Principles and Practice of the Biologic Therapy of Cancer

3rd Edition

Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of health care providers to ascertain the FDA status of each drug or device planned for use in their clinical practice.

PREFACE

Progress in molecular biology and biotechnology has opened extraordinary opportunities for the development of new approaches to the treatment of patients with cancer. The molecular events underlying biologic processes are being increasingly understood. The application of recombinant DNA technology has made it possible to produce large amounts of biologic molecules previously available only in minute quantities. These developments have had a major impact on the treatment of patients with cancer, and this impact is likely to increase substantially in the near future.

This third edition of *Principles and Practice of the Biologic Therapy of Cancer* has been prepared to provide the scientific background and the practical information required to understand and apply developments in this emerging field. Leaders in the field of biologic therapy have provided their expertise for this text.

Each major area of biologic therapy is preceded by a chapter presenting the basic principles and preclinical studies that led to clinical applications. The clinical chapters present a comprehensive analysis of clinical data with an emphasis on the indications for treatment and the practical information necessary to safely apply these new approaches.

Since the first edition of this text was published in 1991, many biologic molecules, such as interleukin-2, α-interferon colony-stimulating factors, and a variety of monoclonal antibodies, have been approved for clinical use. Many other recombinant cytokines, antiangiogenic agents, monoclonal antibodies, and immunoregulatory molecules developed since that time are currently being evaluated in clinical trials. Technical developments have led to increased basic and applied studies in the fields of cancer vaccines and gene therapy, and each of these topics are presented in separate sections of the text.

Advances in biologic therapy will increasingly affect the practice of all oncologic specialties. This text has been designed to present state-of-the-art information to both research scientists and clinicians involved in the development and application of these new cancer treatments.

Steven A. Rosenberg M.D., Ph.D.

Section I
Principles and Practice of Cytokine Therapy

1

Interleukins: Overview

Scott K. Durum

Cytokines

Part of "1 - Interleukins: Overview "

Nomenclature

Cytokines are proteins released by cells that react with receptors on other cells, triggering a response. Cytokines operate in all tissues, but some of the first to be studied and purified were involved in immune and inflammatory processes. In the late 1970s, a large committee of scientists created the interleukin (IL) terminology by applying "IL-1" and "IL-2" to two of the earliest cytokines. Since then, the discoverers of a new cytokine have sometimes pressed to term the protein an *interleukin*, which, although hard to remember, has never erred in being wildly optimistic [i.e., as in *tumor necrosis factor* (TNF), *oncostatin M*, or *leukemia inhibitory factor*]. Hundreds of cytokines are known, although this chapter covers only the 18 currently recognized interleukins. In the future, more cytokines will be discovered.

Clinical potential has driven cytokine research as much as scientific curiosity, judging from the proportion of cytokinology research performed in industry. Cytokines perform powerful activities, which, like those of hormones, are attractive as therapeutics. Cytokines have been difficult to harness, however, and not many have found a direct use in the clinic, except interferons (IFNs), colony-stimulating factors, and erythropoietin, which are not covered in this chapter. Small synthetic molecules that mimic or antagonize cytokines are a great hope. For each cytokine that has not been clinically used, I have tried to indicate some possibilities.

Preclinical and Clinical Studies

Cytokines have been extensively tested in rodents. In humans, IL-1, -2, -11, and -12 have been used in clinical trials. I am not able to summarize all of the preclinical therapeutic observations using the interleukins. When possible, I refer the reader to other reviews. *Ex vivo*, many cytokines have been used to expand human lymphocytes and hematopoietic stem cells, which then have been returned to the patient as a cellular therapy. This will undoubtedly be extended to *in vitro* growth of many other cell types and organs lost to pathologic processes, such as nerves, bones, liver, skin, and pancreas.

Pathologic Roles

Pathologic roles for some cytokines are implicated when their production is excessive or untimely or the reaction to the cytokines is excessive. Such pathology can derive from genetic proclivities or environmental circumstances. IL-1's production in excess is thought to be a key element in chronic inflammation, such as rheumatoid arthritis (RA), and possibly in septic shock. The IL-12 pathway is probably part of the pathology of parasitic diseases. IL-4 production is most likely part of allergy, whereas IL-5 production is probably part of asthma. Researchers strive to produce useful inhibitors of the cytokines. Several available inhibitors for blockade of receptors exist, such as IL-1RA, soluble forms of the cytokine receptors, and antibodies against ligands and receptors. In the future, researchers will create better inhibitors using rational drug design based on crystal structures of the cytokines, receptors, and signal transduction molecules. This same approach will also yield agonists.

Physiologic Roles

The physiologic roles of each cytokine are the primary focus in this chapter. Knockout mice have been produced for many of the interleukins and their receptors, and I have tried to cite papers that deal with this subject. These knockouts have been extremely informative in determining the physiologic roles of a cytokine. For example, knockouts showed that IL-7 is required for normal T-lymphocyte development, the basis of X-linked, severe combined immunodeficiency in man. Knockouts have been helpful in other ways when considering clinical problems. Knockouts showed that IL-4 is required to generate normal immunoglobulin (Ig) E levels, and because IL-4-deficient mice were otherwise fairly healthy, it supports the approach of blocking IL-4 in allergy. Another example is knockout of the IL-1 system, which affects susceptibility to inflammation of joints but has little ill effect on the health of mice, suggesting IL-1 blockade for treatment of arthritis.

Cytokines and Cancer

Two broad areas of cancer studies exist that have been impacted by cytokine research. Cytokine pathways can be involved in carcinogenesis

and can be exploited in cancer therapy. I briefly discuss these areas.

Carcinogenesis

One major function of some cytokines is trophic: they are the signals from the microenvironment that tell a cell it is in the right place. Thus, when a normal cell is in the wrong place, it undergoes a kind of "atrophic" death. Trophic effects of cytokines are subverted by cancer cells, enabling them to live outside their normal microenvironments. In a few cases, tumor cells may make their own autocrines (e.g., IL-9 is implicated in Hodgkin's cells). Some cytokine receptors can mutate and become autosignaling, such as receptors for c-kit ligand, although none of the interleukin receptors seem to be capable of this. Some cytokine receptors normally suppress cell division or survival, which become inactivated in cancer; these include receptors for transforming growth-factor ß and FasL, but, again, interleukin receptors are not among these.

Trophic mutations in cancer that are most relevant to the interleukins occur in their intracellular survival and death pathways. For example, Bcl-2, a mitochondrial protein that protects cells from death, is commonly induced by cytokines as part of their trophic activity and is commonly overexpressed in cancer cells. Moreover, blocking Bcl-2 production kills such cancer cells. Another example is Bax, a death protein that mediates death from cytokine withdrawal and is commonly inactivated by mutation in tumor cells. Thus, knowledge gained in understanding the trophic action of cytokines can have considerable bearing on the mechanisms of carcinogenesis.

Cancer Therapy

The following text covers the use of cytokines in cancer therapy. Here, I briefly mention that all the interleukins and many other cytokines have been tested on rodent tumors *in vitro* and *in vivo.* The types of antitumor effects include angiostasis, differentiation, and inflammation. Extending this research to humans has often produced toxicity and efficacy problems, although IFN is effective in treating hairy cell leukemia, and IL-2 has had positive effects in melanoma. Cytokines can be used to protect bone marrow and gut from the toxicity of radiation and chemotherapy. *Ex vivo* use of cytokines is widely used for expanding immune and hematopoietic cells before transfer into patients.

Omissions

For this extremely compressed review, I had to select a few cardinal points about each cytokine. I apologize for omitting many discoveries of probably equal importance. I particularly neglected to include studies in mice when human results were available. A major area I also neglected is the induction mechanisms of the cytokine genes because of its complexity. I have largely avoided discussing the promoters of these genes. Few mammalian genes exist, not just cytokines, whose induction is understood. Although some proximal regulatory regions have been shown experimentally for most of these cytokine genes, these regions are usually shown to bind many interacting proteins and are influenced by distal regions. Major questions remain in understanding the accessibility of a gene, which is controlled by chromatin structure.

Interleukin-1

Part of "1 - Interleukins: Overview "

IL-1 (1,2) was among the earliest cytokines identified because it has so many potent activities. Many features of the IL-1 system, however, are not particularly representative of cytokines. IL-1 has an unusual mechanism of release from the cells that produce it. The two family members, α and ß, are only distantly related but act on the same receptor. It has two dedicated inhibitors that block ligand-receptor interaction. IL-1 is a powerful inducer of inflammatory processes, both local and global, although knockout of the IL-1 system only modestly reduces these processes. Clinically, the main goals have been to block the IL-1 system in inflammatory states, such as RA and septic shock.

Proteins

Three members of the IL-1 family exist: α, ß, and the receptor antagonist, encoded by a cluster of genes. IL-1α (3) and -ß (4) have little homology to one another, but it is accurate to term them both *IL-1* because they act on the same receptor. Neither α nor ß has a typical signal sequence, and both are released from the producing cell by an unusual mechanism. Mature 17-kd IL-1α is produced from a biologically inactive 31-kd precursor by cleavage (5) with caspase-1. Mature 17-kd IL-1α is also produced by cleavage from a different 31-kd precursor, which is biologically active. The receptor antagonist (6) is produced in two forms by alternative message splicing: one secreted form with a signal peptide and a second intracellular form lacking a signal peptide.

Producers

The most prolific IL-1–producing cells are macrophages following stimulation with a variety of microbial products or other agents, including cytokines. Many other cell types, such as keratinocytes, also produce IL-1. The IL-1 promoters are complex, perhaps accounting for the ability of these genes to respond to so many different stimuli in different cell types. In macrophages, the mechanism of IL-1 induction is partly based on the PU-1 transcription factor in cooperation with other nuclear factors (7,8). IL-1 production is also regulated by message stability, message translation, and the release mechanism. The receptor antagonist is produced concurrently with IL-1α and -ß in many cell types, acting as a natural buffer to the action of IL-1.

Receptors and Cellular Response

Two IL-1 binding proteins exist: IL-1RI, which serves all known receptor function (9), and IL-1RII, which serves as a "decoy"

receptor (10). These genes are also linked to the IL-1 gene cluster in humans, but not in mice. IL-1RI is a member of the "toll" family of receptors. After IL-1 binding, IL-1 receptor accessory proteins (11), a kinase [IL-2 receptor-associated kinase (IRAK)] (12) and TRAF6 (13), are recruited to the complex. IL-18 receptor forms a similar complex (see the section on IL-18). MyD88 serves as an adaptor protein, linking IRAK to the receptor complex (14). Intracellular cascades lead to activation of several types of transcription factors, including NFκB (15) and AP-1 (16). This results in the induction of many genes, including a number of other inflammatory cytokines, such as IL-6. A wide variety of cell types respond to IL-1. IL-18 signaling has many parallels with that of IL-1.

Activities

IL-1 is considered a key mediator of inflammation (2). It has a broad spectrum of inflammatory activities, including local effects, such as induction of prostaglandins, chemokines, and adhesion molecules. IL-1 also has global effects, such as fever, the acute-phase response, and hypotension. Knockout mice show deficiency in local inflammation and delayed-type hypersensitivity and are resistant to collagen-induced arthritis (17). The fact that IL-1 deficiency does not eliminate inflammation has been interpreted to mean that other cytokines with overlapping activities, such as TNF and IL-6, are equally important.

Clinical Use

Trials were performed in cancer patients (18) with some benefit in preventing thrombocytopenia induced by chemotherapy, but significant toxic side effects, such as hypotension, arrhythmia, and pulmonary-capillary leakage, occurred. Intratumoral injection in mouse cancers has shown promising responses. Blocking IL-1 activity via receptor antagonist, soluble receptors, or newly tailored drugs shows promise in controlling inflammatory diseases, such as RA and septic shock, probably most effectively if combined with blockade of other inflammatory cytokines, such as TNF and IL-6.

Interleukin-2

Part of "1 - Interleukins: Overview "

IL-2 was originally discovered as a growth factor for T cells *in vitro* and is one of the most extensively studied cytokines. Knockout of IL-2 in mice suggests complex regulatory roles, perhaps in programming T cells for death. The IL-2 receptor complex shares components with receptors for IL-4, -7, -9, and -15. IL-2 has been used clinically for acquired immunodeficiency syndrome, cancer, and for *ex vivo* expansion of T cells directed against tumors and viruses.

Protein

IL-2 (19,20) is 15 kd, contains one internal disulfide bond, and is a member of a family of cytokines (IL-4, -7, -9, and -15) containing α helixes.

Producers

IL-2 is produced by T lymphocytes after activation by antigen-major histocompatibility complexes (MHC) and costimulators on the surface of antigen-presenting cells. The T helper 1 (Th1) subset of memory T cells retains the capacity to produce IL-2, whereas the Th2 subset loses this capacity, producing IL-4 instead (21).

Receptor and Cellular Response

The IL-2 receptor comprises three chains: α (22), β (23), and γ_c (24). The β and γ_c chains are members of a cytokine receptor superfamily, whereas the α chain is related to IL-15Rα. The β and γ chains are essential for signaling, whereas the α chain increases affinity of the complex for IL-2 but is not required. After binding of IL-2, the janus kinase Jak3 (25,26), associated with the γ_c chain, phosphorylates tyrosines on the β chain, which serve as docking sites for signal transducers and activators of transcription proteins (STATs) 3 and 5. The STATs (22,27) are then phosphorylated and translocate to the nucleus, where they serve as transcription factors. Many other intracellular second messenger pathways are also triggered by IL-2 (28) and involve lck, syk, ras, pl3 kinase, protein kinase C, and Akt. The γ_c chain of the IL-2 receptor is shared by the receptors for IL-4, -7, -9, and -15. Jak3 is also a component of the signaling complex in these receptors.

Activities

The property that led to the discovery of IL-2 was its induction of activated T-cell proliferation (19). Thus, IL-2 is widely used for propagating T-cell lines. Knockout of IL-2 in mice (29), however, resulted in excessive, uncontrolled T-cell proliferation, leading to the concept that IL-2 is not essential for growth *in vivo*, but is essential for programming T cells to die. Other activities of IL-2 include stimulation of cytotoxicity in natural killer (NK) and T cells and acting as a cofactor in activating macrophages and B cells.

Clinical Use

IL-2 has been used clinically in several ways. Treatment of malignant melanoma renal cell carcinoma has shown efficacy (30,31). A significant side effect of IL-2 is the vascular leak syndrome (32). IL-2 has been used for *ex vivo* expansion of lymphokine-activated killer cells, tumor-infiltrating T cells (33), and antiviral T cells (34,35 and 36), which are then returned to the patient. Anti-IL-2 receptor shows promise in blocking rejection of organ transplants (37).

Interleukin-3

Part of "1 - Interleukins: Overview "

IL-3 is produced by activated T cells and induces hematopoiesis. Its receptor shares components with IL-5 and granulocyte-macrophage colony-stimulating factor (GM-CSF). It is used

clinically to sustain explanted hematopoietic stem cells before reinfusion.

Proteins

IL-3 (38,39) is linked to IL-4, -5, -9, and -13 in humans.

Producers

Activated T cells are the major producers of IL-3 (40). Activated mast cells are also producers.

Receptors

Two chains that compose the IL-3 receptor exist in humans: IL-3Rα (41) and β$_c$ (42), which are shared by the receptors for GM-CSF and IL-5. In the mouse, two different β chains exist. Both α and β are members of the cytokine receptor superfamily. Cross-linking of the α to the β chain triggers receptor activation (43). The nature of this cross-linking process is thought to resemble that of the IL-2 and IL-4 receptors, in that the ligand directly binds one chain with intermediate affinity (see the sections on IL-2 and IL-4). The second receptor chain, which cannot bind ligand on its own, then recognizes some features of the complex formed by the ligand and the other receptor component. Jak2 is associated with the β chain (44) and activates STAT 5 (45). A number of other second messenger pathways are also activated (46). The cellular response includes survival, such as the pathway leading to disposal of BAD, the proapoptotic protein (46,47).

Activities

IL-3 stimulates production of macrophages, granulocytes, erythrocytes, and megakaryocytes from primitive pluripotential stem cells. Knockouts indicate that IL-3 is not required during normal hematopoiesis, indicating its importance probably lies in the hematopoietic stimulation during immune responses. Mature myelomonocytic-lineage cells also react to IL-3.

Clinical Use

IL-3 has been tested extensively for a variety of potential clinical uses (48). In individuals with normal hematopoiesis, IL-3 treatment increased platelets, reticulocytes, and leukocytes and showed only mild side effects (49). To increase hematopoiesis, IL-3 has been tested in myelodysplastic syndrome, aplastic anemia, Diamond-Blackfan anemia, chemotherapy, bone marrow transplantation, and stem-cell mobilization. Although responses were observed, it has not been adopted as a therapeutic. IL-3 is widely used as part of a cytokine cocktail to sustain hematopoietic stem cells *ex vivo*, however, for treatment after radiation or chemotherapy (i.e., promoting introduction of recombinant constructs for gene therapy) (50,51).

Interleukin-4

Part of "1 - Interleukins: Overview "

IL-4 is an important cofactor in B-lymphocyte activation, particularly for production of IgE. One type of IL-4 receptor incorporates γ$_c$, as do IL-2, -7, -9, and -15. IL-4 is closely related to IL-13 and can share some receptor components and signaling pathways. It is critical in directing activated T cells into the Th2 pathway. Overproduction is implicated in atopy.

