a normal precursor with coexpression of myeloid and lymphoid markers) would not be routinely detected.

There has therefore not been a consensus on how best to define biphenotypic or mixed lineage leukemia, although most laboratories require more than the coexpression of a single surface marker of a different lineage on an otherwise typical case of AML or ALL. Usually more than one marker from the opposite lineage is required to be expressed on the same leukemic blast to call an acute leukemia biphenotypic. Several “scoring” systems have been proposed that include morphology, histochemistry, immunophenotype, and even gene rearrangements (e.g., T-cell receptor or immunoglobulin gene rearrangements).[130] However, the coexpression of these markers has not been definitively shown to have significant diagnostic or prognostic significance, although treatment in cases of true biphenotypic leukemia is often directed to the dominant phenotype.[131]

Another important variant is observed when a leukemia has more than one type of leukemic blast population in the bone marrow (i.e., mixed populations of blasts that are either lymphoid or myeloid). When these findings are observed in conjunction with consistent morphology, histochemistry and molecular changes (i.e., T-cell receptor or B-cell immunoglobulin gene rearrangements), then the diagnosis of a mixed lineage leukemia can be made.[132,133] The new WHO classification proposal is to refer to such cases as *bilineal leukemia*.[105,106,108] In some circumstances, the conversion from ALL to AML or vice versa may occur in mixed lineage leukemia after treatment. This may occur even though the chromosomal abnormality observed at diagnosis is preserved, possibly as a result of selection of one population as being resistant to initial therapy or to the true plasticity of such cases in terms of their capacity to differentiate along two different lineages.[134] The best treatment of mixed lineage leukemia has not been definitively determined, but often hybrid treatment approaches (i.e., a combination of treatments for AML and ALL) have been utilized.[134,135 and 136]

Although most cases of mixed lineage leukemia are characterized by lymphoid and myeloid markers, there are also cases of more than one pattern of differentiation within the myeloid lineage. For example, cases of erythromegakaryoblastic (M6/M7) leukemia can occur, demonstrating some leukemic blasts with the red cell precursor marker, glycophorin, and other blasts with megakaryocytic markers, such as CD61. Such cases can be explained by the fact that these two lineages are known to share a common precursor that in turn shares expression of certain genes, such as GATA transcription factors.[137,138 and 139] Patients with this type of leukemia are treated with therapies for AML.

The definitive identification of the type of leukemia is usually made by a combination of morphology, histochemical staining, and the pattern of surface antigen expression as determined by immunophenotyping. Cytogenetics has also now taken on a more important role in classifying AML as well as in prognostication.

### Cytogenetics

Another increasingly important component of AML classification is the use of cytogenetic and molecular tools to detect specific chromosomal rearrangements. This depends on the specificity of the presence of these chromosomal changes with unique subtypes of AML. High-resolution chromosomal banding in conjunction with FISH and polymerase chain reaction (PCR) approaches have significantly improved the ability to detect more subtle chromosomal alterations.[140,141 and 142] In most examples thus far examined, the chromosomal translocations or other abnormalities result in the alternation of specific genes that play critical roles in cell survival, differentiation, cell cycle regulation, chromosomal repair, and stability as well as transcription (see the sections Molecular Mechanisms of Leukemic Transformation and Subtypes of Acute Myelogenous Leukemia).[93,143,144] For example, the t(15;17)(q22;q21) translocation is diagnostic of APL. The t(8;21) translocation is more frequently observed in M2 AML, whereas inv(16) abnormalities are commonly found in a variant of myelomonocytic leukemia characterized by the presence of abnormal, basophilic granules (M4Eo). The contribution of cytogenetic and molecular changes to the classification of AML is continuing to grow. A summary of some of these changes, including altered genes and the subtype of AML most commonly associated with the genetic abnormality, is shown in Table 20-4.

**TABLE 20-4. CYTOGENETIC ABNORMALITIES IN CHILDHOOD ACUTE MYELOGENOUS LEUKEMIA (AML)[a]**

The combination of clinical presentation, morphology, histochemistry, immunophenotyping, and cytogenetics currently forms the basis for identifying the subtypes of AML. Although classification schema have had relatively limited relevance to determining therapy or prognosis, more recent subtype classification has begun to take on much greater importance in terms of directed therapy as well as predicting outcome. In addition, subclassification using genomic and RNA expression microarray technologies will clearly have a major impact on the ability to classify and determine appropriate molecularly directed therapies in the future.[145]

## Molecular Mechanisms of Leukemic Transformation

The molecular pathogenesis of AML remains incompletely understood. Most of the molecular insights into leukemic transformation have been derived from cytogenetic analysis. The cloning of chromosomal translocation breakpoints common in AML has demonstrated that the mechanism of AML transformation is distinct from the pathogenesis of other types of leukemia. For example, whereas ALL is most commonly characterized by overexpression of structurally normal transcription factors through juxtaposition of these genes into the genetic loci of highly expressed immunoglobulin or T-cell receptor genes, AML is most frequently associated with the generation of chimeric fusion genes that result from chromosomal translocation. Again, transcription factor encoding genes appear to be the most commonly targeted class of genes that are rearranged by such translocations in AML. For example, the t(8;21) results in fusion of the AML1 gene on chromosome 21 to the ETO gene on chromosome 8, yielding an AML1-ETO fusion protein that retains the DNA-binding properties of AML1 and the protein interaction properties of ETO. The AML1-ETO fusion protein is thought to block the normal function of the normal AML1 protein, part of the core binding factor complex whose activity is critical for normal hematopoietic development.

When considered at the level of cytogenetic analysis, AML appears to be a highly molecularly heterogeneous disease in that a multitude of distinct chromosomal abnormalities are seen in different patients with AML. Further characterization of the molecular consequences of such chromosomal translocations, however, reveals that in fact multiple different translocations actually target the same molecular pathway. For example, the t(8;21), t(3;21), t(16;16), t(16;21), and inv(16) translocations all result in dysregulation different of components of the core binding factor complex described above. In general, it appears that these translocations result in conversion of the normal core binding factor complex, which functions to activate the expression of target genes, into a transcriptional repressor, which functions to silence the activity of those target genes. This occurs through the recruitment of histone deacetylases (HDACs), which function as part of the transcriptional repression apparatus. Other translocations, such as the t(15;17), which results in the PML-RARA fusion seen in APL, also appear to cause leukemic transformation through aberrant recruitment of HDACs that cooperate in the silencing of genes normally activated by the normal RARA nuclear hormone receptor. This convergence of multiple gene rearrangements on a small number of common final pathways has significant therapeutic implications. Rather than having to develop a therapeutic intervention for each of the genetic abnormalities associated with AML, it may be possible to target only a few commonly dysregulated pathways. For example, the development of HDAC inhibitors has been considered as potential “transcription therapy” for AML. Whether such strategies will be effective and sufficiently specific remains to be determined.

Although many cases of AML appear to have only a single cytogenetic abnormality, it is becoming increasingly clear that multiple genetic mutations or “hits” are likely to be required for complete leukemic transformation. For example, in some patients with t(8;21)-positive AML, PCR evidence of the AML1-ETO fusion transcript persists even when patients are in complete remission (CR), suggesting that these patients may have returned to a premalignant state. Further support for this notion that the t(8;21) is not sufficient for leukemic transformation includes data coming from animal models that clearly demonstrate that the AML1-ETO fusion protein is not sufficient to cause leukemia in mice; additional mutations are required to reveal an overt leukemia phenotype.

## Subtypes of Acute Myelogenous Leukemia

The M0 subtype (minimally differentiated AML) comprises a small proportion (less than 3%) of pediatric AML. The leukemic cells are large and usually devoid of characteristic granules (type I blast). Although the blasts are negative for MPO staining with light microscopy, they may show positivity at the electron microscopic level. M0 AML is best defined based on the expression of myeloid-associated markers, such as CD33, CD13, and CD117 (c-Kit), in the absence of definitive evidence of lymphoid differentiation. Most cases are CD34 positive, whereas other markers, such as CD7 or deoxynucleotide transferase, may also be expressed.

The M1 subtype comprises approximately 20% of AML and is characterized by minimal evidence for differentiation. M1 is similar to M0 AML except for the presence of MPO as detected by immunohistochemistry or flow cytometry. More than 90% of the cells in the marrow are myeloblasts, and at least 3% of cells are MPO positive. The presence of Auer rods is variable. The type I blasts are similar to those in M0, and other blasts, usually a minority, may contain up to six azurophilic granules and a lower nucleus to cytoplasmic ratio (type II blasts). Immunophenotyping usually shows positive staining for CD13, CD15, CD33, and CD34.

The M2 subtype represents AML with differentiation. This subtype comprises nearly 30% of patients with AML. The blasts may vary considerably in size and shape, have prominent nucleoli, and usually a pale blue cytoplasm with azurophilic granules and often Auer rods. Greater than 10% of the leukemic blasts must show evidence of differentiation, with less than 20% of these showing monocytic features. The t(8;21) chromosomal translocation is more commonly observed in this subtype, with a frequency of between 10% and 15%.[143,144]

M3 subtype (also referred to as *APL*) represents approximately 5% to 10% of childhood AML and is characterized by extensive promyelocytic differentiation, often with bilobed nuclei and Auer rods. A variant of M3 AML (M3v) is characterized by being micro- or hypogranular. However, these cells are strongly MPO positive. Thus, the M3v subtype of AML should be considered when the bone marrow contains many cells with a hypogranular appearance but that are strongly positive for the peroxidase reaction. This variant may constitute up to 25% of all cases of APL. Nearly all cases of M3 AML, including the microgranular variant, are characterized by the presence of a t(15;17) chromosomal translocation, which involves the fusion of the PML gene on chromosome 15 to the retinoic acid receptor alpha (RARA) on chromosome 17.[143,144] Importantly, this translocation is absent from other subtypes of AML. Thus, the presence of a t(15;17) chromosomal translocation, detected by routine cytogenetics, FISH, or RT-PCR, essentially makes the diagnosis of APL. However, an important cytogenetic variant, t(11;17), has been described that fuses the PLZF gene on chromosome 11 to the RARA gene. These different translocations have particular prognostic significance in terms of response to all- *trans*-retinoic acid (ATRA), with the t(15;17)-positive leukemia showing excellent responses and the t(11;17)-positive leukemia being mostly resistant. [143,144,146,147,148] and [149]

The M4 subtype of AML, called *acute myelomonocytic leukemia*, accounts for approximately 25% to 30% of AML, with an increased frequency in children younger than 2 years of age. M4 AML is characterized by the bone marrow having at least 20% of myeloblasts, whereas monoblasts comprise 20% to 80% of the nonerythroid cells, most commonly promonocytes. There is often a peripheral blood monocytosis (greater than $5 \times 10^9$ per L monocytes) as well as greater than threefold increased serum and/or urine lysozyme levels. In the case in which less than 20% of the bone marrow cells are monocytic, the diagnosis of M4 AML can be made in part based on the peripheral monocytosis. The myeloid blasts of M4 AML are usually MPO and SBB positive and express characteristic surface antigens such as CD13, CD15, and CD33. The monocytic blasts are NSE positive and, in addition to myeloid surface markers, also usually express CD14, CD4, and HLA-DR. A variant of M4 AML, called *M4Eo*, is characterized by the presence of greater than 5% abnormal eosinophilic precursors, which have large, basophilic granules in their cytoplasm. They are strongly chloroacetate esterase positive. This variant is strongly associated with alterations of chromosome 16, most commonly inv(16)(16q22). This chromosomal alteration usually involves the creation of fusion transcript involving the MYH11 and CBFB core binding transcription factor. Some cases of 16q22 abnormalities do make for strict FAB criteria for M4Eo subtype, and have previously been classified as M2 or M5. The new WHO classification should eliminate some of this potential confusion, as 16q22 leukemia is to be considered a unique entity. [104,105,106,107] and [108]

M5 AML (monocytic) can be distinguished from other subtypes, specifically the M4 subtype, by the presence of greater than 80% of the nonerythroid bone marrow cells being of the monocytic lineage. M5 AML represents approximately 15% of AML in children older than 2 years but may account for approximately 50% of AML in children younger than the age of 2 years. This subtype is divided into two subcategories, M5a, in which more than 80% of the bone marrow cells are immature monoblasts, and M5b, in which a mixture of monoblasts and promonocytic and monocytic cells comprise the 80% of cell types. The M5a blasts are characteristically large, contain prominent, multiple nucleoli, a basophilic cytoplasm, and usually lack Auer rods. The M5b subtype shows increased evidence of differentiation with more extensive granulation and sometimes the presence of Auer rods. The blasts are NSE positive and express myeloid surface markers, such as CD33, along with antigens characteristic of the monocytic lineage such as CD14. The t(9;11) chromosomal abnormality is commonly found associated with M5 AML and involves the translocation of the interferon beta1 gene into the MLL gene locus at 11q23-24. [143] In addition, the t(8;16) translocation has been observed in both M4 and M5 AML. This translocation involves the fusion of the MOZ and CBP genes. [143]

The M6 subtype of AML, called *erythroleukemia*, is observed in less than 5% of pediatric cases, but is more commonly observed in adults with secondary AML. [150] M6 AML can be diagnosed when at least 50% of the bone marrow cells are erythroblasts and the nonerythroid bone marrow elements contain 30% blasts. DiGuglielmo's syndrome is a relatively infrequently found subtype of M6 AML that is characterized by greater than 70% of the bone marrow cells displaying highly dysplastic and megaloblastic erythroblasts, often with multiple nuclei. Erythroblasts are strongly PAS and carbonic anhydrase positive. Myeloblasts are MPO and SBB positive. Immunophenotyping is positive for glycophorin.

M7 AML, referred to as *megakaryocytic*, represents less than 3% of adult AML and approximately 5% to 10% of AML in children, with the exception of children with DS younger than 2 years of age when M7 is the most common form of myeloid leukemia.[59,61] Morphologically, M7 AML can be confused with FAB class L2 ALL. The blasts vary in size with nuclei containing finely dispersed chromatin and multiple nucleoli. The cytoplasm is usually abundant and characterized by extensions of blebs similar to that observed with the budding of platelets. Often, the blasts may have clusters of platelets associated with them. The bone marrow may also contain

significant amounts of fibrosis and can result in difficult aspiration attempts, often resulting in “dry” taps. The blasts are negative for MPO and SBB reactivity, but may show localized positive reactions for alpha-naphyl butyrate esterase. Platelet peroxidase can be demonstrated at the electron microscopic level. A key feature to establish this diagnosis is immunophenotyping, which shows the blasts to be positive for CD13 and CD33 along with the megakaryocytic markers, such as glycoprotein IIb/IIIa (CD41) and glycoprotein IIIa (CD61). Factor VIII can also be detected by immunocytochemistry. The t(1;22) translocation has been described to be found in very young patients with M7 AML.[151,152 and 153]

The classification systems being currently used employ features of morphology, histochemical reactions, surface immunophenotyping, cytogenetic abnormalities detected using a variety of methods ranging from classical cytogenetics to molecular methods, such as FISH and PCR approaches to detect chromosomal abnormalities. It is important to realize that with the exception of the M3, M4Eo, and possibly M6/M7 subtypes, the classification schema has limited utility in terms of directing therapies and outcome. An important goal of future studies will be to develop a more detailed and predictive classification schema for malignant myeloid diseases that will help target more effective therapies.

## CLINICAL PRESENTATION OF ACUTE MYELOID LEUKEMIAS

The range of presenting signs and symptoms of children with AML is exceptionally large. Patients may present with minimal symptoms or life-threatening complications due to depletion of normal bone marrow elements and organ dysfunction based on leukemic cell infiltration. Of further importance is that certain subtypes of AML have characteristic presenting signs and symptoms.

### Presenting Signs and Symptoms

Persistent fevers may occur in approximately a third of patients, and are probably secondary to pyrogens released by leukemic cells and/or by macrophages and lymphocytes reacting to the leukemic blasts. Patients may also present with fever secondary to bacterial infections of the sinuses, gingiva, teeth, lung, perirectal area, skin, and septic shock as a result of neutropenia. Although the white blood cell count (WBC) is usually elevated in patients with AML, the number of functional, mature neutrophils is often significantly decreased to less than 1,000 cells per mL.

Pallor can result from decreased hemoglobin (usually a normocytic, normochromic anemia) due to leukemic blast infiltration into the bone marrow, entrapment from enlarged liver and spleen or from blood loss secondary to bleeding as a result of thrombocytopenia, and/or disseminated intravascular coagulopathy (DIC). Additional consequences of severe anemia include fatigue, headache, tinnitus, dyspnea, and congestive heart failure. Bone pain, which occurs in close to 20% of patients, is a result of bone marrow replacement by leukemic blasts; patients may present with limp, long bone or rib pain, as well as back pain.

Some degree of hepatosplenomegaly occurs in approximately one-half of patients and is due to organ infiltration, with the exception of very young children with DS and M7 AML, who may present with hepatomegaly and liver failure due to fibrosis in addition to leukemic involvement. [56] Extramedullary involvement with AML may also result in lymphadenopathy (between 10% and 20% of patients); leukemia cutis (less than 10% of patients), characterized by palpable, nontender nodules or plaques that are colorless to bluish/purplish in color; and gingival hypertrophy (in 10% to 15% of patients); all of these findings are more common in infants and patients with M4 or M5 AML.[154,155] The growth of tumors composed of AML blasts, called *granulocytic sarcomas* or *chloromas*, the latter name because of their bluish-green appearance due to the MPO content, may also occur in a variety of anatomical sites. Chloromas are most commonly found in the orbit or periorbital areas where they can cause ptosis. They may also involve the spinal cord and cause cauda equina syndrome or paraparesis from epidural involvement. [156,157,158,159,160 and 161] Isolated chloromas or granulocytic sarcomas can precede the bone marrow involvement by just a few weeks to up to 1 or 2 years.[162] Involvement of the central nervous system (CNS), which occurs in approximately 2% of patients, can be in the form of leukemic cells in the cerebrospinal fluid or chloromas from which patients can present with headache, nausea and vomiting, photophobia, papilledema, and cranial nerve palsies. [159,163,164,165 and 166] Seizures are not common. CNS involvement is more common in infants and patients with M4 and M5 AML as well as those presenting with a very high WBC. Testicular involvement rarely occurs with AML. [167,168 and 169]

### Bleeding

Petechiae and purpura are a result of thrombocytopenia and sometimes coagulopathy. Overt bleeding may involve the large or small bowels, oral mucosa, or CNS; nose bleeding and menorrhagia may occur. These hemorrhagic complications may result from thrombocytopenia as well as from DIC due to infection or from the release of proteins with anticoagulant activities (i.e., thromboplastin activity) from cytoplasmic granules of leukemic blasts. DIC is most frequently observed in M3 AML (APL) because of the high level of the thromboplastin activity containing granules in promyelocytes. Importantly, the induction of therapy may worsen DIC due to the breakdown of leukemic blasts.[170,171 and 172] The use of low-dose heparin has been proposed by some investigators during initial treatment. [173,174 and 175] The use of ATRA has provided an alternative means to induce remission by the further differentiation of the promyelocytes followed by apoptosis without the acute lysis of leukemic blasts. However, coagulopathy and bleeding complications may still be problematic (see Hematologic Complications).[176,177 and 178] M5 AML is also frequently associated with DIC secondary to the release of proteins with anticoagulant activities.

### Hyperleukostasis

When the peripheral WBC reaches very high levels, usually greater than 200,000 cells per mL, leukemic blasts can start to clump intravascularly, resulting in the condition of leukostasis. This medical emergency occurs as a result of sludging of clumped leukemic blasts in the small vessels and may lead to tissue hypoxia, infarction, and hemorrhage. Lung involvement can result in significant tachypnea and eventual respiratory failure; chest x-rays often show parenchymal infiltrates, engorged vessels, and pulmonary edema. CNS involvement can result in confusion, headache, somnolence, coma, and stroke. Most children will not develop signs or symptoms of leukostasis with WBC under 200,000 cells per mL, but the risk of developing severe complications, such as CNS hemorrhage and pulmonary failure, increase substantially with WBC over 300,000 cells per mL. [172,179,180,181 and 182] Some studies have indicated that children with WBC of greater than 100,000 cells per mL with M5 AML and extramedullary organ involvement may be at greater risk.[172] This may be due to the large size and adherence properties of monoblasts. [172]

### Tumor Lysis Syndrome

Tumor lysis syndrome results when the intracellular contents released from dying leukemic blasts exceeds the ability of the body to adequately metabolize and excrete them. This is most frequently associated with AML presenting with a very high WBC. Hyperuricemia, a result of the metabolism of excess amounts of released nucleic acids, can result in renal failure, which then can further worsen the patient's ability to excrete other metabolites. Increased blood urea nitrogen can adversely affect platelet function and lead to a worsening of any coagulopathy. Hyperphosphatemia and secondary hypocalcemia may lead to further renal failure and the danger of seizures. Hyperkalemia may lead to alterations in the electrocardiogram with increase amplitudes of T waves, arrhythmia, and cardiac arrest.

### Laboratory Findings

A complete blood cell count will show a hemoglobin of less than 9 g per dL in more than one-half of patients, with a range between approximately 2.5 and 14.0 g per dL (median of 7 g per dL).[183] The anemia is usually normocytic and normochromic, but can show teardrop-shaped RBCs and circulating nucleated RBCs, both signs of marrow infiltration. Platelet counts of less than 100,000 platelets per mL occur in nearly 75% of patients. [183] The median leukocyte count is 24 × $10^9$ cells per mL, with up to approximately 20% of patients presenting with a WBC greater than 100,000 cells per mL. [172,184] Sweet's syndrome can be encountered in patients presenting with AML.[185] As noted, hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia may be mild to severe depending on the leukemic burden and leukemic cell turnover rate. Patients with M3 AML (APL) and M5 AML (monocytic) are more likely to show signs of DIC with associated laboratory abnormalities such as prolonged prothrombin time, partial thromboplastin time, and decreased fibrinogen. Patients with M4 and M5 AML may also show increased serum and urine levels of lysozyme, an enzyme stored in the cytoplasm of monocytic blasts. Of interest is that this enzyme may lead to renal tubular dysfunction. [186]

### Differential Diagnosis

The differential diagnosis of AML includes both nonmalignant and other malignant conditions. The former include such disorders as juvenile rheumatoid arthritis, infectious mononucleosis, aplastic anemia, congenital and acquired neutropenia, autoimmune cytopenias, megaloblastic anemia, leukemoid reactions secondary to severe infections or hemolysis, conditions such as infection or marrow infiltrative disorders leading to leukoerythroblastic peripheral blood smears, and transient myeloproliferative syndrome associated in infancy with trisomy 21. Depending on the age and presentation, malignant disorders may include metastatic

neuroblastoma, rhabdomyosarcoma, retinoblastoma, non-Hodgkin's lymphoma, or ALL, as well as MDS and subacute or chronic myeloid leukemias, including juvenile myelomonocytic leukemia, chronic myelomonocytic leukemia, and CML.

A definitive diagnosis of leukemia and type should be made by examination of cells obtained by bone marrow aspirate or biopsy. Usually, a bone marrow aspirate is adequate and a biopsy unnecessary. However, a biopsy is useful in the situation in which leukemia is highly suspected but aspirate attempts do not yield sufficient material for examination, so-called “dry” taps. The bone marrow in AML is usually hypercellular and should contain greater than 25% leukemic blasts. Histochemistry immunophenotyping along with cytogenetic analysis is usually able to definitively distinguish AML from the previously mentioned conditions as well as determine the subtype. If there is still doubt whether a patient has leukemia or not, then most patients can usually be safely watched for approximately another week, at which time a repeat bone marrow examination can be done. In addition to the bone marrow aspirate, the work-up of patients suspected of having AML should include a complete blood cell count and differential; blood type and cross if indicated; coagulation studies; blood chemistries, including electrolytes, uric acid and liver and renal function tests; and a lumbar puncture.

## TREATMENT: REASONS FOR SUCCESS AND FAILURE

The goal of therapy for patients with AML is to eradicate their leukemia while allowing them to lead normal lives. The foundation stones of successful treatment for patients with AML currently include combination chemotherapy, as performed in carefully controlled clinical trials, along with aggressive supportive care. Before 1970, nearly all patients with AML died of their disease. Initial attempts to treat patients with AML were modeled on the first successful approaches used in ALL (i.e., induction therapy followed by prolonged maintenance treatment and cranial radiation). Subsequent improvements arose out of the more intensive dosing of multiple, chemotherapeutic agents with non–cross-resistant drug profiles, leading to transient but severe hypocellular bone marrow. [187,188] Studies done in the 1970s and 1980s that were based on these principles led to a shorter duration of therapy without the need for cranial radiation and resulted in improved remission rates and long-term outcomes, with 5-year survivals reaching the 25% to 35% range (Fig. 20-3).[189]

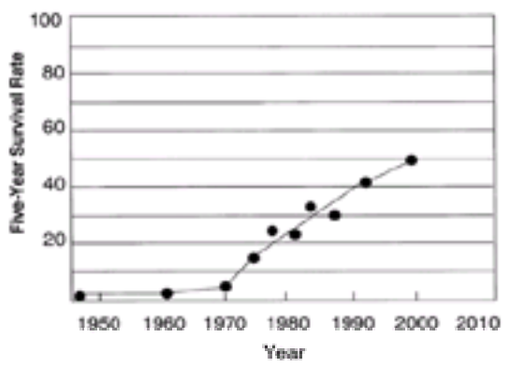

**FIGURE 20-3.** Five-year survival in pediatric acute myelogenous leukemia over the past 50 years. [Adapted from Kersey JH. Fifty years of studies of the biology and therapy of childhood leukemia. Blood, 90:4243;1998; and SEER data (Smith MA, Gloeckler-Ries LA, Gurney JG, Ross JA. Leukemia. In: Ries LAG, Smith MA, Gurney JG, et al., eds. Cancer incidence and survival among children and adolescents: United States SEER Program 1975–1995. Bethesda, MD: National Cancer Institute, SEER Program NIH Pub., 1999:17–34.).]

Building on these concepts, subsequent studies have continued to take advantage of dose intensification using chemotherapy along with autologous or allogeneic bone marrow transplantation. Overall, long-term survival has now been achieved for 45% to 50% of patients with AML. [189] Several important lessons have been learned from such studies, including the importance of dose intensification during the early phases of therapy as well as the role of allogeneic bone marrow transplantation.[190,191 and 192] In addition, the treatment of patients with different subtypes of AML on standardized clinical trials has begun to identify subsets of patients for whom alternative approaches are more efficacious.[193,194 and 195] However, these important advances have come at a significant cost in terms of short- and long-term morbidity and mortality, which have concomitantly increased with the escalation of dose intensification. An increasingly important concern linked to toxicity is the pharmacogenetic basis for drug sensitivity due to the expression of polymorphisms of genes involved in drug metabolism. [196,197] For example, prescreening of patients for such polymorphisms may help to identify patients at particularly high risk for specific toxicities and aid in risk-adapting therapeutic choices. Resource utilization has also significantly increased. Furthermore, despite both the success and the associated treatment related problems, the most common reason for treatment failure in patients with AML remains drug-resistant leukemia.[198,199 and 200] There remains an enormous need for innovative, less toxic, and more effective approaches to treat patients with AML.

Current therapy for AML involves the stabilization of the patient at the time of diagnosis followed by remission-induction therapy and postremission treatment that includes consolidation, intensification, and CNS prophylaxis. In some studies, maintenance therapy is used. This section discusses each of these issues in terms of both progress and unfulfilled challenges.

### Immediate Therapy

The diagnosis of AML often constitutes an urgent situation, and patients should undergo careful evaluation for the hematologic, infectious, and metabolic consequences of their leukemia.

#### *Hematologic Complications*

Thrombocytopenia in a patient with AML takes on special significance in terms of the potential for catastrophic bleeding due to the increased risk of bleeding, even with relatively high platelet counts, secondary to DIC and infection. In such circumstances, platelet counts should be maintained at higher levels than in patients without such risk factors. The goal should be to maintain hemostasis and not necessarily achieve a specific platelet count. Patients with DIC should receive replacement clotting factors through the judicious use of fresh frozen plasma, platelet transfusions, and, on occasion, clotting factor concentrates. The efficacy of using low-dose heparin as prophylaxis and management of DIC secondary to APL remains unproven.[173,174 and 175,178] The use of ATRA for induction in such patients may improve the exacerbation of the coagulopathy associated with induction chemotherapy. However, hemorrhagic complications still occur. Patients with APL and high WBCs are particularly at risk for significant hemorrhage. [176,177] In such circumstances, the immediate goal, in addition to managing the coagulopathy, is to reduce the leukemic burden.

Anemia in patients with AML may be severe and due to the replacement or suppression, or both, of normal red cell production as well as bleeding due to thrombocytopenia and/or DIC. Like the platelet count, it is important to maintain adequate hemoglobin by anticipating blood loss in patients with active bleeding and DIC (see Chapter 40).

#### *Infectious Complications*

Although the WBC count may be high in patients with AML, the absolute neutrophil count is often less than 1,000 cells per mL. When the neutrophil count drops to below 200 cells per mL, the incidence of fever and bacteremia increases dramatically. The low neutrophil count in conjunction with fever, present in at least one-third of patients, is a medical emergency. Patients presenting with fever and neutropenia should have blood and urine cultures sent and be promptly started on therapy with broad-spectrum antibiotic coverage.[201,202,203,204,205 and 206] The risk of developing fungal infection during induction therapy for AML has increased along with the intensification of therapy. Although some studies have suggested the use of antifungal agents as prophylaxis, this is an area of investigation requiring more study, especially in terms of *Aspergillosis*.[207,208,209,210,211 and 212] Cytokines aimed at accelerating the rate of neutrophil recovery have proven to be effective, but have not been unequivocally shown to improve overall outcome and reduce infections in randomized studies. [213,214,215,216,217,218,219,220,221 and 222]

### *Tumor Lysis Syndrome*

The presenting signs and symptoms of tumor lysis syndrome may include renal failure, increased serum uric acid, potassium, and phosphate with secondary hypocalcemia.[223,224] These patients require immediate intervention with intravenous hydration to maintain urine flow, alkalinization with intravenous sodium bicarbonate, and allopurinol or other agents to increase the solubility and renal excretion of insoluble urate. [224,225 and 226] Frequent monitoring of serum electrolytes, in addition to potassium, calcium, phosphorus, creatinine, and urine output, is critical. Although the renal failure associated with tumor lysis syndrome can usually be avoided with anticipatory measures of hydration and administration of allopurinol, occasionally such patients will require dialysis until renal function is reestablished.

### *Hyperleukostasis*

Patients presenting with WBC counts greater than 200,000 cells per mL are at increased risk of developing respiratory insufficiency and CNS complications such as headache, confusion, somnolence, coma, and hemorrhage. Under such circumstances, it is imperative that rapid cytoreduction take place. Leukapheresis or exchange transfusions are able to rapidly lower the WBC, although the effect is usually transient. [172,179,180,181 and 182] Hydration also causes a decrease in WBC due to dilution. The use of cytotoxic agents, however, is critical for effectively sustaining a reduced WBC. Agents such as hydroxyurea can be immediately given while preparing for leukapheresis, and, though the effect of this agent may not be manifest for several hours, it may both lower and prevent a rebound increase in the leukemic blast count after cytapheresis. More definitive cytoreductive therapy (see next section) should be introduced as soon as possible. The use of radiation therapy is not indicated for hyperleukostasis, but may be helpful in the situations in which chloromatous accumulations of leukemic blasts threaten organ function such as with involvement of cranial nerves, eyes, spinal column, or trachea.

## Induction Therapy and Complete Remission

Induction therapy should begin as soon as possible after a definitive diagnosis is made. Although initial intervention is important in metabolically and hematologically stabilizing the patient, the initial cytoreductive therapy is key to inducing a remission and obtaining a return to normal hematopoiesis. Remission is currently defined as the presence of less than 5% blasts in a normocellular marrow with trilineage recovery of peripheral blood counts (granulocyte count of greater than $1 \times 10^9$ cells per L and platelet count greater than $100 \times 10^9$ per L) as well as no evidence of leukemia in other sites. It is important to determine differences in remission criteria when comparing different studies, as these criteria are not used to report results in all studies. [119,227] Some studies have demonstrated that the quality of remission after induction therapy is likely to have a profound impact on outcome regardless of the type of postremission treatment. Although “quality” has not yet been rigorously defined, it correlates closely with the degree of dose intensification and probably the degree of MRD (see under Response to Therapy and Minimal Residual Disease).

The induction of a remission currently requires the use of myelosuppressive cytotoxic agents that result in transient periods of profound marrow hypoplasia. An exception to this is the induction of remission in patients with APL, in whom the use of agents, such as ATRA, allow for the terminal differentiation and apoptosis of leukemic blasts while effectively sparing normal myeloid progenitors (see the section Acute Promyelocytic Leukemia). The periods of hypoplasia and secondary pancytopenia usually last from 20 to 30 days, during which time patients are at high risk for infection and bleeding. Furthermore, the damage to normal tissues, particularly the gastrointestinal tract, creates a significant source for entry of bacterial organisms into the blood stream. Last, intensive chemotherapeutic treatments inhibit lymphocyte function, resulting in various degrees of susceptibility to opportunistic infections. Thus, anticipatory supportive care measures are critical for patients to survive the consequences of induction therapy.

After the induction of remission in patients with ALL using the antimetabolite aminopterin in the late 1940s, the National Cancer Institute sponsored the screening of many cytotoxic agents against leukemia cell lines. In the 1960s, cytarabine (AraC) and anthracyclines were introduced into the treatment of patients with AML, initially as single agents and then in combination. With the introduction of the “7 and 3” regimen consisting of a 7-day intravenous infusion of 100 mg per $m^2$ AraC along with 3 days of bolus daunomycin at 45 mg per $m^2$ per dose, approximately 60% to 70% of patients with newly diagnosed AML may achieve remission. [190,191,228,229,230 and 231]

The addition of other agents to the “7 and 3” regimen or the use of multiple agents sequentially over the course of a week demonstrated remission induction rates from 70% to 85%.[59,188,191,228,232,233,234 and 235] Some studies have demonstrated that the addition of etoposide to “7 and 3” increases the duration of remission. [191,229,236,237 and 238] On the other hand, another study by the Cancer and Leukemia Group B did not observe an increased remission rate or duration with the addition of 6-thioguanine (6-TG) to “7 and 3.”[239] In a randomized trial from the United Kingdom's Medical Research Council (MRC AML10), which compared daunomycin and AraC with either 6-TG or etoposide, no significant difference was observed. [240]

The use of alternative anthracyclines, such as idarubicin (IDA), has suggested remission induction can be achieved sooner and in a greater number of patients than with “7 and 3” using daunomycin.[191,241,242,243,244,245,246 and 247] The MRC/ICRF performed a meta-analysis of results from randomized trials comparing IDA or mitoxantrone versus daunomycin and found that there was a statistically significant improvement in remission rate with IDA and a trend that mitoxantrone was better than daunomycin.[248] The overall disease-free survival, however, was not different among the different groups, although a detailed analysis by age was not done in spite of the fact that the improvement remission induction observed with IDA suggested that there was more of an advantage in younger patients. [248] Other trials have not achieved higher remission rates by introducing IDA.[191,247,249] Part of these discrepancies may involve the issue of dose equivalency, which remains an important variable in studies of this type.

Increasing the dose of AraC during induction has not been shown to consistently result in a greater remission induction rate, but has contributed to increased toxicity, particularly in older patients.[250,251] For example, randomized studies in adults with AML have shown that no significant differences were observed with AraC at 100 to 200 mg per $m^2$.[252,253] Further increases of AraC dose, by even 20 to 30 times (i.e., 1,000 to 3,000 mg per $m^2$ every 12 hours for eight to 12 doses) have also not resulted in significantly improved remission rates. [250,254,255]

Thus, the percentage of patients with AML achieving remission remains between 70% and 85%, with approximately one-half of the failures being due to resistant leukemia and the others to toxicity. Such numbers can, however, be misleading in that remission rates may vary significantly depending on whether patients have favorable or unfavorable characteristics. For example, remission rates may be significantly higher (greater than 80%) in favorable risk patients [e.g., (inv)16 AML] whereas subsets of patients with poor risk factors (e.g., older patients, antecedent MDS, and adverse cytogenetics such as monosomy 7) usually have remission rates below 50% (see the section Prognostic Factors).[251,256] Thus, although “7 and 3”-based regimens have been reasonably successful, they remain significantly limited.

In an attempt to improve remission rates, several studies have more recently tried to build on the observation that AML has been responsive to dose intensification as well as the concept that kinetically based approaches might result in increased leukemic cell recruitment and killing. [191,257,258,259 and 260] Both of these concepts have led to different strategies for dose intensification. In one case, chemotherapy is given on a daily schedule over a contiguous series of days. [239,240,261,262] The other approach delivers chemotherapy over a similar period, but separates the treatment by a gap to provide time for the recruitment of leukemic blasts into a potentially more drug-sensitive, proliferative state [e.g., Children's Cancer Group (CCG) study 2891]. [60,192,257,258,263,264]

The Cancer and Leukemia Group B demonstrated that a “7 and 3” induction was better than a “5 and 2” induction regimen. [261] The MRC AML 9 trial, comparing a “10 and 3 plus 6-TG” induction with a “5 and 1 plus 6-TG,” showed that the longer infusion (i.e., 10 days of AraC) had a higher CR rate. [261] Based in part on these results, the MRC AML 10 trial used AraC for 10 days during induction and compared the addition of etoposide or 6-TG. [240] Whether one used etoposide or 6-TG, this trial resulted in a remission induction rate of approximately 85% after one or two courses of therapy and as high as 92% with four cycles of treatment ( Fig. 20-4).[240] The Leucemia Acuta Mieloide (LAM) 89/91 study used AraC at 1,000 mg per $m^2$ for 5 days and replaced the standard 3 days of daunomycin with 5 days of mitoxantrone (Fig. 20-4). This study showed a remission induction rate of 87% and represented a significant dose increase of both AraC and anthracycline. [265] The Berlin-Frankfurt-Munster (BFM) trials (BFM 83 and 87) also increased exposure to AraC during the first 14 days of treatment and demonstrated a similar remission induction rate to other studies.[266,267,268,269 and 270] Such studies have thus dose intensified, in part, by extending the period of induction therapy as a period of consecutive daily treatments. This has resulted in a trend toward slightly higher remission induction rates.

ICO 2001;19:2705–2713.) MRC AML 10 [322]; LAM 89/91[265]; AIEOP/LAM 87[323]; POG 8821[324]; POG 9421 (from POG Operations Office); CCG 2891[263,721]; CCG 2961 (from CCG Operations Office).]

An alternative strategy was based on the concept that leukemic blasts could be effectively recruited into S phase of the cell cycle by following the initial course of chemotherapy by a 6- to 8-day gap before reinstitution of therapy. This type of timed, sequential, or intensively timed therapy originated from work on leukemic cell cycle kinetic studies.[257] For example, the CCG-2891 trial tested a “standard” versus “intensive” timing induction using the five-drug dexamethasone, AraC, thioguanine, etoposide, and rubidomycin (DCTER) regimen.[60,264] Standard timing delivered the second course of chemotherapy after bone marrow recovery, usually approximately 30 days, unless there was residual leukemia on day 14, in which case, therapy was given at that time. Intensively timed induction therapy gave the second course of DCTER on days 10 to 13 regardless of bone marrow status (Fig. 20-4). The CR rate for the standard and intensive timing arm was 74% and 78%, respectively, a nonstatistically significant difference. [60,264] However, induction mortality was great on the intensively timed induction although there was less refractory leukemia. The addition of G-CSF, as a nonrandomized question part way through this study, showed that there were fewer infectious complications, resulting in a remission rate of 82%. Although these results showed that intensively timed induction therapy did not result in a significantly improved remission rate, follow-up information has demonstrated that there is a significantly improved overall outcome for patients who received the intensive versus standard timing therapy, regardless of the type of postremission treatment (see Postremission Therapy).[60,264]

The results from such studies strongly suggest that the type of therapy received during induction has an important impact on overall outcome. In addition, these results lead to the hypothesis that the quality of the remission obtained using intensively timed therapy was superior to that obtained with standard timing. In biologic terms, quality is believed to be a remission with less MRD. This is currently being tested in prospective trials (see Postremission Therapy).

Although many studies have shown that at least a subset of AML is more responsive to the intensity of therapy during induction, the issue of timing versus dose intensity has not been rigorously answered. For example, the MRC 10, BFM, and LAM studies, which give more therapy by extending the days of induction treatment, have achieved similar results to intensively timed therapy as demonstrated by the CCG-2891 trial. A definitive test of timing versus dose intensification should involve a comparison of the same amount of therapy delivered over the same time period with one group of patients receiving that therapy each day and the other group receiving part of the treatment followed by a gap (to account for kinetic recruitment) and then the rest of therapy ( Fig. 20-5). Future trials may help elucidate the answer to this question.

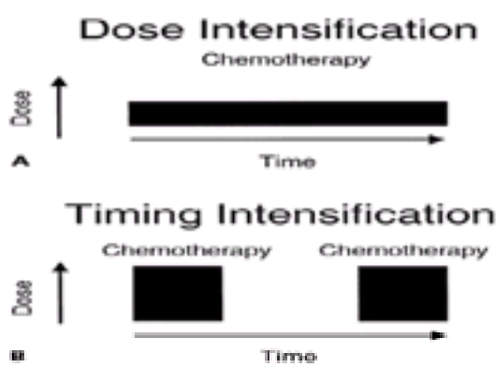

**FIGURE 20-5.** Schema of “dose versus timing” of chemotherapy. **A:** Chemotherapy extended over a contiguous number of days. As more cells cycle into different sensitive phases of the cell cycle, there would be an expected increased killing of leukemic blasts. **B:** A test of timing of the same total dose of chemotherapy as depicted in **A**, but instead given as two periods of chemotherapy, separated by a gap. This latter approach assumes that the first course of chemotherapy will both kill and partially synchronize leukemic blasts so that they will be in S phase and, possibly, in a more chemosensitive state when the second course of therapy is delivered.

Another critical component for success during remission induction has been the development of improved supportive care measures. [271,272] and [273] Although the role of broad-spectrum antibiotic coverage in patients who are febrile and neutropenic has been well established, the role of antibacterial prophylaxis and antifungal prophylaxis is not entirely clear. In addition, the role of hematopoietic growth factors has been extensively tested in patients with cancer after chemotherapy-induced neutropenia.[222,274,275] and [276] In patients with AML, there have been several studies examining the potential role of cytokines, such as G-CSF or granulocyte-macrophage colony-stimulating factor (GM-CSF), to reduce the period of neutropenia and serious infections. [274,275] These studies have demonstrated that the use of hematopoietic growth factors after induction and possibly consolidation therapy reduces the period of neutropenia, although the affect on the incidence of infections and hospitalization has been variable. [274,275,277] Some, but clearly not all, prospective randomized trials in elderly patients have demonstrated significantly improved survival with the use of GM-CSF due to a decrease in treatment-related deaths. [221,278] Similar studies using G-CSF have not shown significant clinical advantages, although minimal reduction in periods of neutropenia have been observed. [213,214,216,217,218,219,220,221] and [222,274,275] Of note, most studies have not shown a consistent effect on the remission induction rate, the duration of responses, or the incidence of relapse.