Proteins

IL-4 (52,53 and 54) is 20 kd with six cysteines involved in intrachain disulfide bonds and forms four α helices. The human IL-4 gene is found in a cluster together with genes for IL-3, -5, -9, and -13.

Producers

Several types of T cells produce IL-4 after activation by antigen-MHC complexes and costimulators on the surface of antigen-presenting cells (21). IL-4 is a key member of the spectrum of cytokines produced by Th2 T cells. In mice, CD4 T cells that express NK1 are also producers, as are a subset of CD8 T cells. Mast cells and basophils also produce IL-4 (55). The induction of Th2 cell development is dependent on IL-4 produced by T cells themselves (56). Production of IL-4 requires the transcription factor GATA3 (57) and possibly c-maf (58).

Receptors

The primary binding chain, IL-4Rα (59), forms two types of receptor complexes: IL-4Rα + γ$_c$ and IL-4Rα + IL-13Rα. (60). These receptor chains are members of the cytokine receptor superfamily. IL-4 first binds to IL-4Rα; γ$_c$ is then recruited to the complex. The janus kinase Jak3, bound to the intracellular domain of γ$_c$, is required for many, but not all, IL-4 effects (61). STAT 6 is required for IL-4 signaling (62). IRS-1 is an important adaptor molecule, coupling the receptor to second messenger pathways other than the Jak-STAT pathway (60,63).

Activities

IL-4 was discovered as a growth factor for preactivated B cells and induces class II MHC expression on B cells. In macrophages, it suppresses production of inflammatory cytokines and it has effects on endothelial cells and fibroblasts. Knockout mice show major defects in Th2-cell generation and in IgE production (64), suggesting that the selective value of IL-4 may be immunity against parasitic infections.

Clinical Use

An overactive IL-4 pathway appears to be one component of atopy (65,66 and 67). Therefore, IL-4 presents a therapeutic target for allergy. IL-4 itself could be used to divert immunity away from autoimmune or inflammatory directions.

Interleukin-5

Part of "1 - Interleukins: Overview "

IL-5 induces production of eosinophils during immune responses, which probably contributes to protection against

some kinds of parasites. It shares a receptor component with IL-3 and GM-CSF.

Proteins

IL-5 (68,69) is a disulfide-linked homodimer, which is unusual among the interleukins and is heavily glycosylated. Its crystal structure resembles that of two IL-4 molecules with two bundles, each with four α helices (70). It is genetically linked to IL-3, -4, -9, and -13 in humans (68).

Producers

IL-5 is produced by activated Th2 cells (21), as well as mast cells and eosinophils.

Receptors

The receptors for IL-5 consist of two chains: IL-5Rα (71) and β$_c$ (42), which is shared by the receptors for GM-CSF and IL-3. Both chains are members of the cytokine receptor superfamily. Cross-linking principles are similar to IL-3, as are the ensuing Jak2-STAT5 pathways and other second messenger pathways (46).

Activities

IL-5 was initially identified as a T-cell factor that induced production of eosinophils (72). Knockout of IL-5 eliminated the eosinophilia induced by helminth infection (73), whereas baseline production of eosinophils was normal. IL-5 also promotes local accumulation (74) and sustains the lifespan and function of eosinophils in tissues, such as the lung and bowel. Evidence exists that IL-5, presumably via its eosinophil activities, contributes to protection from helminth infections (75,76).

Clinical Use

IL-5 has long been implicated in allergic asthma (77). Efforts are therefore being made to develop IL-5 antagonists (78).

Interleukin-6

Part of "1 - Interleukins: Overview "

IL-6 is a key inflammatory mediator produced by many cell types. It is the major inducer of the acute-phase response and fever. IL-6 receptor shares the gp130 chain with several other cytokine receptors.

Proteins

IL-6 is a glycoprotein of 21 to 28 kd.

Producers

IL-6 is produced after stimulation by many cell types, including T and B lymphocytes, macrophages, fibroblasts, and endothelial cells.

Receptors

Two components of the IL-6 receptor exist: a ligand-specific α chain (79) and a signal-transducing gp130 chain (80), which is shared by receptors for leukocyte inhibitory factor (LIF), oncostatin M (OSM), ciliary neurotrophic factor (CNTF), IL-11, and CT-1. The α chain binds IL-6. This complex then cross-links multiple gp130 chains, initiating signal transduction. Unlike many cytokine receptors, the α chain has no intracellular signaling function in this class of receptors. The janus kinases Jak1, Jak2, and Tyk2 are activated, as are the transcription factors STATs 1, 3, and 5, as well as other signal transduction pathways, such as the ras-MAP kinase pathway (81).

Activities

IL-6 (82,83) was originally characterized based on its activity in inducing Ig synthesis by activating B cells. Knockout of IL-6 (84,85) showed defects in a number of inflammatory processes, including production of acute-phase reactants and bone loss after estrogen depletion. Fever responses depend on IL-6 (86). Hematopoietic defects were also found in IL-6 knockouts (87).

Clinical Use

Blocking IL-6 may alleviate RA and may also be effective in other autoimmune, inflammatory, and bone-erosive diseases. In mice, IL-6 is required for development of oil-induced plasmacytomas (88) and is involved in tumor cachexia (89). In humans, IL-6 is a growth factor for myelomas (90), suggesting further applications of IL-6 blockers.

Interleukin-7

Part of "1 - Interleukins: Overview "

IL-7 is produced by stromal cells and is essential for T lymphopoiesis, partly because of a survival or "trophic" effect, a partial role in V(D)J recombination. This is the pathway deficient in X-linked, severe combined immunodeficiency in humans. IL-7 also has trophic effects on mature T and B lymphocytes and is therefore potentially useful in the clinic as an adjuvant.

Proteins

IL-7 is a 25-kd protein predicted to contain four α helices and an internal disulfide bond (91). After secretion, it binds to extracellular matrix via a glycosaminoglycan-binding site (92), which could be the form encountered by developing thymocytes.

Producers

Unlike most interleukins, IL-7 is produced constitutively by nonhematopoietic cells. In the thymus, the IL-7 producer resembles the cortical epithelial cell (93). In bone marrow, the

producer is a reticular stromal cell (94). Other sources include the intestine (95), skin (96), and follicular dendritic cells (94).

Receptors

The primary binding chain for IL-7 is IL-7Rα (97). The IL-7–IL-7Rα complex then recruits γ_c (98,99), bearing Jak3 to the complex. TSLP, a homologue of IL-7, also binds the IL-7Rα chain but does not recruit γ_c and Jak3 (100). Jak1 and a number of other kinases are induced (101), including pI3 kinase. STATs 3 and 5 partly mediate the nuclear effects. Because γ_c is also a component of the receptors for IL-2, -4, -9, and -15, some similarities appear to exist in the signal transduction pathways.

Activities

IL-7 was discovered based on its activity in inducing proliferation of murine pro-B cells (91). B-cell development depends on IL-7 in mice, but not humans (102). Normal T-cell development requires IL-7 based on the knockout phenotypes for IL-7 (103) and its receptor (104), which show a severe block at an early stage in T-cell development. A related block is seen in X-linked, severe combined immunodeficiency in humans, which is in γ_c, a component of the IL-7 receptor. This requirement for IL-7 is partly attributed to its trophic activity on lymphoid progenitors (105) and its promotion of V(D)J recombination (106). In mice, the γδ lineage is particularly dependent on IL-7, perhaps not only during thymic generation, but also for survival in the intestine and skin. Pharmacologic activity of IL-7 has been observed in mice, inducing increases in B and T cells (107,108). Overexpression of IL-7 in mice can induce lymphomagenesis (109). In human skin, IL-7 may provide trophic support for the survival of lymphoma cells (110).

Clinical Use

IL-7 has not been tested clinically. Potential clinical uses of IL-7 include boosting immunity to infectious diseases or prolonging the life of lymphocytes, as in acquired immunodeficiency syndrome. Antagonists to IL-7 might be effective in treating autoimmune diseases, blocking rejection of allografted organs, or treating lymphoma.

Interleukin-8

Part of "1 - Interleukins: Overview "

IL-8 induces chemotaxis and activation of neutrophils. It is one of the chemokines, a large group of chemotactic cytokines. IL-8 signals through seven transmembrane G protein–coupled receptors that are related to other chemokine receptors.

Proteins

IL-8 (111,112,113 and 114) is a 6- to 8-kd glycoprotein containing two intrachain disulfide bonds. At high concentrations, IL-8 homodimerizes via hydrogen bonding. It is presented to neutrophils on endothelial cell surfaces (115). IL-8 was the first to be discovered of the family of cytokines known as *chemokines* (116). More than 50 members have been identified; only IL-8 has the interleukin terminology. IL-8 is one of a subgroup termed *CXC chemokines* and is linked to a group of these genes. Mice lack a close homologue to human IL-8. It is thought that its inflammatory roles are fulfilled in mice by other chemokines using the same receptor.

Producers

Many cell types produce IL-8 after stimulation with lipopolysaccharide, IL-1, or TNF (117), including macrophages, endothelial cells, and keratinocytes.

Receptors

Two functional IL-8 receptors exist: CXCR1 (118) and CXCR2 (119,120). They are both members of the seven-transmembrane family of receptors that includes rhodopsin. These receptors also respond to other chemokines. The two receptors induce some overlapping and distinct responses (121). Receptors are coupled to G proteins, including Gi2α (122), which trigger downstream events involving phospholipase C, diacylglycerol, inositol triphosphate, release of calcium from intracellular stores, RhoA, and the ras pathway.

Activities

IL-8 induces neutrophil chemotaxis, respiratory burst, and degranulation. In rabbits, blocking IL-8 with antibodies has potent inhibitory effects on some inflammatory processes, particularly of the lung (123,124 and 125). Knockouts in mice cannot directly address IL-8 function because no close IL-8 homologue exists in mice. Mice lack CXCR1. Knockout of the receptor CXCR2, however, greatly affects neutrophil attraction to inflamed peritoneum (126), which establishes that chemokines are involved in neutrophil accumulation *in vivo.* IL-8 also induces angiogenesis (127).

Clinical Use

Increased IL-8 is detected in a variety of human clinical conditions, ranging from myocardial infarction to RA (128), and suggests potential applications for IL-8 blockers. In rabbits, a number of studies have shown that anti-IL-8 inhibits inflammation of various tissues. Despite the numerous chemokines that exist, blocking IL-8 alone can be sufficient.

Interleukin-9

Part of "1 - Interleukins: Overview "

IL-9 is related to IL-2, -4, -7, and -15 and has some overlapping activities based most likely on sharing some receptor components. It is produced by T cells and acts on lymphocytes and mast cells, and may be involved in Hodgkin's disease and lymphoma.

Proteins

IL-9 (129,130) is predicted to have an α-helical topology like IL-2, -4, -7, and -15. The human IL-9 gene is found in a cluster together with genes for IL-3, -4, -5, -9, and -13. This does not apply to mice. Ten cysteines exist, implying extensive intrachain disulfide bonding, heavy *N*-linked glycosylation, and a high isoelectric point (approximately ten).

Producers

Memory-helper T cells produce IL-9 after activation (131). This induction involves a cascade of cytokines, including IL-2, -4, and -10, eventually leading to IL-9 production (132). Murine Th2 clones are producers (133).

Receptors

The IL-9 receptor α chain (134) is a member of the hematopoietin superfamily. In humans, the IL-9 receptor α chain is unusual because it is encoded on chromosomes X and Y (135). Four IL-9Rα pseudogenes also exist. The receptor complex shares the γc chain (136) with receptors for IL-2, -4, -7, and -15. After receptor ligation, Jak3 (γc-associated) and Jak1 (IL-9Rα-associated) increase their tyrosine kinase activity, phosphorylating the IL-9Rα chain, adaptor protein IRS-1 (137), and transcription factors STATs 1, 3, and 5 (138,139).

Activities

IL-9 was discovered as a growth factor for T-cell clones (129) and independently as a growth factor for mast-cell lines (130,140). It is not clear, however, whether a normal T-cell growth role should be ascribed to IL-9 because normal T cells have not been found to proliferate in response to it until after 10 days or so of prior *in vitro* stimulation. Some transformed T cells, however, can respond to IL-9, and human T-cell leukemia–transformed T cells produce it (141); overexpression of IL-9 as a transgene induced T-cell transformation (142), suggesting possible autocrine function. This was also suggested for Hodgkin's disease (143). Mast cells and eosinophils, B lymphocytes (144), and hematopoietic stem cells (145) also respond to IL-9. Because its receptor is a member of the γc family, overlapping activities are expected to be present with other cytokines in this group.

Clinical Use

No extensive preclinical data on IL-9 are present. The possibility that it has autocrine activity in Hodgkin's disease and T lymphomas suggests potential uses for IL-9 antagonists.

Interleukin-10

Part of "1 - Interleukins: Overview "

IL-10 is a powerful inhibitor of inflammatory and immune responses, partly via its inhibition of some macrophage functions. It is produced by Th2 cells. Its receptor is related to IFN receptors.

Proteins

Human IL-10 is an 18-kd monomer with little glycosylation and two presumed intrachain disulfide bonds.

Producers

Activated Th2 cells were the originally described IL-10 producers. Other cell types, including macrophages and keratinocytes, however, also produce IL-10. Epstein-Barr virus encodes an active IL-10 homologue (146).

Receptors and Cellular Response

The first identified component of IL-10 receptor (147,148) is related to the IFN receptors. It is expressed by many types of hematopoietic cells. In mice, a second receptor component, CRF2-4, has been identified (149), which is related and linked to the IFN receptors. Jak1 and Tyk2 are activated by IL-10 (150). STAT 3 mediates some downstream effects in macrophages (151).

Activities

IL-10 was originally discovered and cloned (152) as an inhibitor of the ability of Th1 cells to synthesize IFN. This inhibition is largely via effects on antigen-presenting cells, such as macrophages, especially by inhibiting their IL-12 production. Other macrophage functions are also inhibited, such as synthesis of inflammatory cytokines (i.e., IL-1, IL-6, IL-8, and TNF) and phagocytosis. IL-10 knockout mice show extensive pathology, particularly in the gut, thought to arise from unattenuated immune responses to gut flora (153). Receptor knockout mice have similar pathology (149).

Clinical Use

IL-10 has been shown to inhibit some lipopolysaccharide-induced inflammatory responses in humans (154). Clinical trials are under way in inflammatory bowel disease, RA, thoracic-abdominal aortic surgery, acute lung injury, multiple sclerosis, psoriasis, and human immunodeficiency virus infection (155). Evidence exists that the Epstein-Barr virus IL-10 homologue acts as an autocrine in B lymphomas, suggesting benefit in blocking IL-10 (156,157).

Interleukin-11

Part of "1 - Interleukins: Overview "

IL-11 is a mesenchymal cell product with activity on hematopoietic cells. IL-11 has been used to promote hematopoiesis in patients. IL-11 receptor shares the gp130 component with IL-6, LIF, OSM, CNTF, and CT-1. IL-11 is required for embryonic implantation in the uterus.

Proteins

IL-11 (158) is a 19-kd protein with no intrachain disulfide bonds. IL-11 is slightly homologous to IL-6, OSM, and LIF.

Producers

IL-11 is produced by a variety of mesenchymal cells, including keratinocytes, chondrocytes, osteoblasts, fibroblasts, and bone marrow stromal cells (159).

Receptors and Cellular Response

The IL-11 receptor includes a ligand-specific α chain and gp130, which is common to IL-6, LIF, OSM, CNTF, and CT1. Two alternative α chains exist in the mouse. The ligand-binding chains of this family do not contribute to signaling, which is wholly performed by gp130. Thus, the intracellular cascades should be the same for all members (see the section on IL-6 for a discussion of gp130 signaling). As in the IL-6 system, soluble IL-11 receptor can capture its ligand and then associate with cell-bound gp130 and signal (160).

Activities

IL-11 was identified based on promoting growth of a plasmacytoma line (158,159). It stimulates multilineage hematopoiesis when administered to mice and humans and is particularly effective in stimulating thrombopoiesis by inducing production of megakaryocytes. Knockout of the major receptor did not show a requirement in hematopoiesis (161) but revealed an IL-11 requirement in the uterine response to implantation (162).

Clinical Use

Trials performed in breast cancer patients show that IL-11 can significantly restore suppressed hematopoiesis and alleviate thrombocytopenia induced by chemotherapy (163). In mice, IL-11 also protects intestinal cells from damage induced by chemo- and radiotherapy (164).

Interleukin-12

Part of "1 - Interleukins: Overview "

IL-12 is produced by antigen-presenting cells. IL-12 promotes Th1-cell development and IFN production. It is required for development of some types of autoimmunity in mice.

Proteins

IL-12 (165,166 and 167) is a heterodimer consisting of disulfide-linked 35-kd and 40-kd subunits encoded by distinct genes. Both subunits are glycosylated and have intrachain disulfide bonds. Homodimers of p40 are also observed (168) and in mice have receptor-antagonist activity. This does not apply to humans.

Producers

Macrophages, B lymphocytes, and dendritic cells are major producers of IL-12. In macrophages, this synthesis is stimulated by microbial products and during contact with T cells via CD40L-CD40 interaction (169). The two IL-12 chains associate intracellularly before secretion. The p35 subunit is expressed by a much wider range of cell types than the p40 subunit (166,170).

Receptors and Cellular Response

Two components comprise the IL-12 receptor, the ß 1 and ß 2 chains (171,172). Th2 cells fail to respond to IL-12 because they lack the ß 2 chain (173). Many protein kinases are triggered by the IL-12 receptor, including the Janus kinases tyk2 and Jak2 (174), which are associated with the ß 1 and ß 2 chains, respectively (175). STAT 3, STAT 4, and IRF-1 are implicated in gene induction by IL-12 (176,177).

Activities

IL-12 was discovered as a factor promoting cytotoxic T cells and independently for promoting NK cells. These activities include proliferation, differentiation, and cytokine secretion, especially IFN. The IFN-γ-inducing activity of IL-12 is as a cofactor, such as with IL-18 (see the section on IL-18). IL-12 knockout mice (178) showed greatly suppressed IFN production and revealed a requirement for IL-12 in development of Th1 cells in some settings, but not in others (179).

Clinical Use

IL-12 has been tested in cancer patients in phase 1 trials with no major toxicity other than a decrease in circulating lymphocytes, which, nevertheless, showed increased activity (180). In preclinical studies, antitumor activity of IL-12 was detected (181), and increased effects were seen in combination with a pulse of IL-2 (182). In mice, IL-12 is a required component of some types of autoimmunity in tissues, including the bowel, joint, eye, pancreas, and central nervous system (183).

Interleukin-13

Part of "1 - Interleukins: Overview "

IL-13 is a T-cell product closely related to IL-4 and shares a receptor component. It elicits a subset of IL-4 responses and is implicated in Th2-cell generation and IgE synthesis. IL-13 is antiinflammatory.

Proteins

IL-13 (184) is 12 kd and structurally related to IL-4, although the homology is low (185,186). The gene is clustered together with IL-3, -4, -5, and -9.

Producers

IL-13 is expressed in Th2 cells after activation by antigen-MHC complexes and costimulators on the surface of antigen-presenting cells. Unlike IL-4, IL-13 expression is not strictly repressed in Th1 cells. IL-13 is also produced by dendritic cells.

Receptors and Cellular Response

The IL-13 receptor is comprised of IL-13Rα together with IL-4Rα. The same receptor complex also responds to IL-4. Two homologous IL-13Rα chains exist with different affinities for IL-13 in the absence of IL-4Rα: a high-affinity α2 chain (187) and a low-affinity α1 chain (188). Receptors are expressed on

monocytes, macrophages, eosinophils, basophils, mast cells, keratinocytes, and endothelial cells. Human B cells express the receptor, whereas mouse B cells do not. T cells have not been found to express receptors or respond to IL-13. Jak1 and Tyk2 are activated by receptor ligation. Unlike IL-4, Jak3 is not activated (189) because it is associated with γ_c, which is not part of this receptor complex. STAT 6 is phosphorylated and accounts for one set of responses, whereas IRS-2 is phosphorylated and initiates other second messenger pathways.

Activities

Knockout of IL-13 (190) revealed a requirement in Th2 development, which is perhaps indirect given the lack of receptors on T cells. IL-13 induces a subset of IL-4 effects, including effects on human B cells and macrophages, but not T cells. No apparently unique IL-13 effects have been noted. IL-13 activities include inducing IgE synthesis in human B cells. Whereas an IL-4 requirement for B cells to produce IgE was verified by IL-4 knockout, the same logic cannot be applied to IL-13 because mouse B cells do not express IL-13 receptors and do not respond to IL-13. Although IL-13 knockout did reduce IgE production, this may have occurred indirectly via decreased Th2 and IL-4 production. IL-13 (184) is a potent inhibitor of inflammatory product synthesis by macrophages *in vitro* and an effective antiinflammatory *in vivo;* it can also induce monocytes to differentiate into dendritic cells.

Clinical Use

The induction of IgE synthesis implicates blocking the IL-13 pathway as a potential target in atopy. Other applications are suggested by IL-13 inhibiting inflammatory processes in mice.

Interleukin-14

Part of "1 - Interleukins: Overview "

Difficulties have occurred in reproducing the original observations regarding IL-14 and are therefore not discussed.

Interleukin-15

Part of "1 - Interleukins: Overview "

IL-15 resembles IL-2 in its activities on T cells and shares some receptor components with IL-2. It is essential for NK cell development. Unlike IL-2, the IL-15 gene is expressed by many cell types, but little protein is produced.

Proteins

IL-15 (191,192 and 193) is a 15-kd glycoprotein with two internal di-sulfide bonds. IL-15 is predicted to fold into a four α-helical structure like IL-2 and IL-4. It is genetically linked to IL-4, -5, and -9.

Producers

Unlike most of the interleukins, many cell types constitutively transcribe the IL-15 gene. However, considerable constraints on translation imposed by the 5" and signal peptide region of the message exist (194).

Receptors and Cellular Response

The IL-15 receptor shares the β and γ_c chains with the IL-2 receptor (195) but uses its own unique α chain that is expressed on more cell types than the IL-2Rα chain (196). Mast cells appear to have a different receptor (197). Jak1 and 3, and STATs 3 and 5 are activated by the receptor in T cells, whereas Jak2 and STAT5 are activated in mast cells.

Activities

IL-15 was discovered as a T-lymphocyte growth-factor activity. NK cell development can be induced by IL-15 (198). The knockout of IL-15Rα verified its requirement for NK development (199). Mast cells also respond to IL-15, as do mature T and B lymphocytes, which are also deficient in knockouts.

Clinical Use

IL-15 has not been tested clinically. It may find use in boosting innate or T-cell immunity, or in *ex vivo* expansion of NK and T cells before reinfusion. Antagonists could be immunosuppressive.

Interleukin-16

Part of "1 - Interleukins: Overview "

IL-16 is a product of CD8 T cells that has activities on CD4 cells, including chemotaxis. It is implicated in airway inflammation in asthma.

Proteins

IL-16 (200,201 and 202) is the C-terminal 17-kd peptide cleaved from a larger nonglycosylated precursor by caspase-3 (203). IL-16 lacks a typical signal peptide and is therefore released from cells by an atypical process. It is not homologous or linked to other cytokines, has an unusual protein structure with a PDZ domain otherwise found in intracellular proteins, and aggregates in solution (204).

Producers

IL-16 is constitutively transcribed and translated by CD8 T cells. Release of the active form is then induced by stimuli, such as T-cell antigen cross-linking, histamine, and serotonin (205). Other producers include eosinophils (206) and airway epithelial cells (207).

Receptors and Cellular Response

IL-16 binds to CD4, which it appears to cross-link, inducing signaling (208). The second messenger pathway does not require lck, which is associated with CD4. Implications of pl3 kinase and PKC involvement exist.

Activities

IL-16 was discovered based on chemotactic activity for CD4 T cells (200,201 and 202). It is also chemotactic for monocytes and eosinophils. IL-16 induces G_0 to G_1 transition in CD4 T cells, but not entry into S phase, which can be induced by IL-2. IL-16 inhibits the activation of T cells induced by the T-cell receptor, perhaps by sterically inhibiting CD4 interaction with class II MHC (209). It inhibits human immunodeficiency virus replication, not through competing with entry via CD4, but through the human immunodeficiency virus promoter (210).

Clinical Use

IL-16 has been implicated as the attractant for CD4 T cells in asthmatic inflammation of airways in humans (202), suggesting uses for antagonists. It could possibly be used to induce T-cell blast transformation.

Interleukin-17

Part of "1 - Interleukins: Overview "

IL-17 is a product of memory T cells with inflammatory, immunologic, and hematopoietic activities. IL-17 and its receptor bear little resemblance to other genes, although they do bear resemblance to the IL-17 homologue in a herpesvirus.

Proteins

IL-17 (211,212 and 213) is a peptide of 17 kd that can dimerize via disulfide bridges (214).

Producers

IL-17 is produced by activated T cells, particularly the memory CD4 subset (214). The gene was captured by herpesvirus saimiri, whose product is biologically active.

Receptors and Cellular Response

One IL-17 receptor chain has been identified that bears remarkably little resemblance to other receptor types and results in NFκB activation (215). This receptor chain is expressed on many different cell types.

Activities

IL-17 was discovered as a cDNA of unknown function, homologous to a sequence in a herpesvirus of also unknown function (211). It has been shown to trigger several types of responses in cells, including IL-6 and IL-8 induction in fibroblasts (214,215). It also induced production of hemopoietic cytokines and neutrophils in bone marrow cultures and *in vivo* (214). Blocking IL-17 suppresses T-cell proliferative responses (215). This may be partly because it promotes dendritic-cell differentiation. This, in turn, may explain how blocking IL-17 prolonged allografts in mice (216). Preliminary IL-17 receptor knockout data have not shown gross abnormalities (217).

Clinical Use

IL-17 appears to promote immune and inflammatory responses. Thus, blocking its activity in humans could be immunosuppressive as it is in mice.

Interleukin-18

Part of "1 - Interleukins: Overview "

IL-18 was discovered based on its induction of IFN-γ synthesis. Its own structure and that of its receptor system resemble IL-1. It promotes Th1 activities, inhibits Th2 activities, and induces macrophages to produce inflammatory cytokines.

Protein

IL-18 (218,219) is a member of the IL-1 family. Like IL-1ß, IL-18 is synthesized as a biologically inactive proform, which is cleaved by caspase-1, generating the active mature form (220,221).

Producers

Kupffer's cells were the source that led to the cloning of murine IL-18. Blood and tissue macrophages are avid producers, but, unlike most cytokines, IL-18 production and release do not require stimulation of the macrophage (222). Keratinocytes also produce IL-18 constitutively.

Receptors and Cellular Response

The organization of the cellular receptors for IL-18 is remarkably similar to that of IL-1. IL-18 initially associates with a binding chain (223,224), which is encoded near IL-1 receptor (225); this recruits a second signaling chain (226). Like IL-1, a "decoy" receptor exists (227). The active IL-18 receptor complex recruits the same kinase (IRAK) and initiates the TRAF6 pathway, as does IL-1 (228). MyD88 serves as an adaptor that links IRAK to the IL-18 and IL-1 receptor complex (14). The IL-18 receptor is expressed on Th1 cells, but not on Th2 cells. Receptor expression is induced by IL-12 on both T and B cells (229).

Activities

IL-18 was discovered based on its activity in inducing IFN-γ production. It has been verified in IL-18 knockout mice (230) that IFN-γ production is greatly reduced after inflammatory stimuli, although polyclonal T-cell activation induces IFN-γ normally. This is probably explained by the observations that IL-18 primarily participates in IFN-γ induction as a cofactor together with IL-12; this synergy is partly based on IL-12 inducing expression of the IL-18 receptor. IL-18 promotes Th1 activities and inhibits Th2 activities via IFN-γ, such as IgE induction. IL-18 induces macrophages to synthesize secondary inflammatory cytokines, such as IL-1, IL-6, and chemokines.

Clinical Use

Possible clinical uses based on animal studies include giving IL-18 to promote IFN-γ production during viral or mycobacterial

infections. IL-18 may combat allergy or asthma. Antagonizing IL-18 (i.e., by using the decoy receptor) could have antiinflammatory uses.

Introduction

Part of "2 - Interleukin-2: Preclinical Trials "

Interleukin-2 (IL-2) was first described in 1976 as a factor produced by mitogen-stimulated human T cells that mediated selective expansion of T cells from normal human bone marrow *in vitro* (1). Large amounts of highly purified recombinant IL-2 (rIL-2) with full biological activity have become available for *in vivo* studies through the cloning of the gene for IL-2 and its insertion and expression in *Escherichia coli* (2 ,3). IL-2 exerts potent effects on immune cells that can mediate tumor regressions *in vivo;* it is particularly important in the antigen-specific clonal expansion of T cells, but also for the stimulation of nonspecific effectors, such as natural killer (NK) and lymphokine-activated killer (LAK) cells. This chapter reviews the pharmacokinetics, antitumor effects, and mechanisms of activity and toxicity of systemically administered IL-2. This chapter also examines the antitumor effects and mechanism of action of IL-2 delivered locally to the tumor site, whether it be in the form of injected-soluble cytokine, the cytokine gene, tumor cells gene-modified to express IL-2, or IL-2 monoclonal antibody (MAb) fusion protein. Many preclinical investigations have focused on the combination of IL-2 with other cancer therapies. Therefore, this chapter reviews studies that evaluate the role of IL-2 when combined with other cytokines, cytotoxic chemotherapy, radiation therapy, adoptive immunotherapy, and vaccines.

Interleukin-2: Systemic Administration

Part of "2 - Interleukin-2: Preclinical Trials "

Pharmacokinetics

Initial pharmacokinetic studies tested native IL-2 derived from a mitogen-stimulated EL-4-thymoma cell line in C57BL/6 mice (4). IL-2 had a serum half-life of 3.7 ± 0.8 minutes after intravenous (i.v.) injection, with a titer of 2 U per mL detectable for less than 30 minutes. More prolonged serum levels of IL-2 could be achieved by intraperitoneal (i.p.) or subcutaneous (s.c.) administration: after i.p. and s.c. injection, titers remained higher than 2 U per mL for 2 and 6 hours, respectively. Similar results were obtained when rIL-2 was studied. Chang et al. measured a serum half-life of 1.6 ± 0.3 minutes in mice after an i.v. bolus injection of 20,000 U rIL-2, with i.p. and s.c. administration resulting in IL-2 serum levels of more than 1 U per mL for 3 to 5 hours after 10,000 U rIL-2 (5). Rapid clearance from the kidney accounted for the short serum half-life after an i.v. injection (4). Biodistribution studies of radiolabeled rIL-2 indicated that the liver and kidney were the organs of greatest cytokine uptake (6). Chemical modification by forming an ester with polyethylene glycol (PEG-IL-2) prolonged the half-life of i.v.-administered cytokine to 4.5 hours (7).

Antitumor Effects of Systemic Interleukin-2 Administration

Rosenberg and colleagues studied the effect of systemic administration of rIL-2 at escalating doses on established pulmonary metastases from a weakly immunogenic sarcoma, MCA-105 (8). Mice bearing 3-day-old metastases were treated with doses ranging from 3,000 to 170,000 U rIL-2 i.p. t.i.d. for 5 days. When compared with control mice who received saline, mice who received between 3,000 and 8,000 U rIL-2 had 5 ± 5% reductions in metastases. Mice who received between 20,000 and 50,000 U rIL-2 had 22 ± 9% reductions, whereas mice who received between 100,000 and 170,000 U rIL-2 experienced 79 ± 7% reductions in pulmonary metastases. Reductions of 10-day-old pulmonary macrometastases could also be achieved with rIL-2 therapy. Pulmonary macrometastases were reduced by 34 ± 13% with 1,000 to 6,000 U rIL-2, whereas 20,000 to 50,000 U and 100,000 to 200,000 U rIL-2 reduced 10-day-old metastases by 89 ± 4% and 80 ± 5%, respectively. Of note, doses of 50,000 U rIL-2 i.p. t.i.d. were effective in reducing the numbers of 3-day-old pulmonary metastases, whereas lower doses (20,000 U rIL-2 t.i.d.) were effective in the treatment of larger, 10-day-old metastases. As shown in Figure 2-1, the systemic administration of rIL-2 was also effective in the treatment of 3-day-old pulmonary metastases from several other murine tumors, including the nonimmunogenic MCA-101 sarcoma, MC-38 colon adenocarcinoma, and M3 melanoma (9). For each tumor, higher doses resulted in greater antitumor effects.
FIGURE 2-1. Effects of dose titration of recombinant interleukin-2 (rIL-2) on experimentally induced pulmonary metastases from multiple murine tumors. The effect of rIL-2 is demonstrated for two murine sarcomas (MCA-105, MCA-101), a murine adenosarcoma (MC-38), and a murine melanoma (M3). Numbers in parentheses indicate total number of mice. Increasing doses of rIL-2 led to a reduction in the number of pulmonary metastases. Each point reflects the mean percentage reduction for all experiments performed. (Hanks' balanced salt solution.) (From Papa MZ et al. The anti-tumor efficacy of lymphokine-activated killer cells and recombinant interleukin-2 *in vivo:* successful immunotherapy of established pulmonary metastases from weakly- and non-immunogenic murine tumors of three distinct histologic types. *Cancer Res* 1986;46:4973–4978, with permission.)

Using the 3-day-old MCA-105 pulmonary metastasis model, Ettinghausen and Rosenberg evaluated different routes and schedules of rIL-2 administration (10). The same cumulative daily doses of rIL-2 administered intravenously or intraperitoneally once daily or intraperitoneally t.i.d. were compared. The i.p. t.i.d. protocol resulted in the most effective reduction in pulmonary metastases, indicating that sustained lower levels of rIL-2

were more effective than brief, high-peak levels for antitumor activity. It was also shown that the duration of IL-2 administration was crucial because 6 consecutive days of rIL-2 injections resulted in a greater antitumor effect compared with 1 or 3 days.