Although real progress has been made in improving remission induction rates, significant challenges remain. The combination of anthracyclines and AraC was introduced as a relatively effective combination in the 1970s and remains the mainstay of induction therapy. Dose intensification of induction therapy has achieved better quality remissions but at a significant cost in terms of morbidity and mortality. [279] Furthermore, increasing dose intensification with cytotoxic agents that are currently being used is likely to be too toxic. Advances in supportive care, particularly antifungal agents, are needed for incorporation into initial therapy. Future studies will need to take advantage of more specific antileukemic agents that do not contribute to normal tissue toxicity.

## Postremission Therapy

Without some type of postremission therapy, nearly all patients with AML relapse. This was clearly demonstrated by an Eastern Cooperative Oncology Group study.[280,281 and 282] The degree of intensity, scheduling, and duration have been examined in a number of important trials. [282,283] Early studies from Saint Jude Children's Research Hospital (SJCRH AML-76), the CCG (CCG-241), and the German cooperative groups demonstrated that postremission maintenance therapy resulted in a 20% to 25% 2-year relapse-free survival (RFS). [284,285,286 and 287] Essentially all patients who did not receive postremission therapy died from leukemia. Studies from the Dana-Farber Cancer Institute (DFCI), including the initial VAPA trial, attempted to intensify postremission therapy by delivering 14 months of sequential combination chemotherapy, resulting in an EFS of 38%.[288,289] The BFM-78 trial used 2 years of maintenance therapy after an induction and postinduction consolidation period and showed an EFS of 35%, although the role played by the maintenance phase remains unclear. [287]

Similar results were obtained by the Pediatric Oncology Group (POG-8101), which randomized patients to two different maintenance treatments lasting 2 years. [252] The 2-year disease-free survival (DFS) from that study did not differ from previous studies; no difference was observed between the two maintenance arms, which differed primarily in that one group received daunomycin/AraC and 6-TG/AraC/5-azacytidine in addition to AraC/6-TG and COAP [cyclophosphamide, Oncovin (vincristine), arabinosylcytosine, and prednisone]. The DFCI 80-035 and the SJCRH AML-80 studies both intensified postremission therapy by giving non–cross-resistant chemotherapeutic drugs sequentially over approximately 1 year; they did not achieve significantly better results than prior trials. [290,291] Several studies in adults, however, have strongly suggested that increasing the intensity of immediate postremission therapy, especially with high-dose AraC, resulted in a lower relapse rate and with relapses occurring later than in patients receiving less intense maintenance therapy. [292,293] This was especially true for patients with favorable cytogenetics [e.g., t(8;21) or inv(16)]. [294,295]

The CCG-213 trial from 1985 through 1989 assigned patients to a 4-month postremission intensification treatment and then randomized to 2 years of maintenance therapy or no further treatment.[296] This study and the CCG-213P showed that postremission therapy (intensification) impacted positively on the outcome of patients with AML.[296] Other studies, such as the SJCRH AML-83, BFM-83, BFM-87, and POG-8498, all suggested that increasing the dose intensity, particularly with AraC, resulted in a lower relapse rate and increased remission duration than with more conventional lower dosing of AraC. [270,287,291,297] Recent reports from CCG have also linked the degree of intensification of induction therapy to outcome. [60,263,264] In the CCG-2891 trial, patients received induction therapy with standard-timing DCTER or intensified-timing DCTER with or without G-CSF. A significant survival advantage was observed for the intensified DCTER induction over standard-timing DCTER regardless of the type of postremission therapy received ( Fig. 20-6). These results have demonstrated that the type of remission one achieves significantly impacts on the overall treatment outcome for patients with AML.[263,264] An analysis from Europe of the impact of intensifying AraC during induction and consolidation was not, however, able to show a difference in outcome after autologous or allogeneic transplantation. [298]

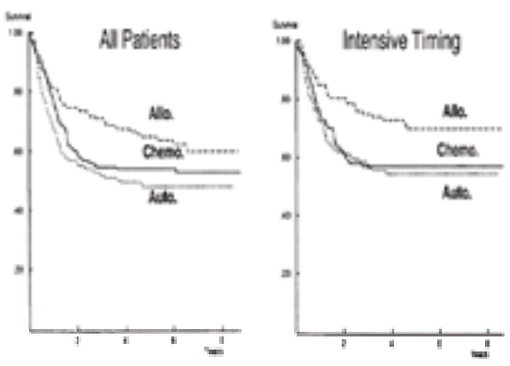

**FIGURE 20-6.** Intensively timed induction therapy results in improved outcome regardless of postremission therapy with allogeneic or autologous transplantation or chemotherapy as reported in the Children's Cancer Group 2891 study.[264] These curves represent numbers for patients going into remission. ## Postremission Intensification with Hematopoietic Stem Cell Transplantation

### *Allogeneic Hematopoietic Stem Cell Transplantation*

In part because of the continuous improvement in EFS in patients with AML receiving intensified chemotherapy, the potential for further intensification using myeloablative therapy followed by allogeneic or autologous hematopoietic stem cell rescue has been an appealing alternative to treat patients with AML. The potential advantages of allogeneic transplantation include the absence of leukemia in the donor graft as well as a graft-versus-leukemia (GVL) response. Treatment related morbidity and mortality are usually due to direct organ damage as well as the effects of graft-versus-host disease (GVHD) and prolonged immunosuppression. Long-term problems include chronic GVHD, growth problems, sterility, and the risk of secondary malignancies. [244,299,300,301,302,303,304,305,306,307 and 308]

The importance of an immune-mediated antileukemic response has been clearly documented in patients with either CML or AML after allogeneic stem cell transplantation. However, most GVL has been difficult to separate from GVHD. For example, attempts to reduce GVHD by extensive T-lymphocyte depletion from donor grafts have resulted in higher relapse rates, particularly for patients with CML. [309,310] This is also strongly suggested by the higher relapse rates when identical twins are used as donors in contrast to matched sibling donors. [311]

Most studies, including those using randomization and analysis by intent to treat, have shown an improved RFS in patients with AML undergoing allogeneic stem cell transplantation using matched sibling donors. [299,300,301,302,303 and 304,312,313 and 314] However, in several studies the overall survival was not initially found to be improved with allogeneic hematopoietic stem cell transplantation (HSCT) because of increased treatment-related mortality. [295,315] As improvements in supportive care and GVHD prophylaxis measures have been developed, treatment-related mortality has significantly decreased for HLA-matched family donor transplantation, resulting in more studies showing an overall survival advantage for transplantation. [300,312,313,316,317]

The first pediatric study published that used biologic randomization was the SJCRH AML-80 trial. [291] Although the 6-year DFS for patients receiving HLA-matched HSCT was 43%, compared to the 31% for those receiving only chemotherapy, these percentages did not achieve statistical significance. However, when deaths due to treatment-related toxicity were excluded from the analysis, the HSCT group had a 70% DFS at 6 years compared to 38% for the chemotherapy-only group. In the CCG-251 study, which began in 1978, patients receiving an HLA-matched HSCT had a significantly better 5-year EFS than those receiving chemotherapy. [232,318] This advantage appeared to be abrogated in the subsequent CCG-213, in which postremission chemotherapy was further intensified. [319] However, when the results of CCG-213 were analyzed by the therapy the patients actually received rather than by intent to treat, a survival advantage was evident for those patients undergoing HLA-matched HSCT.[232,318,319]

Other pediatric studies have also not consistently shown any overall survival advantage for patients receiving HLA-matched HSCT. [291,320,321 and 322] This has been mostly due to the higher treatment-related mortality associated with HSCT compared to intensive chemotherapy. Results from the Associazione Italiana di Ematologia ed Oncologia Pediatrica (AIEOP), the MRC, POG, and more recent CCG trials have demonstrated that relapse-free and overall survival are greater after HLA-matched HSCT (Table 20-5).[229,232,240,264,323,324 and 325] Another important area that has not been definitively examined is the quality of life (QOL) and financial impact of HLA-matched HSCT versus other types of postremission therapy.[326] Nevertheless, for younger patients, allogeneic transplantation using HLA-matched family donors results in the best overall survival outcome in several large, randomized trials analyzed by intent to treat. This point, however, remains controversial in that some study groups now recommend using HLA-matched family donors and transplantation after a first relapse for patients with favorable characteristics. Whether allogeneic transplantation will achieve at least the same overall outcome advantage when used after relapse remains to be determined, with the exception of patients

with APL (see under Acute Promyelocytic Leukemia).

| Study | DFS | | | Allo versus other (p value) | Chemotherapy versus auto (p value) |

Note: Survival with chemotherapy versus auto-HSCT versus allo-HSCT.
*DFS for AIEOP trial is at 5 years; DFS for CCG-2891 study is at 8 years; DFS for AIEOP study is at 5 years; DFS for MRC AML 10 Trial is at 7 years; DFS for POG 8821 is at 3 years.
†MRC AML 10 compared auto-HSCT versus no further chemotherapy. Although fewer relapses were observed in the allo-HSCT group (p = .02), overall survival was not different. In addition, there was no overall survival advantage observed with any of the treatment groups.[60]

**TABLE 20-5. ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION (HSCT) COMPARED TO CHEMOTHERAPY IN CHILDREN WITH ACUTE MYELOGENOUS LEUKEMIA (AML)**

***Autologous Hematopoietic Stem Cell Transplantation***

Attempts to avoid the impact of GVHD but provide stem cell rescue after hematopoietically ablative therapy have included performing autologous transplantation (auto-HSCT) using bone marrow or peripheral blood stem cells.[263,264,327,328,329,330,331,332,333,334,335,336,337] and [338] Several advantages of auto-HSCT include potentially less transplant-related mortality, the lack of acute and chronic GVHD, and the availability of donor cells for most patients. However, the lack of GVL and the potential for returning leukemic cells contaminating the donor bone marrow or peripheral blood stem cells may be significant disadvantages. [339] Genetic marking studies have shown that leukemia cells contaminating bone marrow can contribute to relapse.[340,341] And though *ex vivo* treatment of the autologous stem cell source by MABs or cytotoxic agents has been used, definitive studies that such an approach truly impacts on the extent of relapse are currently needed.

The results for auto-HSCT in adult studies have tended to show an increased RFS compared to nonablative chemotherapy but inferior to HLA-matched HSCT.[299,342,343,344,345,346,347,348,349] and [350] The improvement in survival with auto-HSCT in adults may in part be that intensification can be tolerated with stem cell rescue on a one-time basis, but that sequential, intensified chemotherapy is not as well tolerated. [351] The MRC AML 10 trial showed an advantage for autologous HSCT over no further treatment, but did not directly compare auto-HSCT with another course of chemotherapy.[325]

Several randomized pediatric trials have been completed and analyzed by intent to treat.[60,264,324,325,347] These studies have shown no significant benefit in DFS or EFS for auto-HSCT compared to postremission chemotherapy in these trials. This lack of a significant advantage is in part due to the increased efficacy of intensification for chemotherapy only, but may also be due to the fact that residual leukemia cells are present in the autologous graft as well as to treatment-related mortality during transplantation. The lack of a significant immune-mediated antileukemic response accompanying auto-HSCT or chemotherapy may partly explain the advantage of allogeneic HSCT over these other treatment modalities. Clearly, the ability to generate such responses in the setting of auto-HSCT or postremission chemotherapy would potentially enhance the efficacy of these treatments without the higher incidence of treatment-related morbidity and mortality commonly associated with allogeneic HSCT.

Several conclusions can thus be made in terms of therapy for patients with AML. Dose intensification and supportive care measures have significantly contributed to improved outcomes. Comparison of the most successful approaches to date show that there are several therapeutic strategies that result in similar outcomes as long as significant dose intensification is part of the treatment ( Table 20-6). Although the CCG-2891, LAM-89/91, and the MRC AML 10 studies all use a relatively short duration of therapy, the BFM studies continue to employ longer periods of therapy. In each of these studies, intensification with high-dose AraC appears to an important component. In addition, the escalation of anthracyclines was particularly notable in the MRC AML 10 trial ( Table 20-7). Although the results of the MRC AML 10 trial are excellent, the issue of increasing the cumulative anthracycline dose to such an extent is of concern, especially in very young patients. However, despite dose intensification and the introduction of other chemotherapeutic agents, the primary cause of death in patients with AML remains leukemia.

| Study | Complete remission rate (%) | Patient number | Event-free survival (%) (yr) | Overall survival (%) (yr) |

**TABLE 20-7. COMPARISON OF CHEMOTHERAPEUTIC DOSES IN DIFFERENT PEDIATRIC TRIALS**

Another important lesson from these large clinical trials has been the demonstration that certain subgroups of patients require alternative approaches. For example, outcome is still extremely poor for patients with AML with monosomy 7 or secondary AML.[193,352,353] and [354] Alternatively, patients with DS have improved outcomes with less intense chemotherapy regimens that do not include allogeneic bone marrow transplantation. [59,61,192,193,352,353,354] and [355] Patients with APL have a much improved outcome with the use of ATRA.[356,357] This type of risk group classification is just the beginning of defining subtypes of AML that will be able to be therapeutically targeted based on biologic characteristics.

### Central Nervous System Prophylaxis and Extramedullary Disease

Before the introduction of CNS prophylactic treatment in pediatric patients with AML, the incidence of CNS involvement was reported in the 20% range. [289,358,359 and 360] Most patients who experience a CNS relapse of AML also develop a bone marrow relapse. The highest incidence of CNS leukemia is observed in patients with very high peripheral leukemic blast counts and in M4 or M5 AML subtypes.[358,361] Although pediatric randomized trials have not been performed in terms of patients receiving or not receiving CNS prophylaxis, essentially all treatment protocols or clinical trials include CNS prophylaxis with either intrathecal AraC and methotrexate. The resulting incidence of CNS relapse has been reduced to approximately 5%. [240,263,270,359]

BFM studies have provided an interesting observation on the use of CNS prophylaxis. The BFM-83 study used cranial radiation and intrathecal methotrexate as CNS prophylaxis and observed a similarly low incidence of CNS leukemic relapse. [362] The BFM-87 study attempted to eliminate cranial radiation in low-risk patients by randomizing one group to receive only intrathecal AraC; both groups received high-dose systemic AraC in the postremission period. High-dose AraC treatment results in therapeutic levels of drug in the cerebrospinal fluid. The results showed no significant difference in the incidence of CNS relapses in the two groups, but a higher incidence of systemic incidence in the group of patients who did not receive cranial radiation. [363] These results remain enigmatic, but suggest that the delivery of cranial radiation decreases the chance of later systemic relapse. In contrast to pediatric studies and practice, most adult trials do not include CNS prophylaxis; the incidence of CNS relapse is in the 5% to 10% range, usually associated with systemic relapses.

The occurrence of extramedullary disease in AML usually takes the form of chloromas, which are more commonly observed in patients with M4 and M5 subtypes. Chloromas occur in approximately 10% of patients with AML overall. On occasion, patients may present with an isolated chloroma, but in such situations, systemic disease will become manifest if systemic treatment is not used.[156,164,364] A report from the CCG demonstrated that the EFS was not different for patients who received local radiation treatment to a chloroma in addition to systemic therapy compared to those who received only systemic treatment. In addition, there was no increased incidence of local recurrence at initial sites of chloroma involvement in patients receiving radiation therapy compared to those who did not. [365] In circumstances in which a chloroma may cause significant morbidity, such as loss of vision or spinal cord compression, emergency radiation therapy is usually used. [366,367]

### Acute Promyelocytic Leukemia

APL can be distinguished from other subtypes of AML by virtue of its excellent response and overall outcome as a result of differentiation therapy with ATRA. The PML/RARA fusion protein, resulting from the t(15;17) chromosomal translocation, functions to recruit protein complexes that serve to repress transcriptional activity of different genes. By binding to this fusion protein, ATRA causes a partial release of the repressor complex that results in the expression of genes leading to cell maturation and ultimately apoptosis.[368,369,370 and 371]

When administered as a single oral dose of 45 mg per $m^2$, ATRA achieves peak plasma concentration between 1 to 2 hours with median peak plasma concentrations between 300 to 400 ng per mL.[372,373 and 374] This concentration range is one in which *in vitro* differentiation is induced. The initial trials using ATRA for patients with APL were performed in Shanghai in 1986 with dramatic responses observed.[375] Subsequent studies have confirmed the activity of ATRA in APL patients, with CR rates of greater than 90% being obtained in some studies.[376] CRs achieved with ATRA usually require approximately 5 to 6 weeks of treatment, which is similar to that observed using conventional chemotherapy.[377,378,379,380 and 381] However, remissions obtained using ATRA occur without bone marrow aplasia. Despite the impressive CR rates obtained with ATRA alone, remission duration is relatively short (approximately 3.5 months). [382,383] These results have prompted the use of ATRA followed by postremission chemotherapy, resulting in leukemia-free survival of approximately 71% at 36 months. [379,380 and 381,384,385]

The French APL Group study randomized patients to receive ATRA or chemotherapy with AraC plus daunorubicin. [386,387 and 388] Patients randomized to initial treatment with ATRA received the same chemotherapy when they achieved a CR or earlier for specific levels of leukocytosis. Approximately one-third of patients in the ATRA group received chemotherapy with ATRA initially for WBC greater than or equal to 5,000 per mL and another one-third had chemotherapy added for a rising WBC count. All patients who achieved remission received two consolidation courses of the same chemotherapy. The EFS at 1 year was 83% in the ATRA group compared to 50% in the chemotherapy group ($p$ = .0001). The estimated risk of relapse at 1 year was 13% versus 41% ($p$ = .0006), and survival at 1 year was 91% versus 74% ($p$ = .01) in favor of the ATRA arm.

The North American intergroup trial randomized patients to receive oral ATRA at 45 mg per $m^2$ per day or standard induction chemotherapy with AraC and daunorubicin.[385] All patients who achieved CRs received two courses of consolidation chemotherapy. All patients continuing in remission were then randomized to observation or ATRA maintenance with 45 mg per $m^2$ per day for 1 year. The results from this study showed estimated rates of overall survival at 3 years from entry into the study of 50% for patients who received induction chemotherapy compared to 71% for patients who received induction therapy with ATRA ( $p$ <.001). The overall survival rates by intention to treat showed a similar advantage to the group receiving ATRA, with overall survival being 50% for those assigned to chemotherapy compared to 67% for those assigned to receive ATRA ($p$ <.003).

Two other studies have evaluated induction therapy with the combination of ATRA plus an anthracycline (IDA) without AraC. Estey et al. [389] used ATRA at 45 mg per $m^2$ per day until CR and IDA, 12 mg per $m^2$ per day, on days 5 to 8. CR was achieved in 30 of 39 patients (77%). A larger trial treated 185 patients with untreated APL with ATRA, 45 mg per $m^2$, plus IDA, 12 mg per $m^2$, on days 2, 4, 6, and 8. One hundred fifty-six patients were evaluable for response: ten patients (6%) died within the first week, and the remaining 146 (94%) patients all achieved remission with no cases of resistant leukemia. [390]

Although the introduction of ATRA during induction therapy has not been shown to significantly reduce the risk of severe hemorrhagic complications, the overall induction rate is improved to more than 90%.[385] In addition, maintenance therapy with ATRA has been shown to significantly reduce the incidence of relapse and improve overall survival.[391] These data have thus led to the recommendation of using ATRA during induction and maintenance therapy in the postremission period. [391] Responses and overall results are similar for children and adults, thus showing that in the case of APL, the presence of the t(15;17) translocation is a key therapeutic target. This point is particularly well illustrated by the lack of a significant response in less common variants of APL, including those characterized by the t(11;17) translocation.[146] In addition, some forms of resistance to ATRA may arise from mutations in the PML/RARA fusion protein. [392]

There is also a growing body of data that suggests that the addition of 6-mercaptopurine and methotrexate to ATRA during maintenance therapy may improve overall survival.[393] Additional prospective randomized trials are needed to definitively prove the utility of these other agents in combination with ATRA. Although ATRA provides an important benefit to patients with APL, there are significant side effects that may be associated with its use, some of which, like pseudotumor cerebri, are more frequently encountered in children.[394,395] The acute development of pulmonary edema, also called *ATRA syndrome*, can be a devastating complication that occurs in children and adults. Early diagnosis and treatment with dexamethasone is imperative. [394]

Another important contribution to the treatment of patients with APL has been the introduction of arsenic trioxide, again initially introduced by Chinese investigators. [396] The use of arsenic has been shown to be able to rescue patients who become resistant to ATRA. [397,398] The addition of arsenic to ATRA appears to be synergistic both in an animal model for APL as well as in some patients.[370,397,399] Arsenic trioxide appears to function by inducing differentiation of promyelocytes leading to their death through apoptosis.[370] Randomized clinical trials are ongoing to help determine how best arsenic can be utilized in the treatment of patients with newly diagnosed APL. There are concerns of safety in children exposed to arsenic, particularly to the developing nervous system. Therefore, this promising agent should be carefully studied in children, especially in those who are very young.

### Down Syndrome and Acute Myelogenous Leukemia

Children with DS have an increased risk of developing acute leukemia. Although older studies estimated the excess risk to be three- to 100-fold, more recent studies estimate the risk to be ten- to 20-fold increased.[54,55] Past analysis of leukemia incidence in children with DS have suggested the ratio of lymphoid to myeloid leukemias is approximately 4:1.[54,55] However, a significant number of these cases in children younger than 2 years of age with DS are now known to be due to acute megakaryocytic leukemia (M7 AML), which can be morphologically difficult to distinguish from FAB L2 ALL. In contrast to the rare occurrence of megakaryocytic leukemia in children without DS, M7 AML is now recognized as the most common form of AML in very young children with DS.[400] Overall, children with DS are estimated to have a 400-fold increase in their risk of developing megakaryocytic leukemia. [401]

Children with DS and AML have been shown to have a superior response to AML therapy compared to other children with AML. Initial reports from the CCG reported 20 children with DS and AML treated on CCG studies between 1972 and 1984.[402] These children did not have a worse outcome as measured by EFS ($p$ = .66), survival ($p$ = .17), or RFS ($p$ = .70) in comparison to non-DS children with AML. CCG 251 enrolled 15 children with DS and AML (total enrollment, 508).[233] Patients received doxorubicin (or daunorubicin) (30 mg per $m^2$) for 3 days and AraC (100 mg per $m^2$) for 7 days, with remission achieved in 13 of 15 patients.

CCG reported to the American Society of Clinical Oncology in 1990 results from the CCG-213 study. At that time, 78% of 39 patients with DS were surviving in contrast to 38% of 683 non-DS patients with AML, indicating that DS patients had an improved outcome.[403] The POG reported the results of POG 8821 at the 1992 Societe Internationale d'Oncologic Pediatrique (SIOP) XXIV meeting. Twenty-four children with DS received therapy with daunorubicin, AraC, and 6-TG (DAT), followed by high-dose AraC and subsequently by etoposide and 5-azacytidine. Remission was achieved in 20 of 22 patients. Nineteen of 20 patients were reported to be alive in clinical remission with one death due to infection. The POG subsequently published results of POG 8498, which included 12 patients with DS.[59] Induction therapy again consisted of DAT for two cycles. All 12 patients entered remission, with EFS reported to be 100%. Induction success for DS patients was significantly dependent on treatment intensity in the CCG 2891 study. CR rates for DS patients were 93% and 62% on the standard and intensive timing arms, respectively. The failure to achieve CR with intensive timing induction was a result of treatment-related mortality (33%) rather than persistent disease (5%), whereas the reduction in intensity did not increase CR failure due to disease persistence.

Evaluation of postinduction therapy on the CCG-2891 study produced similar results. For DS patients in CR after induction, postinduction therapy using allogeneic bone marrow transplant resulted in a 67% RFS (at 2 years), whereas the use of high-dose AraC (Capizzi) intensification resulted in 91% RFS at 4 years. This is compared to 86% and 52%, respectively, in the non-DS population. These values reflect RFS from end of induction (EOI). There were 1 (2%) and 12 (5%) toxic deaths among patients with DS and non-DS patients, respectively, during this phase of therapy ( $p$ = .68), indicating the postremission intensification phase was relatively well tolerated by the DS patients. Combined, intensive timing induction and bone marrow transplantation resulted in excessive toxicity such that the 5-year EFS for DS patients was approximately 69%. However, with standard timing induction followed by high-dose AraC, the EFS was 88% for patients with DS at 5 years.

### Transient Myeloproliferative Disorder

TMD is a disorder found in patients with DS during the newborn period. It is characterized by an uncontrolled proliferation of myeloblasts. Evaluation of these blasts has revealed them to be of megakaryocytic origin with varying degrees of differentiation and to be clonal in nature.[404] Information regarding the presentation and natural course of this disease has been based solely on a small series of patients and is limited, with no population-based studies yet performed. This disorder is distinguished from congenital AML primarily by its spontaneous resolution within the first 3 months of life. Recommendations currently are for supportive care only. Hayashi et al.[405] compared DS patients with TMD to those with AML (M7). In this relatively small group of patients, those with TMD had lower blast percentages in their bone marrow than in their peripheral blood. Patients with AML had clonal cytogenetic abnormalities, whereas none were seen in patients with TMD.

TMD may result, however, in significant morbidity and mortality, with some children presenting moribund at the time of birth with severe hydrops fetalis. Organ infiltration, primarily hepatic, may be severe, progressive, and fatal. Of 13 severely affected patients with TMD, reviewed by Zipursky et al.,[406] five were stillborn, and two died later of their disease. Nine of the 13 presented with hydrops fetalis, and four others had hepatosplenomegaly along with pericardial, pleural, and peritoneal effusions. Hydrops in these patients has been ascribed to severe anemia (not often present) or to cardiac dysfunction secondary to tissue infiltration by leukemic blasts, or both. Causes of death also include DIC, renal failure, or hepatic failure, typically occurring in the first few months of life. Although the true incidence of TMD is unknown, Zipursky has estimated the incidence of severe TMD in DS patients to be as high as 10%.[404,407]

It is known that some of these patients go on to later develop acute leukemia (AML or ALL).[408] Lu et al.[409] found that 9 of their 43 (21%) DS patients with M7 AML had a preceding history of TMD. In a review of case reports from the literature, Zipursky identified 7 of 27 (26%) TMD cases who eventually developed acute leukemia. In a subsequent review, 30% of 62 cases of TMD, identified in a questionnaire survey, went on to develop leukemia in the first 3 years of life.[404,410] An important point to keep in mind is that current estimates may be falsely high due to reporting bias. TMD may sometimes require treatment with exchange transfusion or low-dose cytoreductive therapy.

## PROGNOSTIC FACTORS

AML is a collection of related diseases that are heterogeneous in their etiology, pathogenesis, genotype, and phenotype and in response to therapy. Since the 1980s, many studies have attempted to define particular subsets of patients whose treatment could be more precisely targeted to the subtype of AML or to host and disease characteristics. The results from such studies have not been entirely consistent, which may, in part, reflect the manner in which various characteristics are defined, the differing numbers of patients examined in particular studies, as well as differences in the age of patients and types of treatment used. More recently, data obtained concerning cytogenetic and molecular characteristics have started to complement the more traditional variables such as demographics, host characteristics, and disease presentation. It should be kept in mind that prognostic factors are inherently determined in part by the treatment that is used.[411]

### Demographic, Host, and Disease Predictors of Response

Several studies in adults with AML have helped to define several favorable characteristics for patients achieving an initial CR.[412,413 and 414] Some of these characteristics include being younger than 60 years old, absence of secondary AML, a WBC of less than 100,000 per µL, as well as specific chromosomal abnormalities such as t(8;21) or inv(16).[154,193,415,416,417 and 418] In addition, patient characteristics have been defined in terms of their impact on predicting the duration of remission with younger age (younger than 18 years); absence of secondary AML; and chromosomal abnormalities, such as t(8;21), inv(16), and t(15;17), contributing favorably to a longer remission.[413,418,419 and 420] FAB classification has suggested that patients with M1 with Auer rods, M3 or APL, and M4 with eosinophilia have a better outcome.[421,422 and 423]

In the CCG 213 study, adolescents older than age 15 years were shown to have a poor outcome.[320,424] In some of the relatively early trials, infants were reported to respond less well than other children to therapy. For example, in CCG 251 and 213 studies, infants with monoblastic leukemia were shown to have a poorer prognosis than other patients.[320] In addition, infants younger than 1 year of age had a worse outcome than those age 1 to 2 years. In contrast, studies from POG showed that patients younger than age 2 years had a favorable outcome.[297] Of interest, infant leukemia of the M5 FAB type is often associated with translocations involving the 11q23 chromosomal region, which is similar to that observed in podophyllin-induced leukemia.[425] Such secondary AML cases usually have an unfavorable outcome with conventional therapy.

In CCG cross-study analyses, there has been a strong suggestion that non-white patients have a lower induction and EFS rate; this trend achieved significance for patients of Hispanic origin. In CCG 251, 213, and POG 8498, children with DS constitute a group with a significantly better outcome.[59,151,426] CCG 2891 has confirmed this favorable prognosis for DS patients with AML and further demonstrated that less intensive therapy results in an improved outcome.

The role of FAB classification and immunophenotyping with outcome measures has been controversial for pediatric patients.[427,428 and 429] Whereas several studies have shown that monoblastic leukemia portends an unfavorable prognosis, some CCG studies have found that M5 morphology is unfavorable only in infants.[320,421,430] In addition, although most patients with FAB M6 and M7 morphologic subtypes have an overall reduced EFS, young patients with DS and M7 AML have a significantly improved survival.[59,61,431]

Tumor burden and sites of involvement have been shown to correlate with prognosis in multiple studies. In CCG-251 and CCG-213, a WBC of greater than 100,000 per µL was unfavorable.[320] Patients with CNS disease at diagnosis have been reported to have a higher risk of early bone marrow relapse or recurrent CNS disease, or both.[432] Review of CCG patients with isolated chloromas has shown a greater survival compared to those with chloroma and marrow disease. In patients with WBC less than 20,000 per µL, those with chloromas had an improved 5-year EFS compared to others; but for patients with WBCs greater than 20,000 per µL, no difference in 5-year EFS was observed.[365] Radiation therapy did not change the EFS. An important issue to determine will be whether patients with isolated chloroma and low tumor burden may define a unique subset of AML that needs less intensive therapy.

Although chromosomal abnormalities have been reported to correlate with outcome in adults with AML, the same differences have not always been observed in pediatric patients.[415,433] For example, adult patients with t(8;21), inv(16), or t(15;17) (with or without other cytogenetic abnormalities) have been shown to have a

favorable prognosis. An intermediate risk group had AML characterized by trisomy 8, trisomy 21, or t(6;9) with or without other cytogenetic abnormalities. A poor prognosis group has been identified as having AML with t(9;22) or –7 or del(7) or del(11) with or without other cytogenetic abnormalities. [378,415,434]

Results in pediatric trials have not consistently reported a significantly better prognosis for patients with these "favorable" chromosomal abnormalities. SJRCH and the CCG-213 study have reported that patients with t(9;11) and inv(16) abnormalities have an improved outcome. [154,435] Although quite interesting, such results need confirmation in larger, prospective trials. The CCG reported that leukemias with t(8;21), +8, and t(15;17) have improved induction percentages, but that long-term survival was not significantly better. [436] Overt leukemias (in contrast to MDS) with –7 or 7q– show both a reduced remission induction rate as well as an overall worse prognosis of below 20% EFS.[437] In addition, the presence of a t(15;17) translocation clearly defines a group of patients who will significantly benefit by therapies containing ATRA.[437,438 and 439] Studies from POG have demonstrated an improved EFS in patients with inv(16) and t(8;21) of approximately 60% and 45%, respectively, but a worse EFS (approximately 20%) for patients with 11q23 abnormalities. [193] Overall EFS, however, was approximately 35%, which is less than other more recent studies.[193,440] Thus, though cytogenetic analysis may not absolutely define a "very good" prognosis group in pediatric patients with AML, there is considerable evidence that certain chromosomal changes are strongly correlated with extremely poor-prognosis AML.

The prognostic significance of the differentiative state of leukemic blasts has also been extensively examined through the use of cell surface markers, including those representing lineage infidelity such as B- and T-lymphoid antigens. [441,442] Although several studies have claimed that the presence of lymphoid markers on AML blasts represents a poor prognostic variable, this observation has not been unequivocally confirmed. In CCG-251, increased expression of the CD33 myeloid differentiation antigen was associated with a poorer outcome.[436] However, in the subsequent CCG-213, neither CD33 or other surface antigens were found to be of prognostic value. This might have been due to the more aggressive treatment regimen in the CCG-213 trial. [436] Recent CCG studies have identified a leukemia surface antigen, which is recognized by MAB 7.1.[443] The 7.1 MAB has been shown to detect the human homologue of the rat NG2 chondroitin sulfate proteoglycan molecule previously shown to be expressed on human melanoma. The expression of the NG2 molecule in childhood AML was associated with a poor outcome and with some, but not all, cases with 11q23 rearrangements.[418,443] Confirmatory studies should be done to define the expression of this marker with prognosis. The flt-3 receptor, a type III tyrosine kinase receptor, plays an important role in survival and expansion of cells of the myeloid lineage. [444,445 and 446] In approximately 20% to 30% of AML, this receptor is mutated and has an intracytoplasmic tandem duplication or activating single amino acid mutations. These activating mutations have been strongly correlated with a poor outcome in patients with AML.[447,448 and 449]

Since the identification of the multidrug resistance (MDR) P-glycoprotein as a mechanism of chemotherapeutic drug efflux and a cause of tumor cell resistance to specific cytotoxic agents, many studies have examined the expression pattern and potential role of this pathway in AML. [198,199,450] The expression of the MDR P-glycoprotein gene, especially in conjunction with CD34 antigen expression, has been strongly correlated with a poor prognostic group of adult patients with AML.[451,452,453,454,455,456 and 457] Such patients often have relapse or refractory disease or secondary AML. Although both MDR P-glycoprotein and CD34 are expressed on the leukemic blasts in a significant number of pediatric patients with AML, a similar correlation with poor prognosis has not been consistently observed. [458] Although the MDR P-glycoprotein system has been the subject of extensive analysis, it is also clear that other mechanisms of drug resistance function in tumor cells, including those of AML.[198,199,459] Other mechanisms of drug resistance that may have particular importance in AML include the MDR-associated protein, the lung resistance protein, and nucleoside transporters and metabolic pathways. [459,460] Thus, the expression and function of MDR P-glycoprotein and related drug transporters in pediatric AML as prognostic factors or as therapeutic targets remain an important area for further investigation.

More information is also accumulating on the expression and function of a variety of gene products involved in cell proliferation and apoptosis in AML blasts. [93,200] Gene products, such as Ras, are now known to play important roles in the development of AML as well as in the proliferation and survival advantage of AML blasts.[461,462,463 and 464] For example, the importance of Ras is evidenced by the predisposition of patients with NF-1 to develop AML and particularly monosomy 7 and juvenile myelomonocytic leukemia.[465,466,467,468,469 and 470] Patients with NF-1 have a genetic defect in the NF-1 gene that encodes a protein, neurofibromin, which normally accelerates the conversion of active Ras-GTP to inactive Ras-GDP. Decreased neurofibromin activity results in constitutively activated Ras protein, which in turn results in signaling through the MAP kinase pathway leading to cell proliferation. In a mouse NF-1 knock-out model, an increased incidence of myeloid leukemia is observed when the hematopoietic precursors from NF-1 null embryos are transplanted into syngeneic adult animals and particularly after exposure to alkylating agents.[471,472 and 473]

The expression of genes involved in apoptotic pathways has also been examined in leukemia and a variety of other malignancies. [93,200,474] For example, increased expression of bcl-2 has been associated with the decreased ability of a cell to undergo apoptosis and increased resistance to chemotherapeutic or radiation-induced genotoxic damage.[475,476 and 477] The expression and function of other tumor suppressor genes, such as p53, have been correlated with increased resistance to genotoxic agents.[478,479] Several reports have shown that high levels of expression of the Wilms' tumor gene (WT1) is associated with a worse long-term prognosis in AML and that its expression might be used to detect MRD.[480,481 and 482] Genes involved in DNA repair, cell cycle control, proliferation, differentiation, and apoptosis should become increasingly important, not only in terms of diagnosis and risk group stratification, but also as potential therapeutic targets.

Studies in adult and pediatric patients with AML have therefore begun to delineate particularly high-risk, as well as what might be considered better risk, groups. Currently available information has clearly shown that certain groups of patients [e.g., patients with DS and AML or patients with t(15;17) APL] should be treated on separate trials to address unique clinical and biologic features. However, for the remaining pediatric patients with AML, it is much less clear that there is a very good prognosis group that would benefit by decreased therapy. In contrast, other patients may constitute particularly poor prognosis groups, such as AML with monosomy 7, very high WBC at presentation, or secondary AML. Because of small numbers of patients in such subgroups, it may prove very difficult to generate statistical significance for randomized therapeutic comparisons. However, so-called "very high-risk" patients may provide an opportunity for single-arm studies designed to improve outcomes through testing novel therapeutic approaches, including alternative HSCT regimens or targeted cytotoxic agents, as well as further defining the biology of AML subtypes. These studies could also be developed as international trials to accrue larger numbers of patients. Critical to the success of future outcomes will be the close linkage of cellular and biologic studies aimed at identifying risk group characteristics and new therapeutic targets as part of all experimental clinical trials.

**Response to Therapy and Minimal Residual Disease**

The response to initial chemotherapy has proven to play an important role in patients with ALL. [483,484,485 and 486] Although it is likely that the initial response to therapy in AML may also be predictive of outcome, definitive data are currently lacking. The results of intensive timing (e.g., CCG 2891 induction) show that the initial treatment and the resulting quality of remission can predict subsequent outcome. To this end, the response to therapy on day 7 and 14 bone marrow examinations has been reported to predict subsequent outcome.[268] Such data would suggest that level of MRD, both early on during therapy as well at later times, has important consequences for ultimate outcome.

The development of additional methods to accurately detect MRD below the sensitivity level of light microscopy or classical cytogenetic analysis would aid in the ability to test the hypothesis that a certain level of MRD predicts inevitable relapse in AML. The ability to predict patients at highest risk for relapse due to residual leukemia at different stages of therapy would potentially allow alternative treatment interventions.

Several approaches for the detection of MRD have been developed. [114,115,487] The criteria by which such methods are judged must include (a) a strong positive predictive level that is not based just on a statistical probability but is directly related to the presence of residual leukemia; (b) a strong negative predictive value, indicating a high level of specificity and minimizing the number of uncertain results; (c) a high level of applicability so that it can be applied across different subgroups of patients; (d) a rapid turnover of results so that alternative clinical interventions could be made in a timely fashion; (e) cost effectiveness; (f) reproducibility; and (g) availability.[114,115,487] Although no currently available test for MRD perfectly satisfies all these criteria, several methods are available that are likely to be adequate to definitively address the role of MRD in predicting relapse.

The growth characteristics of various AML blasts *in vitro* have been extensively studied, and the outgrowth of colony-forming unit-blast colonies can be observed in agar culture systems. However, this type of approach is methodologically complex and often extremely difficult to quantitatively reproduce. [488,489] Another approach has been to expand residual leukemic cells in immunodeficient mice.[91,92] Several reports have demonstrated that this is possible from relatively small numbers of cells, but these assays are quite laborious, expensive, and the results remain difficult to quantitate. Although the use of FISH methods for the detection of specific chromosomal abnormalities has proven particularly useful, this approach also suffers from not being universally applicable to many patients with AML. [490,491 and 492] In addition, it requires the short-term culture of cells from patients before analysis. The sensitivity of this method to detect specific abnormalities (e.g., trisomy 8) has been

estimated to be approximately $1 \times 10^{-1}$ to $1 \times 10^{-2}$.[114,115,487]

Use of PCR to detect chromosomal rearrangements or resulting chimeric transcripts has provided an extremely sensitive approach to detecting MRD.[114,115,487,493] A disadvantage of this approach, however, is that an informative DNA alteration or transcript must be present in the leukemic blasts. One of the first models developed using this approach has involved detection of the t(9;22) bcr-abl gene fusion associated with CML. Several studies have shown that persistence of the t(9;22) translocation strongly predicts relapse.[494,495,496,497 and 498] There has also been data showing that persistence of the t(15;17) fusion transcript in patients with APL results in a high likelihood of relapse.[499,500,501,502,503,504 and 505] The detection of t(8;21) fusion transcripts has been observed in patients who have been in remission for many years, suggesting that this particular translocation may represent an early event but one not sufficient to produce true leukemia.[506,507,508 and 509] However, a recent report has argued that t(8;21) transcripts do disappear in patients posttreatment who remain in remission.[510] Work on other chromosomal abnormalities, such as inv(16) and 11q23, remains preliminary but may also be complicated by the fact that abnormalities at these locations may be complex and quite heterogeneous, making the application of PCR or RT-PCR methods more difficult.[511,512]

A further important use of PCR or RT-PCR is the detection of mutated genes such as Ras. Mutations in Ras have been observed in greater than 25% of AML in adult and pediatric patients.[496,513,514 and 515] However, though Ras mutations may play a role in the evolution of some cases of AML, it has been observed that relapse samples do not always have the same mutation as in initial diagnostic specimens or may not even show any mutation.[496,513,514 and 515] Thus, because of the apparent instability of Ras mutations as well as their presence in only a percentage of AML, they may not prove to be the best clinical assay for predicting relapse. The expression of WT1 transcripts in leukemia has also been suggested to be potentially useful as a marker for MRD.[481,482,516,517] It has been estimated that approximately 77% of AML cases express WT1 transcripts. However, the FAB subtype of M5 was positive for WT1 expression in only approximately 40% of cases studied.[518,519] Although WT1 is normally expressed at highest levels in the developing kidney, it has also been shown to be transiently expressed during differentiation of normal CD34+ progenitors.[480,481,518] Thus, the expression of WT1 in AML may be in part explained from its transient expression in the normal progenitor compartment. Further work is needed to determine whether WT1 is a useful marker for detecting MRD and predicting relapse for patients with AML.

Another approach being used by several groups is that of multiparameter flow cytometric (MFC) detection of aberrant surface antigen expression on AML blasts.[114,115,487,520,521] MFC is able to simultaneously measure multiple inherent variables, including cell size, granularity, and the expression of several cell surface antigens. By selecting specific sets of parameters, the examination of immature leukemic blast cells can be detected. Using this methodology, it has been estimated that the detection of leukemic phenotypes can be achieved at a sensitivity of approximately $10^{-3}$ when at least 30,000 nucleated cells are counted. Several studies have demonstrated that up to approximately 85% of patients with AML have leukemic blasts with characteristics that are able to be distinguished from normal progenitors by MFC. One potential problem with MFC analysis of residual disease is the possibility of alterations of specific antigen expression patterns, which could give rise to false-negative results.

MFC detection of MRD in AML may be a practical means by which to detect MRD. Wormann et al.[522] used MFC in 45 adult patients with AML and were able to detect residual leukemic cells (defined as greater than 0.5% of aberrant antigen expressing cells) after morphologic remission in approximately two-thirds of the patients, with more than one-half of that group showing relapse within 1 year. A retrospective study of children with AML examined a total of 205 serial bone marrow specimens for the presence of residual leukemia in 39 children who had achieved morphologic remission during their course of treatment for AML and compared these results with the subsequent occurrence of relapse. MFC analyses were performed on bone marrow specimens collected at diagnosis, at the EOI, before and after consolidation, and at the end of treatment.[115,487] At the EOI, leukemic cells manifesting an aberrant constellation of surface antigens were identified in the majority of patients (64%) that achieved morphologic remission. Of the 17 patients with residual leukemia that did not receive an allogeneic bone marrow transplant during first CR, all experienced relapse (median, less than 6 months) with the exception of a child with DS. For seven patients with residual leukemia who received a bone marrow transplant, only one relapsed. Evaluation of multiple samples obtained during remission using a time-dependent Cox regression analysis, which controlled for age, sex, morphologic classification, and WBC at diagnosis, showed an estimated risk of relapse during MFC-positive intervals to be 2.8 times greater than during MFC-negative intervals (95%; confidence interval 1.1 to 7.0; $p = .02$). Another study of MRD using MFC has, in addition, shown that that the presence of MRD at the EOI or consolidation was highly correlated with an MDR P-glycoprotein phenotype and relapse, even after an auto-HSCT.[521] Based on such results, future translational research plans should be to further test the role of MFC in detecting MRD at specific time points during the course of therapy and determining the predictive value of this approach.