Systemic immunotherapy with rIL-2 has also been effective in the treatment of s.c. and hepatic tumors, and disseminated leukemia and lymphomas. Initiation of rIL-2 therapy (200,000 U i.p. t.i.d.) 10 days after the s.c. injection of MCA-105 sarcoma, when palpable nodules with a diameter of 2 to 4 mm are present, resulted in a complete response in one-half of the mice; the rest had a marked reduction in tumor growth (8). Treatment with rIL-2 demonstrated modest effectiveness against 3-day-old metastases from a variety of murine tumors established in the liver (11,12). For example, treatment of mice harboring MCA-105 hepatic metastases with 10,000 U rIL-2 i.p. t.i.d. for 8 days caused a significant decrease in the number of hepatic metastases from a mean of 242 hepatic metastases in control mice to 61 in treated mice. Thompson et al. evaluated the therapeutic efficacy of systemically administered rIL-2 against the disseminated murine leukemia FBL-3 (13). As shown in Figure 2-2, doses of rIL-2 (48,000 U per day) administered on days 5 to 9 after tumor injection cured 50% of the mice. As observed in the treatment of MCA-105 pulmonary metastases, delaying the injections of rIL-2 to treat more established leukemia (i.e., on days 5 to 9) was far more effective than the treatment of early disease (i.e., on days 0 to 4). Everse et al. also evaluated the timing of IL-2 therapy in a disseminated SL-2 lymphoma model (14). Initiation of 5 days of treatment with rIL-2 on days 1 to 6 after tumor initiation was completely ineffective, whereas therapy begun on days 7 to 12 was effective. Maximal effectiveness was seen when rIL-2 therapy was begun on day 9 or 10, which resulted in cures of 80% of the mice.
FIGURE 2-2. High-dose recombinant interleukin-2 (rIL-2) can cure disseminated FBL-3 *in vivo.* C57BL/6 mice inoculated intraperitoneally with 5 × 106 FBL-3 received either no therapy, no IL-2, or treatment with rIL-2 injected intraperitoneally at a dose of 48,000 U or 4,000 U per day (in three equivalent doses) on days 0 to 4 or 5 to 9 with Hanks' balanced salt solution. (From Thompson JA et al. Eradication of disseminated murine leukemia by treatment with high-dose interleukin-2. *J Immunol* 1986;137:3675–3680, with permission.)

Multiple investigators have compared the therapeutic effectiveness of rIL-2 with PEG-IL-2, which has a significantly longer serum half-life. Whereas some investigators found that systemically (15) or intratumorally (16) administered PEG-IL-2 was therapeutically superior to free cytokine, others (7,17) concluded that the therapeutic effectiveness of the two preparations was approximately equivalent; the main advantage of PEG-IL-2 was that less frequent dosing was required.

Mechanisms by which Systemic Interleukin-2 Administration Mediates Tumor Regressions

A strong indication that the antitumor effect of rIL-2 *in vivo* was immune mediated came from the histologic assessment of

regressing pulmonary metastases (8). By 2 days after the injection of rIL-2 into mice bearing 10-day-old pulmonary metastases, lymphocytes were seen infiltrating the periphery of the tumor. At later time points, lymphocyte infiltration progressed as the tumors underwent regression. Evidence that IL-2 was acting through a radiation-sensitive host-immune component came from the observations that the antitumor effect of rIL-2 was eliminated if mice received a prior dose of 500 cGy total-body irradiation (8,11).

Definitive identification of the immune cells involved in rIL-2–mediated tumor regressions came from studies by Mulé et al., who used selective depletion of lymphocyte subsets *in vivo* (18). In the course of these studies, an interesting difference emerged when comparing the treatment of weakly immunogenic (MCA-105 and MCA-106) tumors with that of nonimmunogenic (MCA-101 and MCA-102) sarcomas. The systemic administration of high-dose rIL-2 mediated a significant reduction in established 3-day-old pulmonary micrometastases from weakly immunogenic and nonimmunogenic sarcomas. When 10-day-old pulmonary metastases were treated, however, only those established from weakly immunogenic sarcomas remained susceptible. Ten-day-old pulmonary metastases from nonimmunogenic sarcomas were refractory to IL-2 therapy. Cells with potent LAK activity *in vitro* were identified in the lungs of rIL-2-treated mice. By flow cytometry, the majority of these effector cells were Thy-1⁺, L3T4⁻ (CD4⁻), Lyt-2⁻ (CD8⁻), and ASGM-1⁺. Depletion *in vivo* of ASGM-1⁺ cells eliminated the ability of high-dose rIL-2 therapy to decrease 3-day-old pulmonary metastases from nonimmunogenic sarcomas and also eliminated recoverable LAK cell activity in the lungs. In mice with 3-day-old pulmonary metastases from weakly immunogenic sarcomas (MCA-105 and MCA-106), both Lyt-2⁺ cells and ASGM-1⁺ cells were involved in rIL-2–mediated tumor regression. Lyt-2⁺ cells appeared to be the more potent mediators in the response. Depletion of L3T4⁺ cells had no effect on tumor regression. Because high-dose rIL-2 administration resulted in significant reductions in 10-day-old metastases from weakly immunogenic sarcomas, the effector cell responsible for this effective therapy was also characterized. As shown in Table 2-1, Lyt-2⁺ cells were mediators of rIL-2-induced regression of 10-day-old pulmonary macrometastases from the weakly immunogenic sarcomas.

Table 2-1 Lyt-2 Cells[a] Mediate Reduction of Established 10-Day-Old Pulmonary Macrometastases from Weakly Immunogenic Sarcomas by High-Dose Interleukin-2 (IL-2)

| Tumor | Treatment[b] | | | | No. of Metastases at Day 18 | Mean | p[c] |
	HBSS	IL-2	Anti-L3T4	Anti-Lyt-2			
MCA-105	+	-	-	-	250, 250, 250, 250, 206	241	—
	-	+	-	-	14, 36, 70, 7, 62	38	<.01
	-	+	+	-	80, 16, 41, 49, 39	45	<.01
	-	+	-	+	250, 250, 250, 213, 149	222	NS
MCA-106	+	-	-	-	250, 250, 250, 250, 250, 250	250	—
	-	+	-	-	20, 66, 53, 151, 33, 66	65	<.005
	-	+	-	+	250, 250, 250, 250, 250, 250	250	NS

HBSS; Hanks' balanced salt solution; NS, not significant; +, received treatment; -, did not receive treatment.

[a]Number of tumor cells injected was 6×10^5 and 2×10^5 for MCA-105 and MCA-106, respectively.

[b]IL-2 or HBSS was injected i.p. three times per d for 5 (MCA-105; 50,000 U per injection) or 4 (MCA-106; 100,000 U per injection) consecutive d, starting on d 10 after tumor injection. Antibody was injected i.v. 2 hr before the onset of IL-2 injection.

[c]Wilcoxon rank sum test of treated groups compared with groups receiving HBSS alone (two-sided).

From Mulé JJ et al. Identification of cellular mechanisms operational in vivo during the regression of established pulmonary metastases by the systemic administration of high-dose recombinant interleukin-2. J Immunol 1987;139:285–294, with permission.

Although LAK effectors derived from ASGM-1⁺ precursors eliminated 3-day-old pulmonary micrometastases regardless of tumor immunogenicity, Lyt-2⁺ cells were involved in the elimination of 3-day-old pulmonary micrometastases and 10-day-old macrometastases from weakly immunogenic tumors. These results imply that the effect of high-dose rIL-2 administration may be twofold. One effect is the stimulation of LAK cell activity against small tumor burdens from weakly immunogenic and nonimmunogenic tumors. A second effect may be the stimulation of specific host antitumor responses directed against tumor-associated antigens.

Peace and Cheever used a similar approach to identify the cells responsible for rIL-2–induced tumor regressions in the FBL-3 leukemia system (19). In this model, the therapeutic efficacy of high-dose rIL-2 was dramatically reduced by infusion of MAb to Lyt-2 and L3T4, but not NK-1.1.

Toxicity of Systemic Interleukin-2 Administration

The adverse effects of rIL-2 treatment in mice include: (a) a vascular leak syndrome (manifested as pulmonary edema, pleural effusions, and ascites), (b) hepatocyte necrosis, (c) prerenal azotemia, (d) splenomegaly, (e) anemia, and (f) thrombocytopenia (20). Pulmonary edema and systemic vascular leakage are the cause of mortality. Studies by Rosenstein et al., who used radiolabeled albumin in mice, revealed that rIL-2 induced increases in vascular permeability that were directly related to the dose of rIL-2 and the duration of administration (21). In rats, mortality occurred after 12 daily doses of more than 2.7×10^6 U per kg per day as a consequence of hepatocellular necrosis and anemia (20). The manifestations of rIL-2 toxicity in monkeys were similar to those in mice. Repeated doses of more than 2.3×10^6 U per kg per day resulted in death from vascular leakage,

pulmonary edema, renal and hepatic failure, and hypotension (20).

In vivo immune-cell subset depletions were performed to determine the cells responsible for rIL-2–mediated toxicity. Gately and colleagues showed that the rIL-2 dosage regimens required to produce large granular lymphocytes with LAK activity in the pleural cavities and livers of mice correlated with the induction of pleural effusions and hepatotoxicity (22). Treatment of mice with anti-ASGM-1 antiserum *in vivo* concurrent with IL-2 greatly reduced the severity of pulmonary edema and hepatotoxicity and prolonged mouse survival. Studies by Mulé et al., however, showed that this antiserum treatment severely diminished the therapeutic efficacy of rIL-2 in mice bearing 3-day-old pulmonary metastases (18). Peace and Cheever, using specific MAb to selectively deplete L3T4+, Lyt-2+, or NK-1.1+ cells in mice with FBL-3 leukemia, showed that elimination of NK-1.1+ (but not L3T4+ or Lyt-2+) cells attenuated rIL-2 toxicity without compromising therapeutic efficacy (19). These studies clearly show that ASGM-1+ and NK-1.1+ cells are responsible for rIL-2 toxicity.

Since these initial studies, several agents have been identified that appear to inhibit rIL-2 toxicity without compromising antitumor effects. These include pentoxifylline (23), methotrexate (24), and CNI-1493 (25). Tumor necrosis factor–α (TNF-α) has been implicated in the pathogenesis of rIL-2–induced capillary leak by studies that showed the following:

1. IL-2 induces macrophage-TNF-α production.
2. TNF-α expression is increased in rIL-2–treated mouse lungs (26).
3. Treatment of mice with neutralizing-soluble TNF receptor (26,27) or anti-TNF antibody (Ab) (28) significantly diminished vascular leak.

Anti-TNF Ab, however, also inhibited therapeutic efficacy (28). In one study, pentoxifylline, which suppresses macrophage-TNF gene transcription, inhibited many of the toxic effects of rIL-2 without reducing the therapeutic effect of rIL-2 on MCA-105 pulmonary metastases (23).

DeJoy et al. have shown that methotrexate inhibits rIL-2 vascular leak syndrome and improves the survival of mice receiving high-dose rIL-2 without compromising the efficacy of rIL-2 in the treatment of pulmonary metastases (24). The mechanism by which methotrexate inhibits rIL-2 toxicity is under study.

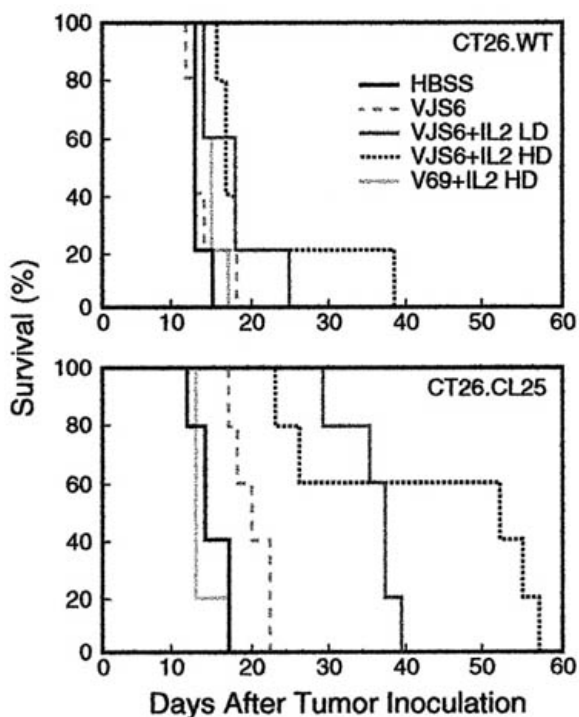
Kemeny et al. have shown that CNI-1493, a tetravalent guanylhydrazone that inhibits macrophage-cytokine production, conferred complete protection against fatal rIL-2 toxicity at rIL-2 doses ten times higher than the maximum tolerated dose in rats (Fig. 2-3) (25). Two of eight hepatoma-bearing rats treated with the maximum tolerated dose (3×10^6 U per m^2 per day) of rIL-2 alone developed tumor regressions. When rats were treated with tenfold higher doses of rIL-2 plus CNI-1493, one-half of the treated rats had no detectable tumor. The remaining one-half had substantial reduction of the tumor mass. CNI-1493 has been shown to inhibit the production of several inflammatory cytokines by monocytes and macrophages, including TNF-α. It remains to be determined whether this inhibition is directly responsible for the observed reduction of rIL-2 toxicity in the treated rats.


FIGURE 2-3. Active immunotherapy is enhanced with exogenous recombinant interleukin-2 (rIL-2) and rubella vaccine–like virus given in concert. BALB/c mice (five per group) were challenged intravenously with 5×10^6 CT26.WT or CT26.CL25 tumor cells. After 3 days, they received a single intravenous injection of medium alone (HBSS, Hanks' balanced salt solution) or medium containing 5×10^6 plaque-forming units of different TK rubella vaccine-like virus expressing (VJS6) or not expressing (V69) γ-galactosidase. Two different regimens of rIL-2 administration were started 12 hours after rubella vaccine-like virus injection: high dose (100,000 Cetus U, twice a day, intraperitoneally for 3 days) or low dose (15,000 Cetus U, twice a day, intraperitoneally for 5 days). Mice were checked twice a day for survival. (From Bronte V et al. IL-2 enhances the function of recombinant poxvirus-based vaccines in the treatment of established pulmonary metastases. *J Immunol* 1995;154:5282–5291, with permission.)

Local Delivery of Interleukin-2 at Sites of Tumors

Part of "2 - Interleukin-2: Preclinical Trials "

To avoid the toxicity of systemic administration of IL-2, several investigators have evaluated ways to locally deliver IL-2 to the tumor site. Direct injection of IL-2 into tumors has been shown to decrease the growth rate or cause regressions of different tumors, including (a) CE-2 sarcoma (29), (b) MC-2 mammary adenocarcinoma (30), (c) line 1 alveolar carcinoma cells (31), (d) MBT2 transitional cell bladder carcinoma (32), (e) SL-2 lymphoma and a mastocytoma (33), and (f) B16 melanoma (34). This effect is dose dependent. On histologic evaluation, this effect is associated with an increased accumulation of macrophages and T cells in the tumor. Dubinett et al. showed that

intratumoral IL-2 therapy was also effective in decreasing tumor growth in athymic, splenectomized mice who had received cyclophosphamide, indicating that a non-T cell immune effector is responsible for tumor regression (31). Similar findings were reported by Sacchi et al., who found that intratumoral IL-2 therapy was effective in the treatment of human tumor xenografts in an athymic mouse model (35).

Although nonspecific effectors, such as macrophages or NK cells, may be responsible for the initial tumor destruction induced by directly injected IL-2, antigen-specific T cell–mediated immunity is then generated. For example, Maas et al. treated i.p. SL-2 lymphomas with i.p. injections of IL-2 and found that 75% of the primary tumors regressed. Fifty percent of s.c. tumors at a distance also regressed (33). No significant regression of an antigenically distinct s.c. tumor was observed. Vaage also observed that local intratumor injection of IL-2 caused regression of the primary tumor and was able to induce systemic immunity, which resulted in complete regressions of MC-2 mammary carcinomas at a distant s.c. site (30). Of note, Yeung et al. showed that peritumoral IL-2 injection was more effective than systemic IL-2 in retarding distant tumor growth and prolonging survival of the treated mice (34).

Investigators have tried to improve the therapeutic effectiveness of locally administered IL-2 by prolonging its release. Egilnez et al. have loaded IL-2 into biodegradable polylactic acid microspheres (36). When IL-2–loaded microspheres were coinjected s.c. with tumor cells, tumor growth was suppressed in 80% of mice. In contrast, bolus injections of PEG-IL-2 were ineffective. NK cells were demonstrated to mediate tumor destruction in this human tumor and severe combined immunodeficiency disease mouse model. Others have shown that IL-2–loaded liposomes can cause reduction of tumor growth in mice bearing hepatic micrometastases (37) and slow-release preparations of IL-2 injected into sc-prostatic carcinomas in rats can cause reductions in tumor growth rates without systemic toxicity (38).

Injection of Interleukin-2-Expressing Adenoviral Vectors into Tumors

Another promising vehicle for local delivery of IL-2 to the tumor site is by direct injection of adenoviral vectors expressing IL-2 into a tumor. Using this approach, Levraud and Kourilsky showed that 70% of 10-day-old, 2- to 5-mm-diameter s.c. P815 tumors underwent complete regression (39). By using a transgenic adenoviral vector that expressed murine and human IL-2, Levraud and Kourilsky showed by polymerase chain reaction that expression of IL-2 was detectable at the tumor site 10 days after vector injection. These investigators made several interesting observations on the mechanism of IL-2–induced tumor regression. It had been postulated that locally injected IL-2 was effective because it induced an immune response by fostering proliferation of antigen-specific cytoxic T-lymphocyte (CTL) precursors or reactivating anergized CTL (40). Levraud et al. did not detect any increase in tumor-specific T cells, using polymerase chain reactions with primers for specific Vß T-cell reactivity rearrangements particular for P815 antigens in the regressing primary tumors. Instead, these investigators found polyclonal T-cell expansion, as well as a marked increase in interferon-γ (IFN-γ) expression, in the regressing primary tumors and at the site of challenge tumors injected into immunized mice. The cell type responsible for IL-2–induced IFN-γ expression in the primary tumors is unclear. At the challenge tumor site, it is likely that IFN-γ is secreted by tumor-reactive CD4+ or CD8+ lymphocytes. We have shown that IFN-γ secretion by adoptively transferred tumor-infiltrating lymphocytes (TIL) was critical for their effectiveness in the immunotherapy of established micrometastases (41). These observations support the concept that tumor destruction induced by local expression of IL-2 in primary tumors and T lymphocytes in challenge tumors is mediated largely by IFN-γ–stimulated nonspecific effectors, such as macrophages.