Although prognostic variables may thus change with the effectiveness of treatment, they can be useful in the identification of patients who can be stratified to specific targeted therapies at diagnosis or, potentially, at different times during treatment. The importance of future genomic-based methods to stratify patients according to predictive molecular features should offer even further capabilities for prognostication and risk-directed therapy.

## TREATMENT OF PATIENTS WITH REFRACTORY/RELAPSED ACUTE MYELOGENOUS LEUKEMIA

Until therapeutic regimens are significantly improved in patients with newly diagnosed AML, the systematic development and testing of new strategies in patients with relapsed or treatment-refractory AML, or both, will continue to be critical. This is particularly relevant in that whereas 75% to 85% of patients with newly diagnosed AML initially achieve a remission, less than 50% are long-term survivors.[523,524,525,526,527 and 528] Patients with relapsed or refractory AML usually respond less well and for shorter duration to reinduction therapies.[336] This clearly relates to the induction of drug-resistant mechanisms and is, in part, related to specific chromosomal abnormalities and the duration of the first remission. The long-term survival for such patients is poor and considered to be less than 20%.[523,529] Outcome in part depends on the time to relapse. For example, patients who relapse on therapy, take a longer time to achieving remission (longer than 50 days), or experience a CR of less than 6 months from diagnosis, have a poor prognosis, with survival at 5 years of less than 20%.[336,523] However, patients who have a CR of greater than a year, may have a 30% to 40% survival at 5 years.[336,523]

Although there is no standard therapy for patients who have relapsed or refractory AML, or both, most studies have demonstrated that the use of high-dose AraC-containing regimens have significant activity at inducing a second remission, even in patients who have previously received this agent at high doses.[525,527,530,531] Frequently, high-dose AraC is used in combination with other agents such as mitoxantrone, etoposide, fludarabine, or 2-chlorodeoxyadenosine.[531,532,533,534,535,536,537,538,539,540 and 541] In many cases, such as with fludarabine and 2-chlorodeoxyadenosine, the combination has been shown to produce synergistic effects.[542,543,544,545 and 546] When used with G-CSF, the fludarabine plus high-dose AraC combination is referred to as the *FLAG regimen* and has been shown to be a very active regimen at inducing remissions in patients with relapsed AML, with up to 70% success rate for patients with a CR1 of greater than 1 year.[536,537 and 538,540] Other data suggest that the addition of IDA to the FLAG regimen (Ida-FLAG) may produce more durable remissions, although significant toxicity may be experienced.[534,538,539,547] Similar results have been obtained with the use of sequential mitoxantrone and high-dose AraC.[525,548] The use of etoposide along with 2-chlorodeoxyadenosine has also been shown to have activity, particularly in monoblastic subtypes.[549] Several single agents have also been tested in patients with relapsed or refractory AML, or both, but the overall response rates and survival (15% and zero, respectively, at 5 years) are significantly lower than that seen with combination therapy (36% and 3% at 5 years).[550,551]

Patients with CNS relapse nearly always develop evidence for bone marrow or systemic disease. Treatment therefore should involve up to six courses of intrathecal chemotherapy (methotrexate or AraC, or both) followed by intensive chemotherapy. Most of these patients then go on to a hematopoietic stem cell transplant and often receive craniospinal irradiation.

In light of the poor results from the use of chemotherapy alone in patients with relapsed or refractory AML, or both, the use of myeloablative allogeneic transplantation is used whenever possible.[552] The type of preparative regimen has not been established.[553] Some centers use combinations of ablative chemotherapy and others use chemotherapy plus total body radiation.[316,554,555,556,557,558,559 and 560] Donors who are HLA matched (or with one antigen mismatches) provide for the best chances of engraftment and least chance of developing significant GVHD.[561,562 and 563] However, in the setting of relapsed AML, alternative sources of hematopoietic stem cell donors are commonly used, including bone marrow or blood as well as cord blood–matched unrelated donors.[564,565,566,567 and 568] By expanding the criteria for an acceptable donor, the majority of patients can usually be offered an allogeneic transplant.[569,570,571,572 and 573] In addition, the use of haploidentical donors provides a potential source of hematopoietic stem cells for essentially all patients.[574,575,576 and 577] As the HLA disparity increases between donor and host, the complications of treatment-related morbidity and mortality also increase significantly, although children appear to be able to tolerate HLA mismatching better than adults.[578,579] In most studies, treatment-related mortality may range from 30% to 50%.[562,571,573,580,581]

Although cord blood donor sources appear to have significantly reduced the risk of GVHD, there exist problems with engraftment as well as the lack of donor

lymphocyte availability for subsequent use to augment GVL effects.[582,583,584,585,586,587,588,589 and 590] The use of matched unrelated donors may result in a higher risk of GVHD, but a lower incidence of nonengraftment as well as a potential source of donor lymphocytes for subsequent use.[591] Haploidentical donor transplants have a significantly higher risk of severe GVHD and nonengraftment.[592] Although these problems can in part be overcome with T-cell depletion of the graft and the administration of immunosuppressive regimens, the risk of severe immunodeficiency accompanied by fatal opportunistic infection or lymphoproliferative disease increase substantially.[593,594]

In spite of the problems associated with the use of allogeneic transplantation, this treatment modality can be effective for patients with relapsed AML, with DFS figures ranging from 20% to 50% for patients with AML, but considerably higher for patients with APL.[569,570,571,572 and 573] The results of hematopoietic transplantation for patients with APL in CR2 are closer to 70% survival.[595,596 and 597] Such results, in combination with the excellent outcome with chemotherapy plus ATRA in newly diagnosed patients, have led to the recommendation not to perform allogeneic transplantation for patients in CR1 with APL.

Another approach to avoiding some of the risks of allogeneic transplantation for patients with relapsed AML is to use autologous transplantation. As noted previously, although this approach has the advantage of not inducing significant GVHD, host cells do not offer a GVL effect either unless possible immunostimulatory approaches are used posttransplantation.[328,598,599 and 600] In addition, the potential for re-infusing leukemia cells with the graft is a proven risk and potentially exists even with attempts at purging leukemia cells.[328,601,602] Nevertheless, some trials have shown significant DFS in selected patients.[556,603,604 and 605]

There is thus a tremendous need for improved therapies for patients with refractory or relapsed AML. The long-term survival for the majority of patients with relapsed or refractory AML, or both, remains poor. This is primarily due to mechanisms of resistance to conventional chemotherapeutic-based treatments. Future challenges will be to develop methods to overcome these drug resistance mechanisms using strategies to inhibit resistance pathways or by the use of novel approaches that circumvent them completely.

## DRUG RESISTANCE MECHANISMS AND FUTURE THERAPIES

Drug resistance can be due to both pharmacologic and tumor cell mechanisms. Important pharmacologic factors contributing to treatment efficacy include drug dose, drug metabolism, and route of delivery.[198,199,606,607,608 and 609] Cellular factors can include (a) changes in drug uptake or drug efflux across tumor cell membrane or between cytoplasm and nucleus (transport mediated resistance), (b) changes in activation or inactivation of drugs within the tumor cell (metabolic resistance), (c) changes in targeted enzymes through altered levels of those targets within tumor cells or through altered affinity of cellular enzymes for the drug (target resistance), (d) changes in DNA repair processes, and (e) changes in the ability of tumor cells to execute programmed cell death or apoptotic mechanisms.[199]

Attempts to inhibit known cellular mechanisms of resistance have met with mixed success. For example, inhibition of the MDR P-glycoprotein drug efflux pump has produced equivocal results in some studies and some advantage in others in patients with AML.[199,607,610,611,612,613,614,615 and 616] In part, this may be due to the dose adjustments made to account for pharmacologic changes that the inhibitors produced as well as levels and type of the inhibitors used. Furthermore, it has become clear that there are multiple drug transporters that are likely not to be equally blocked by a specific inhibitor.[198] Thus, more selective reversal agents based on the expression of functional drug transporters in a patient's leukemia cells may be a useful approach for testing specific types of drug transporter–mediated resistance.[198,199,617]

Another powerful approach to therapy in leukemia takes advantage of MAB or ligand recognition of leukemia or hematopoietic specific surface antigens or receptors.[618] In AML, the primary targets thus far being tested include the CD33 lineage restricted differentiation antigen as well as the GM-CSF receptor.[618,619,620,621,622,623,624,625,626 and 627] In addition, the CD45 antigen has been targeted with radiolabeled MABs with the intent of delivering significant local radiation to the bone marrow while reducing the amount and, thereby, the toxicity of external beam radiation, during bone marrow transplantation.[622,628,629]

The use of the targeted immunotherapy with anti-CD33 MABs, alone or coupled with toxins or radioactive compounds, has proven to be effective therapy at inducing remission in approximately one-third of patients. For example, early phase studies with anti–CD33-calicheamicin immunoconjugates have demonstrated an approximately 37% remission rate in adults with relapsed AML.[618,627,630] A primary advantage of such targeted therapy is that it is directed at cells expressing a lineage-restricted antigen and thus avoids some complications such as mucositis. Thus, although significant periods of neutropenia and thrombocytopenia result from the use of anti–CD33-calicheamicin due to expression on normal hematopoietic progenitors, neutropenia without mucositis appears to be less morbid.[630] However, a significant incidence of hepatic damage, manifested usually by a transient transaminitis, is observed in approximately 25% of patients.[630] Occasional patients have experienced a clinically severe syndrome consistent with veno-occlusive disease. The etiology of the liver toxicity is unclear but may be due to leukemic cell killing in the liver, expression of CD33 on Kupffer cells, or the low level of free calicheamicin observed after the administration of the conjugate. Of additional interest has been the sometimes prolonged time to platelet recovery, resulting in a response criteria of remission without full platelet count recovery.[618,630] It also remains of interest why two-thirds of patients do not respond to this agent, as well as how to use it in conjunction with chemotherapy.

Other mechanisms of drug resistance may result from activation of specific anti-apoptotic pathways. These survival and resistance pathways may be induced as a result of alterations or mutations in genes encoding cytokine receptors (e.g., flt-3 receptor or c-Kit), signal transduction molecules (e.g., Ras), proteins involved in cell cycle progression and/or DNA repair (e.g., p53), or transcription factors (e.g., PML/RARA). Such changes can in turn lead to altered expression of additional anti-apoptotic pathways as in the increased expression of bcl-$X_L$.[631] The development of promising approaches to target such mutant receptors and signal transduction pathways are being actively pursued. For example, STI-571, a small molecule inhibitor of the bcr-abl tyrosine kinase found in CML, also has activity against other tyrosine kinase receptors such as c-Kit and platelet-derived growth factor.[632,633] Clinical trials with this agent are being performed in patients with relapsed AML. Additional compounds that more specifically target receptor mutations or downstream signal transduction pathways are also being developed.[634,635]

The proto-oncogene product, Ras, is mutated in approximately one-third of AML, and Ras-regulated signal transduction is known to play an important part in AML cell growth.[76] Studies have shown that for Ras to function, it must undergo a posttranslational modification, called *farnesylation*, which allows it to be attached to the inner cell membrane. The development of farnesyltransferase inhibitors that can be taken orally and achieve pharmacologically active blood levels have provided the grounds for the further development of this class of compounds in patients with AML.[636,637,638,639,640 and 641] Another interesting approach that is being tested in early phase trials is the use of antisense oligonucleotide inhibitors of bcl-2, a potent anti-apoptotic protein.[642,643,644 and 645]

The mechanisms by which chromatin structure and DNA modification alters gene transcription and subsequent pathways leading to leukemia and, likely, drug resistance, are just now being elucidated. For example, the role of histone acetylation and deacetylation have been demonstrated to play critical roles in transcription by alteration of the nucleosomal contacts with DNA.[646,647 and 648] In addition, the proteins involved in histone deacetylation, called *HDACS*, have been shown to be physically associated with proteins involved in DNA methylation. Both histone deacetylation and DNA methylation contribute to transcriptional repression.[646] In part, the success of ATRA has been its ability to relieve the recruitment by the PML/RARA fusion protein of repression complexes and, thus, allow for the induction of gene expression, leading to promyelocyte maturation.[368,649,650] Other approaches that are being tested in patients involve the use of HDAC inhibitors (e.g., phenylbutyrate) and compounds that inhibit methylation (e.g., azacitidine). The goal of these clinical trials is to induce differentiation followed by apoptosis of AML blasts. An additional benefit of differentiation approaches to treatment may be the induction of surface molecules on leukemic cells that may contribute to immune recognition, stimulation, and subsequent killing.[651]

Although the stimulation of antileukemic immune responses has been the hope of immunologists and oncologists for many years, previous attempts have been compromised by inconsistent methods and responses. However, more recent studies have begun to establish a more scientific basis for developing immunostimulatory vaccine approaches for the treatment of cancer.[652,653]

For example, experimental studies have demonstrated that the transfer into and expression of a wide variety of cytokine genes can result in the immunologic rejection of genetically modified tumor cells in murine models and protection from subsequent tumor cell challenges.[654,655] Although the exact mechanism(s) responsible for this effect generated by different cytokines, particularly GM-CSF, is still uncertain, it is likely to involve the stimulation and recruitment of dendritic cells and their subsequent processing of tumor antigens from dying cells and stimulation of both helper and cytotoxic T lymphocytes.[654,655,656,657 and 658]

Other studies have shown that while tumor cells may express proteins that could serve as potential immune-mediated targets, tumor cells (including most AML cells) do not express critical costimulatory receptors required for appropriate T lymphocyte activation.[652,659,660] Furthermore, if T lymphocytes are allowed to recognize

antigen in the absence of costimulation, then they develop anergy or tolerance to that antigen. [652,659,660] Thus, leukemic blasts may not only escape immune destruction by their lack of costimulatory receptors, they may also tolerize immune effector cells. [652,659,660 and 661] This has been demonstrated to be the case in experiments using murine models of AML, in which AML cells have been transduced with complementary DNAs encoding costimulatory receptors. [656,662,663 and 664] When AML cells are forced to express costimulatory receptors, they are able to generate significant antileukemic cell immune responses, even in animals with established leukemia.[656,662,663 and 664] However, in animals with advanced leukemia (i.e., a large leukemic burden) cytoreduction with chemotherapy followed by a recovery period was required for this vaccine approach to be curative. [665] This corroborates the observation that therapeutic vaccine approaches as well as immunostimulatory approaches using cytokines, such as interleukin-2 or GM-CSF, are likely to be most effective in the MRD setting. [657,666,667,668,669,670,671,672 and 673]

To this end, an ideal minimal disease setting would be following bone marrow transplantation. However, the posttransplantation period is characterized by an often profound immune deficiency with either autologous or allogeneic donor approaches. [674] However, recent experiments in murine systems demonstrate posttransplant periods when immunostimulation by vaccines or cytokines, or both, can be effective at generating antitumor responses. [675] Several clinical trials in patients with AML after autologous or allogeneic transplantation are currently testing this possibility. [600,670,676]

An alternative approach that is being tested involves the *ex vivo* stimulation of T lymphocytes with host leukemia cells and then generated in tissue culture antileukemic cell clones that can be reinfused into the patient. [666,676,677,678 and 679] Although this approach has been feasible and effective in murine models, it has not been shown to be consistently effective in patients. Part of the lack of this approach's effectiveness may be due to the behavior of leukemic cells that allows them to change the expression of immunostimulatory antigens, express immune inhibitory receptors, as well as secrete immunosuppressive substances such as tumor necrosis factor-alpha and FAS ligand. [680,681 and 682]

The use of allogeneic transplantation from major histocompatibility complex–matched family donors for the treatment of AML has proven to be particularly effective, especially in younger patients. This is in part due to a GVL reaction, which, however, is usually impossible to dissociate from GVHD. [683,684,685,686,687,688 and 689] In addition, while complications from GVHD or the immunosuppressive therapy to prevent or limit the outcomes that can be achieved with matched family donors, such complications are even greater with matched or mismatched unrelated donors.[690,691,692,693,694 and 695] Thus, a significant challenge for transplantation is to be able to induce tolerance to normal tissues while preserving a GVL response. This has been achieved in some murine models with the blockade of costimulatory receptors during antigen recognition or with the use of specific cocktails of cytokines that can induce an anergic state in T lymphocytes. [696] The approach of costimulatory receptor blockage in the presence of normal host cells has been attempted in patients with high-risk leukemia in relapse. [697] Although it is too early to assess effectiveness, these studies have shown the feasibility of such an approach in patients. Another important alternative that is being tested is the use of nonmyeloablative allogeneic transplantation with posttransplantation treatment designed to enhance the development of tolerance to host antigens on the part of donor cells.[698,699]

As we approach the future of therapy for patients with AML, there is considerable hope that less toxic and more effective therapies will soon be a reality and not merely an unrealized hope. Instead of dose-intensified combination chemotherapy followed by myeloablative therapy with transplantation, one can anticipate that future protocols for patients with AML will be quite different. They will include genomic expression profiles that help direct lineage-specific differentiation therapies. Cytoreductive therapies will involve nonimmunosuppressive and nongenotoxic inhibitors of signal transduction as well as targeted MAB or ligand conjugates. After the achievement of a minimal leukemia state, either a nonmyeloablative transplant or autologous vaccine may then be used to eliminate residual disease or limit the expansion of leukemic blasts through maintaining antileukemic cell immunity.

## QUALITY OF LIFE AND SURVIVORSHIP

The judgment of whether therapies can be considered successful will depend on not just eradication of leukemia and normal hematopoietic recovery, but also on the QOL that survivors experience. A growing number of studies have documented an increasing number of treatment-related late effects for patients with cancer.[305,306,700,701 and 702] Several of these studies have focused on patients after HSCT and have documented problems with growth, fertility, cardiopulmonary function, psychosocial adaptation, and secondary malignancies. [702,703,704,705,706,707,708 and 709] However, other data demonstrate that some factors, such as cardiac abnormalities, may not be related to complications of transplantation but more on the cumulative dose of anthracyclines. [702,708,710] This is particularly relevant in young children. Recent studies in adults with AML have examined several measures of QOL after bone marrow transplantation versus high-dose AraC-based postremission therapy.[304,711,712,713 and 714] No significant differences were observed between the two treatment groups.

The true clinical effectiveness of a treatment ultimately also includes measures of cost accountability, resource utilization, and impact. Because health care resources are not limitless and have become more carefully scrutinized, an additional important component of any successful treatment program will be how effective it is in terms of both the cost of the actual treatment but also the impact associated with productive life years saved. The ability to accurately assess the cost of care has been examined in several studies.[304,326,715,716,717,718,719 and 720] As non-HSCT treatments have been intensified, requiring prolonged periods of neutropenia as well as blood product and hematopoietic growth factor support, the obvious differences between allogeneic HSCT, auto-HSCT, and intense postremission chemotherapy have diminished. The introduction of ATRA for patients with APL has been shown to significantly reduce the cost of induction therapy. [717] Furthermore, the initial effectiveness of any therapy has been shown to have a great impact on the eventual cost of care in that the treatment of patients in relapse adds considerably to cost and life years lost.

Improvements in the cure rate of children with AML and the reduction of long-term sequelae should ultimately have a major impact on the quality and cost associated with the diagnosis, treatment, and outcome for these patients. This will also hopefully translate into increased use of these approaches throughout the world, with a result being improved outcome for all children and adolescents with AML.

# CHRONIC LEUKEMIAS OF CHILDHOOD

ARNOLD J. ALTMAN

## INTRODUCTION

Chronic leukemias are myeloproliferative disorders characterized by a predominance of relatively mature cells. In contrast to the acute leukemias, these diseases are indolent, with a natural history usually spanning several years. Some subtypes, however, may have a rapidly progressive clinical course.

Chronic leukemias are rare in childhood. The most common type, chronic myelocytic leukemia (CML), accounts for less than 5% of all childhood leukemias. Other chronic leukemias discussed in this chapter include juvenile myelomonocytic leukemia (JMML; formerly known as *juvenile CML*), familial CML, chronic myelomonocytic leukemia (CMML), and chronic lymphocytic leukemia (CLL).

## CHRONIC MYELOCYTIC LEUKEMIA

CML is a clonal panmyelopathy involving all the hemic lineages and at least some of the lymphoid lines. It is characterized by myeloid hyperplasia of the bone marrow, extramedullary hematopoiesis, expansion of the total body granulocyte pool, elevation of the leukocyte count (with appearance of the complete range of granulocyte precursor cells in the peripheral blood), and a specific cytogenetic marker, the Philadelphia (Ph $^{1}$) chromosome.

### Historical Background

CML was the first form of leukemia to be recognized as a distinct clinical entity. Donné [1] described the characteristic hematologic changes in 1844; in 1845, Bennett, [2] Craigie,[3] and Virchow[4] independently described the clinical features and autopsy findings. These early observers were impressed by the marked splenic enlargement and peculiar changes in the color and consistency of the blood. On microscopic examination, the blood contained a predominance of colorless corpuscles similar to those found in small numbers in normal blood and in large numbers in pus. Although he could find no focus of inflammation, Bennett attributed the hematologic findings to “the presence of purulent matter.” Virchow used the descriptive term “white blood,” which, translated into Greek, became “leukemia.” Virchow subsequently subdivided leukemia into two categories: splenic and lymphatic.

In 1870, Neumann[5] suggested that the bone marrow, rather than the spleen, was the source of the excess colorless corpuscles in splenic leukemia; subsequent authors referred to splenic leukemia as *myeloid leukemia*. In 1889, Ebstein[6] recognized the clinical distinction between acute and chronic leukemias, and in 1891, Ehrlich[7] introduced techniques for staining blood cells that permitted the morphologic distinction between myeloid and lymphoid leukemias.

The earliest form of therapy for CML was the use of potassium arsenate (Fowler's solution) by Lissauer in 1865 [8]; this treatment produced limited and temporary improvement. Radiotherapy, introduced by Pusey in 1902,[9] produced better and more predictable effects with much less toxicity and became the standard therapy until the introduction of busulfan in 1953. The cytogenetic hallmark of CML, the Ph $^{1}$ chromosome, was described by Nowell and Hungerford in 1960.[10] This was also the first specific chromosomal abnormality associated with a human malignancy, and its discovery inaugurated the era of cancer cytogenetics.

### Epidemiology

CML is primarily a disease of middle age; the peak incidence is in the fourth and fifth decades. Although CML has been diagnosed in infants as young as 3 months (author's personal experience), more than 80% of pediatric cases of CML are diagnosed after age 4 years and 60% after age 6 years. [11,12] No significant racial or sexual predilection exists, and no hereditary component is demonstrable.

The only environmental factor implicated in the etiology of CML is ionizing radiation. An increased incidence of CML has been reported in radiologists, in survivors of atomic bomb explosions, and in persons exposed to therapeutic radiation for treatment of ankylosing spondylitis and other disorders. However, only 5% to 7% of all patients with CML have documented exposure to excessive radiation, and radiation is rarely implicated in pediatric CML. No infectious agent has been related to the pathogenesis of CML. Investigators have estimated that an average of 8 years is required between the original mutational event and the development of clinical symptoms.

### Cytogenetics

The cytogenetic hallmark of CML is the Ph $^{1}$ chromosome. Initially described as a truncated chromosome 22 (22q–), this anomaly is now recognized to result from the reciprocal translocation t(9;22) (q34;q11) ( Fig. 21-1). Breakpoints on chromosome 9 involve the *c-abl* gene and can vary widely (i.e., greater than 100 kb from case to case); on the other hand, breakpoints on chromosome 22 are virtually always restricted to a small (5.8 kb) segment of DNA known as *the major breakpoint cluster region (*bcr*)*. As a result of the reciprocal 9;22 translocation, two hybrid genes are formed: *bcr/abl* on 22q– and *abl/bcr* on 9q+. Although both of these genes are transcribed, *bcr/abl* appears to have the major role in the pathogenesis of CML.

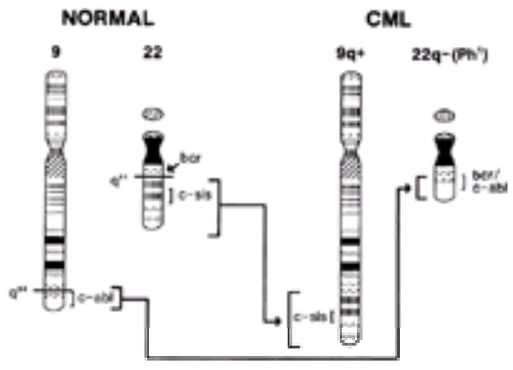

**FIGURE 21-1.** Anatomy of the (9;22)(q34;q11) translocation with formation of the Philadelphia (Ph [1]) chromosome (22q–) containing the hybrid *bcr*/*c-abl* gene. (See text for further explanation.) CML, chronic myelocytic leukemia.

The development of the hybrid *bcr/abl* gene may be a more common phenomenon than is commonly recognized. When studied using a very sensitive reverse transcriptase-polymerase chain reaction (RT-PCR) screening technique, 20% of "normal" adult subjects were found to harbor this translocation. [13] The age distribution of these *bcr/abl*-positive, but otherwise normal, individuals roughly mirrors the age distribution of CML.

Heterochromatin polymorphism patterns indicate an apparent parental bias in the genesis of t(9;22)—that is, the Ph [1] (22q–) chromosome is consistently of maternal origin, whereas the derivative 9q+ is of paternal derivation. [14] If this phenomenon were due to genomic imprinting, the *abl* component of the *bcr/abl* gene would be expected to show an equivalent parental bias; however, molecular analysis indicates that this moiety has an even chance of being the paternal or the maternal copy. [15] These findings may indicate that homologous recombination between 9q22 and 9q34 may be a frequent event and may play a role in the early stages of CML. [16,17]

### *Properties of* c-abl *and Its Protein Product (P145)*

The wild-type *c-abl* gene is the human homolog of the Abelson B cell murine leukemia virus oncogene (v- *abl*) and is universally active in hematopoietic cells at all stages of differentiation. The *c-abl* gene encodes a 145-kd protein (P145) that localizes predominantly in the nucleus. P145 is a multifunctional enzyme that participates in signal transduction and regulation of gene transcription. One major function is to catalyze the attachment of phosphate groups to the tyrosine residues of various proteins [i.e., to act as a tyrosine kinase (TK)]. Members of the TK family are frequently involved in the pathways that transmit signals from the external milieu to the cytoplasm and nucleus; in this capacity, they may act as growth factors, transmembrane receptors, or submembrane catalytic subunits of surface receptors. Under normal circumstances, the P145 TK acts as a negative regulator of cell growth [18]; thus *c-abl* may be regarded as a tumor suppressor gene. As discussed in the section Properties of bcr/abl and Its Protien Product (P210), modifications in *c-abl* may disrupt cell cycle control and result in oncogenesis.

In addition to its TK activity, P145 contains other functional domains ( Table 21-1). The carboxy-terminal portion of P145 contains a domain involved in binding to F actin as well as a separate domain that can bind to DNA; the DNA-binding activity appears to be cell-cycle regulated by the cyclin-activated cdc-2 kinase. At the N-terminal region of P145 (Fig. 21-2) are three domains known as *src-homology (SH) regions* because of their kinship to the viral src oncogene. The first domain is SH1, which manifests weak tyrosine-kinase activity and appears to be tightly regulated by the SH2 and SH3 regions. The presence of SH2 and SH3 regions is significant because these domains play critical roles in intermolecular interactions that specifically mediate protein-protein coupling. The second domain, the SH2 region, can bind to substrates that are tyrosine phosphorylated, whereas the SH3 domain complexes with proline-rich regions involved in coordinating cytoskeletal interactions. Proteins containing SH2 and SH3 domains are classified as adapter molecules because they couple nonreceptor TKs to downstream signaling cascades regulating gene expression.

| Protein | Chromosome | Domain | Function |
|---|---|---|---|
| p145[c-abl] | 9q34 | N-terminal | |
| | | SH1 | Tyrosine kinase |
| | | SH2 | Interacts with tyrosine-phosphorylated proteins |
| | | SH3 | Suppression of tyrosine kinase activity |
| | | Myristylation site | Localization of p145[c-abl] to nucleus |
| | | C-terminal | DNA binding, nuclear localization, actin binding |
| p160[bcr] | 22q11 | N-terminal | |
| | | Coiled-coil motif | Polymerization with other proteins |
| | | Catalytic domain | Serine-threonine kinase |
| | | Central | |
| | | GEF | GDP-GTP exchange factor |
| | | C-terminal | |
| | | GAP | GTPase activating protein for 1HC and 1HC1/G25-related proteins |
| p210[bcr/abl] | t (9;22)(q34;q11) (Ph[1] chromosome) | BCR | |
| | | Coiled-coil motif | Increase tyrosine kinase activity of ABL |
| | | | Enables binding of F-actin to ABL |
| | | Tyrosine residue 177 | Docking site for adaptor proteins |
| | | Serine-threonine kinase | Activation of signal-transduction proteins |
| | | ABL | |
| | | SH1 domain | Phosphorylation of signal and adaptor proteins |
| | | Actin-binding domain | Cytoplasmic location. Interference with adhesion |

GAP, guanosine triphosphate–activating protein; GDP, guanosine diphosphate; GEF, guanosine nucleotide exchange factor; GTP, guanosine triphosphate.

**TABLE 21-1. FUNCTIONAL DOMAIN OF ABL, BCR, AND BCR/ABL PROTEINS**

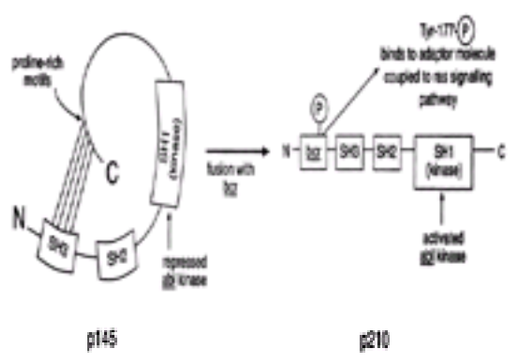

**FIGURE 21-2.** The normal abl tyrosine kinase (TK) component of P145 is carefully regulated by the SH2 and SH3 domains; genetic alterations that prevent interaction of the SH3 domain with proline-rich motifs within the C-terminus result in derepression (constitutive activation) of the TK. In Philadelphia chromosome–positive chronic myelocytic leukemia, fusion with the bcr gene leads to production of a chimeric protein (P210) with activated TK and oncogenic properties. Two domains within bcr are required for its oncogenic effect: domain I mediates oligomerization of *bcr/abl* and promotes phosphorylation of tyrosine residue 177 within domain II, which, in turn, binds to a signaling adaptor molecule coupling *bcr/abl* with the ras signaling pathway. (See text for further explanation.)

### *Properties of* bcr

The *bcr* region is a component of a much larger gene known as *BCR*. BCR has at least three domains (Table 21-1): (a) an N-terminal sequence that encodes a serine/threonine kinase, (b) a central portion that encodes a guanidine nucleotide exchange factor, and (c) a C-terminal portion that codes for a guanosine triphosphatase-activating protein (GAP).

### *Properties of* bcr/abl *and Its Protein Product (P210)*

The *bcr/abl* gene encodes a tumor-specific 210-kd hybrid protein (P210) that differs from the normal abl kinase (P145) in several respects: (a) translocation to the cytoplasm, (b) augmented TK activity, (c) ability to autophosphorylate, and (d) ability to bind F-actin. Similar modifications of *c-abl* proteins have been demonstrated to mediate viral oncogenesis (e.g., v-abl and feline sarcoma virus) and to confer growth-factor independence on various cell lines. [19] In each of these instances, the critical genetic alteration involves a substitution at the N-terminal end of the *abl* gene (Fig. 21-3). The N-terminal serine/threonine kinase domain of *bcr* appears to be integral to the activation of abl kinase in the *bcr/abl* fusion molecule; this process involves both a genetic and a physical interaction ( Fig. 21-2).[20,21 and 22] As mentioned previously, under normal conditions, the abl kinase (SH1) is regulated by two other regions of the abl molecule (SH2 and SH3); SH2 exerts a positive regulatory effect on SH1, whereas SH3 is a negative regulator. In the *bcr/abl* fusion molecule (P210), a direct physical binding between the N-terminal sequence of *bcr* and the SH3 regulatory domain of *abl* may deregulate the abl kinase.[22] Two domains within *bcr* are required for its oncogenic effect: domain I mediates oligomerization of *bcr/abl* and promotes phosphorylation of tyrosine residue 177 within domain II, which, in turn, binds to a signaling adapter molecule coupling *bcr/abl* with the *ras* signaling pathway.[23]

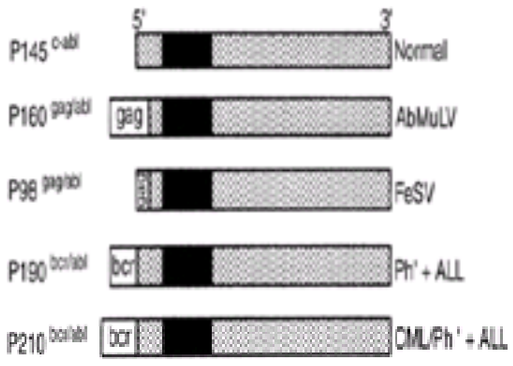

**FIGURE 21-3.** Schematic representation of the normal protein product (P145) of the *c-abl* gene and the modifications associated with leukemogenesis. Note that all variants retain the tyrosine kinase domain (*black area*) and are altered at the 58 end by insertion of the viral gag component in the case of Abelson murine leukemia virus (AbMuLV) and feline sarcoma virus (FeSV) or with bcr segments in the case of Philadelphia chromosome–positive (Ph $^{1}$+) acute lymphocytic leukemia (ALL) and chronic myelocytic leukemia (CML).

As a result of its translocation from the nucleus to the cytoplasm, the constitutively activated *bcr/abl* TK (P210) is exposed to a new spectrum of substrates. Many novel phosphotyrosine-containing proteins are now engendered. Most prominent among these is a 41-kd protein known as *CRKL*.[24,25] CRKL has an overall homology of 60% to CRK (the human homolog of the avian sarcoma viral crk oncogene); like abl protein, CRKL is an adapter protein containing SH2 and SH3 domains that serve as an intermediate in coordinating signal transduction in TK cascades. In normal hematopoietic cells, CRKL is only present in a nonphosphorylated form and, as such, may play a role in differentiation; the constitutive phosphorylation of CRKL in the CML cell may interfere with its ability to complex with other proteins, thereby resulting in loss of function, blocked differentiation, and an expanding pool of immature myeloid precursors. [24,25]

Other phosphorylated proteins found in the CML cell include rasGAP and its associated proteins (p190 and p62), other adapter proteins (GRB-2 and SHC), and the BCR protein itself.[26,27 and 28] These interactions may directly link P210 with the *ras* signal transduction pathway that is central to the regulation of cell proliferation and differentiation.[28] This is consistent with evidence that implicates up-regulation of *ras* function as an essential component of *bcr/abl*'s ability to induce malignant transformation.[29]

### *Other Cytogenetic Consequences of t(9;22)(q34;q11)*

Another gene located on 22q11 and included in the t(9;22) encodes for a cytokine with a broad spectrum of biologic activities, including leukemia inhibitory factor and human interleukin (IL) for DA1 cells. Abnormal regulation of this gene may contribute to the disordered hematopoiesis characteristic of CML. [30]

A reciprocal fusion gene, *abl/bcr*, is formed on chromosome 9q+; this gene, which is also actively transcribed in most patients with CML, has not been well defined. [31] The t(9;22) also results in transposition of c-*sis*, the human homolog of the simian sarcoma virus oncogene, from chromosome 22 to chromosome 9. Normally, c-*sis* encodes sequences of the b-chain of platelet-derived growth factor. Although neither the structure nor the expression of c-*sis* is altered by the translocation event, a subtle transformation of this fibroblast-stimulating gene may possibly play a role in the myelofibrosis seen in some patients with CML.

### *Alternate Splicing Patterns for* bcr/abl

In the genesis of *bcr/abl*, the break in *abl* typically occurs in the first intron between alternate exons la and lb; the break in *bcr* occurs most often between exons 2 and 3 or 3 and 4. During transcription, *abl* exon lb is spliced out, and *abl* exon 2 is spliced to either *bcr* exon 2 or 3. As shown in Fig. 21-4, two distinct messenger RNA (mRNA) species may be encoded (b2a2 or b2a3); these vary in size by 75 bases, and their protein products differ by 25 amino acids. The influence of the splice site on the clinical course of CML has been the subject of much discussion, but no clear conclusion is yet available. [32,33 and 34]

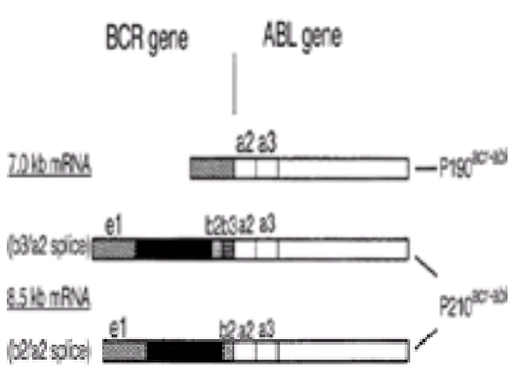

**FIGURE 21-4.** A schematic diagram of alternate splicing patterns for hybrid *bcr/abl* messenger (mRNA). (See text for explanation.) [From Mills KI, Benn P, Birnie GD. Does the breakpoint within the major breakpoint cluster region (M-*bcr*) influence the duration of the chronic phase in chronic myeloid leukemia? An analytical comparison of current literature. Blood 1991;78:1155, with permission.]

As discussed in the section Philadelphia Chromosome–Positive Acute Leukemia, clinicians also recognize an entity known as *Ph$^{1}$-positive acute leukemia.* Approximately half the adults with this condition have *bcr/abl* rearrangements similar to those seen in CML. In the remainder and in nearly 80% of children with Ph$^{1}$-positive acute leukemia, a different rearrangement occurs, with *abl* exon 2 spliced to an exon outside the major *bcr* region (known as *the minor bcr region*).[33] The resultant protein product (P190) has a molecular weight of 190 kd and has approximately a fivefold higher level of TK activity than does P210. This characteristic appears to correlate with a higher transforming ability of P190. Careful analysis has shown that the p190 $^{bcr/abl}$ transcript, traditionally associated with Ph$^{1}$-positive acute leukemia, can be detected at very low levels (corresponding to approximately 0.02% of the total *bcr/abl* transcripts) at diagnosis in virtually all CML patients, apparently arising as a consequence of alternative or missplicing events in the BCR gene. [35] As discussed in the section Detection of Residual Leukemia after Bone Marrow Transplant, quantitation of p190$^{bcr/abl}$ transcript can be utilized to assess total tumor burden and as an early indicator of molecular relapse. [36]

A third *bcr/abl* fusion protein ($p230^{bcr/abl}$) has been associated with a relatively indolent form of chronic leukemia known as *chronic neutrophilic leukemia*. Because the various *bcr-abl* oncoproteins share the same *abl* TK sequences, their different clinical phenotypes must reflect modulation by the unique protein domains contributed by the various *bcr* breakpoints (Table 21-2).[37]

| Fusion gene | *bcr* domains | Clinical phenotype |
|---|---|---|
| P185 (or P190) | Dimerization<br>Binding<br>SH2<br>Serine/threonine kinase | $Ph^1$+ acute leukemia |
| P210 | All of the above plus:<br>Dbl-like<br>Pleckstrin homology | $Ph^1$+ chronic myelocytic leukemia |
| P230 | All of the above plus:<br>Calcium-phospholipid binding<br>One-third of GTPase activating gene for p21 rac (rac-GAP) | Chronic neutrophilic leukemia |

GAP, guanosine triphosphate-activating protein; GTP, guanosine triphosphate.

**TABLE 21-2. RELATIONSHIP OF BCR DOMAINS TO *BCR/ABL* FUSION GENES**

Although the classic t(9;22) is found in approximately 90% of patients with CML, in some instances, other types of translocations may be found.[38,39,40,41] and [42] Approximately 3% of patients with CML have translocations of 22q11 to regions other than 9q34. Another 3% have complex translocations involving three or more chromosomes; such translocations virtually always involve band 9q34. Other patients may have an undetected or "masked" $Ph^1$ chromosome (see $Ph^1$-negative CML). A few patients have, in addition to the $Ph^1$ chromosome, other visible karyotypic abnormalities such as a second $Ph^1$ chromosome, isochromosome 17, or an extra chromosome 8 or 18; these secondary changes appear to represent a mechanism of tumor progression and are found with increased frequency as the disease evolves to a more aggressive phase.

### *Philadelphia Chromosome–Negative Chronic Myelocytic Leukemia*

Approximately 5% to 10% of patients with otherwise typical CML do not manifest the $Ph^1$ chromosome. In some of these patients, the $Ph^1$ chromosome may be masked by translocation of additional genetic material to the 22q11 region.[41] Other patients may have rearrangements or breaks in the 9q34 region without the reciprocal break at 22q11.[17,42] Molecular biology techniques permit identification of *bcr* rearrangements in $Ph^1$-negative patients who have otherwise typical CML.[43,44] In such cases, *abl* and *bcr* are presumed to have been juxtaposed on the molecular level by a mechanism other than that producing the typical t(9;22); this phenomenon may result from an interstitial insertion of *abl* into *bcr* or a complex translocation with the *bcr/abl* fusion gene located on another chromosome.

Patients with a CML-like picture but lacking both $Ph^1$ and *bcr* rearrangement have also been described; such patients appear to have a distinct clinical course characterized by increasing leukocytosis, organomegaly, extramedullary infiltrates, and eventual bone marrow failure.[45]

### *Philadelphia Chromosome–Positive Acute Leukemia*

Although characteristic of CML, the $Ph^1$ chromosome is not exclusive to it. This chromosomal abnormality is found in approximately 3% to 10% of childhood acute leukemias, in 2% to 3% of adult acute myeloid leukemias, and in 25% to 33% of adult acute lymphoid leukemias.[46,47] and [48] $Ph^1$-positive acute leukemias have no antecedent CML features and are clinically and hematologically indistinguishable from other acute leukemias except for a relatively poorer prognosis. In a review of 267 patients with $Ph^1$-positive acute lymphocytic leukemia (ALL), Arico and colleagues[49] found that complete remission was achieved in 82% of cases. These patients could be subsequently stratified into three prognostic groups based on age and initial white blood cell count (WBC) ( Table 21-3). Intensive chemotherapy gave modestly successful results in the most favorable group; however, bone marrow transplant from an HLA-matched donor appears to be the preferred modality for most $Ph^1$-positive ALL patients.

| Prognostic group | Age | Initial white blood cell count | 5-yr disease-free survival |
|---|---|---|---|
| Favorable | <10 | <50,000/mm$^3$ | 49 ± 5% |
| Intermediate | >10 and/or | 50,000–100,000/mm$^3$ | 30 ± 5% |
| Poor prognosis | Any | >100,000/mm$^3$ | 20 ± 5% |

**TABLE 21-3. PROGNOSTIC CATEGORIZATION OF PHILADELPHIA CHROMOSOME–POSITIVE ACUTE LYMPHOCYTIC LEUKEMIA**

Some $Ph^1$-positive acute leukemias may represent blastic presentations of CML, whereas others are apparently true de novo acute leukemias. Few clinical or hematologic features enable the clinician to distinguish between these two entities, although cases associated with basophilia or marked splenomegaly are more likely to be associated with CML. To confuse the issue further, classic chronic-phase CML developed after a period of hematologic and cytogenetic remission in a patient who initially presented with apparent de novo $Ph^1$-positive acute leukemia.[50]

Differences between blastic-phase CML and de novo $Ph^1$-positive acute leukemia are more apparent at the cytogenetic and molecular levels. $Ph^1$-positive acute leukemias usually do not manifest the specific nonrandom chromosomal aberrations (discussed in the section Cytologic Heterogeneity of Blast Phase) that are characteristic of CML as it evolves into blastic phase. Furthermore, the marrow karyotype of the de novo acute $Ph^1$-positive leukemia case usually reverts to normal after therapy, whereas the $Ph^1$ chromosome persists in the bone marrow of the patient with CML. Patients with CML, regardless of phase, almost universally exhibit typical *bcr* rearrangements and production of P210. On the other hand, approximately one-half the patients with de novo $Ph^1$-positive acute leukemias (and virtually all children with this condition) show rearrangements outside the *bcr* region and produce the 190-kd protein.[51,52]

## Biology

The cytogenetic changes in the CML precursor cell are expressed in its descendants by a variety of cytologic alterations that, in turn, produce the neoplastic phenotype (Table 21-4). These biologic features are discussed in the subsequent sections.

| Abnormality | Consequence |
|---|---|
| Reduced adherence to stromal matrix | Decreased stroma/stem cell interaction<br>Abrogation of normal cell surface signal maturation |
| Discordant nuclear:cytoplasmic maturation | Prolongation of late progenitor proliferative phase<br>Opportunity for further divisions before maturation |
| Failure of apoptosis program | Prolonged survival and increased accumulation |
| Production of inhibitory molecules | Suppression of normal hematopoietic stem cells |
| Insensitivity to regulatory molecules | Selective growth advantage for CML cells |

**TABLE 21-4. CYTOLOGIC ABNORMALITIES IN CHRONIC MYELOCYTIC LEUKEMIA (CML)**

### *Clonality*

Independent lines of evidence derived from cytogenetic data and analysis of isoenzyme patterns indicate that CML is an acquired disorder of unicellular origin, and the target of neoplastic transformation is a multilineage stem cell with the potential for generating all the hemic cells (i.e., erythrocytes, neutrophils, basophils, eosinophils, monocytes, and megakaryocytes) and, in at least some instances, the lymphoid lineages. This multilineage potential accounts for the cytologic heterogeneity of the blastic phase of CML (discussed later under Natural History).

#### Cytogenetic Data

The $Ph^1$ chromosome has proved useful in defining the malignant population in CML. This acquired abnormality is demonstrable in virtually all proliferating erythroid, granulocytic, monocytic, and megakaryocytic precursor cells but not in fibroblasts or other somatic cells. A similar pattern of clonal restriction can be demonstrated for other karyotypic markers, such as that found in CML patients with coincident sexual mosaicism or Down syndrome.[53] Routine karyotypic studies do not indicate the presence of the $Ph^1$ chromosome in the lymphocytes of patients with CML. The phenomenon of lymphoblastic transformation in some patients with CML, however, suggests that at least some lymphoid lineages are involved in the malignant process. This suggestion is supported by demonstration of the $Ph^1$ chromosome in a small proportion of B lymphocytes and T lymphocytes when CML blood is cultured *in vitro*.[54] Other studies have documented the presence of $Ph^1$-positive B and T lymphocytes in multilineage colonies derived from CML precursor cells[55]; furthermore, *bcr/abl* transcripts have been detected in T lymphocytes of patients with CML.[56] In comparison with hemic cells, lymphoid cells are relatively long-lived, and therefore most of those present at diagnosis of CML probably antedate the neoplastic transformation event; this may explain the relatively small fraction in the malignant clone.

#### Isoenzyme Patterns

In accordance with the Lyon hypothesis, random inactivation of one X chromosome occurs in each cell during early embryogenesis; the progeny of each of these cells subsequently manifests the same pattern of X chromosome inactivation in a clonal fashion. Because approximately one-half the cells express one X chromosome and half the other X chromosome, females who are heterozygous for an X-linked enzyme should have roughly equal proportions of the two isoenzymes in each tissue. On the other hand, a neoplastic clone arising from a single cell should manifest only a single isoenzyme pattern. Studies of females with CML who are heterozygous for the X-linked enzyme glucose-6-phosphate dehydrogenase have demonstrated that the normal somatic tissues show the expected double isoenzyme distribution, whereas the $Ph^1$-positive hemic lineages contain a single (clonal) isoenzyme phenotype.[57,58] The demonstration that $Ph^1$-positive B lymphocytes also manifest a clonal pattern of glucose-6-phosphate dehydrogenase distribution confirms that this lineage is also derived from the CML stem cell[59,60]; this finding has important implications with regard to the initial transformation event in CML.

### *Initial Transformation Event*

Although clearly germane to the pathogenesis of CML, the formation of the $Ph^1$ chromosome may not be the primary event in the neoplastic sequence. In some documented cases, the typical clinical and hematologic abnormalities of CML antedated the appearance of the $Ph^1$ chromosome[61,62]; in other cases, the $Ph^1$ chromosome disappeared during therapy while the clinical and hematologic features of CML persisted.[63] Isoenzyme studies that indicate clonality of some Ph-negative lymphoid populations also imply a transformation event preceding the (9;22) translocation.[60] Investigators have suggested that a rearrangement or break in the 9q34 band (the locus of *c-abl*) may be the critical initiating step in the evolution from benign to malignant hematopoiesis.[17]

### *Mechanisms Underlying Growth Advantage of Chronic Myelocytic Leukemia Cells*

The expansion of the CML clone from a single transformed cell to predominance in bone marrow and blood is dramatic evidence of its ability to overgrow the normal hemic elements. The mechanisms by which it achieves preeminence have been of great interest to students of the disease. Some clues have been provided by analysis of proliferative kinetics and *in vitro* colony production.

#### Cell Kinetics

In chronic-phase CML, one sees a threefold to 30-fold increase in peripheral blood band and segmented neutrophils and a tenfold to 100-fold increase in the total blood granulocyte pool (TBGP).[64,65,66 and 67] These leukocytes freely exchange between the peripheral blood, bone marrow, and spleen. The average one-half-life of granulocytes in the blood is five to ten times longer in patients with CML than in healthy persons; this phenomenon is partially a reflection of the large number of immature forms, but even the morphologically mature granulocytes of CML have a peripheral blood half-life twofold to fourfold longer than normal.[66] This increased blood transit time contributes to the expansion of the TBGP. Of greater significance, however, is the increased granulocyte production rate.

The hyperproduction of myeloid cells in CML is not attributable to unregulated or unduly rapid proliferation; indeed, measurements of mitotic activity, DNA synthesis, and generation time indicate that CML progenitor cells divide more slowly than normal hemic precursor cells.[64,65,66 and 67] An overproduction of committed myeloid precursor cells can be demonstrated, however, by assays of the colony-forming unit–granulocyte-macrophage (CFU-GM).[67,68,69 and 70] Bone marrow suspensions from patients in chronic-phase CML generate ten to 20 times the number of GM colonies produced by normal marrow. The disparity is even more striking when peripheral blood is studied. The majority of circulating CFU-GM may be generated in the spleen.[71] Colony growth is qualitatively normal (in chronic phase); mature GM forms are produced, and the process depends on the same colony-stimulating factors (CSFs) that are obligatory for *in vitro* colony formation by normal CFU-GM. After chemotherapy or splenic irradiation, the TBGP and the half-life of circulating granulocytes return to normal values coincident with a reduction in the marrow cellularity, a reduction of the bone marrow and peripheral blood CFU-GM, and disappearance of immature cells from the peripheral blood. This change suggests that most of the kinetic abnormalities found in chronic-phase CML do not reflect an intrinsic maturational defect of the neoplastic cells, but are a consequence of the premature release of immature cells from the marrow resulting from the mechanical pressure of an increased granulocytic cell mass. The basic defect appears to be discordant maturation with preferential expansion of the progenitor compartment.[67]

As the disease progresses to blast phase, defects in maturation become more conspicuous. Myeloblasts become abundant in the bone marrow and peripheral blood, whereas the relative and absolute numbers of polymorphs decline. An inverse correlation exists between the percentage of myeloblasts in the marrow and the fraction of these cells in DNA synthesis.[72] This decline in proliferative and maturational potential is reflected in absent or reduced GM colony production *in vitro*.

#### Abnormalities in Feedback Regulation

Under normal circumstances, myelopoiesis is regulated by at least three negative feedback molecular species: lactoferrin (LF), prostaglandin E (PGE), and acidic isoferritins (AIFs) (Fig. 21-5). LF, the product of mature polymorphonuclear leukocytes (PMNs), down-regulates granulocytopoiesis by reducing monocyte-macrophage production of CSF.[73] PGE and AIF, which are derived from subpopulations of monocytes and macrophages, inhibit proliferation of normal

granulocyte-monocyte precursor cells;[73,74] their inhibitory actions appear to be restricted to those cells that express HLA-DR (Ia) antigens.[75,76]

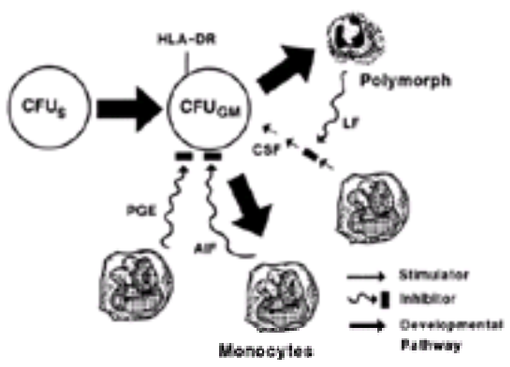

**FIGURE 21-5.** Positive and negative feedback loops regulating myelopoiesis. In this postulated schema, progeny of the pluripotent stem cells (CFU-S) become committed granulocyte-monocyte precursor cells (CFU-GMs). CFU-GMs are induced to proliferate and produce polymorphs and monocytes by colony-stimulating factors (CSFs). CFU-GMs are inhibited from proliferating by lactoferrin (LF) (which inhibits generation of CSF) and by acidic isoferritins (AIFs) and prostaglandin E (PGE) (which act directly on CFU-GMs bearing HLA-DR antigens). In chronic myelocytic leukemia, the neoplastic clone may derive its growth advantage by modifications of these regulatory pathways.

CML cells appear to be relatively insensitive to feedback inhibition by virtue of deficient LF production by the PMNs, decreased responsiveness of the monocyte-macrophage to regulation by LF, and decreased sensitivity of progenitor cells to PGE and AIF.[77,78] The PGE and AIF resistance may reflect deficient HLA-DR antigen expression by CML cells or a decreased proportion of sensitive target cells. CML cells may augment their proliferative advantage by releasing humoral factors to which they are resistant, but that suppress normal hemopoietic precursor cells.[79]

### Altered Adhesive Interactions

Under normal conditions, hematopoietic progenitor cells adhere to the extracellular matrix protein fibronectin in bone marrow stroma via fibronectin receptors (integrins). $Ph^1$+ progenitor cells exhibit reduced adhesion to fibronectin. This may result from an acquired functional defect of the fibronectin receptor or its downstream signaling pathways or both. Several cytoskeletal proteins associated with integrin regulation (e.g., paxillin, FAK, CKRL, and vinculin) are phosphorylated by the *bcr/abl* TK, and their altered status may contribute to abnormal integrin function.[80] Deficient binding of CML progenitors to marrow stroma may lead to release of immature cells into the circulation and may facilitate hematopoiesis in extramedullary sites. Conversely, this defect in adhesiveness may facilitate selection for normal ($Ph^1$-negative) stem cells *in vitro* by inhibiting the survival of CML progenitor cells in long-term culture systems.

### Resistance to Apoptosis

The expansion of a malignant clone reflects an imbalance between the rate of cell proliferation and the rate of cell death. As discussed in the section Cell Kinetics, studies of the kinetics of CML cells suggest that they are not produced at an increased rate; therefore, the massive accumulation of cells in CML probably results from prolongation of cell survival. Under normal circumstances, hemic cells have a limited life span that is regulated by a genetic program of active autonomous cell death (apoptosis); the presence of the *bcr/abl* fusion protein appears to render CML cells resistant to the induction of apoptosis.[81,82] The *bcr/abl* oncoproteins protect cells from apoptosis via several different mechanisms, among which are: inhibition of upstream preapoptotic mitochondrial events (e.g., release of cytochrome C) and downstream inhibition of caspase 3.[83] Many of these effects are mediated by influencing the relative expression levels of apoptosis inhibitors (e.g., BCL-2, BCL-$X_L$) and promotors (e.g., BAX, BAD, BCL-$X_S$) or the subcellular localization of these factors, or both.

In addition to promoting leukocytosis, suppression of apoptosis may also allow cells to accumulate new genetic changes with consequent neoplastic progression. The *bcr/abl*-mediated inhibition of apoptosis is also associated with prolongation of cell cycle arrest at the $G_2$/M restriction point; this delay may give the cell time to repair chemotherapy-induced damage to DNA rather than proceeding to programmed cell death.[84] Because response to many chemotherapeutic agents depends on activation of the apoptosis program, inhibition of apoptosis may limit the susceptibility of CML cells to standard cytotoxic chemotherapy. Thus, resistance to apoptosis may be implicated in several important features of CML: massive clonal expansion, neoplastic progression, and resistance to chemotherapy.

### *Acute Transformation*

In the course of CML, progressively more abnormal stem cell clones evolve sequentially from the original $Ph^1$-positive clone. With the development of new cytogenetic alterations is an increasing dissociation between proliferation and differentiation. The newly evolved clones suppress proliferation of both normal stem cells and the cells of antecedent leukemic clones. Eventually, immature (blast) cells predominate, and the process terminates as an acute leukemia.

In the Preisler model of leukemogenesis,[85] the process of acute transformation involves at least two complementary gene families (Table 21-5). Class I genes code for signal transduction proteins that participate in the chain of reactions that transmit signals from the cell surface to the cytoskeletal elements or the nucleus; oncogenic transformation usually produces an abnormal protein that induces abnormalities of proliferation or differentiation. Class II genes code for proteins that interact directly with the genome and regulate the expression of other families of genes; oncogenic transformation usually results in an abnormality in regulation of expression leading to increased proliferative potential or immortalization.

| Class I (signal transducers) | | Class II (signal effectors) | |
|---|---|---|---|
| **Gene** | **Locus of action** | **Gene** | **Locus of action** |
| *sis* | External milieu (PDGF) | *myc* | Nucleus |
| *erb-b* | Cell membrane (EGF-R) | *p53* | Nucleus |
| *fms* | Cell membrane (CSF-1-R) | *rb* | Nucleus |
| *ras* | Submembrane (G protein) | | |
| *abl* | Submembrane (tyrosine kinase) | | |
| *src* | Submembrane (tyrosine kinase) | | |
| *mos* | Cytoplasm | | |
| *raf* | Cytoplasm | | |
| *mil* | Cytoplasm | | |

EGF-R, epidermal growth factor receptor; CSF-1-R, colony-stimulating factor-1 receptor; PDGF, platelet-derived growth factor.

**TABLE 21-5. CLASSIFICATION OF PROTO-ONCOGENES**

Applying the Preisler model to CML, the chronic phase may be attributed to an abnormal protein (P210) derived from an altered class I protooncogene (*c-abl*). Progression to acute phase does not appear to result from a further change in the *bcr/abl* gene, nor are alterations in other class I genes expected to induce acute transformation. Instead, alteration of a class II gene is more likely to complement the oncogenic potential of the preexisting class I genetic mutation. The low incidence of N-*ras* (class I) mutations and the relatively high incidence (22 to 30%) of p53 (class II) mutations seen in association with blastic transformation of CML are consistent with this model of leukemogenesis.[86,87,88] and [89]

### *Multistep Pathogenesis*

The evolution of CML may be visualized as a multistep process that can be summarized as follows:

1. An initial transformation event (possibly rearrangement of *c-abl*) occurs in a multipotent progenitor cell. This results in production of a clone of "premalignant" hemic (and possibly lymphoid) cells. These cells may be metabolically defective and require a subsequent genetic mutation (e.g., creation of the *bcr/abl* fusion gene) to compensate for the defect and "rescue" them from impending apoptosis.[90]
2. At some point in the evolution of the disease, a recognizable cytogenetic alteration (the Ph [1] chromosome) appears in the transformed clone. The translocation of *c-abl* to chromosome 22 and its fusion with the *bcr* unmask or deregulate TK activity, which, in turn, produces novel tyrosine phosphorylated proteins (e.g., CKRL). The $Ph^1$-positive clone now acquires a growth advantage over normal hemic stem cells, and initially an overproduction of relatively mature cells occurs, particularly those of the granulocytic series.
3. Genomic instability and spontaneous errors in DNA replication may promote the appearance of progressively more abnormal stem cell clones derived from the original $Ph^1$-positive clone; new cytogenetic alterations appear, and an increasing dissociation exists between proliferation and differentiation. The newly evolved clones suppress the proliferation of normal stem cells, as well as the cells of the preceding leukemic clones. Eventually, immature (blast) cells predominate, and the process terminates in an acute leukemia.

## Natural History

The natural history of CML is divided into chronic, accelerated, and blast phases. These phases represent the progressive shift in the nature of the disorder from one of hyperproliferation, with production of mainly mature hemic elements, to one characterized by a differentiation arrest, with production of predominantly immature (blast) cells.

### *Chronic Phase*

The chronic phase is characterized by marked expansion of the hematopoietic pools; morphologically mature blood cells are produced that show only subtle functional abnormalities. Generally, the neoplastic cells are restricted to the bone marrow, liver, spleen, and peripheral blood. Therefore, symptoms are related to organ infiltration, hyperviscosity, and the metabolic consequences of hyperproliferation, all of which are relatively easy to control. On average, the chronic phase lasts approximately 3 years.

## Symptoms

Patients usually present with nonspecific complaints, such as fever, night sweats, weakness, left upper quadrant pain or fullness, and bone pain. Neurologic dysfunction, respiratory distress, visual difficulties, or priapism may complicate cases characterized by marked hyperleukocytosis.

## Physical Findings

The usual physical findings in this phase of CML are pallor, low-grade fever, ecchymoses, hepatosplenomegaly, and sternal tenderness. Signs relating to leukostasis (e.g., neurologic abnormalities, papilledema, retinal hemorrhages, and tachypnea) are seen in patients with extreme hyperleukocytosis.

## Laboratory Findings

A mild normochromic, normocytic anemia, marked leukocytosis with "shift to the left," and thrombocytosis are common laboratory findings. The mean hematocrit at presentation in children (25 mL per dL) is significantly less than that seen in adults.[12,91] The leukocyte count at diagnosis ranges from approximately 8,000 to 800,000 per $mm^3$; the median count in children (approximately 250,000 per $mm^3$) is higher than that seen in adults.[11,12] Extreme hyperleukocytosis (greater than 500,000 per $mm^3$) is also more common in children. The peripheral blood smear shows myeloid cells at all stages of differentiation; myeloblasts and promyelocytes generally comprise less than 15% of the differential count, and no hiatus leukemicus in maturation occurs ( Fig. 1-6). An absolute increase in the numbers of basophils and eosinophils is noted. Hybrid eosinophilic-basophilic granulocytes may also be seen [92]; because similar chimeric granules may be found in normal immature granulocytes, this phenomenon may reflect incomplete maturation.[67] The mean platelet count in children is approximately 500,000 per $mm^3$, which is not significantly higher than that in adults.[91] Serologic findings include elevation of uric acid, lactate dehydrogenase, vitamin $B_{12}$, and vitamin $B_{12}$–binding protein (transcobalamin 1).

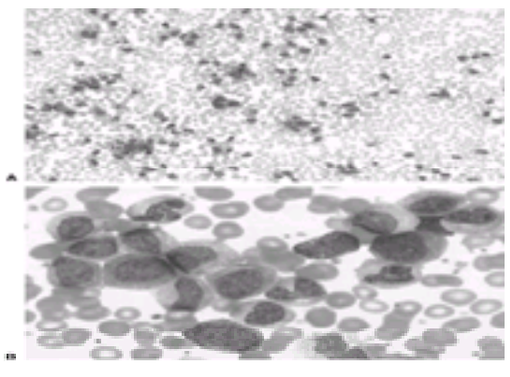

**FIGURE 21-6.** Peripheral blood smear of chronic-phase chronic myelocytic leukemia. **A:** Low-power magnification showing marked leukocytosis. **B:** High-power magnification showing the entire range of myeloid cells from myeloblast to mature polymorphonuclear leukocytes. (Courtesy of Dr. William Rezuke.) (See Color Figure 21-6.)

The bone marrow is hypercellular, mainly reflecting granulocytic (and often megakaryocytic) hyperplasia; orderly granulocyte maturation, eosinophilia, and basophilia are present. Myelofibrosis, which occurs in 30% to 40% of patients during the course of the disease, is uncommon in the early chronic phase. The bone marrow and spleen occasionally contain lipid-laden histiocytes that resemble Gaucher cells or sea-blue histiocytes.

The characteristic histochemical abnormality of the granulocyte population is reduction in leukocyte alkaline phosphatase (LAP) activity. Although this abnormality does not appear to affect PMN function adversely, it is of diagnostic utility in distinguishing the leukocytosis of CML from that of inflammation (in which LAP is generally elevated). Low LAP activity is also seen in paroxysmal nocturnal hemoglobinuria, JMML, CMML, and Fanconi's anemia. Under normal conditions, LAP activity appears very late in the development of granulocytes, and, indeed, may be a terminal marker of granulocyte maturation. [93] In CML, there appears to be no intrinsic defect in the synthesis and translation of LAP mRNA or transport of LAP protein to the plasma membrane; furthermore, LAP activity can be up-regulated under a variety of conditions [e.g., inflammation, leukoreduction, disease progression, and administration of granulocyte colony-stimulating factor (G-CSF)]. Thus, the low LAP levels in CML cells may result from granulocyte immaturity or hypoproduction of G-CSF due to a relative decrease in monocyte mass.[93,94]

LAP activity increases with infection or with a reduction of the granulocyte count after chemotherapy or progression to a more acute phase of the disease. Although subtle functional abnormalities of PMN adherence, chemotaxis, bactericidal activity, and membrane sialylation can be demonstrated in chronic-phase CML, the PMNs are sufficiently effective to prevent infectious complications.[95,96] PMN function deteriorates progressively as the disease evolves.

## Differential Diagnosis

The differential diagnosis of chronic-phase CML includes leukemoid reaction, JMML, and other myeloproliferative disorders. The combination of low LAP score and

the presence of the Ph[1] chromosome usually distinguishes CML from these conditions.

In leukemoid reactions, splenomegaly is usually not marked, the LAP score is high, the Ph [1] chromosome is absent, and an inflammatory focus is often demonstrable. In JMML, the LAP may be low, but the Ph[1] chromosome is absent; leukocytosis and splenomegaly are less marked than in CML, and involvement of skin, lymphoid tissue, and the monocytic lineage is more pronounced. CML can be distinguished from other myeloproliferative disorders by the disproportionate involvement of the granulocyte series and the presence of the Ph[1] chromosome.

***Metamorphosis***

After approximately 3 years, the chronic phase of CML undergoes a metamorphosis into a more aggressive phase; this may occur gradually or abruptly. In approximately 5% of cases, the evolution is explosive, with a rapidly increasing blast cell population in the peripheral blood and concurrent neutropenia and thrombocytopenia ("blast crisis"). Approximately 50% of patients develop a progressive maturation defect resulting in a hematologic picture similar to that of de novo acute leukemia; the remaining 45% have the gradual evolution of a myeloproliferative syndrome.

The onset of metamorphosis is characterized by progressive systemic symptoms (e.g., fever, night sweats, and weight loss), increasing leukocyte counts with a high proportion of immature cells, basophilia, and increasing resistance to chemotherapy. Along with these features is evidence of karyotypic evolution. Mutations in the antioncogene p53 may play a significant role in transformation: p53 mutations are detectable in the late chronic phase of CML and may indicate increasing genomic instability and early progression to blast transformation. [97,98] New karyotypic abnormalities (most commonly, duplication of the Ph[1] chromosome, isochromosome 17, or trisomy 8) also begin to appear. Occasionally, the first manifestation of metamorphosis is extramedullary (i.e., meningeal leukemia or a chloroma arising in soft tissue or bone); such findings usually herald the imminent blast transformation of the marrow.

***Blast Phase***

The blast phase is characterized by loss of the leukemic clone's capacity to differentiate. As a consequence, the clinical picture resembles that of an acute leukemia, with anemia, thrombocytopenia, and increased numbers of blast cells in both the peripheral blood and the bone marrow. A marrow blast percentage of 30% or more is diagnostic of blast phase. The signs and symptoms are those of a de novo acute leukemia; if basophilia is extreme, the patient may also have hyperhistaminemic symptoms (e.g., pruritus, cold urticaria, and gastric ulceration). When the absolute blast count exceeds 100,000 per mm [3], the patient is at risk for hyperleukocytosis syndrome with leukostasis.

**Cytologic Heterogeneity of Blast Phase**

As a reflection of the pluripotent nature of the leukemic stem cells in CML, blast transformation may involve any of the lymphohematopoietic lineages. In approximately 60% to 70% of cases, the blast cell morphology is myeloblastic; unlike de novo acute myelocytic leukemia, however, the blast cells are usually peroxidase negative and rarely have Auer rods. Careful analysis using lineage-specific markers, such as glycophorin-A, platelet peroxidase, and monoclonal antibodies, enables clinicians to identify some of these blast transformations as erythroid, monocytic, or megakaryocytic. [99] Approximately one-third of patients have blast cells with lymphoid morphology. These cells generally express a phenotype corresponding to an early B cell. [99,100] In rare cases, blast cells may express T-lineage markers; these patients usually have marked extramedullary involvement (especially in lymph nodes) and frequently lack a preceding chronic phase. [101] In some patients, the blast cells manifest features of more than one myeloid line or have mixed myeloid-lymphoid features.

The course of transformation of CML from chronic phase to the acute (blastic) phase is often accompanied by further cytogenetic changes. In transformation, the most commonly identifiable karyotypic alterations are duplication of the Ph [1] chromosome (+Ph[1]), trisomy 8 (+8), trisomy 19 (+19), and isochromosome 17q (i17q). A rare consistent chromosomal abnormality, a reciprocal t(3;21)(q26;q22), has been described in patients with CML either before or at the onset of blast transformation. [102,103] and [104] In general, these secondary cytogenetic changes are nonspecific and may indicate a generalized genomic instability rather than directly relate to blastic progression[101]; however, other changes clearly mirror the karyotypic features associated with specific subtypes of de novo acute leukemia and may be directly related to blastic transformation (Table 21-6).[105] The phenotypic features of blast transformation may be determined by these specific secondary genetic events; for example, rearrangements involving chromosome regions containing immunoglobulin genes and T-cell receptor genes have been associated with B-lymphoid and T-lymphoid acute transformations, whereas involvement of region 3q21 may be accompanied by dysmegakaryopoiesis and conversion to acute megakaryoblastic leukemia.[98,103,104]

| | Acute phase | |
|---|---|---|
| | Myeloid | Lymphoid |

**TABLE 21-6. ASSOCIATION BETWEEN CHROMOSOME ABNORMALITIES AND ACUTE PHASE CHRONIC MYELOCYTIC LEUKEMIA**

**Differential Diagnosis**

Because most instances of blast-phase CML occur after a well-documented chronic phase, the diagnosis is usually clear-cut. The rare patient who presents in blast phase without a recognized preceding chronic phase may pose diagnostic difficulty, however. The combination of marked splenomegaly, basophilia, and the Ph [1] chromosome distinguishes blast-phase CML from most types of de novo acute leukemia; the distinction between blast-phase CML and de novo Ph [1]-positive acute leukemia is discussed in the section Philadelphia Chromosome–Positive Acute Leukemia.

**Prognostic Considerations**

Recent advances in the management of CML have improved median survival to 5.0 to 5.5 years (previously 3 to 4 years); 35% to 40% of patients survive 7 to 8 years. Because patients generally die within months of transformation to accelerated or blast phase, the major determinant of survival is the duration of the chronic phase, which can be highly variable. For adults, factors at diagnosis that predict early transformation include splenomegaly (>15 cm below costal margin), hepatomegaly (>6 cm below costal margin), thrombocytopenia (less than 150,000 per mm[3]), thrombocytosis (greater than 500,000 per mm[3]), marked leukocytosis (greater than 100,000 per mm[3]), and high proportions of blast cells or immature granulocytes (greater than 1% or greater than 20%, respectively). [106,107] The role of these factors in the prognosis of pediatric patients with CML is less clear; in one study, only peripheral blood and marrow blast counts at presentation were of prognostic significance. [11]

Once patients have entered the blast phase, the only parameters that correlate with survival are blast cell phenotype and cytogenetic findings. In general, lymphoblastic phenotype and minimal karyotypic evolution augur a more favorable response to therapy. [108]

**Therapy**

Achievement of true remission in CML would require destroying all Ph [1]-positive cells and replacing them with cytogenetically normal precursors. This goal is rarely accomplished with conventional therapeutic approaches, but bone marrow transplantation (BMT) has achieved apparent cure in a significant minority of patients. The

initial goal of treatment for patients in chronic phase has been to provide symptomatic relief by ameliorating leukocytosis and organomegaly. For patients in accelerated or blast phase, the goal is reversion to chronic phase. Before initiating any specific antileukemic therapy, consideration must be given to metabolic, leukostatic, and meningeal complications that pose management problems.

### *Special Management Problems*

#### Metabolic Disorders

Metabolic consequences of rapid cytolysis (e.g., hyperuricemia, hyperkalemia, and hyperphosphatemia) should be anticipated and treated appropriately with hydration, alkalinization, and allopurinol. [109] A detailed discussion of metabolic management is found in Chapter 38.

#### Hyperleukocytosis

The extremely high leukocyte count associated with some cases of CML can cause leukostatic complications in several organs, especially brain, lung, retina, and penis.[110,111] Because leukocytes are less deformable than erythrocytes, the viscosity of the blood increases dramatically as the fractional volume of leukocytes (leukocrit) increases. Myeloblasts, which are larger and more rigid than other leukocytes, contribute disproportionately to viscosity; thus, the patient with myeloblastic transformation is at particularly high risk. If hyperleukocytosis is symptomatic or extreme (leukocytes greater than 200,000 per $mm^3$ or blast count greater than 50,000 per $mm^3$), it should be treated with the simultaneous use of cytotoxic drugs (e.g., hydroxyurea, 50 to 75 mg per kg per day by intravenous infusion) and leukapheresis (or exchange transfusion); erythrocyte transfusions (which increase blood viscosity) should be avoided if possible until the leukocyte count is reduced to a safe level.

#### Thrombocytosis

Thrombocytosis may be associated with thromboembolic or hemorrhagic complications. If thrombocytosis does not respond to the CML treatment regimen, the use of anagrelide (an agent that prevents megakaryocyte maturation) or thiotepa (75 mg per $m^2$ intravenously every 2 to 3 weeks until response occurs) should be considered.[112]

#### Priapism

Persistent painful penile erection may result from sludging and mechanical obstruction by leukemic cells, coagulation within the corpora cavernosa secondary to thrombocytosis, or impingement by the spleen on abdominal veins and nerves. Treatment includes analgesia, hydration, application of warm compresses, radiotherapy (to penis or spleen), and initiation of high-dose chemotherapy (e.g., hydroxyurea, 50 to 75 mg per kg per day intravenously). [110,111]

#### Meningeal Leukemia

Meningeal leukemia is almost unknown in the chronic phase of CML and is rare in blast phase. The incidence may increase with improved survival of patients with blast transformation. The usual neurologic signs are cranial nerve palsies and papilledema; the diagnosis is confirmed by demonstrating pleocytosis, with blast cells in the spinal fluid. Intrathecal methotrexate is effective therapy, [113] but most patients eventually die of the hematologic consequences of the blast transformation. The role of prophylactic central nervous system therapy is undefined. [114]

### *Cytoreduction in Chronic Phase*

#### Single-Agent Chemotherapy

Single-agent chemotherapy with busulfan or hydroxyurea has traditionally been the standard approach to the chronic phase of CML. However, these agents are becoming replaced with interferon-a (IFN-a), and, more recently, STI-571. The goal is to achieve symptomatic relief by lowering the WBC count and by reducing liver and spleen size. True remission is rare, however; in most cases, the bone marrow continues to manifest granulocyte hyperplasia and Ph $^1$-positive metaphases even after the blood count has normalized and organomegaly has resolved. Therefore, even though symptomatic relief is achieved, the blast crisis is not delayed, and survival is not prolonged.

#### Hydroxyurea

Hydroxyurea is an inhibitor of ribonucleoside diphosphate reductase (an enzyme essential for DNA synthesis) and is specific for cells in S phase of the cell cycle. Unlike busulfan, it is relatively short-acting; however, its control of the leukocyte count is less reliable, and it must be used daily for prolonged periods. The recommended beginning dose is 10 to 20 mg per kg per day, [115] and dosages must be adjusted according to the hematologic response. Hydroxyurea appears to be as effective as busulfan in controlling chronic-phase CML, [116,117] while providing a greater margin of hematologic safety and less systemic toxicity.

#### Busulfan

Busulfan, an alkylating agent, is cell-cycle–phase nonspecific; it is characterized by delayed onset and prolonged duration of effect. The usual dosage is 0.06 to 0.10 mg per kg per day orally (adult dose, 4 mg per day). Once treatment is initiated, a lag of 10 to 14 days occurs before the leukocyte count falls significantly and the differential count begins to normalize. Splenic regression lags behind the peripheral blood response, and it may be 3 months before the spleen is no longer palpable. The dosage should be reduced by 50% when the leukocyte count reaches 30,000 to 40,000 per $mm^3$, and the drug should be discontinued when counts fall to 20,000 per $mm^3$ or less. The leukocyte count continues to fall for another 2 to 3 weeks after the last dose. Failure to stop therapy before the count normalizes may result in severe (and possibly irreversible) marrow aplasia. The average patient requires 4 to 6 weeks of busulfan therapy to attain clinical remission; once the leukocyte count has leveled off, the patient may be given continuous maintenance therapy with low-dose busulfan or intermittent courses when the leukocyte count exceeds 30,000 per $mm^3$. In addition to its myelosuppressive effects, busulfan may produce pulmonary fibrosis or an addisonian-like syndrome characterized by hyperpigmentation, wasting, and hypotension.

#### Interferon-a

IFN-a appears to exert a direct antiproliferative effect against both normal and CML myeloid precursors, particularly those of the late progenitor compartment, which is preferentially expanded in CML. [118,119] Other effects include immunomodulation through increase in LFA-3 expression, [120] increase in ability of CML cells to attach to marrow stroma, [121] and modification of expression of HLA-DR antigens. [122] Because IFN-a does not appear to increase bone marrow fibrosis, the difficulties sometimes encountered in obtaining marrow aspirates from patients treated with this medication may reflect the increased cytoadhesion produced by IFN-a; “dry taps” may be avoided by discontinuing IFN-a for 3 to 7 days before the procedure. [121,123,124]

IFN-a is effective in reversing splenomegaly and normalizing the WBC and platelet counts. IFN-a–based protocols can achieve complete hematologic response (Table 21-7) in more than 80% of patients; approximately 5% to 30% of these patients will also achieve complete cytogenetic response (Ph $^1$-negative), while another 10% to 38% show a major cytogenetic response (less than 35% $Ph^1$-positive cells). Patients achieving a major cytogenetic response have projected 7 to 10-year survival rates of more than 80%. One-half of the patients who achieve long-term complete response may become pcr-negative for *bcr/abl*. [125]

| | White blood cell count | Splenomegaly | Percentage $Ph^1$+ cells (marrow)/(%) |
|---|---|---|---|
| Hematologic | | | |
| Complete | <9,000/mm³ (normal morphology) | None | |
| Partial | <20,000/mm³ (>50% decline) | Persistent | |
| Failure | >20,000/mm³ | Persistent | |
| Cytogenetic | | | |
| Complete | | | 0 |
| Partial | | | <35 |
| Minor | | | 35–95 |
| None | | | 100 |

**TABLE 21-7. RESPONSE CRITERIA FOR INTERFERON THERAPY OF CHRONIC MYELOCYTIC LEUKEMIA**

IFN-a appears to be most effective in the early phase of CML. The response rate declines dramatically in patients with long-standing disease (more than 1 year from diagnosis) or with accelerated or blast-phase progression. The addition of low-dose cytosine arabinoside improves the complete hematologic response rate (from 28% to 55%) for patients in the late chronic phase of CML, but not for those in accelerated phase. [126] When used as a single agent, IFN-a achieves a 12% greater 5-year survival than hydroxyurea (59% versus 47%).[127] For patients with good cytogenetic response (less than 35% $Ph^1$-positive metaphases), the actuarial survival at 5 years is in the range of 90%.[128]

In an effort to augment the therapeutic effects of IFN-a, various investigators have combined it with more conventional chemotherapeutic agents. The combination of busulfan and IFN-a produces severe myelosuppression and has not demonstrated significant benefit over IFN-a alone. [129] On the other hand, the combination of IFN-a and hydroxyurea has several clinical benefits, including higher hematologic response rate, rapid disease control with relatively high hematologic remission rate, low incidence of side effects, and longer duration of disease control; however, cytogenetic response rate is similar to that seen with IFN-a alone. [112] The combination of IFN-a with low-dose cytosine arabinoside appears to be superior to IFN-a alone with respect to complete cytogenetic response rate for patients treated in early chronic phase,[126] hematologic remission rate for patients in late chronic phase, [130] and overall survival rate.[131,132]

Because a small proportion of CML patients on IFN protocols are achieving long-term, event-free, pcr-negative survival, some authors are cautiously suggesting the possibility of cure with this regimen.[133] However, most patients with IFN-induced cytogenetic remissions still maintain demonstrable *bcr/abl* rearrangements.[134]

Enthusiasm for IFN-a as a first-line treatment for the chronic phase of CML must also be tempered by a recognition of its cost and potential toxicities. The most frequent side effect is a flulike syndrome (i.e., anorexia, fever, and liver dysfunction); neurologic, psychiatric, and dermatologic symptoms are also common. Occasionally, more severe toxicity, including thrombocytopenia, hypothyroidism with antithyroid antibodies, hemolytic anemia, and systemic lupus erythematosus, may develop.[135]

Tolerance to IFN-a may be improved by adherence to the following guidelines [124]:

1. Initiate therapy with hydroxyurea. Once the WBC count has been reduced below 10,000 to 20,000 per $mm^3$, IFN-a may be started and hydroxyurea gradually tapered.
2. IFN-a may be initiated at a lower dose for the first 3 to 7 days, then gradually escalated to full dose over the next 1 to 2 weeks. It should be administered at bedtime, and the patient may be premedicated with acetaminophen to minimize flulike symptoms.
3. Side effects, such as fatigue, depression, or insomnia, may be managed with a low dose of amitriptyline at bedtime.
4. Indications for dose reduction include: WBC count less than 2,000 per $mm^3$ or platelet count less than 50,000 per $mm^3$ and serious systemic toxicity.
5. Patients should continue IFN-a as long as a cytogenetic response persists or for at least 3 years beyond documentation of a complete cytogenetic response.
6. The serum half-life of IFN may be increased by attaching it covalently to polyethylene glycol (PEG). A phase I study showed PEG-IFN to be easier to administer (only once/week dosing), less toxic, and potentially more effective than standard IFN. [135a] Further studies are in progress to confirm these results and to determine the effectiveness of PEG-IFN in combination with cytarabine.

### Multiagent Chemotherapy

In rare cases, busulfan-induced bone marrow hypoplasia has produced reversion to $Ph^1$-negative status or to stable $Ph^1$-positive/$Ph^1$-negative mosaicism followed by prolonged remission.[136,137] Following up on this observation, several groups have used aggressive multiagent chemotherapy regimens (sometimes in conjunction with splenectomy) in an effort to ablate the $Ph^1$-positive clone.[138,139 and 140] In approximately one-half of the patients so treated, cytogenetic conversion of the marrow is achieved. The effect is usually of short duration, however, and has no significant impact on duration of chronic phase of survival.

### Splenic Irradiation

Irradiation of the spleen in patients with chronic-phase CML reduces splenomegaly, lowers the peripheral leukocyte count, and also reduces the number of immature cells and the mitotic index at sites distant from the spleen (e.g., bone marrow). This distant (abscopal) effect has been postulated to result from the release of an inhibitor into the plasma[141] or an interruption of the flow of CFU-GM from the splenic parenchyma into the circulation. [71] Before the introduction of busulfan, splenic irradiation was the main treatment for chronic-phase CML. Although symptomatic relief was achieved, disease control was generally short-lived (4 to 6 months), and the impact on survival was slight. Splenic irradiation was replaced by chemotherapy as the first-line treatment when a prospective, controlled clinical trial showed that intermittent splenic irradiation was inferior to busulfan in achieving consistent control of the leukocyte count and in prolonging survival. [142] Splenic irradiation may be considered for transient palliation of the symptoms produced by massive splenomegaly in patients refractory to systemic chemotherapy, but this treatment is generally ineffective and may result in profound myelosuppression.

### Splenectomy

The enlarged spleen of the patient with CML contains a substantial burden of leukemic cells, and, in some cases, blast transformation may originate in the spleen. [143] Investigators have proposed that removal of this pool of cells may delay metamorphosis. Several large controlled trials have failed to demonstrate any benefit from splenectomy in prolonging chronic phase or survival, however.[144,145] Splenectomy may be of benefit in selected patients with hypersplenism or painful splenomegaly; it may also be useful in reducing the leukemic burden in patients about to undergo ablative therapy before BMT. However, these potential benefits must be weighed against the risk of overwhelming postsplenectomy sepsis syndrome and extreme thrombocytosis.

### Bone Marrow Transplantation

The theoretical and technical aspects of BMT are discussed in Chapter 16. Three sources of hematopoietic stem cells have been used for transplantation in patients with CML patients: syngeneic (from an identical twin); allogeneic (from an HLA-identical sibling or matched unrelated donor); and autologous (from the patient).