Successful treatment of a murine hepatocellular carcinoma, MH134, using a recombinant adenovirus vector expressing IL-2 has also been reported (42). Fifty percent of mice whose liver tumors were injected with Ad-IL-2 completely regressed. Regression was accompanied by massive infiltration with T cells and macrophages. Mice in whom tumors regressed were immune to repeat tumor challenge at different sites.

Gene Modification of Tumor Cells to Express Interleukin-2

Perhaps the most intensively studied mechanism for the local expression of IL-2 at the tumor site in experimental animal models has been through genetic modification of tumor cells to express IL-2. For most tumors studied, the local secretion of IL-2 by gene-modified tumor cells resulted in their rejection by syngeneic-immunocompetent hosts. Rejected primary tumors included: (a) the CMS-5 murine sarcoma (43), (b) CT26 colon adenocarcinoma (40), (c) P815 plasmacytoma (44), (d) TS/A mammary adenocarcinoma (45), (e) Lewis lung carcinoma (46), (f) MCA-102 sarcoma (47), and (g) J558L plasmacytoma (48). Expression of IL-2 by rat glioblastoma cells inhibited the growth of these tumors when subcutaneously injected, but not when injected intracranially (49).

The mechanism of rejection of the primary tumor was investigated by examining the histologic composition of the regressing tumor, host-cellular subset-Ab depletion studies, and the growth of the tumors in immunodeficient mice. In regressing MCA-102 and J558L tumors, progressive lymphocytic infiltration was observed. Regressing TS/A tumors were noted to be predominantly infiltrated by polymorphonuclear lymphocytes (45). In three reports, selective depletion of CD8+ T lymphocytes enabled a significant fraction of tumors to grow (45 ,47 ,48), indicating that CD8+ T cells play an important role in the rejection of IL-2-secreting tumors. It has been hypothesized that tumor IL-2 expression will bypass the need for CD4+ T-cell help in the generation of CTLs. In accord with this hypothesis, Ab depletion of CD4+ T lymphocytes did not affect tumor rejection (41 ,46 ,48 ,49). The growth of J558L tumors in nude mice was delayed compared with wild-type mice, supporting a role for a non–T-effector cell in tumor growth inhibition (48). Depletion of NK cells impaired the ability of mice to

reject an IL-2-secreting, nonimmunogenic MCA-102 sarcoma (47). Therefore, evidence supports a role for CD8[+] T lymphocytes, NK cells, and polymorphonuclear neutrophils in the rejection of IL-2 gene-modified tumor cells.

In many cases, regression of the primary IL-2-secreting tumor generates a systemic immune response capable of rejecting a secondary parental tumor challenge. For example, rejection of IL-2-secreting CMS-5 sarcomas, CT26 colon adenocarcinomas, and P815 plasmacytomas elicits splenic CTL activity and protects the treated mice from a secondary tumor challenge. In these systems, a causal role for IL-2 in the generation of systemic immunity was not proved because irradiated, nonmodified parental tumor cells could also effectively prevent tumor growth from the secondary challenge. Irradiated IL-2-secreting B16 melanoma provided no better protection than irradiated parental tumor (50). Of note, regression of IL-2-secreting Lewis lung carcinoma did not protect mice significantly from secondary challenge unless the mice were also vaccinated with two boosts of irradiated tumor cells (46). In another study, regression of the nonimmunogenic, but major histocompatibility complex (MHC) class I-expressing, IL-2-secreting MCA-102 sarcoma did not confer resistance to rechallenge (47).

Other work has shown that the development of protective immunity is caused by IL-2 secretion. Studies of the TS/A adenocarcinoma are particularly interesting. A single immunizing dose of mitomycin-C-inactivated TS/A tumor afforded no protection, whereas vaccination with five different IL-2-secreting TS/A tumors protected 50% to 70% of mice from a secondary tumor challenge (45 ,51). Although multiple vaccinations with mitomycin-C-inactivated TS/A tumors could protect mice, IL-2-secreting tumors provided more potent immunity (51). Histologic analyses of the regressing tumor challenge sites revealed a preponderance of lymphocytes and macrophages. Host-cell subset-depletion studies revealed that this protective immunity was caused by CD4[+] T lymphocytes, not CD8[+] or ASGM-1[+] cells. In fact, little CTL activity was detected in a 4-hour (51) chromium-release assay using splenocytes from immune mice against TS/A targets. Therefore, studies in the TS/A tumor system revealed that genetic modification of tumor cells to secrete IL-2 could induce systemic immunity mediated largely by CD4[+] T lymphocytes. Using a murine melanoma model, it was shown that M-3 melanoma cells gene-modified to express IL-2 could induce protective immunity, whereas mock-transfected tumors were ineffective (52). Both CD4[+] and CD8[+] T cells were required for the generation of protective immunity. Of note, the dose of IL-2 expressed by the tumor cells influenced the ability to achieve protective immunity. Expression of 1,000 to 3,000 U IL-2 per 10^5 cells per day was more effective than lower rates of expression of IL-2. Doses higher than 5,000 U IL-2 per 10^5 cells per day, however, led to the loss of ability to generate protective immunity. The reason for the ineffectiveness of high expression rates of IL-2 was unclear: No toxic effects or vascular leak was observed.

IL-2 gene-modified tumor cells have also been used to treat established tumors in rodents. In one study, when IL-2-expressing tumors were directly injected multiple times into 7-day-old TS/A tumors, 60% of mice were cured (51). Multiple injections led to rejections of 14-day-old tumors in 30% of mice. Other studies have shown that IL-2-expressing tumor vaccines could cause regressions of established tumors at distant sites, as summarized in Table 2-2 . In each of these studies, the IL-2-secreting tumor vaccine was superior to irradiated or inactivated control tumor vaccines.

Table 2-2 Treatment of Established Rodent Tumors by Interleukin-2 Gene-Modified Tumor Cells

Tumor System	Tumor Establishment	Treatment	Result	Reference
Lewis lung carcinoma	Footpad inoculation 11 d, 2×10^5	6 weekly i.p. XRT 2×10^6	Decreased number of lung metastases	Porgador et al. (46)
R3327-MatLyLu prostate cancer	a. s.c. 3 d, 10^4 b. Intraprostatic 3 d, 10^4	3 doses 10^6, XRT ID 3 d apart	a. 60% to 100% survival b. Prolonged survival	Vieweg et al. (53)
TS/A mammary adenocarcinoma	s.c. or i.v., 1 d, 7 d, 14 d	1 dose s.c. 10^5 weekly × 3 or biweekly × 3	20% survival with d 7 or d 14 s.c., d 7 i.v.	Cavallo et al. (51)
MBT-2 bladder cancer	Bladder wall implant 7 d, 2×10^4	3 weekly i.p. XRT 5×10^6	50% survival	Saito et al. (54)

ID, individual dose; XRT, x-ray therapy.

Some investigators have gene-modified tumor cells to express multiple cytokines or costimulatory molecules in addition to IL-2. For example, Rosenthal et al. cotransfected IL-2-expressing tumor cells with IFN-γ or granulocyte-macrophage colony-stimulating factor (GM-CSF) (55). In this model, CMS-5 fibrosarcomas transfected with IL-2, IFN-γ, and GM-CSF alone, and with the combination of IL-2 and GM-CSF progressively grew, whereas tumors expressing IL-2 and IFN-γ were rejected. It was postulated that this enhanced effect was secondary to IFN-γ-induced upregulation of MHC class I molecules on the tumor cell surface. Induction of protective immunity was not assessed in this study. In another report, it was shown that murine pancreatic carcinoma cells, which coexpressed IFN-γ and IL-2, were more effective than tumors expressing either IFN-γ or IL-2 alone in the treatment of 3-day-old established micrometastases (56).

Strome et al. have evaluated tumor cells that were modified to coexpress IL-2 and IL-4 (57). Coexpression led to rejection of primary tumor challenges and induced systemic immunity more effectively than tumor cells mixed with *Corynebacterium parvum.* Of interest, these investigators and Rosenthal and colleagues found that, although coexpression of two cytokines by a single tumor cell did lead to tumor regression, a mixture of tumor cells expressing only one cytokine did not. Rejection of IL-4- and IL-2-secreting tumors was not dependent on CD4[+]

or CD8⁺ T cells. CD4⁺ T cells, however, were required for the generation of protective immunity.

Multiple investigative groups have double gene-modified tumor cells to express the costimulatory molecule B7.1 plus IL-2. The rationale for this approach is an attempt to induce tumor cells to act as their own antigen-presenting cells by presenting tumor antigens in the context of MHC class I and providing costimulation to T cells. Thus, the induction of T-cell anergy is avoided. For example, Emtage and colleagues directly injected an adenoviral vector containing B7.1 and IL-2 genes into established s.c. polyoma middle T-transformed breast adenocarcinoma tumors (58). Whereas 100% of the tumors injected with the B7.1/IL-2 vector completely regressed, only 38% and 42% of the tumors injected with vectors containing B7.1 or IL-2 alone, respectively, regressed. All mice in whom the tumor regressed were protected from secondary tumor challenges. In addition, Gaken et al. have shown that irradiated B7.1 and IL-2 gene-modified adenocarcinomas are more effective than tumors expressing B7.1 or IL-2 alone in the therapy of small s.c. tumors at a distance from the vaccine site (59). Although these antitumor results are potentially important, it is unclear from these experiments whether antigen presentation was accomplished by the transfected tumor cells per se, or by host-derived, antigen-presenting cells.

Another approach to deliver IL-2 locally to the tumor site consists of the injection of IL-2-secreting fibroblasts directly into a tumor. In a murine leukemia model, mice immunized with parental tumor cells plus gene-modified fibroblasts secreting IL-2 were able to prevent challenge tumor growth in 60% of cases, comparing favorably with tumors modified to express the gene encoding for GM-CSF (20% protection) (60). The combination of irradiated tumor cells plus IL-2-secreting fibroblasts, however, did not prolong the survival of mice given an i.v. injection of leukemia cells 3 days before the vaccine. In contrast, when IL-2-secreting fibroblasts were mixed with irradiated CT26 colorectal carcinoma cells, protective immunity was induced in 65% of mice (compared with 33% of mice protected with irradiated tumor cells alone) (61). In therapy experiments, some regressions of established CT26 tumors were seen. IL-2-secreting fibroblasts have also been used to treat intracerebral gliomas, resulting in a small, but statistically significant, improvement in survival (62). Interesting studies by Sun and Cohen have demonstrated that DNA from various tumors can be transfected into fibroblasts, which had previously been gene modified to express IL-2. In this manner, immunologic specificity was purportedly transferred to a cell line designed to produce IL-2 with modest antitumor effect (63).

Interleukin-2 Fusion Proteins

Another promising method for delivering IL-2 to the local tumor site is by using Ab-IL-2 fusion proteins. Becker and Reisfeld transfected B16 melanoma cells with the gene for ganglioside GD2, forming a cell line B78-D14 (64 ,65). They constructed a fusion protein containing an Ab to GD2 and human IL-2. When 50-mm³ s.c. tumor nodules were treated with an i.v. injection of fusion protein, 37% of tumors completely regressed, and 63% partially regressed. This fusion protein was also used to treat 1-week-old pulmonary metastases induced by the i.v. injection of a mixture of B78-D14 and B16 (GD2-negative) tumor cells at a 5:1 ratio. Treatment with this IL-2 fusion protein was ineffective against B16 melanoma but effectively decreased the number of pulmonary metastases in mice injected with the mixture of B78-D14 and B16 tumors. The authors postulated that bystander killing of GD2-negative B16 tumors was induced and suggested that this strategy might be useful in the treatment of antigenically heterogeneous tumors. Of note, treatment with the IL-2 fusion protein was clearly more effective than concomitant treatment with the anti-GD2 Ab and systemic IL-2 or treatment with a nonspecific MAb–IL-2 fusion protein. IL-2 fusion protein treatment was effective in C57BL/6 beige/beige mice, indicating that NK cells were not involved in tumor destruction, but was only marginally effective in T-cell-deficient C57BL/6 severe combined immunodeficiency disease mice. In addition, Ab plus complement depletion of CD8+ T cells decreased the effectiveness of this fusion protein, indicating that CD8+ T cells were involved in IL-2 fusion protein–induced primary tumor regressions. These authors speculated that IL-2 fusion proteins may be operative by activating naïve T cells that were not previously activated, because peptide MHC or costimulatory molecules were at low levels, or by enhancing antigen-presenting cells phagocytosis of tumor cells. Long lived, tumor-specific protective immunity was established in mice that were cured of their tumors by IL-2 fusion protein therapy. Further experiments have shown that IL-2 fusion proteins can also effectively treat gene-modified, GD2-expressing neuroblastoma-hepatic metastases (66).

Other investigators have evaluated the efficacy of fusion protein-targeted IL-2 therapy. Melani et al. demonstrated that treatment with a fusion protein composed of IL-2 plus a single-chain Fv to α-folate receptor was able to reduce the volume of s.c. tumors (67). Liu and colleagues formed a fusion protein with IL-2 and an antiidiotype Ab that recognized the murine B-cell lymphoma 38C13. The IL-2 fusion protein inhibited lymphoma growth *in vivo* to a greater extent than combined therapy with anti-Id Ab plus systemic IL-2 (68). Using the same tumor system, Penichet et al. demonstrated that multiple injections with an IL-2-anti-Id fusion protein were effective in preventing tumor growth in the majority of animals but were ineffective in generating protective immunologic memory (69). Taking a different approach, Epstein et al. used IL-2 fusion proteins to selectively alter tumor vascular permeability in an attempt to deliver greater doses of Iodine 125-labeled MAbs to the tumor site (70). They found that pretreatment with a fusion protein consisting of IL-2 and an antifibronectin Ab, TV-1, led to a threefold higher uptake of radiolabeled Ab in the tumor compared with control mice treated with MAb TV-1 alone.

Interleukin-2: Combination Therapy

Part of "2 - Interleukin-2: Preclinical Trials "

Interleukin-2 and Other Systemic Cytokines

Systemic IL-2 therapy has been combined with other systemically administered cytokines in an attempt to enhance antitumor

effectiveness and decrease dose-limiting toxicity. In a series of preclinical murine tumor studies conducted in Rosenberg's laboratory, synergistic antitumor effects of immunotherapy were obtained by the combined administration of rIL-2 with TNF-α alone or with TNF-α plus IFN-α (71 ,72). Although enhanced therapeutic efficacy of the combination was achieved against the weakly immunogenic MCA-106 sarcoma at both s.c. and visceral sites, no significant antitumor effects were observed against the nonimmunogenic MCA-102 sarcoma. Wigginton and colleagues evaluated combination therapy with IL-2 and IL-12 (73). Whereas daily IL-2 therapy (300,000 IU per day) was prohibitively toxic, pulse treatment with IL-2 once per week combined with low-dose daily IL-12 injections was well tolerated and cured 60% of mice with established s.c. renal cell carcinoma (RenCa). This treatment strategy was also used in the adjuvant setting to treat metastatic disease after nephrectomy to remove the primary RenCa tumor. IL-2 or IL-12 alone had limited effectiveness, whereas the combination of low-dose IL-12 and pulse IL-2 resulted in cure for nearly all the mice.

Vallera et al. demonstrated that the combination of M-CSF and IL-2 delivered continuously by a pump protected approximately 80% of mice from a challenge with EL-4 lymphoma cells; this was significantly better than the protection elicited by either cytokine alone (74).

Interleukin-2 and Chemotherapy

Systemic IL-2 has also been combined with chemotherapy. In most of these studies, cytotoxic chemotherapeutic agents were administered first, followed by IL-2, with the rationale that lymphocytes would recover from cytotoxic chemotherapy sooner than the tumor cells. Papa and colleagues demonstrated that cyclophosphamide increased the effectiveness of IL-2 in the treatment of 10-day-old pulmonary metastases formed by two different tumors: the MCA-106 sarcoma and MC-38 adenocarcinoma (75). In similar experiments, doxorubicin hydrochloride (Adriamycin) and bischloroethylnitrosourea did not enhance the effectiveness of IL-2 therapy. Gautam et al. also evaluated the combination of IL-2 and doxorubicin hydrochloride (76). RenCa tumors treated with doxorubicin hydrochloride 14 days after implantation completely regressed in 90% of the mice but then recurred within 2 weeks in all mice. If mice were treated with doxorubicin hydrochloride, then followed by IL-2 daily for 10 days, tumor recurrence was delayed, and 25% of mice remained tumor free for 4 months. Treatment with IL-2 alone, in contrast, produced no antitumor responses. Mice rendered tumor free by treatment with doxorubicin hydrochloride and IL-2 were resistant to secondary tumor challenge.

Studies by other investigators of the combination of doxorubicin hydrochloride plus IL-2 (77); DTIC plus IL-2 (77); and cyclophosphamide, etoposide, and cisplatin plus IL-2 (78) have also demonstrated enhanced antitumor effects using the combination approach.