***Syngeneic or Allogeneic Transplantation.*** Allogeneic BMT remains the only well-documented curative therapy for patients with CML. Disease status at the time of BMT has been considered to be the most powerful predictor of survival. In early studies, the best results had been obtained in patients who had undergone BMT in early first chronic phase (49% to 86% long-term survival); the chances for long-term survival became progressively worse when BMT is done in second chronic phase (30% to 58%), accelerated phase (15% to 35%), or blast phase (10% to 20%).[146,147 and 148] More recent studies have not confirmed that delaying transplant in chronic phase is necessarily an independent adverse prognostic factor. [149,150 and 151]

Some investigators have attempted to ameliorate the morbidity and mortality of graft-versus-host disease (GVHD) by depleting the donor marrow of T cells before engraftment. Various techniques have been used for this purpose, including purging with monoclonal antibodies, elutriation, and soybean lectin

agglutination/E-rosette depletion.[152,153,154,155,156,157,158,159] and [160] In general, T-cell depletion has reduced the incidence and severity of GVHD, but at the cost of an increase in the leukemia relapse rate, which negates any long-term survival advantage ( Table 21-8). Similarly, the use of autologous or syngeneic (identical twin) BMT has been accompanied by virtually no GVHD but a high leukemia recurrence rate. On the other hand, development of moderate-to-severe GVHD after administration of an allogeneic or unrelated donor graft appears to confer protection against relapse ( Table 21-8). These results indicate that the intense chemotherapy-radiotherapy conditioning regimens used in conjunction with BMT are often inadequate to eradicate the CML clone without augmentation by a graft-versus-leukemia (GVL) effect.

| Type of transplant | Relapse rate (%) |
|---|---|
| Autologous | 100 |
| T-cell depleted | 50–70 |
| Twin (syngeneic) | 40–70 |
| Allogeneic | 10–20 |
| Without GVHD | 11 |
| With GVHD | 5 |
| Unrelated | |
| Matched | 3 |
| Mismatched | 0 |

**TABLE 21-8. RESULTS OF BONE MARROW TRANSPLANTATION IN CHRONIC MYELOCYTIC LEUKEMIA**

Fewer than 35% of patients with CML have an HLA-identical sibling, with perhaps another 5% having an acceptable, partially histocompatible related donor. For the remaining 60% to 70% of patients, HLA-matched unrelated donors present an alternative source of donor stem cells. Data from the National Marrow Donor Registry [161] indicate that a subset of patients with a combination of favorable prognostic features ( Table 21-9) can expect a 63% DFS at 3 years (DFS defined as lack of evidence of hematologic or bone marrow relapse). In a Seattle study, a similar favorable subset (<50 yr, HLA/DR matched, transplanted within 1 year of diagnosis) had a 74% probability of 5-year survival, an outcome comparable with recipients of fully matched sibling donor transplants. [161a]

| Variable | Relative risk of death |
|---|---|
| Acute GVHD <grade III | 0.36 |
| Chronic phase | 0.67 |
| Age (≤35 yr) | 0.69 |
| Early BMT (≤1 yr from diagnosis) | 0.72 |
| CMV seronegative recipient | 0.80 |

BMT, bone marrow transplant; CMV, cytomegalovirus; GVHD, graft-versus-host disease.

**TABLE 21-9. FAVORABLE RISK FACTORS FOR UNRELATED DONOR MARROW TRANSPLANTATION IN CHRONIC MYELOCYTIC LEUKEMIA**

Treatment options for patients who relapse after allogeneic BMT include use of IFN-a, [162] second transplants, or infusion of lymphocytes from the original donor, or both. Remissions may be induced by the use of IFN-a alone, but at least one-half of these patients ultimately have a relapse again. [163] The survival rate after a second BMT is poor and is complicated by increased procedure-related morbidity and mortality. [164,165] Patients with relapsed CML may also be restored to complete cytogenetic remission by administration of IFN-a together with leukocyte transfusions from the donor [166,167] or by the use of donor leukocyte infusions (DLIs) alone.[168] DLIs can induce second remission in up to 70% of patients; the probability of success is greater if the DLI is administered before hematologic relapse is evident. [169] The risk of GVHD is minimized if an escalating dose schedule of DLI is followed. [170,171] The durability of these remissions (which presumably result from a GVL effect) has not been established.

***Autologous Transplantation.*** Initial attempts at autologous BMT used marrow or peripheral blood cells collected from the patient during chronic phase and stored until there was evidence of metamorphosis. At that point, the patient received myeloablative chemotherapy or radiotherapy, followed by infusion of the chronic-phase cells, in an effort to restore a second chronic phase. This was, at best, a temporizing approach because the marrow was reconstituted with cells of the Ph $^{1}$-positive clone. Usually, the blast-phase cells proved resistant to even the most intensive regimens, and the second chronic phase was brief (median duration, 4 months); fewer than 30% of patients treated in this fashion survived for 1 year. [172,173]

Current approaches to autotransplantation center on the use of grafts that have been manipulated to purge Ph $^{1}$-positive stem cells and enrich for Ph$^{1}$-negative stem cells. Among the techniques currently used for purging are the following: incubation of the cells in long-term bone marrow culture to select for Ph $^{1}$-negative progenitors[174]; exploiting differential responses of normal versus Ph $^{1}$-positive clonogenic cells to various biologic agents (e.g., macrophage inflammatory protein-1a)[175]; separating cells based on differences in immunophenotype[176]; and harvesting peripheral blood stem cells during early hematopoietic recovery from intensive chemotherapy.[177] Carella and colleagues have developed a technique whereby Ph $^{1}$-negative cells are collected from the peripheral blood in the recovery phase after high-dose chemotherapy (idarubicin/cytarabine/etoposide) has been administered in conjunction with G-CSF. [178] The patient then is subjected to myeloablative therapy with busulfan and subsequently autografted with the previously harvested peripheral stem cells. A majority of such patients has achieved a Ph$^{1}$-negative state, which has been durable in some cases.

Preliminary results indicate that at least transient Ph $^{1}$ hematopoiesis can be achieved in 40% to 70% of patients treated with myeloablative therapy in chronic phase and reinfused with autologous marrow or peripheral blood preparations that have been treated to remove Ph $^{1}$-positive precursors.[174,176] Potential obstacles to maintaining permanent remission in these patients are as follows:

1. Contamination of the graft with residual Ph$^{1}$-positive stem cells: Studies using transduced gene markers indicate that Ph $^{1}$-positive cells persist in purged stem cell concentrates and are identifiable in clinical relapses. [179] This problem may be addressed by improved methods of selecting for Ph$^{1}$-negative stem cells.
2. Failure of the conditioning regimen to eradicate residual *in vivo* Ph$^{1}$-positive cells: This problem may be approached by performing BMT in early chronic phase, intensifying the preharvest chemotherapy regimen, and using a more rigorous myeloablative conditioning protocol.
3. Lack of GVL effect: This problem may be approached by the use of immunomodulatory agents such as IFN-a.[174]

***Detection of Residual Leukemia after Bone Marrow Transplant.*** Residual leukemic cells may be detected with increasing sensitivity at the morphologic (hematologic or bone marrow changes), cytogenetic (reappearance of the Ph $^{1}$ chromosome), or molecular level. Molecular relapses can be detected using RT-PCR analysis for *bcr/abl* mRNA transcripts or fluorescent *in situ* hybridization to assess interphase nuclei at the DNA level. More recently, molecular chimerism in myeloid (CD34$^{+}$) precursor cells and detection of p190 $^{bcr/abl}$ have emerged as novel markers of CML evolution that may identify impending cytogenetic relapses after BMT. [180]

Serial assessments of patients with CML have indicated that persistence or reappearance of Ph $^{1}$-positive cells does not necessarily indicate the inevitability of clinical relapse and an unfavorable outcome. Indeed, these patients may show various karyotypic responses after BMT, including (a) complete eradication of the Ph $^{1}$-positive clone, (b) cytogenetic relapse in the presence or absence of hematologic relapse, (c) transient reappearance of Ph $^{1}$-positive cells in the absence of hematologic

relapse, and (d) late (more than 1 year) disappearance of Ph[1]-positive cells in the absence of further therapy. [181,182]

Some investigators find PCR positivity to be limited primarily to patients studied in the first 12 months after BMT [183,184] or in patients given T-cell–depleted grafts, [185] whereas other investigators have found the majority of patients to be PCR positive regardless of the interval after BMT or the T-cell content of the graft. [186,187] and [188] Approximately 70% of patients are RT-PCR negative at 1 year posttransplant and remain so indefinitely. Ph [1] or PCR positivity up to 6 months after BMT may not have adverse prognostic significance, whereas persistence beyond this period identifies patients at a relatively high risk of relapse. [182,183] and [184,189] Predicting the prognosis for patients who vacillate between PCR-positive and PCR-negative status is more difficult. The transitory nature of Ph [1] or PCR positivity in some patients may reflect the persistence of a few long-living T or B lymphocytes or myeloid cells that lack proliferative potential; alternatively, these PCR-positive patients may have mechanisms (e.g., GVL effect) for continuous suppression of residual clonogenic leukemic cells *in vivo*.[190]

### Novel Strategies

The limited success, and excessive toxicity, of conventional chemotherapeutic, immunotherapeutic, and stem cell rescue techniques has stimulated the search for novel therapeutic approaches to the treatment of CML. Promising new approaches include the exploitation of the unique molecular biology of CML cells.

***Pharmacologic Inhibitors of Tyrosine Kinase Activity.*** A specific abl kinase inhibitor known as *STI 571* has demonstrated significant activity in chronic-phase CML patients, even in those who are refractory to interferon. [191] TKs function by transferring phosphate groups from adenosine triphosphate (ATP) to tyrosine residues on various substrates. STI 571 functions as a TK inhibitor by blocking the binding of ATP to *bcr/abl*, thereby inhibiting its TK activity. It is relatively selective in its activity, blocking all abl kinases (including p210 *bcr/abl*, p185 *bcr/abl*, v-*abl*, and the *c-abl*); however, it inhibits no other TKs (except for platelet-derived growth factor receptor and cKit kinase).[192,193] STI 571 also appears to be selectively toxic *in vitro* to cells expressing the *bcr/abl* TK. In a phase I trial, STI 571, as a single agent, induced cytogenetic responses in 45% of IFN-resistant chronic phase patients within 5 months of initiating therapy (10% of patients becoming 100% Ph-negative). [191] Responses were also achieved in 55% of patients with myeloid blast transformation (complete responses in 22%) and in 82% of patients with lymphoid blast crisis or Ph-positive ALL (55% complete responses).[194] All of the blast transformation patients subsequently relapsed, however, indicating the ability of CML cells to develop resistance to STI 571.

***Inhibition of Individual Signaling Pathways Downstream of* bcr/abl.** As the specific signal transduction events that contribute to leukemogenesis become elucidated, efforts may be made to develop rational therapeutic interventions designed to block these pathways. One example is the use of STI 571 to inhibit the TK activity of *bcr/abl* (discussed in the previous section). In addition, molecular strategies may be used to inhibit individual downstream mediators of the *bcr/abl* such as *ras*,[195] raf,[196] *jun* kinase,[197] and *myc*.[198]

***Immunotherapy.*** The junction site of *bcr* and abl generates a sequence of amino acids that is unique to the CML cell, thereby presenting a tumor-specific antigen that has the potential of activating an immune response. A *bcr/abl*-derived peptide vaccine that has demonstrated tumor-specific immunogenicity and a good safety profile is currently in clinical trials. [199]

### *Management of Blast Phase*

Blast phase is generally a treatment-resistant state that terminates fatally within weeks to months. Regimens developed for the treatment of acute myelogenous leukemia have proved disappointing in blast-phase CML (Table 21-10).[9,200,201,202,203,204,205,206,207,208,209] and [210] Patients with myeloblastic morphology have a median survival of 3 months after blast transformation. A regimen of alternate-day plicamycin (mithramycin) and daily hydroxyurea has been reported to convert myeloid blast phase back to chronic phase in occasional cases.[210] The subset of patients with lymphoblastic transformation is more sensitive to chemotherapy; approximately two-thirds of such patients revert to chronic phase after treatment with vincristine-prednisone regimens. [9] The response is of short duration (median less than 6 months), however, and fewer than 20% of patients survive for 1 year. The use of more intensive acute lymphoblastic leukemia regimens, such as the Memorial Hospital L10 or L10M protocols, may extend the median survival to 15 months.[197]

| Regimen | Number of patients | Complete response (%)[a] | Partial response (%)[b] | Reference |

[b]Decline in blast count.

**TABLE 21-10. RESULTS OF CHEMOTHERAPY TREATMENT OF BLAST-PHASE CHRONIC MYELOCYTIC LEUKEMIA**

The results of BMT in blast phase are uniformly poor; fewer than 15% of patients achieve long-term survival with current regimens. In view of the dismal results achieved with other approaches, however, BMT is worth considering in selected cases.

## JUVENILE MYELOMONOCYTIC LEUKEMIA

As a result of review by the International Juvenile Myelomonocytic Leukemia (JMML) Working Group and the European Working Group of Myelodysplasia (EWOG-MDS) in Childhood, an international consensus has been reached whereby the condition known previously as JCML has been reclassified as JMML. [211,212] These groups have also suggested a group of minimal diagnostic criteria for the diagnosis of JMML (Table 21-11).

| Categories | Criteria |
|---|---|
| Suggestive clinical features | Hepatosplenomegaly |
| | Lymphadenopathy |
| | Pallor |
| | Fever |
| | Skin rash |
| Minimal laboratory criteria (must fulfill all three) | Peripheral monocytosis (>1 × $10^9$/L) |
| | Bone marrow blasts <20% |
| | Absence of Philadelphia chromosome and *bcr/abl* rearrangement |
| Further criteria (minimum of two required) | Elevated hemoglobin F (corrected for age) |
| | White blood cell count >10 × $10^9$/L |
| | Immature myeloid cells on peripheral smear |
| | Clonal cytogenetic abnormalities (including monosomy 7) |
| | Hypersensitivity of myeloid progenitors to granulocyte-monophage colony-stimulating factor (*in vitro*) |

**TABLE 21-11. DIAGNOSTIC CRITERIA FOR JUVENILE MYELOMONOCYTIC LEUKEMIA**

Like adult-type CML, JMML is a clonal panmyelopathy involving the pluripotent stem cell. [213] Individuals with neurofibromatosis type 1 (NF-1) are at particularly high risk for developing JMML (approximately 200 to 500 times the general population). [214] Monosomy 7, another myeloproliferative disorder of childhood, shares many of

the features of JMML, but it is usually associated with a lower level of hemoglobin F (Hgb F).[215,216] Although the exact relationship between these two conditions remains unresolved, both the International JMML Working Group and the EWOG-MDS have recommended that they be treated in a similar fashion.[217] It is more important to distinguish JMML from chronic viral infections (especially cytomegalovirus, Epstein-Barr virus, and human herpesvirus-6), which can also produce hepatosplenomegaly, lymphadenopathy, leukocytosis, thrombocytopenia, and elevated Hgb F levels. Serologic studies to detect an antibody response to one of these viruses are helpful. Bone marrow examination may be helpful in that viral infections may produce hemophagocytosis, which is not a feature of JMML. The distinctive granulocyte-macrophage colony-stimulating factor (GM-CSF) sensitivity manifested by JMML marrow cells in tissue culture (discussed in the following section) may also be useful in making the distinction.[218]

**Biology**

Hematologic and cytogenetic evidence confirms that JMML is a clonal disorder, with the leukemic progenitor cell capable of giving rise to erythroid, myeloid, monocytic, and megakaryocytic lineages[213,219,220 and 221] (and possibly lymphoid lineages as well). The predominant cell in the peripheral blood and the bone marrow appears to be a primitive monocytic precursor, however.[208,219,222,223] The high incidence of NF-1 and *ras* mutations in JMML (see Cytogenetic Features) suggest that deregulation of the *ras* signal transduction pathway may be a major mechanism in the pathogenesis of JMML. This may occur either via activating mutations of the *ras* genes or inactivating mutations in genes regulating *ras* (e.g., NF-1) whereby *ras* remains locked in an activated ATP-bound state, transmitting continuous signals for proliferation. A murine model using homozygous deletions of the NF-1 gene has confirmed the role of *ras* deregulation in promoting hypersensitivity to GM-CSF.[224]

A characteristic *in vitro* finding has been the excessive production of monocyte-macrophage colonies without a requirement for exogenous growth factors; this apparent spontaneous proliferation actually reflects an exquisite sensitivity of the JMML progenitor cells to low concentrations of various endogenous cytokines, including GM-CSF, tumor necrosis factor-a (TNF-a), and IL-1b.[225,226,227,228 and 229] Although it is not definite which of these molecules is the primary regulator of the JMML clone, some evidence suggests that autocrine secretion of TNF-a by the leukemic cells stimulates the production of GM-CSF by target cells, which, in turn, stimulates further proliferation and accumulation of leukemic monocytes and macrophages; IL-1 may represent an important accessory factor that augments the effects of TNF-a and GM-CSF.[227] TNF-a may augment the growth advantage of the malignant clone by inhibiting normal hematopoiesis.[228]

The exquisite sensitivity of the JMML clone to GM-CSF does not appear to result from abnormalities in the GM-CSF molecule or its receptor.[221] Instead, there appear to be aberrations in the *ras* pathway by which GM-CSF transmits growth signals to the nucleus.[229] This pathway may be inappropriately amplified either by mutations in *ras* genes themselves[230] or by defective regulation of *ras*. Neurofibromin, the protein that is altered in NF-1, is normally a GAP and thereby, a negative regulator of *ras*; loss of normal neurofibromin control of *ras* can result in unregulated myeloid proliferation.[231,232] This may account for the increased incidence of JCML in NF-1 patients.

In support of cytogenetic data, functional studies have also implicated the erythroid lineage within the JMML clone. Clonogenic cells of the erythroid series have been demonstrated in large numbers in both the peripheral blood and the bone marrow of patients with JMML.[233] As with myeloid progenitors, these burst-forming unit erythroid cells require minimal concentrations of their “poietin” (erythropoietin in this instance) for *in vitro* colony production.[216,233,234] Furthermore, constitutive expression of erythroid markers can be demonstrated in clonogenic cells of patients with JMML.[235]

**Clinical Features**

Most patients with JMML are diagnosed before the age of 2 years. Presenting physical findings include cutaneous lesions (e.g., eczema, xanthomata, and café-au-lait spots), lymphadenopathy, hepatosplenomegaly, and hemorrhagic manifestations. Respiratory symptoms (e.g., chronic tachypnea, cough, and expiratory wheezing) may be prominent.

**Laboratory Features**

The peripheral blood is characterized by anemia, leukocytosis, and thrombocytopenia. The leukocytosis is generally not as pronounced as in adult CML and is associated with a relatively high proportion of blasts (including normoblasts), lymphocytes, and monocytes. The bone marrow shows both erythroid and myeloid hyperplasia; immature cells of the monocytic series are prominent, and megakaryocytes are infrequent.

The erythrocytes show many features characteristic of fetal-type erythropoiesis, including high Hgb F level, fetal glycine-alanine ratio in the c chain of Hgb F, fetal-type glycolytic enzyme pattern, and low I antigen expression.[236,237] The LAP score is low in approximately 40% of patients.[11] Immunologic abnormalities include strikingly high immunoglobulin levels, high incidence of antibodies to nuclear antigen and immunoglobulin G,[238] and possible inability to control Epstein-Barr virus infection.[239]

**Cytogenetic Features**

The cytogenetic pattern of JMML is heterogeneous, the only consistent feature being absence of the Ph $^{1}$ chromosome. Abnormalities, when found, most commonly involve chromosomes 7 and 8.[213,239] Monosomy 7 is found in approximately 25% to 33% of JMML patients.

At the molecular level, gene changes are found quite frequently in JMML cells. Approximately 15% of JMML patients have clinical features of NF-1 with accompanying NF-1 mutations, whereas another 15% have NF-1 gene mutations in the absence of other manifestations of neurofibromatosis.[240] Approximately 30% of JMML patients have mutations in the *ras* genes, usually in codons 12 or 13 of N-*ras* or K-*ras*.[241] NF-1 and *ras* mutations do not occur concurrently in the same patient.[240]

**Natural History**

The course of JMML is quite variable and hard to predict. Some patients may experience relatively indolent disease with prolonged survival, whereas others progress to death from infection or other complications of bone marrow failure. Transformation to an acute leukemic blast crisis is an unusual event in JMML, occurring in approximately 15% of patients.[242] Overall median survival time for patients with JMML is less then 9 months. Prognosis varies with age at diagnosis, however; infants may survive for extended periods (mean 5-year survival is 67%), whereas children older than 1 year have virtually 0% long-term survival.[243] Most patients die of infection; fewer than 20% progress to a terminal blast phase. As in adult CML, the blast phase of JMML may be heterogeneous: cases of B-cell[244] and stem cell transformation have been reported. JMML may also terminate in an erythroleukemia-like phase, characterized by anemia, erythroblastosis, and megaloblastic erythroid hyperplasia of the bone marrow.[245]

**Therapy**

Generally, chemotherapy has been of limited value in JMML. Oral 6-mercaptopurine, either alone or in combination with subcutaneous cytarabine, has produced symptomatic relief in some patients,[246] but supportive care has been as effective as vigorous chemotherapy in most cases. In some cases, intensive multiagent chemotherapy (as used for treatment of acute nonlymphoid leukemias) has produced clinical remissions lasting as long as 27 months or longer.[247] However, intensive multiagent chemotherapy has generally been associated with high morbidity and generally short-lived remissions.[212,248] Thus, the First International Workshop on MDS in Childhood has recommended that such an approach should only be used in the setting of a pretransplant regimen.[217] The combination of hydroxyurea and IFN-a may also show activity in JMML.[249] Stem cell transplantation is currently the gold standard for treatment of JMML with overall 5-year survival rates in the range of 20% to 30%; the major barrier to cure with this modality has been the high relapse rate (greater than 50%).[217]

***Biologic Approaches to Juvenile Myelomonocytic Leukemia***

**Isotretinoin**

Isotretinoin (13-*cis*-retinoic acid) has been demonstrated to attenuate the *in vitro* “spontaneous” proliferation of monocyte precursors and their selective hypersensitivity to GM-CSF.[250] An overall response rate of 40 % to 50% has been reported in a phase II clinical trial using doses of *cis*-retinoic acid as high as 200 mg

per $m^2$.[251] However, sustained unmaintained responses are rare.

### Inhibitors of *ras* Farnesyl Protein Transferase

A critical prerequisite for *ras* function is localization to the inner leaflet of the plasma membrane; this can only occur if newly synthesized *ras* undergoes sequential posttranslational enzymatic processing, a process known as *prenylation*.[252] The initial and rate-limiting step in this sequence is catalyzed by the enzyme farnesyl protein transferase. Inhibitors of farnesyl protein transferase have shown the ability to down-regulate *ras* function by preventing proper localization of the ras protein; this results in an antiproliferative effect. [253] Preclinical studies have indicated that farnesyltransferase inhibitors are well tolerated in laboratory animals and cause regression in some tumors.[254]

### Other Approaches

Other novel biologic approaches that are specifically designed to target the molecular peculiarities of JMML cells include: analogues of GM-CSF that antagonize its effect on JMML cells[255] and GM-CSF/diphtheria toxin fusion molecules.[256]

## FAMILIAL CHRONIC MYELOCYTIC LEUKEMIA

A familial form of CML has been reported in at least three pairs of infant siblings. [257,258] This disorder is indistinguishable from JMML by standard clinical and laboratory criteria; however, its evolution is less predictable. In each of the families studied, one sibling died of progressive leukemia, and the other had long-term asymptomatic survival.

### Chronic Myelomonocytic Leukemia

Chronic myelomonocytic leukemia (CMML) is a rare disorder of childhood characterized by recurrent upper respiratory and pulmonary infections, anemia, unexplained monocytosis, neutropenia, thrombocytopenia, and progressive splenomegaly. [259,260 and 261] Atypical monocytoid cells with unipolar hairy projections are seen in the peripheral smear, and the bone marrow is hypercellular, with a high proportion of young myeloid and monocytoid forms. In some patients, the course of the disease may be relatively indolent, and aggressive chemotherapy may actually shorten survival by producing severe pancytopenia. Low-dose cytarabine has achieved complete remissions in some adults with CMML.[262]

## CHRONIC MONOCYTIC LEUKEMIA

Chronic monocytic leukemia is characterized by anemia, neutropenia, and thrombocytopenia in association with an increased number of mature monocytic elements in the blood and bone marrow. Extramedullary tissues, such as skin, gums, and viscera, may also be involved. Only a few cases of childhood chronic monocytic leukemia have been reported, and some of these may actually represent cases of acute monocytic leukemia, histiocytosis, or JMML. [263,264]

## CHRONIC LYMPHOCYTIC LEUKEMIA

CLL is a disease primarily of elderly adults; only rare cases have been reported in children. [265,266,267,268,269,270 and 271] The neoplastic cell appears to be a small B lymphocyte closely resembling the B cells residing in the mantle zone of secondary lymphoid follicles.

### Clinical and Laboratory Features

Presenting features include pallor, hepatosplenomegaly, and generalized lymphadenopathy. Hematologic findings include anemia, lymphocytosis, and infiltration of the bone marrow with small mature lymphoid cells. Lymph node architecture is obliterated by a diffuse population of small lymphocytes. Functional immunologic defects of both B-cell and T-cell populations are demonstrable. These include hypogammaglobulinemia, inadequate antibody response to antigenic stimuli, and decreased responsiveness to mitogens.

The characteristic phenotypic features of the CLL B lymphocyte is coexpression of CD5 and faint amounts of surface immunoglobulins (sIg). Monoclonality of the lymphoid population is demonstrable by analysis of membrane sIg and of immunoglobulin gene rearrangement. These techniques have been applied to only a handful of pediatric cases, however. [265,266 and 267]

### Cytogenetics

Common nonrandom cytogenetic abnormalities in adult CLL include trisomy 12, 14q+ translocations, trisomy 3, and abnormalities of chromosome 6. [272,273] In a pediatric case, t(2;14)(p13;q32) with breakpoints at or near the k light chain and heavy chain loci was reported.

### Therapy

Historically, CLL has been treated in a palliative fashion using alkylating agents (chlorambucil or cyclophosphamide), and sometimes steroids. Only two reported pediatric cases[258,261] have been treated in this fashion, and both patients responded well. At least two others [260,270] have had stable courses without any chemotherapy. New approaches have employed interferon-alpha, monoclonal antibodies (rituximab-anti CD20; Campath-1H–anti CD52). [274,275]

# MYELOPROLIFERATIVE AND MYELODYSPLASTIC DISORDERS

FRANKLIN O. SMITH
WILLIAM G. WOODS

## INTRODUCTION

The vast majority of cases of myeloproliferative (MPS) and myelodysplastic (MDS) disorders occurs in the elderly, but can on occasion occur in childhood. These diseases represent a heterogeneous group of clonal stem cell disorders that are manifest as ineffective hematopoiesis and an increased risk of developing acute myeloid leukemia (AML).[1,2,3,4,5,6,7,8,9 and 10] In MDS, ineffective hematopoiesis results in progressive pancytopenias, whereas in the MPS disorders, at least initially, ineffective hematopoiesis is characterized by excessive peripheral blood counts. Another feature common to the MDS and MPS disorders has been a relative inability to cure patients with conventional agents. Although a number of nontransplant treatment strategies have been explored for these disorders, cure for these disorders has most often been achieved with myeloablative therapy followed by allogeneic stem cell transplantation.

As illustrated in Figure 22-1, it may be helpful to consider pediatric MPS and MDS syndromes in the following manner: The MPS disease seen most commonly in children is the adult form of chronic myelogenous leukemia (CML) characterized by the Philadelphia (Ph) chromosome ( *bcr/abl*-positive) (discussed in Chapter 21). Other forms of MPS that are seen with some frequency in adults are exceedingly rare in children. Therefore, polycythemia vera, essential thrombocythemia, and agnogenic myeloid metaplasia (AMM)/myelofibrosis are only briefly discussed in this chapter. Interested readers are referred to the cited references and adult textbooks for a more in-depth discussion of these disorders. The MDS syndromes of childhood can be considered in terms of de novo (primary) MDS or secondary MDS. The secondary MDS syndromes may be thought of in terms of MDS resulting from exposure to chemotherapy or radiation; secondary to congenital, constitutional disorders (e.g., Down syndrome); or the result of associated bone marrow failure syndromes (e.g., Fanconi anemia and congenital neutropenia). Finally, a group of disorders that “bridge” the MPS and MDS disorders is discussed. This group includes juvenile myelomonocytic leukemia (JMML), which, though rare, is among the most common of these disorders in children. Also included in this group is chronic myelomonocytic leukemia (CMML) in the proliferative phase, a disorder that is extremely rare in children.[11] Finally, although familial monosomy 7 may predispose patients to the development of myelodysplasia,[12] MDS and myeloproliferative disorders characterized by abnormalities in chromosome 7 (e.g., monosomy 7 syndrome) are no longer considered to be a distinct entity or represent a separate diagnostic category.

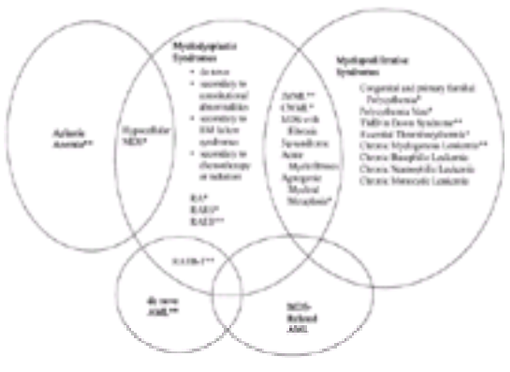

**FIGURE 22-1.** Conceptual model for myelodysplastic (MDS) and myeloproliferative (MPS) disorders. *Reported incidence. **Common form of MDS or MPS. AML, acute myeloid leukemia; BM, bone marrow; CMML, chronic myelomonocytic leukemia; JMML, juvenile myelomonocytic leukemia; RA, refractory anemia; RAEB, refractory anemia with excess blasts; RAEB-T, refractory anemia with excess blasts in transformation; RARS, refractory anemia with ringed sideroblasts; TMD, transient myeloproliferative disorder.

## MYELODYSPLASTIC SYNDROMES

Until recently, the MDS syndromes of children, previously called *chronic monocytic leukemia*, *pre-leukemia*, and *hematopoietic dysplasia*, have been poorly defined, characterized, studied, and reported. In fact, one review of the classification of pediatric cancers failed to include MDS on its list of childhood malignancies.[13] This lack of understanding has been further complicated by the rarity of this disorder, lack of uniform diagnostic criteria, confusing nomenclature, and a poor understanding of the biologic mechanisms of disease. Further complicating a better understanding of these disorders in children has been the use of classification and prognostic systems designed for adult patients with MDS. These classification and prognostic systems, which have proven to be useful tools in the understanding and treatment of adult MDS, have proven to have little utility for children with MDS, in whom the pattern of disease, natural history of the disease, cytogenetic abnormalities, and associated anomalies are strikingly different from those of adults with MDS. As a result of these limitations, much of what has been described about childhood MDS has been generated from studies of adults with MDS, with the inclusion of small numbers of pediatric patients in these reports. Therefore, the accuracy and usefulness of much of the current information regarding children remains uncertain.

In recent years, however, many of these limitations have been addressed. International agreement has been reached with regard to uniform diagnostic criteria for many of these diseases, encompassing the use of morphology, immunohistochemistry, immunology, cytogenetics, and molecular biology. The number of scientists interested in childhood MDS has increased dramatically, and children with MDS are now being prospectively enrolled in large cooperative group clinical trials sponsored by the European Working Group on MDS of Childhood (EWOG-MDS), the Children's Oncology Group (COG), and others to help better define the true nature of these diseases and their response to uniformly delivered therapies.

## Definition

The MDS syndromes are a heterogeneous group of disorders of hematopoiesis that are characterized by ineffective hematopoiesis; impaired maturation of hematopoietic cells; progressive cytopenias associated with dysplastic changes in bone marrow cells; hypercellular, normocellular, or hypocellular bone marrow; and an increased risk of developing AML.

## Diagnosis

Morphologically, these disorders are characterized by dysplastic features of the peripheral blood and bone marrow in the granulocytic, megakaryocytic, monocytic, or erythrocytic lineages, occurring in a single lineage or in multiple lineages. However, precise definitions for the morphologic changes that constitute dysplastic changes have not been generally agreed on by hematopathologists. Although dysplastic features of marrow and peripheral blood cells are critically important in identifying MDS, dysplasia itself is not specific for MDS and can be the result of numerous other inciting events, unrelated to MDS. In fact, it has also been demonstrated that otherwise normal adults, with normal peripheral blood counts, who are donating bone marrow for allogeneic transplantation may have ringed sideroblasts and dysplastic features in granulocytes and erythroid cells. [14]

Dysplastic features in the granulocytic lineage of the bone marrow include dysgranulopoiesis with hypogranulation, nuclear hyposegmentation, megaloblastoid maturation, and a left shift with an increased number of myeloblasts. The peripheral blood may show dysgranulopoiesis with circulating myeloblasts, hypogranulation of neutrophils and eosinophils, and Pelger-Huet–type abnormalities. Dysplastic features of the bone marrow involving the erythroid lineage include megaloblastoid maturation, nuclear budding and multinucleated forms, and ringed sideroblasts. The peripheral blood may demonstrate dyserythropoiesis with polychromasia. Dysmegakaryocytopoiesis may be manifest in the bone marrow as micromegakaryocytes and abnormal megakaryocyte nuclei, with the peripheral blood demonstrating agranular and giant platelets. Dysplastic features of the monocyte lineage include an increase in bone marrow monocytes, abnormal granulation with persistence of azurophilic granules, hemophagocytosis, abnormal nuclei, and giant forms. The peripheral blood may demonstrate an increased number of monocytes and blasts forms.

Cytogenetic abnormalities may differ in patients with de novo MDS and those with therapy-related MDS. In children and adults with de novo MDS, cytogenetic analysis performed in a laboratory experienced in performing this test in malignant cells demonstrates clonal cytogenetic abnormalities in approximately 80% of patients[15,16] with an increasing percentage of patients with cytogenetic abnormalities as the disease progresses. [17] Most chromosomes have been reported to be involved in adults with MDS, although those most commonly involved are chromosomes 5, 7, 8, 9, 11, 12, 18, 19, 20, and 21. [18] Involvement of these chromosomes may involve complete or partial chromosome loss (e.g., monosomy 7 and 7q–, respectively), chromosome gain (e.g., trisomy 8), and various chromosome translocations. However, chromosome abnormalities, including t(8;21), t(15;17), t(9;11), and inv(16), commonly found in de novo AML, are not commonly seen in MDS. It is perhaps appropriate to consider a diagnosis of de novo AML with low blast count in children thought to have MDS characterized by chromosomal abnormalities commonly found in AML [e.g., t(8;21) and inv (16)].

Greater than 50% of children with de novo MDS (with a higher percentage in secondary MDS) have a detectable chromosome abnormality. The karyotypic abnormalities most commonly seen in de novo MDS in children include –7, 7q–, and +8. The addition of chromosomes 6, 9, and 11 as well as deletions of chromosomes 11, 12, and 13 are rarely present, but have been reported in pediatric MDS patients. Of importance is the finding that certain chromosomal abnormalities commonly present in de novo MDS in adults, including –5, 5q–, and –Y, are not present in pediatric MDS.

Karyotypic analysis is routinely performed using standard chromosome banding techniques. These techniques have significant limitations, including contracted metaphases, poor chromosome spreads, and limited ability to identify complex translocations and small insertions. Fluorescence *in situ* hybridization techniques have helped to overcome some of these technical limitations, [19] but are still limited to abnormalities that have been previously characterized. The recent development of multicolor spectral karyotyping may augment conventional banding techniques, as it increases the ability of cytogeneticists to identify unidentified chromosomal aberrations.[20,21] These technical advances may aid in the identification of significant, currently identified chromosomal abnormalities in children with MDS.

Flow cytometric analysis may also be used to gather additional evidence of dysplasia as determined by aberrant cell surface antigen expression. As an adjunct to morphology, flow cytometry can also be used to quantitate the percentage of myeloblasts and CD34 $^{+}$ cells in the marrow.[22] Additionally, in the evaluation of pediatric patients for the rare disease, paroxysmal nocturnal hemoglobinuria (PNH), flow cytometric analysis for the cell surface antigen CD91 (glycosylphosphatidylinositol-linked cell surface proteins), is a more sensitive and specific measure of PNH-like cells than the traditional Ham's test. [23] However, although many adult patients with MDS have been demonstrated to have PNH-like cells in all lineages, clinical evidence of hemolysis is not usually detectable. [23] Therefore, although flow cytometry may serve as a useful tool to aid in the diagnosis of MDS, current classification and prognostic criteria do not require flow cytometry results for classification or prognostication.

## Classification

A number of criteria for classifying MDS syndromes have been proposed. The most commonly used criteria for adults is that proposed by the French-American-British (FAB) Cooperative Group in 1982.[24,25] and [26] As is illustrated in Table 22-1, this classification recognizes five distinct forms of MDS: refractory anemia (RA), RA with ringed sideroblast (RARS), RA with excess blasts (RAEB), RA with excess blast in transformation (RAEB-T), and CMML. Some studies suggest additional subtypes of MDS in children and adults that do not easily fit into the current FAB classification. These include therapy-related MDS, hypoplastic MDS, refractory cytopenias with trilineage dysplasia, and MDS with associated myelofibrosis. [27,28,29,30,31] and [32] This classification system, though commonly used for children, has been of limited value in pediatric MDS patients. [33,34,35] and [36] The current FAB classification fails to account for MDS disorders associated with inherited conditions (e.g., certain congenital neutropenia, Shwachman syndrome, Down syndrome, type I neurofibromatosis, and Fanconi anemia), complex congenital abnormalities and the mitochondrial cytopathies.[37,38]

| Classification | Bone marrow blasts (%) | Peripheral blood blasts (%) | Sideroblasts (%) | Peripheral blood monocytes |
|---|---|---|---|---|
| Refractory anemia | <5 | ≤1 | ≤15 | ≤1 × 10⁹/L |
| Refractory anemia with ringed sideroblasts | <5 | ≤1 | >15 | ≤1 × 10⁹/L |
| Refractory anemia with excess blasts | 5–20 | ≤5 | Variable | ≤1 × 10⁹/L |
| Refractory anemia with excess blasts in transformation | 21–30 or Auer rods present | ≥5 or Auer rods present | Variable | Variable |
| Chronic myelomonocytic leukemia | ≤20 | <5 | Variable | ≥1 × 10⁹/L |

From Bennett JM, Catovsky D, Daniel MT, et al. Proposals for the classification of the myelodysplastic syndromes. Br J Haematol 1982;51:189–199, with permission.

**TABLE 22-1. FRENCH-AMERICAN-BRITISH CLASSIFICATION OF MYELODYSPLASTIC SYNDROMES**

Using the FAB criteria, RA, RAEB, and RAEB-T have been reported in children, with RA being uncommon and RARS only rarely reported. [35,39,40,41,42,43] and [44] CMML is only rarely seen in children. CMML shares many characteristics with JMML. [11,40,45,46,47,48] and [49] However, the main distinguishing characteristic is the high percentage of fetal hemoglobin in JMML children. JMML is also most common in children younger than 5 years of age, whereas CMML is extremely rare in children younger than 5 years.

As a result of limitations in the FAB classification system, the World Health Organization (WHO) recently proposed changes to the FAB criteria. [50,51] Among the WHO's proposed changes are the elimination of the subtype RAEB-T, a reduction in the marrow blast count to 20% for a diagnosis of AML, the division of the RAEB subtype into RAEB-I (consisting of 5% to 10% marrow blasts) and RAEB-II (11% to 20% blasts), and removal of Auer rods as having any impact on the assignment of FAB

subtype. WHO also proposes the creation of two new subtypes for patients with refractory cytopenias with multilineage dysplasia (excluding erythroid dysplasia and less than 5% blasts) and a new category for unclassified MDS, including severe myelofibrosis, 5q–, 17p1, etc. ( Table 22-2). Finally, CMML is removed from the FAB schema and reclassified as a MPS. Although this new classification of CMML accounts for the proliferative phase of CMML, it does not allow for classification of the nonproliferative phase of the disease. These proposed changes remain untested and are considered to be controversial. Their utility in pediatric MDS remains unclear.

## Incidence and Epidemiology

Despite an increasing number of case reports, the true incidence of pediatric MDS is unknown, but generally is estimated to account for approximately 3% to 7% of childhood hematologic malignancies. Only three actual population-based studies have been reported. [52,53 and 54] In the study based in Denmark, an annual incidence of 4.0 cases per million was determined, representing 9% of all pediatric hematologic malignancies in that country. More recently, the annual incidence of pediatric MDS in British Columbia, Canada, was determined to be 3.1 cases per million, representing 6% of hematologic malignancies in British Columbia. [54] In contrast, data from the Surveillance, Epidemiology, and End Results survey for the years 1990 to 1995 suggest an annual incidence for de novo AML in children age 15 years or younger is 7.0 cases per million.[55] Most observers think that pediatric MDS has an incidence of approximately 10% of that of AML. Hence, if this estimate is accurate, the annual incidence of MDS in the United States may be in the range of 0.8 cases per million.

A number of environmental exposures and genetic disorders may predispose patients to the development of MDS. Exposure to alkylating agents (e.g., cyclophosphamide and nitrogen mustard),[56,57] topoisomerase II agonist and antagonist (e.g., etoposide), and ionizing radiation may increase the probability of MDS and AML. Many children with MDS have other associated anomalies, with Down syndrome being seen most frequently. Other congenital syndromes, such as neurofibromatosis and bone marrow failure syndromes, including Kostmann's congenital neutropenia, Schwachman syndrome, Blackfan-Diamond syndrome, thrombocytopenia with absent radii, trisomy D, Klinefelter's syndrome, familial thrombocytopenia, and Fanconi anemia, have been demonstrated to predispose these children to an increased probability of MDS and subsequent AML. [55,58]

## Etiology and Pathophysiology

The etiology of MDS is not well understood. The inciting events in MDS have been difficult to discern. This is in part due to significant heterogeneity of these diseases as well as a poor understanding of the numerous molecular and cellular abnormalities likely responsible for initiation of the disease versus those abnormalities that are secondary to genetic instability in MDS clones. Like Ph chromosome–positive ($Ph^+$) CML, MDS is thought to originate in a single immature hematopoietic stem cell. However, unlike CML, in which the basic molecular defect (*bcr/abl* translocation) has been identified, a single molecular abnormality has not been identified in MDS. Evidence for involvement of an immature hematopoietic stem cell with subsequent clonal involvement of multiple lineages was first suggested in studies of adult females with MDS using a marker of X-chromosome inactivation, glucose-6-phosphate dehydrogenase isoenzymes,[59,60] and cytogenetic marker studies.[2,61,62,63,64,65 and 66] Newer assays to determine clonality, including X-linked restriction fragment polymorphisms, polymerase chain reaction of the phosphoglycerate kinase gene, and X-chromosome human androgen receptor locus assays, demonstrate the clonal involvement of granulocytes and erythrocytes, [4,67] with possible, but still controversial involvement of the B- and T-lymphocyte lineages.[5,68,69,70,71,72 and 73] It should be noted, however, that these studies have not been widely performed in pediatric MDS patients. Most studies of clonality in MDS have been performed in older adults in whom clonal and oligoclonal hematopoiesis may occur, even in apparently normal individuals.[74,75] Additionally, to account for heavy Lyonization with skewing of patterns of clonality, normal, uninvolved somatic tissues (e.g., skin fibroblasts) have not always been used as appropriate negative controls in these studies, [76] making interpretation of the results difficult. Despite these limitations, however, clonality appears to be an early event in the origin of MDS.