Interleukin-2 and Radiation Therapy

Seminal observations on the ability of IL-2 to enhance local tumor responses to radiation therapy were provided by Cameron, Spiess, and Rosenberg (79). Mice bearing 6-day-old hepatic metastases induced by an intrasplenic injection of the MC-38 colon adenocarcinoma were treated with saline, rIL-2 (50,000 U rIL-2 i.p. t.i.d. for 5 days), 750 cGy irradiation to the liver, or radiation plus IL-2. Although IL-2 alone did not improve survival, irradiation was associated with a median survival time of 20 days versus 11 days in control mice (p <.0001). The addition of IL-2 to local radiation therapy further improved the median survival time to 38 days (p <.0001 compared with radiation therapy alone). Hunter et al. showed a similar IL-2–induced enhancement of the effects of radiation therapy on lung metastases, although no improvement was seen in the treatment of the same tumor in an intramuscular site (80).

Younes and Haas investigated whether the combination of radiation therapy and IL-2 would enhance systemic immunity (81). In a RenCa pulmonary metastasis model in mice, treatment of the left lung with radiation therapy decreased the number of metastases present in a dose-dependent fashion but had no effect on the number of metastases in the opposite lung. Addition of IL-2 both decreased the number of metastases in the irradiated (left) lung and also caused a marked decrease in metastases in the right lung. These authors postulated that this systemic effect was caused by a radiation-induced increase in tumor MHC class I expression and showed that depletion of either ASGM1[+], CD4[+], or CD8[+] cells abrogated the antitumor effect.

In s.c. SL-2 lymphoma and M8013 adenocarcinoma models in mice, Everse and colleagues showed that the combination of IL-2 with radiation therapy improved local tumor responses and disease-free survival, compared with treatment with either modality alone (82). For example, treatment of M8013 tumors with IL-2 or radiation therapy alone resulted in some partial responses, but tumors progressed in all mice. Treatment with radiation and 10 days of IL-2 resulted in cures of 50% of mice. To test for induction of systemic immunity, tumors were injected subcutaneously on both flanks. Only one side was treated with radiation and intratumoral IL-2. Systemic immune effects of the combination therapy were modest: only 30% of contralateral tumors achieved a partial or complete regression, and all of these mice died as a result of progressive tumor growth.

Interleukin-2 and Adoptive Immunotherapy

Before the identification of IL-2, adoptive immunotherapy was largely limited to the transfer of splenocytes from immunized mice. The recognition of IL-2 as a T-cell growth factor and its purification broadened the methods by which T cells with antitumor reactivity could be generated. Incubation of lymphoid cells in high-dose IL-2 resulted in the formation of LAK cells, which were characterized by their ability to lyse tumor cells, but not normal cells, *in vitro.* When LAK cells were adoptively transferred to tumor-bearing mice, the marked tumor regressions that were obtained were dependent on the systemic coadministration of IL-2 (11 ,83). rIL-2 has also made possible the growth of lymphocytes from viable tumor preparations, called *TILs.* Culture of TIL from tumors in high doses of IL-2 (1,000 U per mL) resulted in TIL with nonspecific cytolytic activity,

whereas culture in lower doses of IL-2 (10-20 U per mL) generated TIL that exhibited immune specificity (84) and were more potent effectors in adoptive therapy of established tumors (85). Although high doses of TIL administered without IL-2 could mediate regressions of 3-day-old established pulmonary metastases, coadministration of systemic IL-2 significantly enhanced their therapeutic effectiveness (86), presumably by stimulating their proliferation *in vivo.*

Chang and Shu used a technique termed *in vitro sensitization* (IVS), whereby lymph node cells from tumor-bearing mice were cultured in the presence of IL-2 and irradiated tumor cells to generate cells that caused tumor regression on adoptive transfer to mice. As with TIL, IVS cells grown in low-dose IL-2 were more potent than IVS cells cultured in high-dose IL-2 when used to treat tumor-bearing mice (87). Furthermore, their effectiveness *in vivo* was also enhanced at least threefold by the concomitant administration of systemic IL-2 (88). These IVS effectors derived from tumor-draining lymph nodes were a mixture of CD4$^+$ and CD8$^+$ T lymphocytes, and Ab depletion studies have shown that both cell types were required for effective adoptive immunotherapy of tumor micrometastases (89). Of interest, administration of systemic IL-2 to CD4$^+$ T cell depleted, activated tumor-draining lymph node cells restored the therapeutic effectiveness of the CD8$^+$ T cells. It was postulated that IL-2 was able to substitute for CD4$^+$ T-cell mediated "help" for CTLs *in vivo.* (Exogenous administration of IL-2 did not restore the antitumor efficacy of the adoptively transferred, CD8$^+$ T-cell depleted cells.) Similar observations were made with CD8$^+$, CD4$^-$ TIL cultures: coadministration of TIL with IL-2 resulted in potent antitumor effects (41). Of note, TIL cultured in low-dose IL-2 and injected intravenously could provide protection against subsequent tumor challenge for as long as 6 weeks, even in the absence of exogenous IL-2 (90).

Various strategies involving IL-2 have been used in an attempt to improve the efficacy of adoptive immunotherapy. Loeffler and Ochoa demonstrated that treatment of hepatic metastases using *in vitro-*stimulated splenocytes from tumor-bearing mice was more effective when IL-2 is delivered in liposomes rather than as free cytokine (91). Ohno et al. attempted to improve the potency of lymph node-derived effector cells by immunizing mice with an IL-2 gene-modified MCA-205 sarcoma (92). Tumor-draining lymph node cells harvested from mice bearing the IL-2 secreting tumors and activated *in vitro* were approximately threefold more effective than cells harvested from lymph nodes draining the control parental tumor. In similarly designed experiments with the poorly immunogenic B16-BL6 melanoma, Arca and colleagues demonstrated that tumors modified to express GM-CSF were more effective than IL-2-secreting tumors for priming lymph node cells for the generation of antitumor effectors (93). Finally, Nakamura et al. used an adenoviral vector to gene modify murine TIL to secrete IL-2 (94). These TIL were slightly more effective than nontransduced TIL in a B16 melanoma lung metastasis model.

Interleukin-2 and Vaccines

In 1982, Rosenberg et al. demonstrated that IL-2 administration *in vivo* could enhance the generation of cytotoxic cells directed against alloantigens (95). In these experiments, both normal and previously immunized C57BL/6 mice were injected with irradiated allogeneic P815 tumor cells, then treated with IL-2 for 3 days starting the day after tumor challenge. At 7 days, the antigen-specific cytotoxicity of splenocytes was greatly increased in mice that received IL-2. No enhanced activity was noted when IL-2 was given before or concurrently with antigen challenge.

Numerous subsequent investigators have confirmed the finding that IL-2 can enhance the effectiveness of tumor vaccines. O'Donnell et al. immunized mice with 3 s.c. injections of irradiated line 1 (L1) alveolar carcinoma cells (96). IL-2 was administered by different routes and schedules after each immunization. Mice were then challenged with live L1 tumors. The addition of IL-2 markedly increased the percentage of mice surviving the tumor challenge; its daily administration for 7 days was more effective than shorter courses. The antitumor effect required that IL-2 be injected adjacent to the site of the L1 vaccine; s.c. injection at a distant site or i.p. injections were not effective. Similar experiments using irradiated B16 melanoma as a vaccine also showed that IL-2 could enhance the development of protective antitumor immunity (97).

Arroyo et al. evaluated the value of IL-2 in combination with a vaccinia colon cancer oncolysate vaccine (98). Mice bearing 4-day-old CC-36 colon carcinoma hepatic metastases were treated with vaccinia oncolysate with or without IL-2. Although the vaccine alone had no effect on the number of hepatic tumor nodules and only a slight effect on survival, the combination of vaccinia plus IL-2 markedly decreased the number of hepatic metastases and resulted in survival of 67% of the treated mice (98 ,99). Similar results were obtained when a vaccinia virus IL-2 construct was used in place of free IL-2 (99). Bronte and colleagues also demonstrated that IL-2 could enhance the antitumor effectiveness of a vaccinia-virus vaccine. These investigators treated mice bearing 3-day-old pulmonary metastases from a ß-galactosidase-expressing CT26 carcinoma with a ß-galactosidase-expressing recombinant vaccinia virus (100). Results showed negligible survival benefit from the vaccine alone or when the vaccine was administered with GM-CSF, TNF, or IFN-γ. Marked improvement in survival occurred, however, with the systemic injection of IL-2 in conjunction with vaccine (see Fig. 2-3). Furthermore, insertion of the copy DNA encoding IL-2 into the vaccinia virus enhanced vaccine effectiveness, whereas GM-CSF, TNF, and IFN-γ gene insertion did not. In similar experiments, McLaughlin and associates showed that IL-2 could enhance the effectiveness of a recombinant vaccinia virus carcinoembryonic antigen (rV-CEA) vaccine (101). Seventy percent of mice bearing palpable CEA-expressing MC-38 tumors were cured by treatment with rV-CEA plus IL-2, compared with no long-term survivors when treated with rV-CEA alone or with control virus plus IL-2. Splenocytes from mice treated with rV-CEA plus IL-2 showed enhanced antigen-specific proliferation, cytotoxicity, and IFN-γ secretion.

The efficacy of combination therapy with IL-2 and a herpes simplex virus thymidine kinase vector "suicide" gene has also been evaluated. Chen and colleagues showed that hepatic metastases could be induced to undergo necrosis by direct injection of an adenoviral vector containing the herpes simplex virus

thymidine kinase vector gene, followed by treatment with ganciclovir (102). Protective immunity against subsequent challenge, however, only developed in mice infected concurrently with an adenoviral IL-2 vector.

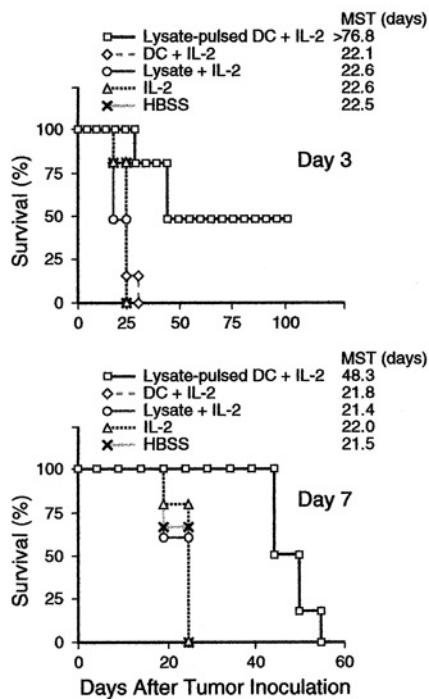
Shimuzu et al. demonstrated that low-dose IL-2 could enhance protective and therapeutic immunity resulting from tumor lysate-pulsed dendritic cell (DC) vaccines (103). Mice harboring 3-day-old MCA-207 sarcoma pulmonary metastases were immunized with DC on days 3 and 7 and treated with low-dose IL-2 on days 3 to 10. Fifty percent of the mice treated with DC plus IL-2 were cured of tumor. Immunization of mice bearing 7-day-old tumors with DC vaccine followed by IL-2 administration resulted in a greater reduction in pulmonary metastases than that obtained with DC vaccines treatment alone (Fig. 2-4). Furthermore, when IL-2 was combined with three DC immunizations in the treatment of 14-day-old s.c. MCA-207 tumors, 80% of mice could be rendered disease free.


FIGURE 2-4. Treatment with the combination of tumor lysate-pulsed DC and interleukin-2 (IL-2) can prolong survival and result in cures of mice bearing established pulmonary metastases. Mice harboring MCA-207 lung metastases were immunized three times on days 3, 7, and 11 *(upper graph)* or days 7, 10, and 13 *(lower graph)* after tumor injection. IL-2 was given intraperitoneally twice daily at 20,000 IU per dose *(upper)* or 40,000 IU per dose *(lower)* for 3 consecutive days after each immunization. Control groups of mice received Hanks' balanced salt solution (HBSS) tumor lysate plus IL-2, unpulsed DC plus IL-2, or IL-2 alone. Survival was monitored over time after tumor injection, and the mean survival time (MST) in days was determined. (From Shimizu K et al. Systematic administration of interleukin 2 enhances the therapeutic efficacy of dendritic cell-based tumor vaccines. *Proc Natl Acad Sci U S A* 1999;96:2268–2273, with permission.)

Conclusion

Part of "2 - Interleukin-2: Preclinical Trials "

The lymphokine IL-2 is a glycoprotein secreted predominantly by Th1 cells that mediates a variety of immunologic effects *in vitro* and *in vivo.* Large quantities of rIL-2 became available in the early 1980s through DNA technology. In addition, the advent of new technologies to efficiently insert, by recombinant, viral, or other means, the copy DNA encoding for IL-2 into a variety of mammalian target cells has allowed for the local production of IL-2 at tumor sites. As described in this chapter, extensive preclinical studies of IL-2, alone or combined with other biotherapeutic agents, in the immunotherapy of established cancer have been conducted in a variety of animal models. When administered systemically to mice, IL-2 can mediate substantial regressions of s.c. tumors, as well as visceral metastases. Importantly, the antitumor efficacy of IL-2 can be enhanced by its combination with other therapies, allowing for lower effective doses with reduced toxicity. Preclinical animal studies have also provided important insight into the characteristics of tumor cells that determine sensitivity or resistance to IL-2-based immunotherapies, particularly with respect to the expression of MHC molecules and relative tumor immunogenicity *in vivo.* Moreover, the dissection of the *in vivo* mechanisms underlying IL-2–mediated tumor regression, as well as toxic side effects in animal models, has shown that it may be possible to selectively inhibit IL-2 toxicity while maintaining (or increasing) therapeutic efficacy. Lastly, the combination of IL-2 with new vaccine strategies that use either potent DCs or recombinant viral vectors have provided new promising applications of IL-2 for cancer treatment.

Interleukin-2: Clinical Applications

3.1

Principles of Administration and Management of Side Effects

Douglas J. Schwartzentruber

- Interleukin-2
- Systemic Effects of Interleukin-2 Treatment and Management of Toxicities
- Surgery and Immunotherapy
- Approaches to Reduce Interleukin-2 Side Effects

Interleukin-2

Part of "3.1 - Principles of Administration and Management of Side Effects "

Interleukin-2 (IL-2) is a hormone that was first described as a T-cell growth factor in 1976 (1). The many immune-modulating properties of IL-2 led to its use in the treatment of cancer patients. The first reported use was in 1983 by Bindon and colleagues (2), who treated two melanoma patients with natural IL-2 derived from stimulated normal lymphocytes. Shortly after, Lotze and colleagues treated acquired immunodeficiency syndrome and cancer patients with IL-2 that was derived from the Jurkat cell line, a human T-cell tumor (3,4). Patients treated with this preparation had measurable changes in various immunologic parameters. No antitumor responses were observed, however, because small doses were used. Large-scale use of IL-2 was not feasible until recombinant IL-2 (rIL-2) became available. This was made possible when the gene for IL-2 was discovered (5) and subsequently expressed in the bacteria *Escherichia coli.* This new molecule was shown to be biologically and functionally similar to natural IL-2 (6,7).

A variety of doses and routes of administration of rIL-2 and Jurkat-derived IL-2 were explored (4,8,9). These studies defined the maximal tolerated doses and toxicities of IL-2. Initially, tumor regressions were not seen until rIL-2 was combined with lymphokine-activated killer (LAK) cells (10). The first patient to respond to this treatment was a woman with widely metastatic cutaneous melanoma who experienced a complete disappearance of tumors. Shortly after, responses to rIL-2 administered alone were observed (11). Randomized studies demonstrated that IL-2 was as effective alone as when combined with LAK cells in patients with metastatic renal cell cancer and melanoma (12) (SA Rosenberg, *personal communication*).

The use of high-dose bolus intravenous IL-2 regimens, as developed by Rosenberg et al. (10), was based on laboratory models, indicating that tumor responses correlated with dose intensity (13). Many studies using this regimen of IL-2 alone have described partial or complete tumor regression in 14% to 20% of patients with metastatic melanoma or renal carcinoma (14,15,16,17 and 18). These conditions are reviewed in other chapters. Based on such studies, the U.S. Food and Drug Administration approved the use of IL-2 for the treatment of metastatic renal carcinoma in 1992 and for metastatic melanoma in 1998.

rIL-2 has also been used by continuous intravenous infusion: one day a week (19,20), 4 to 5 days per week (21,22,23,24,25,26,27 and 28), or for 21 to 90 days (9,29,30) (Table 3.1-1). The most common regimens in the United States and Europe consist of daily subcutaneous IL-2 administration (31,32,33,34,35,36 and 37) (see Table 3.1-1). The various routes, doses, and schedules of IL-2 administration have resulted in different toxicities and immunomodulatory effects (8,20,30,38,39,40 and 41). Comparative studies to define the optimal regimen are needed. One such study is currently under way (42). Other less frequent routes of IL-2 administration have included intraperitoneal (43,44,45 and 46), intrapleural (47,48 and 49), intralesional (50,51), intracranial (52,53,54,55,56 and 57), intravesical (58,59), intraarterial (60,61), perilymphatic (62), intralymphatic (63), continuous subcutaneous (64), intramuscular (40), and by inhalation (65) (see Table 3.1-1).

Table 3.1-1 Routes of Interleukin-2 Administration

Daily subcutaneous (31,32,33,34,35,36 and 37)

Bolus intravenous every 8 h

  High dose (14,15,16,17 and 18)

  Low dose (42)

Continuous intravenous infusion

  1 d/wk (19,20)

  4-5 d/wk (21,22,23,24,25,26,27 and 28)

  21-90 d (9,29,30)

Infrequent routes of interleukin-2 administration

  Intraperitoneal (43,44,45 and 46)

  Intrapleural (47,48 and 49)

  Intralesional (50,51)

  Intracranial (52,53,54,55,56 and 57)

  Intravesical (58,59)

  Intraarterial (60,61)

  Perilymphatic (62)

  Intralymphatic (63)

  Continuous subcutaneous (64)

  Intramuscular (40)

  Inhalation (65)

Many unique and diverse side effects can be associated with the various routes and regimens of IL-2 administration. This chapter focuses on the side effects associated with the most intense form of administration—high-dose intravenous therapy in adult patients. Low-dose IL-2 administered as an outpatient generally manifests a lesser degree of toxicity but can affect the same organ systems as high-dose IL-2 and is potentially as severe (66). Interest in the use of IL-2 to treat pediatric malignancies is growing (67,68,69 and 70). The role of IL-2 in the treatment of this patient population remains to be defined.

Pharmacology

Proleukin(R) (Aldesleukin) is presently the only commercially available rIL-2 that is approved for human use in the United States. This preparation, produced by Cetus Oncology Division of Chiron Corporation, varies from natural IL-2 because it is nonglycosylated, the cysteine at amino acid position 125 has been replaced by serine, and it lacks the N-terminal alanine. rIL-2 has been shown to be biologically and functionally similar to

natural IL-2 (6,7). Other companies (i.e., Hoffmann-LaRoche, Ortho, and Biogen) have supplied IL-2 with comparable biologic activity and toxicities in clinical trials. All preparations vary according to unit system and are administered according to body weight or body surface area. To help standardize the use of IL-2, the World Health Organization defined international units based on an international standard (71). This standard replaced the interim reference reagent previously established by the biologic response modifiers program of the National Cancer Institute (72). One Cetus (Chiron) unit is equivalent to 6 international units and is approximately 2.3 Hoffmann-La Roche units.

IL-2 is rapidly cleared from the circulation after intravenous administration. Initial clearance (α distribution) of rIL-2 is rapid, with a half-life of 7 to 13 minutes, followed by a longer β clearance with a half-life of 60 to 85 minutes (8,73). The later delayed clearance is consistent with a two-compartment model of rapid initial egress of IL-2 into the extravascular space, then a slower return into the plasma. With subcutaneous administration, lower peak serum levels of IL-2 are achieved than with intravenous administration, and levels remain fairly constant for 8 hours (73,74). IL-2 is eliminated from the body primarily by metabolism in the kidneys, as demonstrated in a murine model (75).

Immunologic Activity

Immunologic changes are among the earliest measurable consequences of the systemic administration of IL-2 to the human body. Lymphopenia develops within minutes of a single dose of IL-2 (8,23,38,41,76,77). With ongoing therapy, whether bolus or continuous infusion, the lymphopenia is profound and persistent. This phenomenon is thought to occur secondary to margination and egress of lymphocytes into the extravascular space. Twenty-four to 36 hours after discontinuation of IL-2, a rebound lymphocytosis of 2- to 70-fold above baseline occurs, which persists for 2 to 7 days; this rebound is dose and schedule dependent (23,38,41,77).

Paralleling the rapid lymphopenia is the acute loss of LAK precursors and natural killer activity from the circulation, occurring within 15 minutes of a single (bolus) dose of intravenous IL-2 (8,78); cytolytic activity is recovered in 24 to 72 hours. During continuous infusion of IL-2, peripheral blood mononuclear cells regain cytolytic activity by 5 to 7 days (8,79). One to 2 days after discontinuation of bolus or continuous IL-2, cytolysis of Daudi and K562 rebounds above baseline in a dose- and schedule-dependent fashion (8,38,39,41,79). When IL-2 is given subcutaneously and the dose escalated weekly, natural killer and LAK killing by fresh peripheral blood mononuclear cells at day twenty-eight is increased when compared with baseline (80). Phenotypically, increases in CD56+ cells can be measured during or after continuous or prolonged therapy with IL-2, as well as increased CD2 expression on CD56+ cells (27,81,82 and 83).

Peripheral blood mononuclear cells display decreased proliferative responses to IL-2, mitogens, and soluble antigens during IL-2 therapy (8,79,84,85), responses that rebound after IL-2 discontinuation. With repetitive IL-2 administration, lymphocytes become activated, as demonstrated by the expression of the IL-2 receptor (CD25) on the cell surface (8,27,38,39,86). Soluble IL-2 receptors shed from the cell surface are increased in the serum (40,86,87,88 and 89); soluble CD8 increases as well (88). Other activation markers, such as HLA-DR expression, increase on CD3+ and CD56+ cells (38,39,90). The expression of the adhesion molecule ICAM-1 increases on large granular lymphocytes after beginning IL-2 (91). At the tissue level, profound lymphocytic infiltrates have been documented in a variety of organs and tumors (92,93 and 94). After IL-2 therapy, patients can develop immediate hypersensitivity to skin test recall antigens (85). Delayed-type hypersensitivity responses, however, are depressed (84,85).

The effects of IL-2 on B cells and their function have been less well characterized. B-cell numbers decrease with IL-2 infusion (20,84,95,96). Several days after discontinuation of IL-2, B cells return to baseline but do not rebound to the same extent as T cells (84). B-cell products, immunoglobulin (Ig) G, IgM, and IgA, are moderately decreased during IL-2 infusion (79,84,85,96) but return to normal or higher levels after stopping IL-2. This phenomenon may be partly a result of redistribution changes secondary to fluid shifts characteristic of vascular leak syndrome (VLS). Tetanus-specific IgG is increased during IL-2 therapy after tetanus reimmunization, suggesting that B-cell function is preserved (79). Markedly depressed tetanus- and KLH-specific Igs were noted, however, after vaccination of patients receiving IL-2 within 3 weeks of intensive chemotherapy or bone marrow transplantation when compared with non–IL-2 recipients (96). This suggests that B-cell function may be impaired by IL-2 therapy in the setting of recent chemotherapy.

Neutrophil counts have generally been unaffected by IL-2. Severe neutropenia during or shortly after IL-2 therapy is rare (15,16,41,97). In fact, increased neutrophils are noted in the first 24 hours of IL-2, along with a shift to immature forms (77,98). Transient neutrophil dysfunction occurs, however, as noted by decreased Fc-receptor expression and decreased chemotaxis while bacterial phagocytosis is preserved (98,99).

Many cytokines, including tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ), granulocyte-macrophage colony-stimulating factor, macrophage colony-stimulating factor, granulocyte colony-stimulating factor, IL-4, IL-5, IL-6, IL-8, and IL-10, have been measured in the serum after IL-2 administration (23,78,100,101,102,103,104,105,106,107,108,109 and 110). Serum IL-2 levels have been measured primarily in the context of pharmacokinetic studies and are proportional to the treatment dose. IL-2 levels with successive cycles of treatment have not been well studied. IL-2 levels progressively decreased, whereas the secondary production of TNF-α increased during four consecutive cycles of treatment (23). This phenomenon was not attributed to the development of antibodies to IL-2. Anti-IL-2 antibodies are frequent after intravenous IL-2 (20,63,111) and are generally nonneutralizing. In contrast, neutralizing antibodies have developed after subcutaneous IL-2 administration (32,112). Serum sickness has not been observed (63,113). The implications of anti-IL-2 antibodies are unknown.

Systemic Effects of Interleukin-2 Treatment and Management of Toxicities

Part of "3.1 - Principles of Administration and Management of Side Effects "

IL-2 has systemic effects that depend on route, dose, and schedule of administration and variably impact every organ system in the body. High-dose bolus intravenous IL-2, as developed by Rosenberg and colleagues in the Surgery Branch of the National Cancer Institute, has been associated with the most frequent and intense side effects (Table 3.1-2). Less toxic regimens using lower doses of IL-2 administered intravenously or subcutaneously, however, have the potential to result in significant toxicity (Table 3.1-3).

Table 3.1-2 Toxicity Associated with the Administration of High-Dose Interleukin-2 Alone in 447 Consecutive Treatment Courses

Category	Toxicity (% of Courses)
Systemic	Malaise[a] (14.5), chills[a] (18.3), pruritus[a] (8.9), weight gain >5% body weight (70.9), edema causing neurovascular compression (0.9)
Hemodynamic	Hypotension requiring pressors (52.1)
Cardiac	Arrhythmia (6.5), angina (1.1), myocardial infarction (0.4)
Pulmonary	Respiratory distress (4.0), intubation (2.9), pleural effusion requiring thoracentesis (1.1)
Renal	Oliguria (26.1), elevated creatinine (2.1 mg/dL–6.0 mg/dL = 62.0; >6.0 mg/dL = 6.3)
Gastrointestinal	Mucositis[a] (0.4), nausea/vomiting[a] (38.0), diarrhea[a] (30.2)
Hepatic	Hyperbilirubinemia (2.1 mg/dL–6.0 mg/dL = 62.4; >6.0 mg/dL = 21.9)
Neurologic	Disorientation (13.9), somnolence (4.9), coma (2.2)
Hematologic	Anemia requiring transfusion (21.0), thrombocytopenia (20,000/mm³-60,000/mm³ = 29.3; ≤20,000/mm³ = 3.6)
Infectious	Infection (4.0), line sepsis (2.0)
Death	Treatment related (0.7)

[a]Grade 3 and 4 toxicity only.

IL-2, interleukin-2

[a]720,000 IU/kg every 8 hr, up to 15 consecutive doses and repeated in 10–14 d.

[b]72,000 IU/kg every 8 hr, up to 15 consecutive doses and repeated in 10–14 d.

[c]250,000 IU/kg/d for 5 of 7 d in wk 1 and 125,000 IU/kg/d in wks 2 to 6.

From Yang JC, Rosenberg SA. An ongoing prospective randomized comparison of interleukin-2 regimens for the treatment of metastatic renal cell cancer. *Cancer J Sci Am* 1997;3:S79-S84.

In many studies, a variety of cytokines and cellular therapies have been combined with IL-2. When possible, this review focuses primarily on IL-2 without the concomitant use of biologic agents, which may add to the toxicity profile. Interest exists in developing less toxic treatment regimens that maximize immunologic and clinical response. No good *in vitro* predictors of clinical

response to IL-2 alone have been identified (114). Although various clinical and treatment-related parameters have been associated with higher clinical responses (100,115), none have been useful in selecting patients for therapy.

Before initiating therapy with IL-2, patients should be carefully screened with histories, physical examinations, and laboratory measurements. The extent of tumor involvement should be assessed with magnetic resonance imaging of the brain; computed tomography of the chest, abdomen, and pelvis; and a bone scan. The presence of brain or spinal cord metastases has generally excluded patients from high-dose IL-2 therapy. Patients with abnormal renal, hepatic, cardiac, or pulmonary function are not candidates for high-dose therapy and should be considered for less aggressive regimens. Suggested screening guidelines for high-dose IL-2 include a serum creatinine less than or equal to 1.6 mg per dL, bilirubin less than 1.6 mg per dL, and pulmonary function tests higher than 65% of that predicted. Mandatory cardiac stress testing for patients older than 50 years and the exclusion of those with silent coronary artery disease have reduced the cardiac toxicity of high-dose IL-2 (116,117). The intensity of patient monitoring during therapy depends on the dose, route, and schedule used and must be tailored to each individual (Table 3.1-4). Assessment of tumor response should be performed approximately 2 months after IL-2 therapy. Therapy should be discontinued if the disease has progressed. Patients with stable or regressing disease are candidates for additional therapy.

Table 3.1-4 Guidelines for Monitoring Patients Receiving Interleukin-2 Therapy

Parameter to Monitor	Frequency Inpatient Not Requiring Vasopressors	Requiring Intensive Care Unit/Vasopressors	Outpatient
Vital signs	Every 4 h	Every 1 h	As needed
Intake and output	Every 8 h	Every 1 h	Not strictly measured
Weight	Daily	Daily	Daily
Mental status	Every 8 h	Every 4 h	Daily
Intravenous site/injection site	Every 8 h[a]	Every 8 h[a]	Daily
Complete blood cell count and differential	Daily	Twice daily	Weekly
Electrolytes, blood urea nitrogen, creatinine, glucose	Daily	Twice daily	Weekly
AST, ALT, alkaline phosphates and bilirubin	Daily	Daily	Weekly
Albumin, CA^{2+}, Mg^{2+}, and phosphorus	Daily	Daily	Each course
Creatinine phosphokinase	Daily	Daily	Weekly
Prothrombin time, partial thromboplastin time	Every 3 d	Every 3 d	Weekly
Thyroid-stimulating hormone and free T_4	Each cycle	Each cycle	Each course
Urinalysis	Each cycle	Each cycle	Each course
Electrocardiogram	Each cycle	Each cycle	Each course
Chest x-ray	Each cycle	Each cycle	Each course

ALT, alanine aminotransferase; AST, aspartate aminotransferase.

[a]Change peripheral i.v. every 3 d.

The toxicities of IL-2 administration have been reviewed (118,119,120,121,122 and 123) and can involve virtually every organ system in the body. The maximal tolerated dose of IL-2 is 7.2×10^6 IU per kg when given by intravenous bolus and 2.16×10^4 IU per kg per hour when given by continuous infusion (8). For a given dose, continuous-infusion IL-2 (i.e., over 24 hours) is more toxic than the same dose given by bolus infusion (38). Thus, greater total quantities of IL-2 can be given when administered by intermittent bolus. The typical clinical course of patients receiving high-dose IL-2 (i.e., 7.2×10^5 IU per kg every 8 hours) begins with fever and chills. Moderate hypotension and tachycardia develop soon after and are initially asymptomatic. Oliguria may manifest within 24 hours of starting IL-2 and generally responds to fluid administration. As treatment progresses, hypotension and oliguria may worsen and require pharmacologic intervention. Nausea, vomiting, and diarrhea are most prominent as therapy nears completion. Peripheral edema, pulmonary congestion, and weight gain are common. Transient thrombocytopenia and elevated serum creatinine can be measured. Most side effects resolve within 2 to 3 days of IL-2 discontinuation.

A variety of concomitant medications have been useful in diminishing the side effects of IL-2 and are listed in Table 3.1-5 . Many of the toxicities of IL-2, including TNF induction, can be ameliorated with steroids (124,125), but these are not currently used because of the possibility of interfering with therapeutic response. In murine studies, corticosteroids abrogate the side effects of IL-2 and also eliminate antitumor responses (126). As experience has been gained with high-dose IL-2, the safety profile has improved (117). Treatment-related mortality in the Surgery Branch of the National Cancer Institute was 0.7% in 1,241 patients and occurred primarily during early experience with high-dose IL-2 (117). Despite the many systemic effects of high-dose IL-2, this therapy is safe when administered by experienced physicians.

Table 3.1-5 Concomitant Medications Used during Interleukin-2 Therapy

Medication	Dose/Frequency/Route	Side Effect Treated
Acetaminophen	650 mg q4h, p.o./p.r.	Fever, myalgia
Indomethacin	50-75 mg q8h, p.o./p.r.	Fever, myalgia
Meperidine hydrochloride	25-50 mg q1h, i.v. prn	Chills
Ranitidine hydrochloride	50 mg q8h, i.v.	Gastritis
Aluminum hydroxide, 200 mg; magnesium hydroxide, 200 mg; simethicone, 20 mg	30 mL q3h, p.o. prn	Gastric upset
Droperidol	1 mg q4-6h, i.v. prn	Nausea
Prochlorperazine	25 mg q4h, p.r. prn or 10 mg q6h, i.v. prn	Nausea
Ondansetron hydrochloride	10 mg q8h, i.v. prn	Nausea
Granisetron hydrochloride	0.01mg/kg daily, prn	Nausea
Lorazepam	0.5-1.0 mg q6h, p.o./i.v. prn	Nausea, anxiety
Haloperidol	1-5 mg q1h, i.v./i.m. prn	Agitation, combativeness
Loperamide	2 mg q3h, p.o. prn	Diarrhea
Diphenoxylate hydrochloride 2.5 mg, atropine sulfate 25 μg	q3h, p.o. prn	Diarrhea
Atropine sulfate	25 μg	—
Codeine sulfate	30-60 mg q4h, p.o. prn	Diarrhea
Tucks	Apply locally, prn	Perianal discomfort
Hydroxyzine hydrochloride	10-20 mg q6h, p.o. prn	Pruritus
Diphenhydramine hydrochloride	25-50 mg q4h, p.o. prn	Pruritus
Oatmeal powder/baths	Apply locally prn	Pruritus
Lubriderm, 8 oz with 0.25% camphor and 0.25% menthol	Apply locally prn	Pruritus
Sodium bicarbonate 6 tsp/1,500 mL	Swish and swallow prn	Mucositis
Lidobenalox oral	5 mL q3h, p.o. prn	Mucositis
Pseudoephedrine hydrochloride	30 mg q6h, p.o. prn	Sinus congestion
Temazepam	15-30 mg qhs, p.o. prn	Insomnia
Zolpidem	5-10 mg qhs, p.o. prn	Insomnia
Normal saline	250-500 mL i.v. prn	Oliguria, hypotension
Dopamine hydrochloride	100 mg/250 mL, i.v. prn (2 μg/kg/min)	Oliguria
Phenylephrine	40 mg/100 mL, titrate i.v. (0.1-2.0 μg/kg/min)	Hypotension
Calcium gluconate 10%	1 g (over 1 h), i.v. prn	Hypocalcemia
Magnesium sulfate	1 g (over 1 h), i.v. prn	Hypomagnesemia
Potassium phosphate	10-15 mmol (over 6h), i.v. prn	Hypophosphatemia
Potassium chloride	10 mg (over 1h), i.v. prn	Hypokalemia
Cefazolin	1 g q6h, i.v.	Prevent central line sepsis
Clindamycin	900 mg q8h, i.v.	Prevent central line sepsis

prn, as needed.