It is generally thought that MDS involves an abnormality in an immature stem cell that leads to the proliferation of a MDS clone of cells along with normal hematopoietic elements. This mosaicism of normal and abnormal hematopoiesis may coexist for prolonged periods. [77] However, as additional injuries and molecular defects occur in this abnormal, MDS clone, the abnormal clone appears to develop a competitive advantage over normal hematopoietic elements, leading to suppression of normal hematopoiesis[70,73,78] and eventually to only ineffective, clonal hematopoiesis. [2,79,80] As these MDS cells may have maturation defects and normal hematopoiesis is impaired, peripheral cytopenias eventually occur. As additional defects are acquired (e.g., karyotypic abnormalities, *ras* gene mutations, *FHIT* gene alterations, mutations in *WT1*, and *p53* gene abnormalities) as the result of additional toxic exposures or as a result of a generalized genetic instability in these abnormal clones, transformation to AML may occur.[2,79,80,81,82,83,84,85,86,87 and 88]

A number of distinct cytogenetic abnormalities may occur as these abnormal clones evolve. The most common abnormalities include the complete loss of specific chromosomes (e.g., chromosome 7), partial chromosome losses [e.g., the long arm of chromosomes 7 (7q–)] or the addition of extra chromosomes (e.g., trisomy 8).[62,64,89,90,91,92,93,94,95,96,97,98,99,100,101,102,103,104,105 and 106] It is not known if abnormalities in these chromosomes are inciting events leading to the development of MDS or secondary events. The biologic implications of these chromosomal abnormalities are also unclear. It is known, however, that a number of genes presumed to be important in the control of hematopoiesis are encoded on these large areas of DNA that are gained or lost during the evolution of MDS clones. For example, chromosome 5q, commonly seen in older adult females with 5q– syndrome but rarely seen in pediatric MDS, contains genes encoding for granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage CSF, interleukin-3 (IL-3), IL-4, and IL-5, erythrocyte glutathione reductase-1, and interferon regulatory factor 1. [107,108 and 109] Many of these genes have significant roles in the regulation of hematopoiesis. The clinical impact of abnormalities to these genes is not well described. For childhood MDS, little is known of the genes involved in abnormalities of chromosome 7, the most commonly described karyotypic abnormality in children. However, it has been suggested that MDS characterized by familial monosomy 7 or 7q– may be the result of multiple genetic events because the predisposition to MDS is not located within a consistently deleted segment on the long arm of chromosome 7.[12]

Additionally, although the genes responsible for MDS have not been clearly identified, it has been postulated that molecular abnormalities in certain tumor suppressor genes, also located on these involved chromosomes, may be responsible for the evolution of the MDS clones to overt AML. [110] For example, children with inherited abnormalities of the neurofibromatosis type 1 (*NF1)* gene are at increased risk of MDS, MPS, and AML after loss of the normal allele. However, loss of heterozygosity has not been found in adults with MDS.[111] Loss of heterozygosity of *NF1* or in other growth regulatory and tumor suppressor genes has not yet been demonstrated in children or adults.[112,113 and 114]

Finally, whereas mutations in the proto-oncogene *ras* have been reported in many human malignancies, including 30% to 40% of children with MDS, the true frequency of point mutations in *ras* is uncertain.[115,116,117 and 118] It has been demonstrated that an increasing frequency of *ras* mutations occurs with progression of MDS,[119,120] but it is not currently thought that activating point mutations in *ras* alone is sufficient for the initiation of MDS. Rather, it is currently believed that *ras* mutations represent a later, secondary event in the progression of MDS and are the result of an overall genetic instability inherent to MDS clones.

Based on these data, it has been suggested that MDS represents a hyperproliferative disorder that is initially held in check by apoptosis mechanisms, perhaps induced by events that cause DNA damage that results in cell cycle arrest. [121] Progression of MDS and transformation to AML occur as the genetically unstable clones

develop additional molecular abnormalities. This same multistep pathogenesis has been implicated in the tumorigenesis of adult carcinomas.

Thus, it may be very important to differentiate truly de novo AML, in which the blast count is irrelevant, from that of MDS-related disease. [121] In this model, RA and RAEB may be indicative of MDS, whereas RAEB-T may be truly de novo AML with a lower blast count. Differentiation between diseases in these two categories is very important as these diseases may respond to different therapies. Although this model may accurately reflect the mechanism of disease for truly de novo AML, MDS, and MDS-related AML in the elderly, it remains unclear if this mechanism represents operant mechanisms for de novo MDS in children. [121,122]

**Clinical Presentation**

The presenting signs and symptoms of MDS in children are nonspecific and are usually the result of pancytopenia. However, it is not unusual for abnormalities in the peripheral blood to be determined on routine health screens in asymptomatic children. Symptomatic children will frequently present with signs of marrow failure, including pallor, fatigue, bruising, petechiae, and infections. In addition, infectious complications in patients whose MDS is characterized by monosomy 7 may be due, in part, to defects in neutrophil chemokinesis and chemotaxis. [123,124] Although common in the MPS syndromes, lymphadenopathy, hepatomegaly, and splenomegaly are unusual presenting signs for children with MDS.

**Differential Diagnosis**

A careful history, physical examination, and evaluation of the peripheral smear and bone marrow for dysplastic features and clonal cytogenetic abnormalities easily identify most cases of MDS in children. However, other diseases must be considered in the differential diagnosis, particularly when the diagnosis is complicated by an absence of clonal cytogenetic abnormalities and an aplastic marrow. The possibility of various associated anomalies, such as Down syndrome, and congenital marrow failure syndromes, such as congenital neutropenia, Fanconi anemia, Shwachman syndrome, Blackfan-Diamond syndrome, the congenital dyserythropoietic anemias, and hereditary sideroblastic anemia, should be considered. Severe aplastic anemia (SAA) can be difficult to distinguish from hypoplastic MDS. While rare, PNH can occur in childhood and should be considered. However, as PNH-like cells have been reported in MDS, care should be taken in the evaluation of patients for PNH. [23] Certain nutritional deficiencies, including vitamin $B_{12}$ and folate deficiency can result in megaloblastoid changes that appear similar to dysplastic changes present in MDS. Other nutritional deficiencies of iron, riboflavin, pyridoxine, and thiamine [125] should also be considered. The differential diagnosis should also include AML with low blasts counts,[126] MPS disorders, mitochondrial cytopathies, viral infections (e.g., human immunodeficiency virus, [127,128] parvovirus, Epstein-Barr virus, human herpes virus 6, and cytomegalovirus), toxins (e.g., insecticides and chemotherapy), and changes secondary to cytokine and radiation exposures.

**Treatment and Outcome**

Given the clonal origin of MDS in an immature hematopoietic stem cell, these diseases are generally thought to be incurable with conventional therapies. Although a number of supportive care measures, chemotherapy combinations, hematopoietic growth factors, hormones, immune modulators, and differentiating agents have been studied, cures are generally achieved only after myeloablative chemotherapy and radiation with allogeneic transplantation.

Supportive care approaches have been attempted in some children with RA. Although the natural history of RA has not been well described in children, long-term survival has been seen in some children with RA who receive only supportive care. In addition, rare MDS patients whose disease is characterized by the presence of monosomy 7 have achieved spontaneous hematologic and cytogenetic remissions.[129]

Hormones (e.g., glucocorticoids, androgens, and danazol), [130,131,132,133 and 134] differentiating agents (e.g., 13-*cis*-retinoic acid, all-*trans* retinoic acid), [135,136,137,138 and 139] and hematopoietic growth factors (e.g., GM-CSF, granulocyte colony stimulating factor, and erythropoietin) [140,141,142,143 and 144] have been studied extensively in adults with MDS, generally with results that do not support their role in the routine management of MDS patients. The role of these agents in MDS of childhood has been largely untested.

Amifostine, a phosphorylated aminothiol, has been shown to protect hematopoietic progenitor cells and other normal tissues from the toxic effects of alkylator and organoplatinums while maintaining the antitumor effects of these agents. [145,146 and 147] Although the mechanism of chemoprotection in normal cells is not clearly understood, amifostine is thought to be mediated through oxygen-free radical scavenging pathways. [148] *In vitro* studies of amifostine and MDS cells have demonstrated that exposure to amifostine enhances the survival of primitive hematopoietic progenitors, [149] increases the numbers of normal colonies with decreasing colonies derived from abnormal progenitors,[150] and reduces the proportion of apoptotic early progenitor cells. [151] Amifostine has been studied in phase I and phase II studies in adults with MDS.[152,153,154 and 155] These studies have suggested that amifostine may be effective in ameliorating MDS-induced cytopenias in a portion of patients. In the largest of these adult studies, single or multilineage cytopenias were improved in 41% of patients, with a decrease in bone marrow blasts in 35% of patients. [155] Amifostine has been used in conjunction with melphalan for children with refractory malignancies as part of a phase I, dose escalation trial. [156] Dose-limiting toxicities were not encountered, with transient hypotension, flushing, nausea, and vomiting seen as non–dose-limiting toxicities. These results in adults with MDS and children with other malignancies are encouraging. However, there are currently no data on the use of amifostine for the treatment in children with MDS.

Low-dose chemotherapy approaches have been variably explored in both children and adults with MDS based on the theory that they may play some role in the differentiation of the malignant clone. Agents tested include cytarabine, melphalan, hydroxyurea, etoposide, topotecan, 5'-azacytidine, 6-mercaptopurine, and busulfan.[11,157,158,159 and 160] Most of these low-dose approaches to therapy have resulted in only partial and temporary responses in a small portion of patients. Most observers believe that the role of low-dose chemotherapy is only in reducing toxicity, with a concomitant lowering of efficacy. Therefore, the use of low-dose chemotherapy is generally not thought to be of particular benefit in the treatment of children with MDS.

Intensive, AML-like chemotherapy has been investigated in the setting of adult MDS [161,162,163,164,165 and 166] and pediatric MDS with and without subsequent hematopoietic stem cell transplantation.[42,43,165,167,168] Results from these studies demonstrate conflicting results with regard to the efficacy of high-dose, intensive therapy. There are, however, accumulating data that some forms of MDS (i.e., RAEB-T) do respond to chemotherapy, both in adults and children, like patients with AML. Overall, however, the role of AML-like intensive chemotherapy with or without subsequent stem cell transplantation and its applicability to subgroups of MDS patients are unclear, are considered to be controversial, and are being prospectively studied. [168]

Allogeneic hematopoietic stem cell transplantation was initially attempted in children and adults with MDS as a result of the inability of conventional forms of therapy to cure these diseases.[170,171,172,173,174,175 and 176] Before 1990, there were few reports of the efficacy of this approach. Since 1990, there have been a number of reports demonstrating the success of allogeneic transplantation for the treatment of children and adults with MDS. [177,178,179,180,181,182,183,184,185,186,187,188,189,190,191,192,193 and 194] Despite this proliferation of published transplant results, most of the studies include pediatric patients only as a part of larger adults series, thereby making it difficult to determine overall results for children. Several reports specific for pediatric patients have recently been published. [180,193,195,196,197 and 198] Although these reports are helpful in that they exclude adults, these studies are complicated by very small numbers of patients and the inclusion of children with other diseases, including SAA or AML. Therefore, information is generally lacking for allogeneic transplantation in children, aside from that available in larger series of patients that include both children and adults. Despite this, stem cell transplantation is generally considered the treatment of choice for children with the proliferative forms of MDS, particularly for children with HLA-matched related donors.

The largest reported series of children and adults with MDS was reported by investigators at the Fred Hutchinson Cancer Research Center in Seattle. [189] Between 1981 and 1996, 251 children and adults were transplanted from an HLA matched related donor (n = 147), unrelated donor (n = 70), or HLA-mismatched related donor (n = 34). Patients had a median age of 38 years (range, 1 to 66 years) with a median time from diagnosis to transplant of 8 months (range, 1 to 192 months). One hundred and forty-four patients had advanced disease (i.e., RAEB, RAEB-T, or CMML), 107 had less advanced disease (i.e., RA or RARS), and 36 had therapy-related MDS. Using the criteria of the International Prognostic Scoring System (IPSS) for MDS ( Table 22-3, Table 22-4 and Table 22-5, Fig. 22-2),[199] cytogenetic results were available to classify 241 of these patients into risk-based categories. One hundred and ten patients were classified as good-risk, 53 intermediate-risk, and 78 were poor-risk. Various preparative regimens were utilized, with 172 patients receiving a total body irradiation (TBI)–based regimen and 79 receiving a busulfan-based preparative regimen. At a median follow-up of 3.7 years, the 3-year cumulative incidence of non-relapse mortality (NRM) was 42%, with longer disease duration and older age being most predictive of NRM. The 3-year cumulative incidence of relapse was 17%, with advanced disease, poor-risk cytogenetics, and transplantation among the earlier cohorts of patients being most predictive of relapse. Three-year actuarial disease-free survival (DFS) was 41%, with younger age, less advanced morphology, and good-risk cytogenetics predictive of better survival. Similar results have been reported by other groups. [179,200,201]

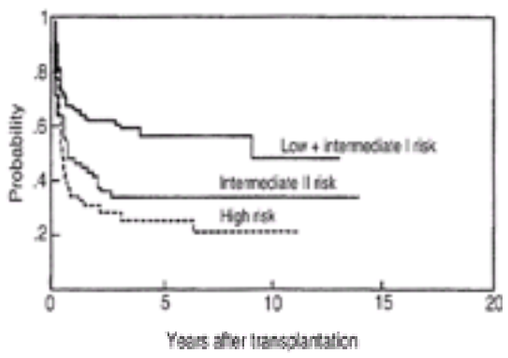

**FIGURE 22-2.** Impact of International Prognostic Scoring System on disease-free survival for transplanted myelodysplastic patients. [From Appelbaum FR, Anderson J. Allogeneic bone marrow transplantation for myelodysplastic syndrome: outcomes analysis according to IPSS score. Leukemia 1998;12(Suppl 1):S25–S29, with permission.]

Most of the patients transplanted for MDS have received bone marrow grafts from HLA-matched related donors. However, given the fact that HLA-matched related donors are available for only a minority of patients in need of allogeneic transplantation, the use of alternative donors has been increasingly utilized. [193,196,200,202,203,204 and 205] The largest series of unrelated bone marrow donors for the transplantation of children and adults with MDS and MDS-related AML was reported by the Seattle group.[184] These results were strikingly similar to those previously reported for the larger series of patients transplanted from unrelated donors, HLA-matched related donors, and HLA-mismatched related donors.[189] A 2-year actuarial probability of NRM was 48%, with older age and longer duration of disease most predictive of transplanted-related death. The 2-year actuarial probability of relapse was 28%, with higher relapse rates in patients with MDS-related AML and RAEB-T. The 2-year actuarial probability of DFS for this series of patients was 38%. Other reports of unrelated donor transplants in similar patient populations [200,203,204] have also shown high probabilities of NRM and relatively low DFS.

A variety of preparative regimens have been used in the transplantation of children and adults with MDS. Most of these regimens are based on the use of TBI with cyclophosphamide or busulfan and cyclophosphamide. Although comparative studies of these regimens for children have not been performed, larger studies inclusive of children and adults suggest similar results for these regimens, particularly for less advanced diseases. [180,183]

The timing of allogeneic transplantation for the treatment of children with MDS has not been well defined. The difficulty in ascertaining the most appropriate timing of transplantation is related to uncertainty about the natural history of childhood MDS, particularly in lower risk groups (e.g., RA), as well as significant toxicity associated with the transplant procedure. The decision to proceed with allogeneic transplant must take into account the disease morphology, cytogenetic abnormalities, and potential stem cell sources.

As there are little published data in children, it is considered reasonable to observe children with RA who are not having infectious complications or are transfusion independent until progression of their disease, until they are at risk of infectious complications as a result of neutropenia, or until they become transfusion dependent. It is also generally recommended that children with “symptomatic” RA and RAEB with a matched-related stem cell donor proceed to transplantation as soon as possible with consideration for an alternate donor transplant if matched-related donor is not available. Because RAEB-T may represent AML with low blast count, it may respond to AML-like chemotherapy. It is recommended that children with RAEB-T receive AML chemotherapy as initial therapy with transplantation if a matched-related donor is available. Consideration for alternate donor transplantation occurs when chemotherapy fails. Although the IPSS may be useful in helping to

determine the rapidity with which adult patients with MDS should proceed to allogeneic transplantation, [189] the role of the IPSS in determining which children should be observed and which should proceed more rapidly to transplantation has not yet been determined.

### Prognosis

The FAB classification system for MDS alone has not been shown to be a reliable method of predicting the outcome of patients with MDS, even in adults. Therefore, a large number of widely disparate methods have been proposed for evaluating the outcome of patients with MDS. [16,25,42,199,206,207,208,209,210,211,212,213 and 214] These methods have variably included features such as age, morphology according to FAB classification, the percentage of bone marrow blasts, cytopenias, karyotype, lactate dehydrogenase levels, and numerous other features.[16,25,42,199,206,207,208,209,210,211,212,213 and 214] However, many of these methods for predicting clinical outcome have suffered from a lack of consensus on the nomenclature and definitions of MDS and insufficient sensitivity or specificity, thereby severely limiting their effectiveness. Many of these problems have been addressed in the proposed IPSS.[199] As illustrated in Table 22-3, Table 22-4 and Table 22-5, this method uses the percentage bone marrow blasts, karyotype, and the number of cytopenias to assign a score value. Based on the score value, patients are placed into one of four risk subgroups (i.e., low, intermediate-1, intermediate-2, and high) with further stratification based on age (e.g., 60 years old or younger and older than 60 years) ( Fig. 22-3). Proportional hazards analysis using the IPSS has suggested that blast percentage is the best predictor of outcome, followed by cytogenetic abnormalities, age, and gender. Compared to prior methods, the IPSS is increasingly used for adult MDS patients, as it appears to more accurately predict outcome for adult MDS patients. [199] However, this study was comprised primarily of elderly adult patients. Its use for pediatric patients is limited, as it fails to account for cytogenetic abnormalities common in the pediatric forms of MDS and associated congenital anomalies. Therefore, the relevance of this risk-based method of prognosis for children with MDS is unknown, but unlikely to be beneficial.

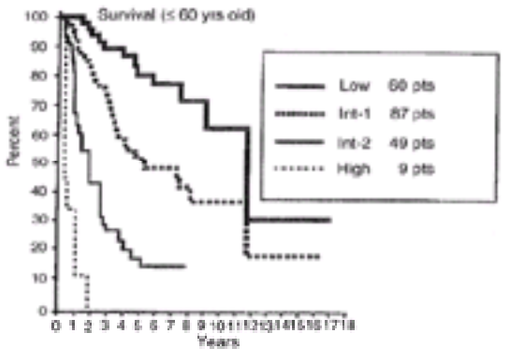

**FIGURE 22-3.** Survival according to age and International Prognostic Scoring System risk group for 816 patients with primary myelodysplastic syndrome. [From Greenberg P, Cox C, LeBeau MM, et al. International scoring system for evaluating prognosis in myelodysplastic syndromes (Published erratum appears in Blood 1998;91:1100). Blood 1997;89:2079–2088, with permission.]

Few risk-based classification schemas specific for pediatric MDS have been developed and prospectively validated. The lack of consensus on nomenclature and the rarity of MDS in pediatric MDS patients has greatly inhibited the development of an accurate method with which to determine clinical outcome. One attempt to create a pediatric-specific risk-based classification was recently proposed. [42] This method uses a modified FAB classification, platelet count, fetal hemoglobin level [hemoglobin F (HbF)], and cytogenetic complexity score to generate a pediatric scoring system [pediatric FPC (Hb *F-p*latelets-*c*ytogenetics)] to assign a score value. Validation of this method in a single institution suggested that this method of risk-based classification was highly predictive of survival for pediatric MDS patients. [42] The accuracy and usefulness of the pediatric FPC scoring system can only be determined in larger, prospective studies.

### Hypoplastic Myelodysplastic Syndrome

Despite significant progress in understanding the cellular and molecular properties of MDS, it continues to be very difficult to distinguish hypoplastic MDS from SAA. The disorder called *hypoplastic MDS* is not included in the FAB classification of MDS. In fact, the original classification schema required at least a normocellular or hypercellular marrow for a diagnosis of MDS.[25] It has been observed that some patients with SAA may develop dysplastic peripheral blood and marrow features, including dyserythropoiesis, megaloblastic changes, dysgranulopoiesis, ringed sideroblasts, atypical monocytes, PNH-like cells, and elevated fetal hemoglobin levels, particularly in the regenerative phase of the disease. [215] Various groups have also shown that some patients with SAA may have clonal hematopoiesis. [216,217] In addition, a significant portion (e.g., 10% to 30%) of patients with SAA eventually develop clonal hematopoietic abnormalities, including MDS, AML, and PNH. [218,219,220 and 221] Furthermore, it has also been observed that some patients with MDS respond to immunosuppressive therapy analogous to that used to treat SAA. [222,223 and 224] It therefore, remains very difficult for hematopathologists and clinicians to distinguish MDS with a hypocellular marrow from SAA. Many clinical and laboratory features must be taken into account in the diagnostic process, including the presence of conditions that have a predisposition to develop into MDS (e.g., congenital neutropenia, Fanconi anemia, PNH, and Shwachman-Diamond syndrome), morphology, single or multilineage dysplasia, reticulocyte counts, immunology, and cytogenetic abnormalities.

Some investigators have sought to use magnetic resonance imaging (MRI) as a tool to discriminate these disorders. MRI has a characteristic appearance in aplastic anemia by virtue of the absence of cellular elements and the presence of fatty marrow. [225,226,227,228,229 and 230] MRI is also able to identify areas of focal or diffuse areas of increased cellularity in adult patients with a diagnosis of MDS. [230,231] However, although MRI may be an aid in the identification of area of cellularity in an otherwise aplastic marrow, MRI alone is not sufficient to distinguish between SAA and MDS.

Accurate discrimination between SAA and MDS has tremendous prognostic and therapeutic significance. A high percentage of children with SAA and an unknown percentage of children with MDS respond to immunosuppressive therapy. Although immunosuppressive therapy may not, in itself, be harmful to children with MDS, it is not curative and does present some risk, including allergic reactions, infectious risks, and a delay in other potential therapies. In addition, children with HLA-matched related donors undergoing transplantation typically receive preparative regimens, which, though adequate for SAA, may not be adequate for MDS. Conversely, if an alternate donor stem cell transplant is performed for SAA or MDS, the morbidity and mortality are significant. Thus, alternate donor transplants are reserved for children with SAA only if unresponsive to immunosuppressive medications. Therefore, an accurate diagnosis is critically important in guiding the treatment of these children.

### Myelodysplastic Syndrome in Children with Down Syndrome

Children with Down syndrome have an increased probability of developing MDS and acute leukemia. Based on morphologic examination, it is extremely difficult, and unnecessary, to differentiate MDS from AML in children with Down syndrome. Therefore, these entities are generally considered together.

#### *Incidence and Epidemiology*

The true incidence of MDS and acute leukemia in children with Down syndrome is unknown. Some studies suggest that the increased risk of MDS and acute leukemia risk to be in the order of ten- to 20-fold. [232,233 and 234] Although older reports suggested that acute lymphoblastic leukemia (ALL) was the predominant form of acute leukemia in these children,[232,233 and 234] the frequency of MDS and AML is higher than previously thought, as improved methods to better identify megakaryocytic leukemias have been developed. Before the use of flow cytometry, megakaryocytic leukemias were easily confused morphologically, with ALL blasts having L2 morphology. Given these advances in diagnosis, there is consensus that the ratio of ALL to AML in children with Down syndrome is 1:1. [234]

It has been estimated that children with Down syndrome have a 400-fold increased probability of developing megakaryocytic leukemia (FAB M7), the most common form of AML in children with Down syndrome.[235,236] Large studies to better define the incidence and epidemiology of MDS and acute leukemia in children with Down syndrome are currently under way.

### *Etiology and Pathophysiology*

The reasons for the increased risk of MDS and acute leukemia in children with Down syndrome is not known, but some data suggest abnormalities related to chromosome 21 may be, at least in part, responsible for the increased risk of leukemogenesis. Genes that may have a causative role that are located on chromosome 21 include genes for superoxide dismutase, cystathionine-b-synthetase, and carbonyl reductase. In addition, many of the phenotypic features of Down syndrome have been mapped to chromosome 21, band q21.1-22.1, also site of the *AML-1* gene, a gene commonly involved in numerous AML-associated translocations [e.g., t(8;21)].[237,238,239,240,241 and 242] It is anticipated that information derived from the DNA sequencing of human chromosome 21 will help to identify other genes that may contribute to the development of leukemia in these children.[243] Taken together, available data have led to the postulate that children with Down syndrome are at an increased risk of developing MDS and acute leukemia as a result of developmental errors that disrupt hematopoiesis, ineffective regulation of granulopoiesis, immune deficiencies that lead to impaired immune surveillance, abnormal cell cycle kinetics, susceptibility to viral infections, a genetic predisposition to nondisjunction, increased chromosome fragility, impaired DNA repair mechanisms, and oncogene activation.[232]

### *Treatment and Outcome*

It has been demonstrated in several studies that children with Down syndrome, MDS, and AML can be cured with chemotherapy of moderate intensity.[240,244,245,246 and 247] In the largest of these studies, 118 children with Down syndrome and MDS or AML (Table 22-6) were prospectively treated with either intensively timed chemotherapy or conventional, standard-timed AML chemotherapy with or without subsequent matched related donor bone marrow transplantation.[240] Patients receiving intensively timed chemotherapy and those undergoing bone marrow transplantation had increased mortality as a result of excessive toxicity. Patients receiving standard-timing chemotherapy had a 4-year DFS of 88%, compared to 42% ($p$ <.001) for similarly treated patients with de novo AML who did not have Down syndrome (Fig. 22-4). This is exactly opposite to the outcomes of normal children who develop AML.[248] Based on the exceptionally good outcomes after only moderately intensive chemotherapy, investigators have postulated that MDS and AML are different or the host is different, or both, in children with Down syndrome.[240]

| | | DS | | No DS | |

FAB, French American British Cooperative Group.
*FAB M0 includes only those who had not transformed to acute myelogenous leukemia. M0 was included in Children's Cancer Group Study-2891 only in a 1:1 for DS and M6 for others. Ninety-four percent of cases were classified by FAB criteria.
From Lange BJ, Kobrinsky N, Barnard DR, et al. Distinctive demography, biology, and outcomes of acute myeloid leukemia and myelodysplastic syndrome in children with Down syndrome: Children's Cancer Group Studies 2861 and 2891. Blood 1998;91:608–615, with permission.

**TABLE 22-6. PRESENTATION OF ACUTE MYELOID LEUKEMIA OR MYELODYSPLASTIC SYNDROME (MDS) IN CHILDREN WITH AND WITHOUT DOWN SYNDROME (DS)**

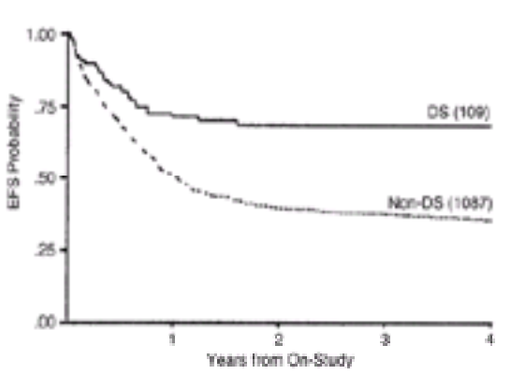

**FIGURE 22-4.** Kaplan-Meier plot of actuarial event-free survival (EFS) in children with and without Down syndrome (DS) in Children's Cancer Group studies 2861 and 2891. Numbers in parentheses indicate number at risk. EFS in DS is 68% (95% confidence interval, 47% to 84%); in non-DS, 35% (95% confidence interval, 30% to 41%). (From Lange BJ, Kobrinsky N, Barnard DR, et al. Distinctive demography, biology, and outcome of acute myeloid leukemia and myelodysplastic syndrome in children with Down syndrome: Children's Cancer Group Studies 2861 and 2891. Blood 1998;91:608–615, with permission.)

Potential differences in MDS and AML of Down syndrome and these diseases in children without Down syndrome are not readily apparent.[240] Investigations are focusing on the obvious differences in morphology (e.g., high predominance of megakaryocytic differentiation in Down syndrome), karyotype (e.g., an extra copy of chromosome 21), and immunophenotype between these different populations of patients. Differences in the host have included investigations of altered metabolism of cytarabine[240,249] and other drugs in children with Down syndrome. Despite these investigations, it is still not clear why children with MDS and AML have extremely good outcomes, but also are at greater risk of toxicity from therapy than children without Down syndrome.

### Therapy-Related Myelodysplastic Syndrome

Children and adults who have received ionizing radiation, cytotoxic chemotherapy (or both), particularly with alkylating chemotherapy and topoisomerase II inhibitors, are at an increased probability of developing therapy-related MDS. Given the different etiology, clinical characteristics, poor response to therapy, and generally poor prognosis, these disorders should be considered separately from de novo MDS.

Alkylating agents used to treat children and adults with Hodgkin's disease[250,251 and 252] and non-Hodgkin's lymphoma[252] are most commonly associated with the development of therapy-related MDS,[253] but MDS after the treatment of other diseases has also been reported.[254,255 and 256] Treatment-related MDS after exposure to alkylating agents develops approximately 5 years after exposure to the inciting agent. Cytogenetic abnormalities in chromosomes 5 and 7 are commonly seen.[257,258] In contrast, exposure to topoisomerase inhibitors, such as the epipodophyllotoxins (e.g., etoposide), are associated with abnormalities in chromosome band 11q23[258,259 and 260] and, hence, more AML and less MDS.

Nontransplant approaches to the treatment of patients with therapy-related MDS have been limited.[261] Hematopoietic stem cell transplantation has been used, but results, even in adults, are difficult to identify because most series report patients with therapy-related MDS among results for patients with de novo MDS, SAA, and AML. However, a review of published studies[175,177,181,183,184,185,186,187 and 188,262,263,264,265,266,267,268,269 and 270] suggests a very high probability of NRM, high probability of relapse, and a small, but not insignificant, chance of DFS. As seen in Figure 22-5, a transplant study of children with therapy-related MDS demonstrated a DFS probability at 2 years of 24%, with relapse and NRM both accounting for the majority of deaths.[267] However, overall survival for children with therapy-related MDS may be less than this as many children may not survive long enough to receive a transplant procedure.

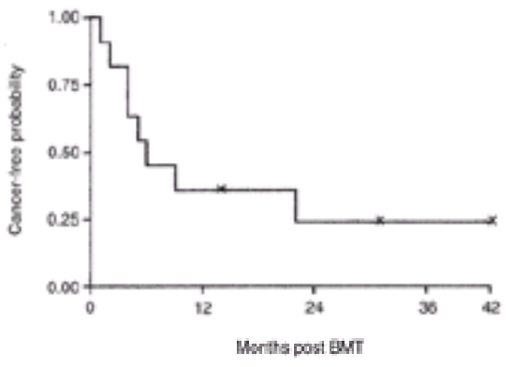

**FIGURE 22-5.** Kaplan-Meier plot of cancer-free survival after allogeneic bone marrow transplant (BMT) for therapy-related leukemia. Censored patients are shown by a cross. (From Leahey AM, Friedman DL, Bunin NJ. Bone marrow transplantation in pediatric patients with therapy-related myelodysplasia and leukemia. Bone Marrow Transplant 1999;23:21–25, with permission.)

As a result of dose escalation regimens and autologous transplantation for an increasing number of malignant [251,271,272] and nonmalignant disorders, there is general concern that an increase in the incidence in therapy-related MDS will be seen in the next decade.

## MYELOPROLIFERATIVE DISORDERS

### Transient Myeloproliferative Disorder in Children with Down Syndrome

#### *Incidence and Epidemiology*

Transient MPS disorder (TMD) is typically seen in the first several months after birth in children with Down syndrome. Although the true incidence of TMD is unknown, the incidence of severe TMD has been estimated to be as high as 10% for children with Down syndrome. [273,274] There are no published epidemiology studies of TMD in children with Down syndrome.

#### *Etiology and Pathogenesis*

TMD is characterized by an uncontrolled proliferation of myeloblasts. This disorder is differentiated from congenital AML by its tendency to resolve spontaneously within the first 3 months of life (range, birth to 7 months). [274,275,276,277,278,279] and [280] Differentiating between TMD and congenital AML can be difficult. Little data exist comparing TMD to congenital AML. As demonstrated in Table 22-7, children with TMD have a lower percentage of blasts in their bone marrow than in their peripheral blood. As a general pattern, TMD patients also have no cytogenetic abnormalities in their blasts, whereas AML patients had clonal cytogenetic abnormalities identified.

| Feature | TMD (n = 15) | AML (n = 13) |
|---|---|---|
| Age | 4 (0–34) days | 21 (6–30) months |
| Peripheral white blood cell count (× 1,000) | 72.9 (26.8–248.6) | 10 (1.8–40.6) |
| Peripheral blasts (%) | 57 (20–89) | 30 (0–68) |
| Hemoglobin | 17.1 (14.5–19.9) | 9.3 (3.6–14.9) |
| Platelets (× 1,000) | 137 (29–853) | 38 (10–56) |

From Hayashi Y, Eguchi M, Sugita K, et al. Cytogenetic findings and clinical features in acute leukemia and transient myeloproliferative disorder in Down syndrome. Blood 1988;72:15–23, with permission.

**TABLE 22-7. COMPARISON OF PRESENTING CHARACTERISTICS OF CHILDREN WITH DOWN SYNDROME AND TRANSIENT MYELOPROLIFERATIVE DISORDER (TMD) OR ACUTE LEUKEMIA (AML)**

Like AML, the myeloblasts in TMD are clonally derived [281] and frequently are of megakaryocytic origin with varying degrees of differentiation. [273,275]

#### *Clinical Presentation*

Because no population-based studies have yet been performed on TMD, information regarding the presentation and natural history of this disorder are based on several small series of patients. TMD typically presents in the first 3 months of life. Children may present at birth with hydrops fetalis secondary to anemia or cardiac dysfunction secondary to infiltration of cardiac muscle with myeloblasts. Other presenting signs and symptoms include organ infiltration with resulting hepatosplenomegaly; pleural, pericardial and peritoneal effusions; disseminated intravascular coagulopathy; renal failure; and respiratory failure. The complete blood cell count typically demonstrates an elevated white blood cell count with circulating myeloblasts.

Children with Down syndrome and TMD are known to develop AML and ALL. [282] Although the true incidence of progression to acute leukemia is unknown, one study found that 9 of 43 (21%) of children with Down syndrome and AML had a preceding history of TMD. [282]

#### *Treatment and Outcome*

The treatment for Down syndrome patients with TMD is generally supportive. Unless there is significant organ dysfunction, children with TMD can be followed closely without medical intervention. If significant organ dysfunction is present, therapeutic approaches include exchange transfusion, leukapheresis, and chemotherapy of varying intensities, with cytosine arabinoside most often used.

Although TMD commonly undergoes a spontaneous remission, it is not a benign disorder. Children with TMD can die as a result of hydrops fetalis, organ infiltration, renal failure, hepatic failure, respiratory failure, disseminated intravascular coagulopathy, and progression to AML or ALL. [275,283] The true mortality rate, however, is not currently known.

### Juvenile Myelomonocytic Leukemia

JMML is a rare, clonal abnormality of the pluripotent stem cell that is manifest as an MPS disease of early childhood. Besides the adult form of Ph $^{+}$ CML, JMML constitutes the most common form of MPS in childhood. As illustrated in Figure 22-1, JMML is probably a “bridging” disorder between the MPS and MDS diseases.

#### *Nomenclature and Diagnosis*

JMML represents a common name now generally accepted for this MPS disorder that has been referred to by many other names. JMML has been variously called *juvenile granulocytic leukemia*,[47,48] *infantile monosomy 7 syndrome*,[39,42,284,285] *chronic* and *subacute myelomonocytic leukemia*,[40] and the more commonly used term,

*juvenile CML* (JCML).[45,46] Because of the similarity of the name *JCML* to $Ph^+$ CML, many clinicians inappropriately considered JMML to be the childhood form of adult $Ph^+$ CML. Despite a similarity in the names, JMML and the adult form of CML have few clinical or biologic similarities. Confusion has also resulted because of apparent similarities in the characteristics for JMML and the adult form of MPS, CMML. These disorders have now been demonstrated to have some distinct differences, including differences in age of presentation, in the *in vitro* growth characteristics,[286] a lack of elevated fetal hemoglobin in CMML, and more complex cytogenetic characteristics in CMML. Given the confusion in nomenclature and similarities to other diseases, defining the clinical and laboratory characteristics of JMML has been challenging. Until recently, there were no widely accepted nomenclature or clinical and laboratory criteria for JMML.

An international consensus panel consisting of the JMML Working Group and the EWOG-MDS met in 1994 [11,43,287] and agreed on common clinical and laboratory criteria to diagnose JMML. The widespread acceptance of the term *JMML* and the international diagnostic criteria [11,43,287] (Table 22-8) have helped to decrease the significant confusion that previously existed for this disorder.

| |
|---|
| Required laboratory criteria (all three required) |
| No Philadelphia chromosome, or no *bcr/abl* rearrangement |
| Peripheral blood monocyte count >1 × $10^9$/L |
| Bone marrow blasts <20% |
| Suggestive clinical features |
| Hepatomegaly |
| Lymphadenopathy |
| Pallor |
| Fever |
| Skin rash |
| Additional criteria (minimum of two required) |
| Increased fetal hemoglobin (age corrected) |
| Myeloid precursors in peripheral blood |
| White blood cell count >10 × $10^9$/L |
| Clonal abnormalities, including monosomy 7 |
| Granulocyte-macrophage colony-stimulating factor hypersensitivity of myeloid progenitors in vitro |

**TABLE 22-8. DIAGNOSTIC CRITERIA FOR JUVENILE MYELOMONOCYTIC LEUKEMIA**

### *Biology*

Although early clonality studies suggested that JMML arose at the level of at least an immature myeloid precursor cell, [11,288,289,290,291] and [292] recent data suggest that JMML may arise in a pluripotent stem cell with involvement of the myeloid, erythroid, and megakaryocyte lineages as well as B lymphocytes and T lymphocytes.[11,293,294] This finding is further supported by the observation that JMML cells maintained in long-term culture-initiating cell assays maintain clonality. [11,295] This is in contrast to $Ph^+$ CML, also a disease initiating in a pluripotent hematopoietic stem cell, which becomes polyclonal in long-term culture-initiating cell assays.

Several potential causative mutations in JMML cells have been identified, including loss of heterozygosity of *NF1*[296] and activating *ras* mutations.[297,298] and [299] Approximately 15% of patients with JMML have clinically evident neurofibromatosis. [11,43,296,300,301] Abnormalities in *NF1* are also detectable in an additional 15% of JMML patients who do not have clinical manifestations of neurofibromatosis. [11,302] Activating point mutations in *RAS* genes have also been detected in 15% to 30% of JMML patient samples.[11,297,302,303] These groups of JMML patients with abnormalities in *NF1* and *RAS* (most commonly *N-RAS* and*K-RAS*) appear to be mutually exclusive.[302,303] The RAS family of proteins are of significance in JMML in that they are involved in signaling pathways for GM-CSF. [11,287,294,304] This deregulation in signaling results in the well-described pattern of GM-CSF hypersensitivity in *in vitro* dose response assays.[286] However, JMML cells do not show selective hypersensitivity to IL-3 despite similar signaling components to those of GM-CSF. [286] It has also been shown that *NF1* encodes for the protein neurofibromin, a protein that functions as a guanosine triphosphatase–activating protein, which inactivates Ras from its active guanosine triphosphate–bound state. [11,305,306] and [307] Therefore, *NF1* may act as a tumor suppressor gene in immature hematopoietic cells by negatively regulating Ras. [11,296,301]

A potential mouse model of JMML has recently been developed.[11,298,299] Mice that have homozygously deleted *Nf1* (termed $Nf1^{-/-}$) have an embryonic lethal defect that prevents development beyond day 13 to 14 of gestation. However, when hematopoietic stem cells present in the embryonic liver of the $Nf1^{-/-}$ mice are grown in *in vitro* colony assays, they demonstrate a pattern of GM-CSF hypersensitivity similar to that seen with JMML cells. In addition, when these cells are transplanted into irradiated recipients, the recipient mice develop an MPS disorder similar to that seen in children with JMML. [11] These data suggest that deregulated Ras signaling is a molecular hallmark of JMML, evident in 50% to 60% of JMML patients.[11] The molecular abnormalities occurring in the remaining patients have yet to be determined.

### *Epidemiology*

The true incidence of this disorder has not yet been established. Patients with JMML have a male predominance, and, though occasionally presenting at ages older than 5 years of age, it is most common in children younger than 5 years. As a result of the rarity of the disease and the absence of uniform registration of patients, epidemiologic studies to address potential environmental and genetic factors have not yet been possible.

### *Clinical Presentation*

As is indicated in Table 22-8, children with JMML usually present with signs and symptoms indicative of a heavy tumor burden of organ-infiltrating cells. Hence, hepatomegaly, splenomegaly, generalized lymphadenopathy, and skin rash are commonly seen. Due to a relatively high association with neurofibromatosis, patients may also have neurofibromas and café-au-lait spots. Laboratory abnormalities include an elevated white blood cell count with monocytosis, anemia, thrombocytopenia, elevated fetal hemoglobin, and hypergammaglobulinemia. JMML may transform to a blastic phase, but this is unusual, occurring in less than 20% of patients.[39] Patients die as a result of resistant disease with organ infiltration (i.e., skin, lungs, liver, spleen, and intestines), which results in organ dysfunction, infection, and bleeding.

### *Treatment*

JMML has a very heterogeneous clinical course with at least three patterns. Many patients die within a year of diagnosis with a rapidly progressive course while a second group may have a period of treatment-responsive disease with intensive, AML-like therapy, followed by progressive disease. [40,309] Rare patients, however, have long-term survival with spontaneous remissions. Although age, platelet count, and HbF at diagnosis may be predictive for the length of survival in patients not undergoing transplantation,[43] the biologic parameters that identify patients with differing clinical courses and response to therapy have not been clearly identified.

Although the potential value of intensive, AML-like chemotherapy for patients with JMML has been suggested based on superior survival for intensively treated patients in comparison to those patients who received less intensive therapy, [43,309] many JMML patients fail to enter a remission with chemotherapy. For those patients who do achieve a remission after intensive therapy, these remissions tend to be of a short duration. [43,126,165,310,311] To gather more information about the role of AML-like chemotherapy for the induction of remission in JMML, the Children's Cancer Group has prospectively enrolled JMML patients in recent AML trials using intensively timed combination chemotherapy.[168] Preliminary results from the Children's Cancer Group demonstrate that some JMML patients respond initially to aggressive chemotherapy, and that results after aggressive chemotherapy may be better than limited therapy.

Lower dose chemotherapy regimens (e.g., cytosine arabinoside) has been used with some responses noted. [312,313] However, the overall efficacy of this therapeutic approach is currently unknown. Similarly, interferon-a, while demonstrating inhibitory effects on spontaneous cell growth *in vitro*, has shown little efficacy in the treatment of JMML.[314]

Isotretinoin (13-*cis*-retinoic acid), like interferon-a, also has an inhibitory effect on spontaneous growth *in vitro*, but unlike interferon-a, may induce remission in at least a portion of JMML patients.[308] The efficacy of isotretinoin in a portion of JMML patients has been suggested in a phase II clinical trial. [308] Despite this preliminary

success, it is clear that therapy with isotretinoin is not curative.

Newer agents, including the farnesyltransferase inhibitors (FTIs),[294,295,315] novel retinoids,[316] GM-CSF antagonists,[317,318] and GM-CSF/diphtheria immunotoxins,[319] are also being developed. These new agents specifically target mechanisms thought to be operative in JMML. The new class of agents targeted to the Ras pathway, the FTIs, are particularly interesting. For Ras proteins to serve as a "master switch" for signal transduction, they must be bound to the inner surface of the plasma membrane. To do this, they must undergo a series of posttranslational modifications, the first of which is the addition of a 15-carbon isopropenyl group to Ras.[315,320,321,322,323 and 324] This step is catalyzed by the enzyme farnesyl-protein transferase. A number of inhibitors of this enzyme (e.g., FTIs) have been developed that demonstrate antitumor effects in various *in vitro* and xenogeneic mouse models.[325,326,327,328,329,330,331,332,333 and 334] Some of these agents have shown efficacy in inhibiting JMML cell growth *in vitro* and in *NF1*-deficient cells.[294,335,336] The utility of these agents in the treatment of children with JMML is not yet known, but will soon be studied in prospective clinical trials.

Allogeneic hematopoietic stem cell transplantation continues to offer the greatest probability of long-term DFS.[43,180,337,338,339,340 and 341] However, despite the curative potential of allogeneic transplantation, frequent and early relapse of JMML is problematic, with survival in 20% to 30% of patients.[43,180,337,338,339 and 340,342] Although allogeneic stem cell transplantation is potentially curative in a minority of patients, a number of issues involving transplantation remain controversial.[341] These unresolved issues include

1. The preferred stem cell source if an HLA-matched related donor is not available
2. The safety and efficacy of intensive chemotherapy before transplantation
3. The role of splenectomy pre-transplant and inclusion of TBI as part of the conditioning regimen
4. The role of T-cell depletion
5. The strength of the graft-versus-leukemia reaction in JMML

Children with JMML should be enrolled in prospective clinical trials currently in progress in Europe (EWOG-MDS), in North America (COG), and elsewhere.

### Other Myeloproliferative Disorders of Childhood

$Ph^+$ CML and JMML represent the vast majority of the MPS disorders of childhood. There are, however, rare, anecdotal reports of other MPS diseases in children that are far more common in adults.[11] These other disorders include polycythemia vera,[11] and primary familial and congenital polycythemia (PFCP).[343,344] Although traditionally classified as MPS disorders, essential thrombocythemia and AMM may be more similar to the MDS syndromes or represent "bridging" disorders ( Figure 22-1).[32,345,346 and 347]

#### *Polycythemia Disorders*

Polycythemia in a child may be the result of primary polycythemia due to polycythemia vera or PFCP, secondary polycythemia resulting from multiple causes, including abnormal hemoglobins and excessive erythropoietin, or the relative polycythemias that are the result of decreased plasma volume.

Polycythemia vera, rarely reported in children, is a clonal disorder of hematopoietic stem cells that may effect the erythroid, myeloid, and megakaryocytic lineages. It may progress to a more rapidly progressive MPS disorder or to AML. It has been suggested that polycythemia vera may be associated with a hypersensitivity of stem cells to insulin-like growth factor-1.[348] Children, like adults, may present with signs and symptoms associated with the increased red cell mass such as headache, dizziness, fatigue, night sweats, and pruritus. As a result of the increased red cell mass, patients may have hyperviscosity of the blood that can result in thrombosis and central nervous system ischemia. Physical examination may be remarkable for facial redness and hepatosplenomegaly. Laboratory evaluation demonstrates an elevated hematocrit. A moderate leukocytosis and thrombocytosis are also commonly present. The same criteria for a diagnosis of polycythemia vera, commonly used in adults, should be used in children.[349]

Numerous approaches, with variable safety and efficacy, have been used in the treatment of polycythemia vera in adults. These include phlebotomy, busulfan, chlorambucil, $^{32}P$,[350,351] hydroyurea,[352,353] and interferon-a.[354] Aspirin[355] and anagrelide[11] have been used in attempts to control thrombotic complications. Aspirin has not been shown to be useful, whereas the efficacy of anagrelide is unknown. As a result of the long survival of adult patients with polycythemia vera,[356,357] allogeneic hematopoietic stem cell transplantation has only rarely been used in the treatment of these patients.[358,359,360 and 361] Of nine reported transplants, five patients are reported to be long-term, disease-free survivors. Consideration of stem cell transplantation is generally given only to patients with a history of significant thrombotic events or polycythemia vera that has progressed to AML.

PFCPs are not true MPS disorders. They are inherited in an autosomal dominant fashion. Although this disorder is generally benign without the need for therapy, thrombotic events have been reported.

#### *Essential Thrombocythemia*

Essential thrombocythemia is extremely rare in children. It is characterized by an isolated increase in the megakaryocytic lineage with abnormal platelet function. However, an elevated platelet count in children is far more common as a result of other MPS disorders, nutritional causes, or as an acute phase reaction secondary to infection or inflammation. Adult patients with essential thrombocythemia may present with thrombotic episodes or splenomegaly. Diagnostic criteria for essential thrombocythemia have been proposed.[362] Adult patients have a median survival of at least 10 years,[355,357] with most deaths secondary to thrombosis. Progression to AML has been noted in some patients, but usually only those exposed to chemotherapy agents. Although it is generally recommended that young, asymptomatic patients not be treated, treatment has been attempted with hydroxyurea, interferon-a, and anagrelide.[11] Successful hematopoietic stem cell transplantation has been reported in three adult patients.[361]

#### *Agnogenic Myeloid Metaplasia/Primary Myelofibrosis*

Although rare, AMM has been reported in children.[347] This "bridging" disorder (Fig. 22-1) is characterized by marrow fibrosis, splenomegaly, anemia, and extramedullary hematopoiesis. It has been suggested that AMM in children may in fact be FAB M7 AML. Patients typically present with signs and symptoms resulting from splenomegaly and anemia. In children, AMM should be differentiated from metastatic neoplasms, connective tissue disease, and metabolic and bone diseases. Survival in adults is variable, ranging from 1 to 30 years.[357,363,364] A prognostic scoring system has been proposed.[364] Numerous treatment approaches have been attempted with variable degrees of success. These include the use of splenectomy,[363,365,366] splenic irradiation, transfusions, androgens, corticosteroids, hydroxyurea, and interferon-a. Hematopoietic stem cell transplantation has been successfully used to treat AMM, with a total of 29 patients reported.[347,361,367,368,369,370,371,372 and 373] After transplantation, surviving patients with donor engraftment had the resolution of myelofibrosis. It is therefore generally recommended that stem cell transplantation be considered in young patients with poor prognostic scores.[364]

## FUTURE DIRECTIONS

Given the rarity of the MDS and MPS disorders, the success of future treatment approaches is critically dependent on a unified approach to therapy. As the European community (EWOG-MDS), North America (COG), and others embark on novel, prospective clinical trials that will likely capture the majority of children with these disorders in these geographic regions, it is anticipated that new knowledge and improvements in treatment will be forthcoming.

# HODGKIN'S DISEASE

MELISSA M. HUDSON
SARAH S. DONALDSON

## INTRODUCTION

The original paper by Hodgkin in 1832 was entitled “On Some Morbid Appearances of the Absorbent Glands and Spleen.” [1] In that era of anatomic description of disease, investigators were concerned with differentiating inflammatory disease from infection or idiopathic hypertrophy of the lymphoid organs. Not until the second half of the nineteenth century, as the criteria for making diagnoses came to depend more on microscopic morphology, did investigators recognize that abnormal giant cells were present in Hodgkin's material. Sternberg in 1898 [2] and Reed in 1902 [3] are generally credited with the first definitive and thorough descriptions of the histopathology of Hodgkin's disease. Reed in particular gave a precise description of the multinucleated giant cells in this disease, which led her finally to refute the idea that it was an unusual form of tuberculosis despite the frequent association of the two diseases in the same patient. After the histologic definition of the disease was established, Fox, [4] in 1926, reexamined the histologic features of Hodgkin's original seven patients and concluded that three of them, one of whom was a pediatric patient, met the new criteria for definition of the disease.

In the ensuing years, although Hodgkin's disease was recognized as a possible malignancy, the potential of an infectious or autoimmune etiology was still considered. [5] The pleomorphic nature of the cellular infiltrate in Hodgkin's disease made investigators uncomfortable with the idea that this was a clonal proliferation of a single malignant cell. However, the successful cultivation of Reed-Sternberg cells [6] permitted the demonstration of the cells' malignant nature and reinforced the idea that Hodgkin's disease was truly a malignant disorder.

Initial attempts with radiotherapy for this disease were disappointing; dramatic regression was followed by recurrence and, inevitably, death. [7] Improvements in radiation therapy technology eventually resulted in the cure of early stage disease with radiotherapy alone. In 1940, as a by-product of wartime work on compounds related to the mustard gases, nitrogen mustard's powerful lymphocytolytic effects were discovered. [8] Experimental studies indicating the advantage of using combinations of non–cross-resistant antineoplastic agents with nonoverlapping toxicities led to the introduction in 1964 of the four-drug MOPP regimen [mechlorethamine (nitrogen mustard), Oncovin (vincristine), procarbazine, prednisone]. [9] MOPP chemotherapy was the first effective systemic therapy for Hodgkin's disease. Trials using MOPP chemotherapy in adult patients produced prolonged disease-free survival in approximately 50% of patients when MOPP was administered at full doses. [10] Subsequently, pediatric trials demonstrated similar or better outcomes after MOPP chemotherapy. [11,12,13,14 and 15] With improved survival after MOPP, investigators appreciated that both adults and children were vulnerable to its adverse effects, which consist of an increased risk of acute myelogenous leukemia (AML) and infertility. The development of the non–cross-resistant ABVD regimen [Adriamycin (doxorubicin), bleomycin, vinblastine, dacarbazine] in the 1970s provided effective systemic therapy for Hodgkin's disease that was not associated with an excess risk of secondary AML or infertility. [16] ABVD was initially used in adult trials to salvage patients who did not respond to MOPP chemotherapy. [17] The lack of leukemogenesis and permanent gonadal toxicity and superior treatment outcomes has led to the standard use of ABVD in adults with newly diagnosed Hodgkin's disease. However, the sole use of ABVD therapy in children has been less popular because of concerns about potential cardiopulmonary toxicity.

With greater appreciation of treatment sequelae after standard-dose radiotherapy and non–cross-resistant chemotherapy, pediatric investigators modified treatment strategies in the 1980s to address the specific needs of children. Combined-modality therapy regimens evolved in which cycles of chemotherapy replaced a portion of the radiation therapy in laparotomy-staged children with Hodgkin's disease. [11,18,19] The success of this approach coupled with advances in diagnostic imaging technology ultimately resulted in the abandonment of surgical staging in the 1990s. This decade also saw the evolution of risk-adapted trials in which patients with favorable clinical presentations received combined-modality treatment prescribing fewer cycles of multi-agent chemotherapy and lower radiation doses and treatment volumes. [20,21,22,23 and 24] Currently under investigation are novel approaches using compacted dose-intensive multi-agent chemotherapy for patients with advanced and unfavorable disease.

## EPIDEMIOLOGY

Hodgkin's disease has a unique bimodal age distribution that differs geographically and ethnically. In industrialized countries, the early peak occurs in the middle to late 20s and the second peak after the age of 50 years. In developing countries, the early peak occurs before adolescence. Epidemiologic studies demonstrate three distinct forms of Hodgkin's disease: a childhood form (in patients aged 14 years or younger), a young adult form (in patients aged 15 to 34 years), and an older adult form (in patients aged 55 to 74 years). [25] There is also a slight overall male predominance in the incidence of Hodgkin's disease, which is most marked in the childhood form. [26] In adolescents, the incidence between males and females is roughly equal, and most older adolescent patients are white. Hodgkin's disease is rarely diagnosed in children younger than 5 years.

The childhood form of Hodgkin's disease tends to increase with increasing family size and decreasing socioeconomic status. In contrast, the young adult form of Hodgkin's disease is associated with a higher socioeconomic status in industrialized countries. The risk for young adult Hodgkin's disease decreases significantly with increased sibship size and birth order. [27] Histologic subtypes also show variability related to age at diagnosis. Mixed cellularity (MC) Hodgkin's disease is more common at younger ages, whereas nodular sclerosing Hodgkin's disease has a higher incidence in more affluent societies.

### Epstein-Barr Virus and Hodgkin's Disease

The epidemiologic characteristics of Hodgkin's disease suggest that its etiology may vary by age at presentation. [5,28] In the young adult form, delayed exposure to an infectious agent has been proposed as a risk factor for the development of Hodgkin's disease because its epidemiologic features are similar to that seen with paralytic poliomyelitis. Early and intense exposure to an infectious agent might increase the risk for the childhood form of Hodgkin's disease. Epstein-Barr virus (EBV) has been implicated in the causation of Hodgkin's disease by both epidemiologic and serologic studies. The large proportion of patients with Hodgkin's disease who have high EBV antibody titers suggests that enhanced activation of EBV may precede the development of Hodgkin's disease. This hypothesis is also supported by *in situ*

hybridization evidence of EBV genomes in Reed-Sternberg cells.[29] In cases associated with EBV, the virus is localize to the Reed-Sternberg cell, EBV latent gene products are expressed, and the EBV infection is clonal. EBV-associated antigens have been demonstrated in Hodgkin's tissues.[30] Both Reed-Sternberg cells and their variants consistently express Epstein-Barr nuclear antigen 1, but Epstein-Barr nuclear antigen 2, viral capsid antigen, early antigen, and membrane antigen have not been found.[30] EBV strain subtypes identified within Reed-Sternberg and Hodgkin's disease also vary geographically. EBV strain type 1 is predominant in the United Kingdom, South Africa, Australia, and Greece, whereas EBV type 2 is predominant in Egypt. The presence of infection by both EBV strains in 21% of cases supports the possibility of an underlying immune deficiency in these cases.

The incidence of EBV-associated Hodgkin's disease varies by age, sex, ethnicity, histological subtype, and regional economic level.[31,32] EBV-positive tumor genomes are more frequently observed in children aged 10 years or younger and in children living in developing countries. The incidence of EBV-associated Hodgkin's disease also varies by ethnic background, as evidenced by its presence in 93% of Asian, 86% of Hispanic, 46% of white, and 17% of African-American children with Hodgkin's disease in one series. EBV latent membrane protein (LMP) 1 expression varies among the histologic subtypes and is found in up to 96% of patients whose disease is characterized by MC, in 34% of patients with nodular sclerosing disease, and in 10% of those with lymphocyte predominance.

Clonality studies indicate EBV infection precedes expansion of the tumor cell population. Infected Hodgkin's and Reed-Sternberg (HRS) cells express high levels of LMP1, a viral protein that resembles a constitutively activated member of the tumor necrosis factor (TNF) receptor superfamily. LMP1 interacts with TNF receptor–associated factors that lead to activation of transcription factor NFkB and modulation of apoptotic and growth pathways.[33] LMP1 expression is also associated with up-regulation of cellular bcl2, interleukin-10 (IL-10), and major histocompatibility complex class I proteins in some but not all cell lines. These data have led to the speculation that EBV is directly involved in the pathogenesis of some cases of Hodgkin's disease. Whether EBV, either alone or with other carcinogens, plays a direct role in the pathogenesis of Hodgkin's disease is unknown. The disease may represent a common result of multiple pathologic processes that include viral infection and exposure of a genetically susceptible host to a sensitizing agent.

### Familial Hodgkin's Disease

Clustering of cases of Hodgkin's disease within families or races may suggest a genetic predisposition to the disease or a common exposure to an etiologic agent. Studies of affected families have suggested an increased association of Hodgkin's disease with specific HLA antigens.[34] The concordance of Hodgkin's disease in first-degree relatives (including siblings), particularly of the same gender, and in parent-child pairs has been noted in numerous reports.[31] In families in which twins are concordant, elevated risk of Hodgkin's disease ranges from threefold among first-degree relatives to sevenfold in siblings.[35]

Reports of Hodgkin's disease in both marriage partners are extremely rare, as are data suggestive of transplacental transmission. Hodgkin's disease is diagnosed more commonly in persons whose immune system is abnormal, a finding that may reflect the slight increase in familial incidence.[36] The etiologic factors underlying the immune deficiency include genetic (e.g., ataxia-telangiectasia), infectious (e.g., human immunodeficiency virus), and iatrogenic agents.[36]

## BIOLOGY

The HRS cells, lymphocytic and histiocytic (L&H) cells, and their variants compose the malignant cells of Hodgkin's disease. Until recently, their limited numbers in affected tissues hampered the elucidation of their nature and origin. Advances in the field of immunohistology and molecular biology have improved understanding regarding the origin and clonality of these atypical multinucleated giant cells. The presence of identical immunoglobulin gene rearrangements in HRS cells in 90% of cases and L&H cells in 100% of cases supports their origin from a single transformed B cell that undergoes subsequent monoclonal expansion.[37,38] Immunohistological studies demonstrate two distinct immunophenotypes of the malignant cells in Hodgkin's disease ( Table 23-1). Immunophenotype I is characterized by the consistent expression of CD20 and J chain, and absence of CD30 and CD15. Immunophenotype II is characterized by the consistent expression of CD30, frequent expression of CD15, and consistent absence of J chain. L&H cells have immunophenotype I, whereas other HRS cells have immunophenotype II, a variation that correlates well with the unique clinical features of localized lymphocyte predominance disease. This distinction forms the basis for the revised European-American classification of lymphoid neoplasms, which proposes to combine all histological subtypes with immunophenotype II, including nodular sclerosis (NS), MC, and lymphocyte depletion, under the designation of classical Hodgkin's disease.[38] These findings designate a clear distinction between lymphocyte predominance Hodgkin's disease and classical Hodgkin's disease. In this classification, the histologic subtype that is similar in growth and cellular composition to lymphocyte predominance, but has immunophenotype II characteristic of classical Hodgkin's disease, is designated as nodular lymphocyte–rich classical Hodgkin's disease.

| | Immunophenotype I: Lymphocytic predominance Hodgkin's disease | Immunophenotype II: Classical Hodgkin's disease |
|---|---|---|
| Antigen | | |
| J chain | +(-) | - |
| CD20 | + | -/+ |
| CD79a | + | -/+ |
| CD30 | - | + |
| CD15 | - | +/- |
| Cell type | | |
| Lymphocytic and histiocytic | + | - |
| Hodgkin and Reed-Sternberg | - | + |

**TABLE 23-1. IMMUNOPHENOTYPES OF LYMPHOCYTIC AND HISTIOCYTIC CELL AND CLASSICAL HODGKIN AND REED-STERNBERG CELL**

Immunophenotypic evaluation of L&H cells of lymphocyte predominance Hodgkin's disease uniformly demonstrates the expression of B-cell antigens (CD19, CD20, CD22, CD79a), consistent with their derivation from B lymphocytes.[39,40] HRS cells of classical Hodgkin's disease usually lack lineage-specific antigens and express some unusual molecules, including those characteristic of dendritic antigen-presenting cells (restin, fascin, thymus, and activation-regulated chemokine).[39] Rearrangement and somatic hypermutation of the immunoglobulin heavy-chain variable genes suggest that Reed-Sternberg cells derive from germinal center B lymphocyte that carries nonproductive immunoglobulin genes and resists culling by apoptosis.[40] Recent studies have provided evidence that suggests that deregulation of the nuclear transcription factor NFkB in HRS cells may be a mechanism that prevents apoptosis. In 10% to 20% of cases of classical Hodgkin's disease, the antigen profile of HRS cells supports a derivation from activated T lymphocytes (CD3, CD4, CD8, T-cell receptor b chain).[40] Unequivocal evidence of T-cell–derived HRS, however (e.g., the presence of clonally rearranged T-cell receptor genes) has not been demonstrated.[41]Table 23-2 summarizes the surface phenotype of the histologic subtypes of Hodgkin's disease.

| | Histologic subtype | | | | |
|---|---|---|---|---|---|
| Antigen | Lymphocytic predominance | Nodular sclerosing | Mixed cellularity | Lymphocytic depletion | Anaplastic large cell lymphoma |
| LCA (CD45) | + | - | - | - | - |
| Ki-1 (CD30) | +/- | + | + | + | + |
| EMA/MI (CD15) | - | + | + | + | + |
| CBF (CD20) | + | +/- | +/- | +/- | +/- |

**TABLE 23-2. IMMUNOPHENOTYPE OF HODGKIN'S DISEASE SUBTYPES AND ANAPLASTIC LARGE CELL LYMPHOMA**

Immunophenotyping of HRS cells has indicated expression of certain activation antigens, including the IL-2 receptor, Ki-1, the transferrin receptor, and HLA-DR epitopes. Initial reports that CD30 expression was restricted to HRS cells proved erroneous. The antigen was subsequently found to be expressed on activated or transformed cells, including T and B lymphocytes and macrophages, as well as in other lymphoproliferative disorders, including anaplastic large cell lymphoma. [42] Soluble CD30 levels in sera of patients with Hodgkin's disease have correlated with disease activity. [43] Table 23-2 contrasts the immunophenotype of the Hodgkin's histologic subtypes and anaplastic large cell lymphoma (see Chapter 24).

Hodgkin's disease is characterized by cytokine-producing and cytokine-responding cells. Many of the nonspecific clinical features in patients with Hodgkin's disease result from cytokine production by HRS cells and neighboring inflammatory cells. Among these are high levels of CD30 and CD40, members of the TNF receptor superfamily.[44] CD30, CD40, or EBV LMP1 can activate NFkB and c-*Jun* N-terminal kinase pathways, which regulate HRS cell proliferation, expression of adhesion molecules, and secretion of cytokines.[44] The unique histopathologic features, such as eosinophilia and collagen sclerosis, have been attributed to the production of cytokines such as IL-4, IL-5, eotaxin, IL-6, IL-7, TNF, lymphotoxin, transforming growth factor-b (TGF-b), and basic fibroblast growth factor. [44] Adhesion molecules regulated by cytokines are thought to influence the interaction of HRS cells with neighboring T lymphocytes and metastatic capacity of Hodgkin's disease. Systemic symptoms have been best correlated with elevated serum levels of IL-6 and immunosuppression in untreated patients with TGF-b. [44] Elevated serum levels of CD30 and CD25 have been associated with advanced stage, constitutional (B) symptoms, and poor outcome. [43] The unusual expression of CD30 and CD25 on HRS cells forms the basis of novel immunotherapies targeting tumor cells with lethal toxins or effector immune cells. [45,46] Table 23-3 summarizes the relationship among cytokine production and common clinical and pathologic features of Hodgkin's disease.

| Clinical and pathologic features of Hodgkin's disease | Cytokines |
|---|---|
| Constitutional ("B") symptoms | TNF, LT-α, IL-1, IL-6 |
| Polykaryon formation | Interferon-γ, IL-4 |
| Sclerosis | TGF-β, LIF, PDGF, IL-1, TNF |
| Acute phase reactions | IL-1, IL-6, IL-11, LIF |
| Eosinophilia | IL-5, granulocyte M-CSF, IL-2, IL-3 |
| Plasmacytosis | IL-6, IL-11 |
| Mild thrombocytosis | IL-6, IL-11, LIF |
| T-cell and Hodgkin's and Reed-Sternberg cell interaction | IL-1, IL-2, IL-6, IL-7, IL-9, TNF, LT-α, CD30L, CD40L, B7 ligands (CD80 and CD86) |
| Immune deficiency | TGF-β, IL-10 |
| Autocrine growth factors (?) | IL-6, IL-9, TNF, LT-α, CD30L, M-CSF |
| Increased alkaline phosphatase | M-CSF |
| Neutrophil accumulation/activation | IL-8, TNF, TGF-β |

IL, interleukin; LIF, leukemia inhibitory factor; LT, lymphotoxin; M-CSF, macrophage colony-stimulating factor; PDGF, platelet-derived growth factor; TGF, transforming growth factor; TNF, tumor necrosis factor.

**TABLE 23-3. CLINICAL AND PATHOLOGIC FEATURES OF HODGKIN'S DISEASE RELATED TO CYTOKINE PRODUCTION**

## PATHOLOGY

Hodgkin's disease is unique among the lymphomas because its malignant cells account for less than 1% of the total cell population of the tumor. The majority of the tumor is composed of an infiltrate of inflammatory cells (e.g., histiocytes, plasma cells, lymphocytes, eosinophils, neutrophils) and fibrosis, which develops as a result of cytokine release. The HRS cell (or its variant) and reactive cellular background are required to establish the diagnosis, because cells similar to the HRS cell may occur in other neoplastic and reactive processes, including lymphoid hyperplasia associated with infectious mononucleosis, non-Hodgkin's lymphomas (NHLs), and nonlymphoid malignant diseases, including carcinomas and sarcomas. The classic Reed-Sternberg cell is large (greater than or equal to 15 to 45 µm in diameter), with abundant cytoplasm and either multiple or multilobed nuclei. The nuclear membrane is usually intensely stained, and the delicate chromatin network within it typically gives way to a peculiar halo-like clear zone around the nucleolus that is often said to resemble an “owl's eye.” The nucleoli are also large and prominent ( Fig. 23-1).

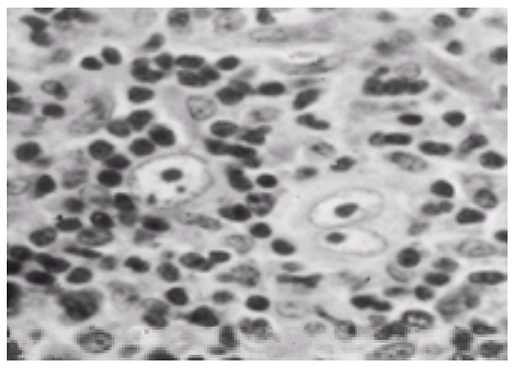

**FIGURE 23-1.** Characteristic Reed-Sternberg cell and mononuclear variant of Hodgkin's disease (hematoxylin and eosin; ×400).

Variants of the Reed-Sternberg cell include the lacunar cell, characteristically seen in nodular sclerosing disease. This variant appears as a cell in a space because of the artifactual retraction of the abundant pale cytoplasm after formalin fixation. Another variant, the frequently seen Hodgkin's cell, has the nuclear and nucleolar features of the Reed-Sternberg cell. In some patients, Hodgkin's cells are more pleomorphic and may be difficult to distinguish from cells present in diffuse pleomorphic histiocytic lymphoma.[47]

## DEFINITION OF HISTOLOGIC SUBTYPES

The most universally accepted histologic classification, the Rye classification system, defines four histologic subtypes of Hodgkin's disease: lymphocytic predominance (LP), MC, lymphocytic depletion (LD), and NS.[47] Historically, prognosis in the first three categories was linked to the ratio of lymphocytes to abnormal cells. Since the development of highly curative treatment regimens, however, all histologic subtypes of Hodgkin's disease are equally responsive to treatment.

In LP Hodgkin's disease, the lymph node architecture may be partially or completely destroyed. Because the cellular proliferation consists of benign-appearing lymphocytes and, sometimes, histiocytes, this subtype may be misinterpreted as reactive hyperplasia. Multiple tissue sections may need to be examined before a diagnostic Reed-Sternberg cell is identified; fibrosis usually is not seen. LP Hodgkin's disease affects 10% to 15% of patients, is more common among male and younger patients, and usually presents as clinically localized disease.

Reed-Sternberg cells and their variants are often numerous (5 to 15 per high-power field) in tissue samples of MC Hodgkin's disease. The lymph node is usually diffusely effaced and contains an inflammatory background of lymphocytes, plasma cells, eosinophils, histiocytes, and malignant reticular cells. Fine interstitial fibrosis may be seen, and focal necrosis may be present but usually is not marked. This subtype is observed in approximately 30% of patients, is more common in children aged 10 years or younger, and frequently presents as advanced disease with extranodal involvement. [48]

LD Hodgkin's disease is rare in children, but it is common in human immunodeficiency virus–infected patients. The presence of numerous, bizarre, malignant reticular cells, many Reed-Sternberg cells, and few lymphocytes characterizes this subtype. Diffuse fibrosis and necrosis are common. Clinical features of LD Hodgkin's include widespread disease that involves the bones and bone marrow. A significant proportion of cases previously designated LD Hodgkin's disease may actually represent diffuse large cell lymphoma.

Affecting approximately 40% of younger patients and 70% of adolescents, NS Hodgkin's disease is the most common subtype.[48] It is characterized by the lacunar variant of the Reed-Sternberg cell and, in most cases, a thickened lymph node capsule. Orderly collagenous bands emanate from the capsule and divide the lymphoid tissue into circumscribed nodules (Fig. 23-2). This process has a striking propensity to involve the lower cervical, supraclavicular, and mediastinal lymph nodes. Because of the abundance of collagen, the radiographic appearance of these lesions (particularly in the mediastinum) may only slowly return to normal, even when the patient is responding to therapy.

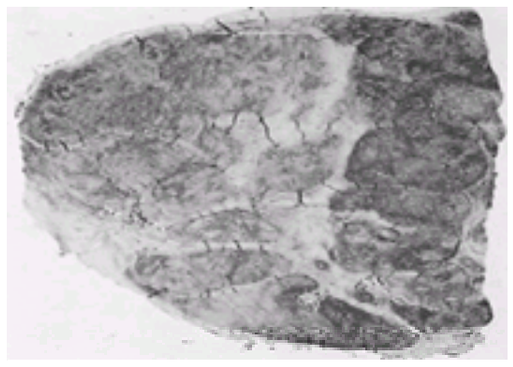

**FIGURE 23-2.** Lymph node, nodular sclerosing Hodgkin's disease. Cellular nodules are surrounded by dense fibrous bands (hematoxylin and eosin; ×8).

## CLINICAL PRESENTATION

### Lymphadenopathy

Usually patients present with painless supraclavicular or cervical adenopathy. Affected lymph nodes are firmer than inflammatory nodes, they feel rubbery, and they may be sensitive to palpation if they have grown rapidly. At least two-thirds of patients present with some degree of mediastinal involvement ( Fig. 23-3), which may cause a nonproductive cough or other symptoms of tracheal or bronchial compression. Posteroanterior and lateral thoracic radiographs should be performed as soon as Hodgkin's disease becomes part of the differential diagnosis. Airway patency should be fully assessed before the patients undergo any procedure requiring sedation. In younger children, mediastinal lymphadenopathy may be difficult to distinguish from a large, normal thymus. Infrequently, axillary or inguinal lymphadenopathy is the first presenting sign. Primary disease presenting in a subdiaphragmatic site is rare and occurs in only approximately 3% of cases. [49]

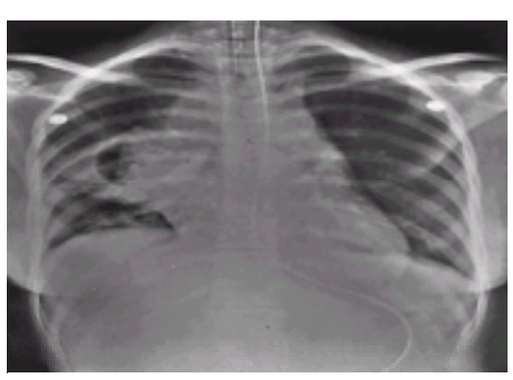

**FIGURE 23-3.** Anteroposterior chest film of a patient with significant tracheal compression below the distal endotracheal tube. Emergency radiotherapy may be required for such patients before staging procedures can be performed.

### Systemic Symptoms

Nonspecific systemic symptoms may include fatigue, anorexia, and slight weight loss. Three specific constitutional symptoms correlate with prognosis: unexplained fever with temperatures above 38.0°C orally, unexplained weight loss of 10% within 6 months preceding diagnosis, and drenching night sweats. Some studies suggest that night sweats are less prognostically important than other systemic symptoms.[50,51]

Pruritus is another systemic symptom commonly observed in patients with Hodgkin's disease, which lacks the prognostic significance associated with fever, sweats, and weight loss. Pruritus generally occurs more frequently in patients with advanced-stage disease, may accompany other systemic symptoms, may be more common in women, and is usually generalized.[52,53] Pruritus may be mild or severe enough that excoriations are produced from scratching. Proposed explanations of Hodgkin's-associated pruritus include cholestatic liver disease and peripheral sensory neuropathy. Pruritus typically resolves when the Hodgkin's disease is treated. [54]

Another unusual syndrome associated with Hodgkin's disease is alcohol-induced pain.[52] The pain usually begins within minutes of drinking alcohol and occurs in areas of nodal enlargement. Pain may also develop in the chest and radiate to the extremities or back. Alcohol-induced pain resolves with treatment of Hodgkin's disease; its mechanism is unknown.

### Laboratory Profile

Hematologic and chemical blood parameters show nonspecific changes that may correlate with disease extent. Abnormalities of peripheral blood counts may include neutrophilic leukocytosis, lymphopenia, eosinophilia, and monocytosis. At the onset of disease, the absolute lymphocyte count is usually normal in children, [55] although adults with extensive disease commonly have lymphopenia. Anemia may indicate the presence of advanced disease and usually results from impaired mobilization of iron stores.[56] Hemolytic anemia associated with Hodgkin's disease may be Coombs' positive and is accompanied by a reticulocytosis and normoblastic hyperplasia of the bone marrow.[57]

Several autoimmune disorders have been observed in association with Hodgkin's disease, including nephrotic syndrome, autoimmune hemolytic anemia, autoimmune neutropenia, and immune thrombocytopenia (ITP). ITP has been reported in 1% to 2% of cases of Hodgkin's disease and may occur in association with autoimmune hemolytic anemia.[58,59] and [60] Thrombocytopenia may develop before, at the same time, or after the diagnosis of Hodgkin's disease.[58,59] ITP frequently occurs in patients in remission after completion of therapy for Hodgkin's disease and is not usually associated with relapse. The treatment approach recommended for ITP in patients with Hodgkin's disease is similar to that in patients without malignancy. Response to ITP therapy is also similar.

The erythrocyte sedimentation rate, serum copper, and ferritin levels may be elevated, reflecting activation of the reticuloendothelial system. These nonspecific tests, if abnormal at diagnosis, may be useful in follow-up evaluation.[61]

### Immunologic Status

Patients with Hodgkin's disease exhibit immune system abnormalities at diagnosis that may persist during and after therapy.[62] In addition to the defects summarized in Table 23-4, natural killer cell cytotoxicity may be reduced in untreated patients.[55,62] Typically, enhanced sensitivity to suppressor T lymphocytes present at diagnosis

results in abnormal cellular immunity. After treatment, humoral immunity may be transiently depressed. *In vitro* studies have provided insights regarding the mechanism of immune dysregulation in Hodgkin's disease.[63,64] A variety of cytokine interactions have been proposed to explain the paradoxical presence of extensive inflammatory infiltrate, ineffective host antitumor response, and generalized cellular immune deficiency. [44]

| Activity | Untreated active disease | Disease-free survivors |
|---|---|---|
| Antigen-induced antibody production | Normal | Transiently depressed |
| Polymorphonuclear function | | |
| Chemotaxis | Decreased | Decreased |
| Metabolic reactivity | Decreased | Decreased |
| Delayed hypersensitivity skin tests | | |
| Recall antigens | Anergic | Reactive |
| Neoantigens | Anergic | Anergic |
| E rosette formation | Decreased | Decreased |
| Mitogen-induced T-cell proliferation | Decreased | Decreased |
| Mixed lymphocyte-induced proliferation | | |
| Autologous | Decreased | Decreased |
| Allogeneic | Slightly decreased | Slightly decreased |
| Sensitivity to suppressor monocytes | Enhanced | Enhanced |
| Sensitivity to suppressor T cells | Enhanced | Enhanced |
| CD4:CD8 ratio | Slightly decreased | Decreased |

**TABLE 23-4. IMMUNE PROFILES IN HODGKIN'S DISEASE**

## DIFFERENTIAL DIAGNOSIS

Hodgkin's disease must be differentiated from other inflammatory causes of lymphadenopathy, particularly those with an indolent course (e.g., atypical mycobacterium infections and toxoplasmosis). NHL may have similar presenting signs and symptoms, but the growth rate of the affected lymph nodes is often more rapid than in Hodgkin's disease. In addition, NHL more frequently causes elevated uric acid or lactic dehydrogenase levels (see Chapter 24). Occasionally, biopsy of recurrent or persistent lymphadenopathy originally attributed to infectious mononucleosis or reactive hyperplasia yields the diagnosis of lymphoma. The cervical lymphadenopathy of Hodgkin's disease must also be differentiated from metastatic adenopathy of other primary tumors (e.g., nasopharyngeal carcinoma and soft tissue sarcoma).

A more difficult problem is that of a mediastinal mass that must be differentiated from normal thymus in an otherwise asymptomatic patient. The thymus is maximal in size in children aged approximately 10 years and may be differentiated from tumor on thoracic computed tomographic (CT) scans by its texture. [65] Ultimately, however, only biopsy can definitively confirm a diagnosis.

## DIAGNOSTIC WORKUP

Table 23-5 shows the recommended steps in the diagnostic workup of a child with Hodgkin's disease. An excisional lymph node biopsy is the preferred procedure to establish the diagnosis, as it permits evaluation of the malignant HRS cells within the background of characteristic architectural changes associated with the specific histologic subtypes. A careful physical examination with assessment of all node-bearing areas, including Waldeyer's ring, is essential, with measurement of enlarged nodes so changes can later be quantitated. If high cervical nodes are involved, a CT scan of the neck should be performed to evaluate Waldeyer's ring.

| |
|---|
| Physical examination with measurement of lymph nodes |
| Complete blood cell count with differential, erythrocyte sedimentation rate, renal and hepatic function tests, alkaline phosphatase level |
| Lymph node biopsy |
| Chest radiograph with measurement of mediastinal ratio |
| Computed tomography of neck and chest |
| Computed tomography or magnetic resonance imaging of abdomen and pelvis |
| Lymphangiogram[a] |
| Bone marrow biopsy[b] |
| Bone scan[c] |
| Gallium scan |
| Surgical staging with lymph node sampling[d] |

[a]Recommended for children with equivocal infradiaphragmatic imaging if expertise is available at center.
[b]Recommended for all children except those with stages IA/IIA.
[c]Recommended for children with bone pain and elevated alkaline phosphatase.
[d]Recommended in selected cases only.

**TABLE 23-5. DIAGNOSTIC EVALUATION FOR CHILDREN WITH HODGKIN'S DISEASE**

The chest radiograph provides preliminary information about mediastinal involvement and intrathoracic structures. Patients with “bulky” mediastinal lymphadenopathy measuring greater than or equal to 33% of the maximum intrathoracic cavity may benefit from a combined-modality treatment approach. The pulmonary parenchyma, chest wall, pleura, and pericardium are the most commonly involved extranodal sites of disease and should be further assessed by CT. Rostock and associates [66] found that approximately 50% of previously untreated patients had disease discovered on CT that had been missed on plain film, including pericardial or chest wall invasion, retrocardiac masses, and pulmonary parenchymal involvement. Although magnetic resonance imaging (MRI) is an effective tool for evaluating intrathoracic structures, the pulmonary parenchyma is best evaluated by thoracic CT.

The presence of infradiaphragmatic disease may be evaluated by CT, MRI, or lymphography (LAG). Administration of both oral and intravenous contrast agents is required to delineate accurately lymphadenopathy from other infradiaphragmatic structures by CT. Evaluation of the extent of abdominal and pelvic disease by CT scan is further complicated in children by the lack of retroperitoneal fat. Baker and colleagues [67] found that CT had a sensitivity of only 40% in detecting abdominal adenopathy. Standard MRI may provide better contrast resolution of infradiaphragmatic structures than does CT, and MRI provides better evaluation of fat-encased retroperitoneal lymph nodes.[68] LAG is unique in its ability to display the internal architecture of lymph nodes. This modality differentiates large normal reactive lymph nodes from those that contain tumor, and it is able to evaluate nodes too small for visualization by CT or MRI. However, LAG is more invasive and requires specific expertise to perform and interpret. If LAG is performed, the retroperitoneal lymph nodes remain opacified for months after the procedure, which permits monitoring of response to therapy by abdominal radiograph and facilitates design of infradiaphragmatic radiotherapy treatment portals.

Splenic involvement occurs in 30% to 40% of patients with Hodgkin's disease, and the size of the spleen may not correlate with the degree of disease involvement. Liver size and liver function studies are also unreliable indicators of hepatic disease. Organ size and degree of involvement do not strictly correlate because tumor deposits may be less than 1 cm in diameter and not visualized by diagnostic imaging modalities. Both CT and MRI scans may suggest splenic or hepatic involvement when these organs appear enlarged with areas of abnormal density. Because of the limitations of diagnostic imaging, only histologic assessment provides definitive evaluation of the spleen and liver. With advances in diagnostic imaging modalities and the standard use of systemic chemotherapy in contemporary pediatric treatment regimens, however, surgical staging of these organs currently has limited indications.

Nuclear imaging studies are often used in patients with Hodgkin's disease as a diagnostic and monitoring modality. Gallium-67 ( $^{67}$Ga) may be particularly useful in the evaluation of supradiaphragmatic Hodgkin's disease. Although this modality does not differentiate inflammatory lesions from lymphoma, the mediastinum demonstrates increased avidity in 60% to 70% of patients with previously untreated disease. In patients with mediastinal disease that has not completely regressed after therapy, persistent $^{67}$Ga avidity may indicate residual disease.[69] “Rebound” growth of the thymus after therapy may lead to increased thymic avidity for $^{67}$Ga, however.[70] $^{67}$Ga may also be useful in evaluating patients with normal physical examinations and recurrent systemic symptoms or abnormal laboratory values suspicious for disease recurrence. Positron emission tomography is currently under investigation as a diagnostic and monitoring tool for Hodgkin's disease.

Bone marrow involvement at the time of initial presentation of Hodgkin's disease is uncommon and rarely occurs as an isolated site of extranodal disease. The pattern of infiltration in the bone marrow may be diffuse or focal and is often accompanied by reversible marrow fibrosis. A bone marrow aspirate alone is not adequate to assess the marrow for disease. A bone marrow biopsy should be performed in any patient with clinical stage III to IV disease or B symptoms, or in any patient at the

time of disease recurrence. The exceedingly low yield of an abnormal bone marrow in a patient with newly diagnosed clinical stage I to IIA disease does not support its routine use during staging.

A technetium-99 bone scan with corresponding plain radiographs of abnormal areas aids in the assessment of skeletal metastases and should be reserved for the child who has bone pain, a serum alkaline phosphatase concentration elevated beyond that expected for age, or extranodal disease identified by other staging studies.

## STAGING

Hodgkin's disease appears to spread along contiguous lymph nodes until late in the course of disease. [52] The currently used Ann Arbor staging system, adopted in 1971, is based on this observation (Table 23-6).[71] The anatomic locations of lymph node chains designated as regions for the purpose of staging [72] are illustrated in Figure 23-4.

| Stage | Definition |
|---|---|
| I | Involvement of a single lymph node region (I) or of a single extralymphatic organ or site ($I_E$) |
| II | Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site and one or more lymph node regions on the same side of the diaphragm ($II_E$) |
| III | Involvement of lymph node regions on both sides of the diaphragm (III), which may be accompanied by involvement of the spleen ($III_S$) or by localized involvement of an extralymphatic organ or site ($III_E$) or both ($III_{SE}$) |
| IV | Diffuse or disseminated involvement of one or more extralymphatic organs or tissues with or without associated lymph node involvement |

Note: The absence or presence of fever higher than 38°C for 3 consecutive days, drenching night sweats, or unexplained loss of 10% or more of body weight in the 6 months preceding admission are to be denoted in all cases by the suffix letters A or B, respectively.

**TABLE 23-6. ANN ARBOR STAGING CLASSIFICATION FOR HODGKIN'S DISEASE**

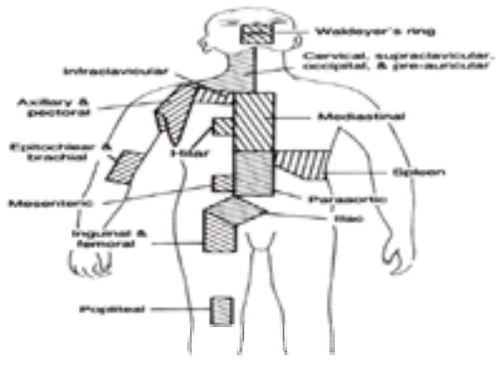

**FIGURE 23-4.** Anatomic definition of separate lymph node regions used for staging purposes. (Adapted from Kaplan HS, Rosenberg SA. The treatment of Hodgkin's disease. Med Clin North Am 1966;50:1591.)

The substage classifications A, B, and E amend each stage based on defined clinical features. Substage A indicates “asymptomatic” disease. B symptoms include fever exceeding 38°C for 3 consecutive days, drenching night sweats, and an unexplained loss of at least 10% of body weight over 6 months. Substage E denotes minimal extralymphatic disease; originally, this designation identified extralymphatic disease so limited that it could be subjected to definitive treatment by radiotherapy.[52] Disease limited to the spleen or splenic hilar or porta hepatis nodes has been said to have a more favorable prognosis relative to other stage IIIA disease and is designated IIIA1 (Fig. 23-5).[73]

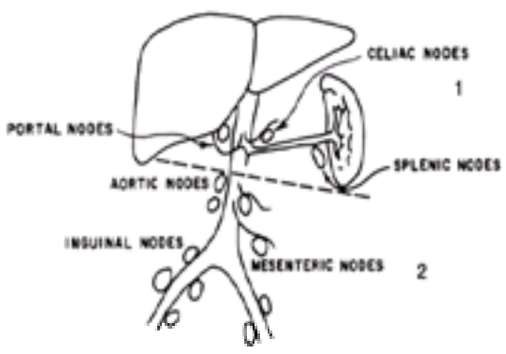

**FIGURE 23-5.** Diagram of lymph node regions in the abdomen showing the demarcation of stage $IIIA_1$ disease (nodal involvement limited to groups above the line) from stage $IIIA_2$ (nodal involvement below the line). (From Desser RK, Golomb HM, Ultmann JE, et al. Prognostic classification of Hodgkin's disease in pathologic stage III, based on anatomic considerations. Blood 1977;49:883, with permission.)

Pathologic staging, based on the findings of a staging laparotomy, including splenectomy, was routinely used in the 1970s to identify infradiaphragmatic disease. The importance of the staging laparotomy was emphasized after the discovery of an unusually high number of patients with clinically unsuspected splenic involvement at presentation.[74] In the 1980s, several factors brought about the widespread use of clinical staging: (a) advances in diagnostic imaging technology permitted more accurate evaluation of the retroperitoneal lymphatics, (b) the increasing use of systemic therapy for children precluded the need for confirmation of microscopic abdominal disease, and (c) the appreciation of infectious and neoplastic complications after splenectomy motivated the desire to maintain intact splenic function. Currently, surgical staging, most typically nodal sampling without splenectomy, is pursued only if the anticipated findings will significantly alter the treatment plan.

## TREATMENT

### Principles of Radiotherapy

The radiation responsiveness and radiocurability of Hodgkin's disease was recognized shortly after the discovery of x-rays. Even in the 1950s, when only orthovoltage equipment was available, investigators realized that patients with Hodgkin's disease could be treated effectively by irradiating all involved areas with high doses. With the development of megavoltage irradiation equipment—specifically the linear accelerator—Kaplan [52] devised techniques allowing treatment of large fields to high doses, with resultant cures. These pioneering efforts provide much of the basis for current standards of practice. In the early years, all patients, irrespective of age, were managed and treated alike. Not until 1970 was the first protocol devised specifically for the management of children. Today in the United States, the standard of care for the very large majority of children and adolescents with Hodgkin's disease is risk-adapted combined-modality therapy using low-dose, involved-field radiation in conjunction with multi-agent chemotherapy. An exception can be made for older adolescents and fully-grown patients with well-staged, favorable, nonbulky,

localized disease in whom high-dose, extended-field radiation alone can be curative. However, the desire to avoid radiation-related organ dysfunction and solid malignant neoplasms has resulted in the infrequent use of this treatment approach in the pediatric setting. Chemotherapy-alone protocols for children with early stage, nonbulky disease are under investigation.

The decisions regarding use of radiotherapy in the treatment program are a function of patient age, tumor burden, and concern about potential complications of treatment. All children with newly diagnosed Hodgkin's disease should be treated with curative intent. Good treatment planning with evaluation of sites of disease is an essential component of patient management.

***Radiotherapy Techniques***

The linear accelerator is the treatment machine of choice for the radiotherapy of Hodgkin's disease, with 6 mV the desired energy in most instances, particularly for supradiaphragmatic treatment. The 6-mV beam is sufficiently penetrating to produce reasonable beam homogeneity throughout an irregular treatment field, with most accelerator beams characterized by a reasonably flat beam profile. The point of maximal ionization of a 6-mV beam is close enough to the skin surface to avoid underdosing superficial lymph nodes, as in the neck. There remains a 10% to 20% dose inhomogeneity in a typical mantle field treated with a 6-mV beam, however, primarily from different separations in the superior and inferior portions of the field. Multiple off-axis site points should be measured and compensating filters used to minimize this dose in homogeneity. A beam energy greater than 6 mV may occasionally be useful for a large adolescent/young adult for subdiaphragmatic treatment.

A 4-mV linear accelerator is less desirable than a higher energy megavoltage machine. Many 4-mV accelerators have unusual beam profiles, especially with large irregular fields, in which the beam characteristics may be flat at a depth of 10 cm, but near the surface, the dose may be greater at the edge of the field than at the center. This characteristic, in combination with sites of lesser separation, such as the neck and axilla, may cause even greater dose heterogeneity requiring a compensating filter. Cobalt 60 units have the problem of dose falloff at the edge of a field, resulting in underdosing at the field edge. Additionally, the penumbra in a cobalt unit causes significant scatter radiation, which should be avoided in children. Orthovoltage is contraindicated. An extended source-to-skin distance is necessary to achieve large treatment volumes. Distances of less than 80 cm should be avoided because of poor depth-dose characteristics. Each field must be simulated and should be treated daily, five times per week. Appropriate gaps must be calibrated when adjacent areas are treated. Field edges should be permanently marked with tattoos.

Good immobilization is essential to the accuracy of radiotherapy. In very young patients who may move or in whom the fields may vary, a customized alpha cradle in conjunction with a chin band will improve reproducibility. For neck treatment, a face mask with a headrest will help assure a reproducible field. Children generally do not tolerate a bite block well. Arm position will vary according to the age of the patient. The akimbo arm position can be reproduced by simply having the child place his or her thumb in the waistband or belt.

Custom shielding blocks are essential. Divergent blocks are generally cast from a low-melting-point alloy such as Lipowitz metal (Cerrobend) and mounted on the collimator of the accelerator. These blocks are of a thickness calculated to reduce the transmitted beam by five half-values, which is approximately 3% of the prescribed dose. In addition to the 3% transmitted from the primary beam through the full-thickness Cerrobend block, there is some dose from radiation scattered internally from other tissues within the path of the beam. At the edge of the treatment field, the actual dose is approximately 50% of the prescribed dose with rapid dose falloff as the distance increases from the beam edge.

***Fields and Volumes***

An involved field includes not only the individual clinically involved or enlarged lymph nodes but also the surrounding lymph nodes within the same lymph node region, as delineated in Figure 23-4. A standard involved field is the minimum radiation field size used for Hodgkin's disease, and is appropriate in combined-modality programs. It is not acceptable to use a postage stamp–sized radiation field over an involved lymph node even in combined-modality therapy. The rare adolescent or young adult treated with radiation alone as the sole therapeutic modality is more appropriately treated with an extended field, subtotal lymphoid, or total lymphoid irradiation. For details regarding these fields, the reader is referred to a standard textbook of adult Hodgkin's disease. [75]

The mantle field is the most complex and important treatment field used in the management of Hodgkin's disease.[76] It encompasses the submandibular, submental, cervical, supraclavicular, infraclavicular, axillary, mediastinal, and pulmonary hilar lymph nodes. [52,77] The tumor volume may be enlarged to include the entire cardiac silhouette or lungs, or these organs may receive a lower dose through the use of a partial transmission block. [78] Because the mantle field treats a large volume, specific beam-shaping devices must be added. Blocks should be used over the occipital area, larynx, humoral heads, and spinal cord to avoid unnecessary morbidity. Axillary blocks may also be individualized. The “shrinking-field” technique is important when treating a patient with a large mediastinal mass, because as little as 10 to 15 Gy may lead to a dramatic response. Based on the response, blocks may be redesigned, thereby increasing protection to critical normal structures. An initial course of mantle irradiation in a symptomatic patient with extensive mediastinal disease often promptly relieves respiratory distress and enables the continuation of staging evaluation. Alternatively, one can use initial chemotherapy to provide tumor response and thus use a smaller radiation field for consolidative radiation in the situation in which one is faced with large mediastinal disease.

More common, when involved-field radiation is used, the mantle field is modified to exclude uninvolved areas. For example, the bilateral axillae are excluded when there is no initial axillary involvement ( Fig. 23-6). This is especially important in girls, for the axillary fields allow exposure to much of the breast, which should be avoided whenever possible. The modified mantle does not necessarily cover the entire neck and infraclavicular areas. When there is disease in the mediastinum, the modified mantle field includes the mediastinum, bilateral hila, and low neck, but not the mid- and high neck, unless these sites are specifically involved. The inferior border of the mediastinal involved field varies depending on the most inferior extent of disease but need not extend as low as the diaphragm, as is typical in the traditional mantle field. When the initial disease is located in the superior mediastinum, a modified mantle field would shield the pericardium and subcarinal areas for at least a portion of the treatment, allowing a 3- to 5-cm margin below the most inferior extent of disease. The minimantle field excludes the mediastinum entirely and is designed to treat the bilateral neck with or without the axillae. A Waldeyer's ring field ( Fig. 23-7) is used when the Waldeyer's ring structures or preauricular lymph nodes are involved, or when there is high cervical nodal disease that cannot be adequately covered by anterior/posterior opposed fields. It is a laterally placed field designed to cover the preauricular, postauricular, submental, retropharyngeal, occipital, parotid, submandibular and upper cervical areas. It is often matched to the upper border of an anterior/posterior opposed neck or mantle field at approximately the level of the thyroid notch. The Waldeyer's field may be treated with photons or electrons.

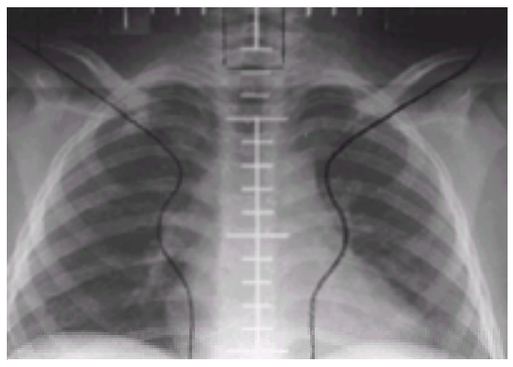

**FIGURE 23-6.** Modified mantle radiotherapy field, anterior port. Shaped blocks are used to contour the mediastinal-hilar silhouette and to treat the involved areas while shielding the uninvolved critical normal structures.

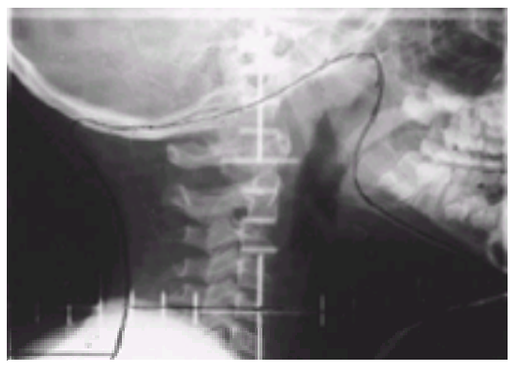

**FIGURE 23-7.** A Waldeyer's ring radiotherapy field involves a shaped field to treat the involved and adjacent lymph nodes in the upper neck areas, avoiding normal structures. Often, it is matched to a modified mantle field, as shown in Figure 23-6, using a split-beam technique.

It is unusual to have splenic disease without associated para-aortic disease. Thus, often these two areas are treated simultaneously when using involved-field radiation (Fig. 23-8). In this situation, a significant volume of the left kidney may be exposed with traditional opposing fields. The use of CT treatment planning is recommended, as it allows one to determine the volume of both the spleen and nearby left kidney. This allows one to contour the splenic field to avoid excess exposure to the left lung base, which otherwise might result in a left pleural base reaction or excess left kidney radiation. In cases of ipsilateral inguinal-femoral disease, a unilateral field covering these areas is appropriate. When there is ipsilateral iliac disease, the involved fields would be enlarged to cover all three sites as a hemipelvis field. When there is bilateral involvement of iliac, inguinal, or femoral areas, a pelvic field with gonadal shielding is used.

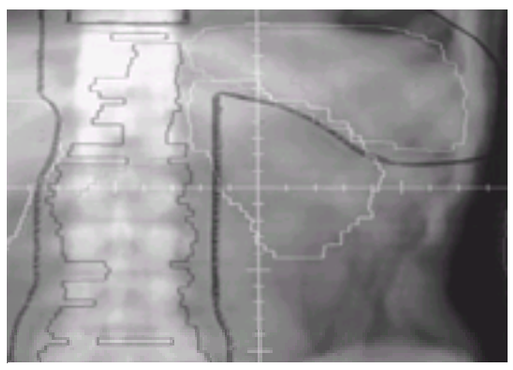

**FIGURE 23-8.** Spleen–para-aortic radiotherapy field as visualized on a digitally reconstructed radiograph taken from a three-dimensional conformal treatment plan. The spleen and kidneys are projected so the portal can be shaped and contoured.

In young women who require pelvic irradiation, transposition of the ovaries to a central midline position enables the use of a midline pelvic block to protect ovarian function.[79] The dose to the transpositioned ovaries can be decreased to 8% of that to the adjacent pelvic lymph nodes. [80] In male patients, a testicular shield minimizes the scatter radiation to the testes to 0.75% of the pelvic lymph node dose. [81] A conventional testicular shield is effective in postpubertal males; individual shielding devices must be fabricated for pubertal males.

In planned combined-modality programs, radiotherapy limited to involved sites requires judgment and flexibility. The involved field might better be termed a reasonable field. The goal with this approach is to treat the appropriate field to minimize retreatment match line problems in the event of a subsequent recurrence, and to minimize late effects. Table 23-7 provides functional definitions of involved radiation fields for various regions, but treating physicians must be flexible and use judgment considering the original site of disease and chemotherapy program used. The concept of involved-field radiation is most clear when dealing with stage I to II disease. For patients with stage III and select IV sites, the involved field could represent subtotal lymphoid irradiation or total lymphoid irradiation.

| | |
|---|---|
| Mantle | Supradiaphragmatic disease involving mediastinum as well as one or both cervical, supraclavicular, infraclavicular, or axillary lymph nodes. |
| Minimantle | Bilateral supramediastinal disease involving axilla, supraclavicular, infraclavicular, or cervical lymph node chains. |
| Hemiminimantle | Unilateral supramediastinal disease involving axilla, supraclavicular, infraclavicular, or cervical lymph node chains. |
| Mediastinum | Disease in mediastinum, one or both hila. |
| Para-aortic-splenic hilar-spleen | Subdiaphragmatic disease in spleen, splenic hilar, or para-aortic areas. |
| Spade | Subdiaphragmatic disease in spleen, splenic hilar, paraaortic, and iliac areas. |
| Pelvis | Disease in bilateral iliac and inguinal-femoral areas. |
| Hemipelvis | Disease in unilateral iliac and inguinal-femoral areas. |
| Inverted Y | Subdiaphragmatic disease in spleen, splenic hilar, para-aortic, and pelvic areas. |

**TABLE 23-7. INVOLVED-FIELD REGIONS**

### *Dose and Time Factors*

The radiation dose response curve has demonstrated that with a radiation dose of 36 to 40 Gy, local control exceeds 95%. For subclinical disease, doses of 30 Gy or greater provide local control in greater than 95% of patients. [82] However, for bulky disease, the control rate with radiation alone is less good and combined-modality therapy is needed. When combined-modality programs are used, lower radiation doses in the range of 20 Gy achieve a local control rate of 97%. [11] It is these data that prompted the use of low-dose, involved-field radiation with chemotherapy for children. The current pediatric protocols generally use between 15 and 25 Gy with chemotherapy, often with the radiation dose being determined by the response to chemotherapy. Residual radiographic abnormalities, particularly in the mediastinum, after a planned course of therapy are common and do not necessarily represent active Hodgkin's disease. A positive $^{67}$Ga scan at the end of therapy is rarely seen but raises concern of residual active disease, thus necessitating biopsy confirmation. A negative $^{67}$Ga has a lower predictive value, however, particularly in patients with stage III and IV disease. In one series of children and adults, the negative predictive value of $^{67}$Ga was only 64.5% for patients with stage III to IV disease, resulting in a relapse-free survival of only 48%. [83] Thus, a negative $^{67}$Ga scan does not necessarily mean the patient is disease free. The appropriate dose-time relationship in the treatment of Hodgkin's disease is less clear than the dose-response data. In light of normal tissue tolerance, patient acceptance, and tumor control, tumor doses of 1.5 to 1.8 Gy per day, five times a week, are most appropriate. When treating larger volumes, doses of 1.5 Gy are best tolerated, and no indication for using larger fraction sizes exists.

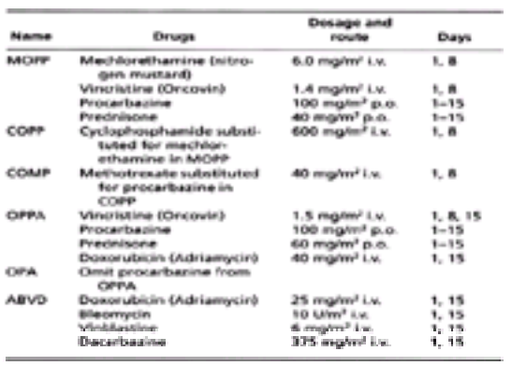
### Combination Chemotherapy

Current effective multidrug regimens for Hodgkin's and other pediatric malignancies combine non–cross-resistant agents with the following properties:

1. Each agent should be individually active against the tumor.

2. The agents should differ in the mechanism of antineoplastic activity, thereby targeting different cellular or biochemical events and preventing development of resistance.
3. Toxicities of the agents should not overlap, so that each drug can be administered at full single-agent dose.

The agents selected for the original combination therapy of Hodgkin's disease (MOPP) fulfilled these qualifications ( Table 23-8).[9] The MOPP combination, with agents delivered at full doses, produces long-term disease-free survival in approximately 50% of adult patients with advanced disease. [10] Additional maintenance therapy does not extend remission but rather predisposes to excess morbidity from higher cumulative exposures of agents with dose-related toxicity. Children with Hodgkin's disease have similar or better treatment outcomes after MOPP therapy compared to adult patients [11,12,13,14] and [15] but are also at risk for adverse MOPP-related sequelae including AML and infertility. Both toxicities are correlated with the cumulative doses of alkylating agent chemotherapy. The risk of secondary AML has been dramatically reduced by restricting cumulative doses of alkylating agent chemotherapy and substituting other, less leukemogenic alkylating agents (e.g., cyclophosphamide for mechlorethamine).[84] Similarly, the risk of infertility, which is almost universal in boys following treatment with six to eight cycles of MOPP therapy, may be reduced when treatment with gonadotoxic alkylating drugs, especially procarbazine, is limited to three cycles. [85,86]



| Name | Drugs | Dosage and route | Days |
|---|---|---|---|
| MOPP | Mechlorethamine (nitrogen mustard) | 6.0 mg/m² i.v. | 1, 8 |
| | Vincristine (Oncovin) | 1.4 mg/m² i.v. | 1, 8 |
| | Procarbazine | 100 mg/m² p.o. | 1–15 |
| | Prednisone | 40 mg/m² p.o. | 1–15 |
| COPP | Cyclophosphamide substituted for mechlorethamine in MOPP | 600 mg/m² i.v. | 1, 8 |
| COMP | Methotrexate substituted for procarbazine in COPP | 40 mg/m² i.v. | 1, 8 |
| OPPA | Vincristine (Oncovin) | 1.5 mg/m² i.v. | 1, 8, 15 |
| | Procarbazine | 100 mg/m² p.o. | 1–15 |
| | Prednisone | 60 mg/m² p.o. | 1–15 |
| | Doxorubicin (Adriamycin) | 40 mg/m² i.v. | 1, 15 |
| OPA | Omit procarbazine from OPPA | | |
| ABVD | Doxorubicin (Adriamycin) | 25 mg/m² i.v. | 1, 15 |
| | Bleomycin | 10 U/m² i.v. | 1, 15 |
| | Vinblastine | 6 mg/m² i.v. | 1, 15 |
| | Dacarbazine | 375 mg/m² i.v. | 1, 15 |

**TABLE 23-8. CHEMOTHERAPY REGIMENS FOR HODGKIN'S DISEASE (REPEAT CYCLE EVERY 28 DAYS)**

The development of the ABVD in the 1970s provided another effective non–cross-resistant chemotherapy regimen that did not produce an excess risk of secondary AML or infertility (Table 23-8).[87] Dose-related toxicity attributed to agents in the ABVD combination includes cardiomyopathy and pulmonary fibrosis, resulting from the doxorubicin and bleomycin, respectively. ABVD was initially used as salvage therapy for adult patients with MOPP-resistant disease, and later alternated with MOPP in an effort to enhance antineoplastic activity. [88] Subsequent studies in adult patients demonstrated that ABVD was superior to MOPP alone and had comparable efficacy to MOPP alternating with ABVD.[17] Superior treatment results and absence of leukemogenesis and permanent gonadal toxicity have made ABVD the preferred frontline regimen for adults with Hodgkin's disease. However, concerns regarding potential cardiopulmonary sequelae have restricted its use as the sole regimen in pediatric patients. Currently, ABVD, or similar hybrid combinations, are incorporated into risk-adapted treatment regimens prescribing fewer cycles of chemotherapy for children with localized, favorable Hodgkin's disease. In patients with advanced and unfavorable Hodgkin's disease, ABVD is more likely to be alternated with MOPP or similar hybrid combinations to improve disease control and reduce dose-related toxicity related to alkylating agent, anthracycline, and bleomycin chemotherapy.

### Treatment Results

Optimal therapy involves a multidisciplinary approach from the time of diagnosis. This is particularly important, as treatment decisions are currently based on risk features present at diagnosis, including the presence of B symptoms, stage, nodal bulk, and number of involved nodal regions. Assignment of stage and treatment are best determined after the pediatric and radiation oncologists have had the opportunity to examine the patient and review staging study results, preferably with simultaneous input from a diagnostic imager. In this way, a consistent plan for chemotherapy and radiation therapy can be presented to the family by all health care providers and reviewed periodically after response evaluations.

#### *Combined-Modality Therapy*

From the 1960s to 1980s, standard-dose (35 to 44 Gy), extended-volume radiation therapy was commonly used in conjunction with combination chemotherapy to enhance local tumor control. The observation of substantial late effects in children who received high-dose radiotherapy provided the impetus for studies evaluating combined-modality treatments prescribing low-dose (15.0 to 25.5 Gy), involved-field radiation therapy. [11,89] As more trials established that local disease control was maintained with reduced radiation, six cycles of non–cross-resistant combination chemotherapy evolved as the standard pediatric approach in combined-modality regimens. Table 23-9 and Table 23-10 summarize the results of major pediatric trials organized from the 1970s through the 1990s that established the efficacy of combined-modality therapy.[11,12,13] and [14,18,19,20,21,22,23] and [24,90,91,92,93,94] and [95]

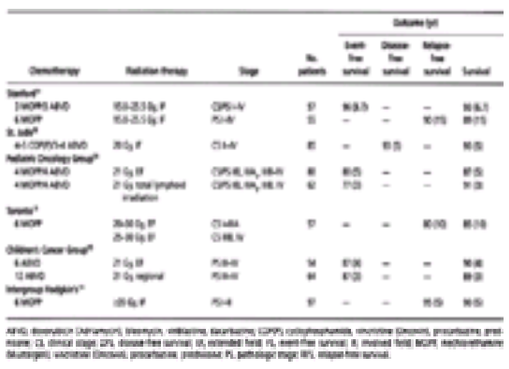


**TABLE 23-9. TREATMENT RESULTS OF NORTH AMERICAN PEDIATRIC COMBINED-MODALITY TRIALS**

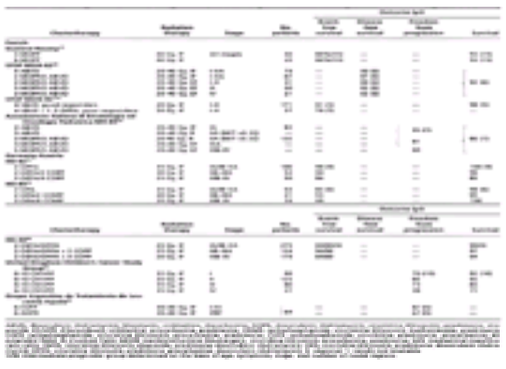

**TABLE 23-10. TREATMENT RESULTS OF EUROPEAN AND SOUTH AMERICAN PEDIATRIC COMBINED-MODALITY TRIALS**

### *Combined-Modality Therapy versus Chemotherapy Alone*

Multiple trials have established the efficacy of treatment with non–cross-resistant chemotherapy alone for pediatric Hodgkin's disease ( Table 23-11).[15,19,93,95,96,98,100,101,102,103,104 and 105,113] This treatment approach offers advantages for children managed in centers without access to radiation facilities, trained personnel, and diagnostic imaging modalities needed for clinical staging. The use of systemic therapy also avoids the potential long-term musculoskeletal complications, organ dysfunction, and solid tumor malignancies associated with high-dose, extended-volume radiation therapy.

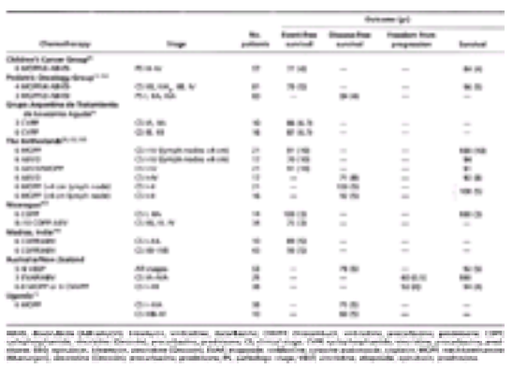

**TABLE 23-11. TREATMENT RESULTS OF PEDIATRIC CHEMOTHERAPY-ALONE TRIALS**

Earlier chemotherapy-alone trials prescribed 6 to 12 cycles of MOPP or hybrid therapies containing alkylating agents [ChlVPP (chlorambucil, vinblastine, procarbazine, and prednisone) and CVPP (cyclophosphamide, vinblastine, procarbazine, and prednisone)] in clinically staged children. [15,96,97 and 98] Acute hematologic and infectious toxicities associated with these treatments were acceptable and easily managed. Follow-up data regarding long-term toxicity have not been reported, although preliminary reports suggest a high frequency of gonadal toxicity in boys. [15,99]

Contemporary chemotherapy-only trials have used alternating non–cross-resistant regimens [MOPP/ABVD, COPP (cyclophosphamide, vincristine [Oncovin], procarbazine, prednisone)/ABV hybrid, CVPP/EBO (etoposide, bleomycin, and vincristine)] or combinations without alkylating agent chemotherapy [ABVD, EVAP (etoposide, vinblastine, cytarabine, and cisplatin)/ABV]. [100,101,102,103,104,105,106 and 107] Early results from these studies demonstrate treatment outcomes similar to those achieved with combined-modality therapy. Again, acute hematologic and infectious toxicities related to these regimens appear acceptable, but long-term cardiopulmonary sequelae have not been evaluated.

Evaluation of the efficacy of chemotherapy-only treatment regimens has been difficult because most reports describe outcome after nonrandom treatment assignments in small clinically staged cohorts. Some trials specifically exclude patients with unfavorable risk features based on bulk and number of involved nodal sites. Only a few randomized pediatric trials have compared treatment outcome after chemotherapy alone to combined-modality therapy. The Grupo Argentino de Tratamiento de Leucemia Aguda prospectively evaluated CVPP chemotherapy alone to CVPP plus involved-field radiotherapy. [107] Treatment outcomes after both regimens were comparable in stage I–II patients. Combined-modality therapy with CVPP plus radiation compared to CVPP chemotherapy alone, however, resulted in better disease-free survival in patients with localized unfavorable [more than two involved nodal areas, bulky peripheral (greater than 5 cm) and bulky mediastinal lymphadenopathy] and advanced stage disease. The next Grupo Argentino de Tratamiento de Leucemia Aguda trial demonstrated comparable event-free survival among patients with favorable disease presentations (as defined by a prognostic factor index based on age, presence of B symptoms, stage, and number of involved nodal regions) randomly assigned to three or six cycles of CVPP. [93]

North American pediatric cooperative group randomized trials have also prospectively compared treatment with combined-modality therapy to chemotherapy-alone. A Children's Cancer Group trial showed equivalent efficacy of 12 cycles of alternating MOPP/ABVD and six cycles of ABVD plus low-dose (21-Gy) involved-, extended-, or total-lymphoid radiation fields in children with pathologic stage III–IV Hodgkin's disease. [95] Although event-free and overall survival were not statistically different between the two groups, children randomized to combined-modality therapy showed higher 4-year event-free and overall survival rates (87% and 90%, respectively) compared to those who received chemotherapy alone (77% and 90%, respectively). A Pediatric Oncology Group study prospectively assessed the benefit of combining low-dose radiation therapy to eight cycles of alternating MOPP-ABVD in children with advanced-stage Hodgkin's disease. [94] Analysis of results based on treatment intent failed to show an advantage for combined-modality therapy. However, analysis based on treatment actually delivered showed a superior outcome in patients treated with chemotherapy and radiation therapy. Limited information is available regarding late treatment effects due to the brief follow-up period after the Children's Cancer Group and Pediatric Oncology Group trials, but one would anticipate higher risks of leukemogenesis, infertility, and cardiopulmonary toxicity related to the higher cumulative doses of alkylating agents, doxorubicin and bleomycin, prescribed in the chemotherapy-alone regimens compared to the combined-modality regimens.

In summary, several studies have demonstrated that chemotherapy alone is effective therapy for pediatric Hodgkin's disease. The advantage of this approach is the elimination of radiation-associated adverse sequelae including musculoskeletal maldevelopment, cardiac dysfunction, and solid tumor induction. Chemotherapy-alone treatment protocols rely on higher cumulative doses of agents with established dose-related toxicity, however, especially alkylating agent chemotherapy, which may contribute to acute and late treatment morbidity. The limited results of controlled randomized trials suggest that the addition of radiation therapy may improve outcome in children with unfavorable and advanced-stage Hodgkin's disease. However, further investigation is clearly needed to identify the prognostic features of patients who may benefit from the addition or omission of radiation therapy.

### *Risk-Adapted Therapy*

#### Favorable Clinical Presentations

In the 1990s, pediatric Hodgkin's trials confirmed that disease-free survival was not compromised by reducing the number of multi-agent chemotherapy cycles, radiation doses, and treatment volumes in clinically staged patients with “favorable” clinical presentations. [20,21,22,23 and 24,86,108,109] The favorable designation has varied among the individual studies but is typically characterized by localized nodal involvement in the absence of B symptoms and bulky disease. *Bulky* mediastinal lymphadenopathy is designated when the ratio of the maximum measurement of mediastinal lymphadenopathy to intrathoracic cavity on chest radiograph equals or exceeds 33%. Risk factors considered in other studies include the number of involved nodal regions, the presence of hilar adenopathy, the size of peripheral lymphadenopathy, and extranodal extension. Pediatric investigations of risk-adapted therapy for localized, favorable clinical presentations of Hodgkin's disease are summarized in Table 23-10.

#### Unfavorable Clinical Presentations

Clinical presentations are designated *unfavorable* when associated with the presence of B symptoms, bulky mediastinal or peripheral lymphadenopathy, extranodal extension of disease, and advanced (stage IIIB–IV) disease. Two standard treatment approaches have been used for pediatric patients with unfavorable clinical presentations. Conventional therapy prescribes non–cross-resistant chemotherapy derived from MOPP or ABVD administered on a twice-monthly schedule for a total of 6 months. COPP has more recently replaced MOPP because cyclophosphamide is less myelosuppressive and leukemogenic than mechlorethamine. [84] Low-dose (15.0 to 25.5 Gy), involved-field radiation therapy may be delivered between treatment cycles or, more commonly, following completion of chemotherapy to consolidate remission. Treatment results for unfavorable pediatric Hodgkin's disease using combined-modality therapy with conventional chemotherapy regimens [e.g., MOPP/ABVD, COPP/ABVD, OPPA (vincristine [Oncovin], procarbazine, prednisone, doxorubicin [Adriamycin])/COPP] are summarized in Table 23-9.

The second treatment approach uses the strategy of abbreviated dose-intensive multi-agent chemotherapy featured in adult trials, such as the MOPP/ABV hybrid combination and the Stanford V regimen.[110,111 and 112] Advantages of these regimens include reduced therapy duration and cumulative chemotherapy doses. Chemotherapy is administered at weekly intervals for a period of 3 to 5 months during which myelosuppressive agents are alternated with nonmyelosuppressive

agents. Consolidative radiation therapy, usually standard-dose in the adult setting, is administered to sites of bulky or residual disease. Ongoing trials of the North American pediatric cooperative groups support the feasibility of this approach combined with low-dose radiation therapy. Long-term follow-up is not yet available to evaluate efficacy and treatment sequelae.

Recent trials evaluating the substitution of non-alkylating agent chemotherapy (e.g., methotrexate or etoposide) as an alternative to alkylating agent chemotherapy demonstrated an inferior event-free survival among patients with unfavorable clinical presentations. [23,113,114] The results of several studies support the designation of an intermediate risk group, however, which includes patients with clinically localized disease (stages I–IIIA) with unfavorable presentation, including bulky lymphadenopathy or extranodal extension. Long-term results of the German Pediatric Oncology Group trials indicate that event-free survival has not been compromised with reduction from six to four chemotherapy cycles in children with these “intermediate” risk features. [23]

**Relapsed Disease**

Most relapses in patients with Hodgkin's disease occur within the first 3 years, although some patients may relapse as long as 10 years after initial diagnosis. The excellent outcome for the majority of children with Hodgkin's disease has limited opportunities for pediatric investigators to evaluate salvage therapy programs in large patient cohorts. Treatment and ultimate prognosis after relapse is largely dependent on the initial therapy type and time of relapse. As many as 50% to 80% of patients who relapse after radiation therapy alone can be salvaged with chemotherapy or combined-modality therapy. Standard multi-agent chemotherapy and radiation therapy may salvage 40% to 50% of children with 1-year or longer initial remissions, but subsequent treatment sequelae, including second malignancies, may reduce ultimate survival.[115] Patients who develop refractory disease during or within 1 year of completing therapy respond poorly to conventional salvage therapy, as do patients with multiple relapses. For these high-risk patients, consolidation with myeloablative therapy followed by hematopoietic stem cell transplantation (HSCT) provides the best opportunity for a durable remission. Several studies support the feasibility and efficacy of this approach, which produces overall survival rates ranging from 30% to 50% in children and adolescents with relapsed Hodgkin's lymphoma. [115,116] The acute morbidity and mortality associated with HSCT may be substantial and are influenced by previous therapy exposures in the often extensively pretreated patients. Transplant-associated mortality occurs in approximately 10% of patients and most commonly results from infectious, cardiopulmonary, or neoplastic complications. [115,117] Patients have been reported to be at risk for relapse as late as 5 years after HSCT, emphasizing the need for heightened surveillance to assure continued remission status and monitor for late treatment sequelae.

The use of HSCT as initial therapy remains controversial because of the overall excellent prognosis of children with advanced and unfavorable Hodgkin's disease. Consensus has not been established among investigators regarding prognostic features that justify the risks of this aggressive approach. Until these issues are further clarified, HSCT should be reserved for patients after relapse or for those who are refractory to primary conventional therapy, including alkylating agents. Similar to trials in adults with Hodgkin's lymphoma, cooperative group investigations are required to address the issues of prognostic factors, optimal conditioning regimens, and timing of stem cell transplantation in children.

Allogeneic bone marrow transplantation has also been used for relapsed Hodgkin's disease. [118] Allogeneic bone marrow transplantation is associated with a lower relapse rate, perhaps related to an immunologic effect against the tumor. The high treatment mortality after these transplants, however, results in event-free survival rates similar to patients treated with autologous transplants.

Novel therapeutic approaches for relapsed Hodgkin's disease are currently under investigation. Immunotoxin therapy targeting antigens expressed by HRS cells include CD25 (the IL-2 receptor) and CD30 (the Ki-1 antigen). Clinical trials to date have included only small numbers of patients. [45,46] The feasibility of adoptive immunotherapy with cytotoxic clones of T lymphocytes specific for EBV LMP1 continues to be explored for patients with EBV-associated Hodgkin's disease. [119]

**Acute Toxicity**

***Acute Radiation Effects***

The short-term side effects of irradiation are generally not serious (see Chapter 11). They are a function of the total dose delivered and the volume irradiated, with the most acute toxicity reported after high-dose, large-volume, radiation-only programs, which today are seldom used in children. Low-dose, involved-field radiation as used in combined-modality treatment programs is well tolerated. Potential toxicity from the radiation component of the combined-modality program may include moderate erythema, hyperpigmentation, or both, of the irradiation skin. There may be transient partial hair thinning at the occiput from a high neck radiation field. Mild gastrointestinal disturbance may occur and possible alteration in taste or xerostomia if a large Waldeyer's ring field is required to a moderately high dose. Granulocytopenia and thrombocytopenia may occur but usually reflect bone marrow suppression from prior chemotherapy. Lhermitte's syndrome, a sensation of an electric shock radiating down the back and into the extremities on flexion of the neck, is rare, self-limited, and does not represent a prodrome of later neurologic dysfunction. In general, acute radiation effects are self-limited and reversible.

***Immediate Effects of Chemotherapy***

Multi-agent chemotherapy programs can cause nausea and vomiting. The efficacy of serotonin receptor antagonist antiemetics, such as ondansetron, greatly improve tolerance to chemotherapy. Anticipatory nausea, which commonly occurs in teenagers, often responds to premedication with benzodiazepines. Nitrogen mustard, vincristine, and doxorubicin may cause severe local tissue damage if infiltrated into the subcutaneous tissues. Vinblastine and dacarbazine may cause a local burning sensation as they are injected. Many chemotherapy programs produce some degree of reversible alopecia. The neurotoxicity of vincristine, the cardiac toxicity of doxorubicin, and the pulmonary toxicity of bleomycin, as well as other side effects, are discussed in Chapter 10. A thorough review of the toxicities of individual chemotherapy agents should be made before any are administered either alone or in combination.

***Infection***

The most common dose-limiting acute toxicity of multi-agent chemotherapy is myelosuppression. Courses of treatment may need to be delayed because of low blood counts. It is preferable to give therapy on schedule at full doses and thus the use of transfusion or simulating factors may be needed for patients receiving aggressive therapy for advanced disease. Some patients may require hospitalization for antibiotic therapy if they develop fever during a period of neutropenia.

The risk of serious bacterial infection, once attributable to splenectomy associated with staging laparotomy, [120] is less frequently observed now that surgical staging is seldom performed. Patients who have undergone a prior splenectomy or splenic radiation, however, should be given a prophylactic antibiotic regimen and guidelines to follow during febrile illnesses. In addition, vaccines available against pneumococcus, *Haemophilus influenzae,* and meningococci may further decrease the risk of serious bacterial infection for these patients, although sustained antibody titers have not been achieved in patients with Hodgkin's disease. [121]

Herpes zoster and varicella infections are seen in 35% of children with Hodgkin's disease. The frequency is directly related to the intensity of treatment. [122] Prompt administration of antiviral therapy has reduced the severity and morbidity of these infections. The management of immunosuppression with these and other infections is discussed in Chapter 40.

**Late Effects**

***Soft Tissue and Bone Growth Alterations***

Early reports described a disproportionate alteration in sitting height compared with standing height among a group of children who received axial skeletal radiation. [123] A follow-up study demonstrated that prepubertal children who received high-dose radiotherapy (greater than 33 Gy) to the entire spine experienced a significant height loss.[124] Pubertal and postpubertal children given similar treatment and prepubertal children given less than 33 Gy to more restricted radiation volumes did not show clinically significant height impairment. [124] Other investigators have confirmed that lower doses of involved-field radiation used with chemotherapy are most probably not associated with clinically significant growth retardation. [48]

Other musculoskeletal abnormalities observed after high-dose radiation include narrowing of the thoracic apex, intraclavicular narrowing with symmetric shortening of the clavicles, and atrophy of the soft tissues of the neck. Rare sequelae include retroperitoneal fibrosis and brachial plexopathy. Avascular necrosis of the femoral

head has been seen with corticosteroid use, but high-dose radiation may also be a contributing factor. The current treatment protocols with lower dose and smaller volumes of radiation are expected to lessen or eliminate the marked changes seen in young patients treated in the past.

### *Pulmonary Sequelae*

Acute and chronic pulmonary complications reported after therapy for Hodgkin's disease include radiation pneumonitis, pulmonary fibrosis, and spontaneous pneumothorax, although these sequelae are uncommon and are a result of therapy given years ago. [89] However, more current pediatric Hodgkin's disease therapy using radiation therapy and ABVD have shown a significant incidence of asymptomatic pulmonary dysfunction after treatment, which appears to improve with time.[90,91,125,126] However, grade 3 and 4 pulmonary toxicity has been reported in 9% of children receiving 12 cycles of ABVD followed by 21-Gy radiation. [95] In addition, ABVD-related pulmonary toxicity may result from fibrosis induced by bleomycin or “radiation recall” pneumonitis related to administration of doxorubicin. Pulmonary veno-occlusive disease has been observed rarely and has been attributed to bleomycin chemotherapy. [127] This incidence of veno-occlusive disease may be underreported, as some cases have been misdiagnosed as pulmonary fibrosis.

### *Cardiovascular Sequelae*

Both radiation therapy and chemotherapy used in the treatment of Hodgkin's disease may have toxic effects on the heart and blood vessels, although symptomatic sequelae are uncommon. They include cardiomyopathy with congestive heart failure, acute pericarditis, pericardial effusion, chronic constrictive pericarditis, coronary artery disease with myocardial infarction, conducting system abnormalities, valvular dysfunction, and peripheral vascular disease. Reduction of anthracycline chemotherapy doses and radiation doses and volumes in contemporary pediatric regimens have diminished the frequency of acute toxicity. However, delayed subclinical cardiovascular injury and its effect on the progression of degenerative cardiovascular disease is just now becoming apparent as survivors of pediatric Hodgkin's disease enter their third and fourth decades.

Cardiac injury from radiation is also related to dose, volume, and fraction size. Both the pericardium and myocardium may be affected. The spectrum of cardiac dysfunction ranges from asymptomatic radiographic abnormalities to life-threatening illness (e.g., constrictive pericarditis requiring pericardiectomy). The incidence of cardiac injury after high-dose mantle irradiation is approximately 13% in both children and adults. Arterial vascular injury, including underdevelopment of the great vessels, coronary artery disease with coronary fibrosis, and accelerated atherogenesis, has been observed in long-term survivors of Hodgkin's disease treated with high-dose mantle irradiation.[89] Clinically apparent cardiac disease occurs infrequently in survivors of Hodgkin's disease treated during childhood or adolescence with modern radiotherapy techniques. However, morphologic abnormalities of screening echocardiograms observed in high frequency in some pediatric cohorts emphasize the importance of longitudinal follow-up to determine the incidence of clinically significant pericardial disease and myocardial dysfunction in this age group. [128,129] and [130]