Outpatient therapy with subcutaneous or intravenous IL-2 uses much smaller doses than the inpatient regimen. The most common side effects associated with outpatient therapy include fever, chills, skin changes, fatigue, diarrhea, nausea, vomiting, anorexia, hypotension, myalgia, arthralgia, stomatitis, and pain and swelling at the injection site (66). Particularly common with subcutaneous IL-2 administration are generalized fatigue and local

pain and induration at the site of injection. The subcutaneous induration at injection sites slowly resolves over several months (31). Guidelines for the management of IL-2 side effects in nonhospitalized patients have been published (66). This chapter focuses on the management of side effects of IL-2 as they pertain to each body system and to patients receiving high-dose therapy.

Pathophysiology (Vascular Leak Syndrome)

The toxicities of IL-2 are believed to result in part from lymphoid infiltration, which is seen in many organs (92), as well as VLS (127). VLS has been documented by the rapid disappearance of radiolabeled albumin from the circulation (128,129). Mechanisms of VLS include (a) the induction of circulating cytokines, such as TNF-α (125) and IL-5 (leading to eosinophilia and extravascular degranulation) (110); (b) generation of complement-activation product C5a (130); (c) neutrophil activation (131); and (d) activation of endothelial-cell antigens (132).

Manifestations of VLS include generalized edema, weight gain, pulmonary congestion, hypotension, oliguria, pleural effusions, and ascites (9). Organ edema is difficult to quantify but is likely responsible for many of the observed toxicities. Patient weight gain greater than 5% above baseline occurs in 71% of courses with high-dose IL-2 (15); this gain is dependent on the intensity of therapy and the amount of additional fluids used to correct hypotension. In a randomized study comparing the efficacy of colloid versus crystalloid for fluid resuscitation during IL-2 therapy, patients receiving saline boluses experienced more oliguria than colloid recipients and had lower albumin levels (133). These patients experienced no difference in weight gain or other parameters, including hypotension. The current practice is to use saline (as opposed to colloid) when additional fluids are needed, judiciously balanced with the use of vasopressors. After stopping IL-2, the fluid shift reverses rapidly and the majority of patients are discharged at or below admission weight in a median of 3 days (134). Despite improved safety and reduction in multiple treatment-related toxicities, maximal weight gain during IL-2 has remained constant in a 12-year-period review (117).

Fever and Chills

Without premedication, shaking chills develop 1 to 2 hours after bolus intravenous IL-2 and are followed by fevers up to 40.5°C

1 to 2 hours later (8,9,11,113,135,136). It was learned in these early studies that fevers, myalgias, arthralgias, and malaise could be ameliorated by pretreatment with acetaminophen and nonsteroidal antiinflammatory agents, such as indomethacin (Indocin). These agents should be started at least 8 hours before IL-2 and continued for 8 to 24 hours after the last IL-2 dose (see Table 3.1-5). The occurrence of fevers at times other than after the first or second dose of IL-2 should arouse the suspicion of infection and prompt a diligent search for a source.

Induction of circulating TNF-α has been postulated as a mechanism for the febrile response to IL-2 (103). TNF-α induction can be completely eliminated with the use of steroids (125), but the use of steroids may be contraindicated. Chills occur primarily after the first and second doses of IL-2; they can be treated with warm blankets and repeated doses of intravenous meperidine hydrochloride (Demerol). Malignant hyperthermia is extremely rare but has resulted in one death (121).

Hemodynamic and Cardiovascular Toxicity

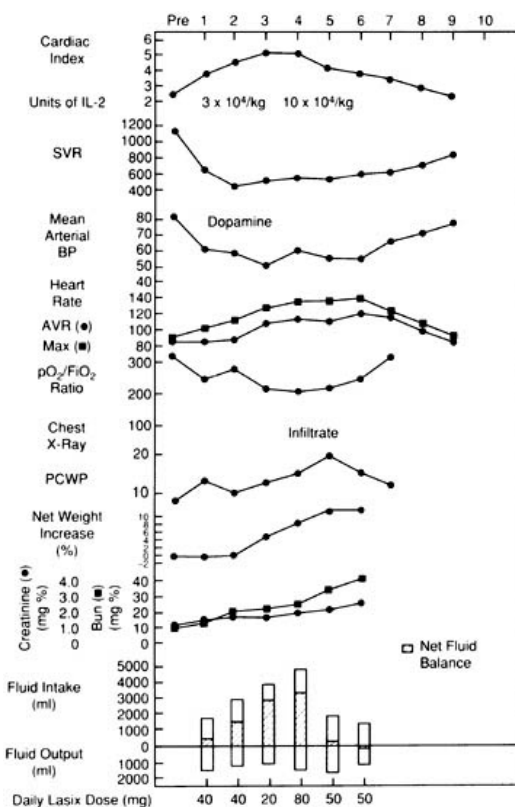
Two hours after administration of high-dose IL-2, a drop in systemic blood pressure and a rise in heart rate can be measured (128). Invasive monitoring also reveals a decrease in systemic vascular resistance and an increase in cardiac index (Fig. 3.1-1). These effects persist during therapy (128,137,138,139 and 140) and reverse within 24 to 48 hours of IL-2 discontinuation. For that reason, hypertensive patients should discontinue antihypertensive medications during IL-2 therapy. β-blocking agents should be weaned before initiating treatment. At the time of hospital discharge, all medications should be resumed because IL-2 does not have long-term antihypertensive effects (141).


FIGURE 3.1-1. Sequential hemodynamic measurements in a patient who received interleukin-2 (IL-2) (30,000 U per kg) administered three times daily on days 1 through 3, and 100,000 U on days 3 through 6. Systematic vascular resistance (SVR) (dyne·s·cm^{-5}) and mean arterial blood pressure (BP) (mm Hg) decreased. The cardiac index (L per min per m^2) increased. The pulmonary capillary wedge pressure (PCWP) (mm Hg) and net weight increased during both cycles. A rapid return to normal was noted after discontinuation of treatment. (AVR, accelerated ventricular rhythm; FiO$_2$, fraction of inspired oxygen.) (Adapted from Lee RE et al. Cardiorespiratory effects of immunotherapy with interleukin-2. *J Clin Oncol* 1989;7:7–20)

Intravenous fluid administration is the initial therapy for hypotension. Cautious use of fluids is necessary because they may compound the edema and pulmonary toxicity associated with VLS. Systolic blood pressure of less than 90 mm Hg that is not responsive to fluids (up to 1.5 L per day above maintenance) indicate the need for vasopressor support (phenylephrine, up to 2.0 μg per kg per minute) via a central line. Hypotension requiring vasopressors occurs in approximately 50% of treatments (116), although the incidence has decreased to 31% (117). Hypotension is usually preceded by oliguria. Renal-perfusion doses of dopamine (2 μg per kg per minute) should be initiated as well. As therapy nears completion, higher doses of vasopressors may be needed to maintain the systolic blood pressure, which is most labile 4 to 6 hours after each IL-2 dose. When the peak effects have passed and phenylephrine can be weaned to 0.5 μg per kg per minute, additional IL-2 dosing can be considered.

Central venous pressures and pulmonary capillary wedge pressures can decrease during therapy and should be cautiously interpreted. Fluid resuscitation based on the goal of correcting low central-venous pressures can lead to excessive hydration. As a choice of fluids, crystalloid is favored over colloid based on a randomized study that demonstrated both were equally effective in supporting blood pressure (133).

Nitric oxide is a potent vasodilator that has been implicated in the etiology of hypotension associated with IL-2 therapy. Plasma nitrate and nitrite (oxidation products of nitric oxide) levels increase during IL-2 administration (142,143,144 and 145). In preliminary clinical studies, *N*-methyl-L-arginine (inhibitor of nitric oxide synthase) reverses IL-2–induced hypotension (146). Studies are under way to confirm this finding. Another agent that may work through the nitric oxide pathway is melatonin. In one randomized study of patients, melatonin reduced grades 1 and 2 hypotension associated with subcutaneous IL-2 therapy (147).

Left ventricular ejection fraction or stroke-work index decreases significantly during high-dose IL-2 therapy and generally returns to baseline on follow-up (116,128,137,138,148,149). Lower doses of IL-2 that do not result in ventricular wall motion abnormalities impair left ventricular filling rate as measured by echocardiography or radionuclide scans (150,151). The observed cardiac dysfunction may be mediated by circulating

myocardial depressant factors, cytokines, or lymphoid cell infiltration in the heart. Myocarditis owing to lymphocyte and eosinophil infiltration has been described (152,153 and 154). Creatine kinase isoenzymes with MB-band elevations have been noted, suggesting myocardial injury or inflammation as a consequence of IL-2 administration (116,138,148,153,154 and 155). MB-band elevations were observed in 2.5% of 199 patients (156) and occurred 1 to 2 days after the last dose of IL-2. These elevations, which were generally asymptomatic and detected by routine creatine kinase screening, returned to normal in 1 to 2 days. Accompanying electrocardiogram, echocardiogram, and thallium tests revealed transient abnormalities that generally reversed by follow-up. One patient had persistent dysfunction as long as 6 months after IL-2. Cardiac catheterizations performed in patients with cardiac toxicity have generally shown normal coronary arteries. Some patients have been uneventfully retreated with IL-2 after documenting normalization of cardiac function. Decisions to retreat patients that sustain cardiac toxicity must be carefully individualized.

Myocardial infarctions, occurring in 2.5% of patients receiving high-dose IL-2 alone in early trials (14), have been virtually eliminated with aggressive cardiac screening and patient selection, including mandatory stress thallium screening for patients older than 50 years or anyone suspected of having a prior cardiac event (117). Such screening may not be necessary for low-dose IL-2 regimens because hemodynamic changes are not common (157). A history of cardiovascular disease has not been an exclusion criteria for subcutaneous IL-2.

Arrhythmias, which occur during 6% of treatment courses (15,116), are primarily supraventricular (atrial fibrillation and tachycardia), of short duration, and rarely hemodynamically compromising. Usually, they occur at the peak of systemic toxicities and in the presence of multiple electrolyte and metabolic abnormalities. The treatment includes (a) discontinuation of IL-2, (b) correction of serum abnormalities (i.e., hypokalemia), (c) maintenance of proper oxygenation, and (d) diuretics if intravascular fluid overload exists. Acute intervention, with agents such as digoxin, verapamil, diltiazem, or adenosine, is frequently used. Digoxin is generally not continued after a successful loading dose. Future retreatment is safe because only a minority of patients develop arrhythmias again.

Ventricular tachycardia is rare, usually of short duration, and generally does not require intervention except for discontinuation of IL-2. Unifocal premature ventricular contractions are not infrequent and do not require treatment with antiarrhythmics. Patients experiencing premature ventricular contractions should receive IL-2 in a monitored setting. If premature ventricular contractions become multifocal or frequent (i.e., bigemini), IL-2 therapy should probably be terminated.

Pulmonary Toxicity

High-dose IL-2 administration can result in the progressive development of interstitial pulmonary edema (128,158,159,160,161 and 162), principally caused by VLS. Transient cardiac dysfunction may compound the problem. In early series of patients receiving IL-2 and LAK cells, dyspnea at rest occurred in as many as 30% of patients. Intubation was required in 5% to 7% of patients (118,128,158). Patients receiving high-dose IL-2 alone develop severe respiratory distress in 3% of treatment courses and require intubation in less than 1% (116). The need for pulmonary intubation has diminished over time as greater experience with IL-2 has been obtained (117).

Selective transcutaneous monitoring of oxygen (O_2) saturation for patients experiencing shortness of breath during treatment has been extremely helpful. O_2 should be delivered by nasal cannula to maintain saturation above 95%. If this level is not met with 4 L per minute by nasal cannula or 40% O_2 by mask, IL-2 dosing should be discontinued. The auscultation of rales as high as the midlung fields or a markedly abnormal chest x-ray should also caution against further IL-2 dosing. Radiographic evaluation of the chest is performed selectively and the results are used to supplement the clinical examination. Although 42% to 52% of patients may develop pleural effusions radiographically (158,159,160 and 161), pleural effusions requiring aspiration are rare (<1%) (116). Chest tube drainage during IL-2 therapy should be avoided because of the concern for infectious complications. After stopping IL-2, pulmonary congestion rapidly improves if diuresis can be achieved. Nasal congestion is not uncommon during IL-2 therapy (10). Symptomatic relief can be obtained with room vaporizers and pseudoephedrine.

Pretherapy screening should include pulmonary function testing for patients with smoking histories or those with large tumor burdens in the lung. High-dose IL-2 therapy should be declined if forced vital capacity or forced expiratory volume is less than 65% of that predicted. Smokers are strongly advised to quit smoking 2 weeks before therapy. Patients experiencing hemoptysis should undergo bronchoscopy. The presence of endobronchial lesions causing significant airway obstruction have generally been an exclusion criteria for high-dose IL-2 therapy because of the concern for postobstructive pneumonia.

Renal Toxicity

Most of the effects of IL-2 on kidney function have been described as prerenal (134,156,163,164,165,166,167,168 and 169). Hypotension, impaired cardiac function, and decreased intravascular volume lead to decreased renal perfusion and prerenal azotemia. Renal carcinoma patients, by virtue of prior nephrectomy, are at greater risk for dysfunction (134,170). Oliguria, elevated serum creatinine, and low fractional excretion of sodium occur in the majority of patients receiving high-dose IL-2 therapy and resolve promptly after IL-2 discontinuation. Severe oliguria has occurred in 26% of treatment courses with high-dose IL-2 alone (15). Creatinine values higher than 2.0 mg per dL were observed in 68% of courses.

In a series of 199 patients (134), the highest mean peak creatinine value during therapy with high-dose IL-2 was 2.7 mg per dL (Fig. 3.1-2). After stopping IL-2, creatinine values returned promptly to baseline. Elevation in creatinine was dose limiting in 11% of courses. In all studies, the creatinine values returned to baseline in the majority of patients by 7 to 14 days. The use of hemodialysis has been extremely rare.
FIGURE 3.1-2. Mean serum creatinine for 199 patients during course 1 of high-dose interleukin-2 (IL-2) therapy. Mean creatinine values (± SEM) are plotted against the mean number of days when they occurred. (Discharge, day when patient went home; Follow-up, clinic visit or last available follow-up; Peak, highest creatinine value; Pre, before IL-2; Stop, when IL-2 dosing was discontinued.)

Oliguria during therapy is initially treated with fluids. If 1.0 to 1.5 total L of crystalloid fluid boluses, in addition to maintenance fluids, do not result in improved urine output, a urinary

catheter should be inserted and dopamine (2 µg per kg per minute) should be started. Although low-dose dopamine appears to be effective in improving IL-2–induced oliguria (171), the routine use of prophylactic low-dose dopamine to prevent oliguria is not justified (172). Urine output higher than 10 to 20 mL per hour should be established before additional IL-2 dosing. The development of pulmonary insufficiency during IL-2 therapy should encourage less aggressive fluid replacement to correct oliguria (and earlier use of vasopressors in hypotensive patients). Generally, when serum creatinine values reach 3.0 mg per dL, high-dose IL-2 therapy should be discontinued. Diuretics are rarely effective at the peak of renal dysfunction. After stopping IL-2 (and vasopressors, if used), diuretics should be liberally administered to initiate diuresis and promote the rapid return to normal fluid balance.

Urinalyses during therapy reveal proteinuria and bilirubinuria, as well as granular casts, which resolve completely on follow-up (134). Transient increases in white and red blood cells are also observed in urinalyses and may be attributed to the use of indwelling urinary catheters.

Other changes observed during IL-2 therapy include hypomagnesemia, hypocalcemia, hypophosphatemia, and decreased serum bicarbonate (163,164). These have not been attributed to altered renal function and have been accompanied by hypoalbuminemia. Minerals are generally replaced to achieve serum levels in the lower range of normal and bicarbonate is corrected to achieve values of greater than 19 mEq per L; albumin is generally not replaced.

Pretherapy screening for high-dose IL-2 has generally excluded patients with hypercalcemia or serum creatinine values greater than 1.6 mg per dL. Patients with ureteral stents have also been generally excluded because of the presumed risk of increased infection and stent occlusion during therapy.

Gastrointestinal Toxicity

Anorexia, nausea, vomiting, and diarrhea occur to some degree in most patients receiving IL-2 (14,118) and may be dose limiting. Many antiemetics are available to treat nausea (see Table 3.1-5) and should generally be alternated until the most effective agent is found. Droperidol is one of the most effective agents. It is equivalent to ondansetron in controlling emesis caused by high-dose IL-2 (173). At the first sign of loose or frequent bowel movements, antidiarrheals are initiated (see Table 3.1-5). Antidiarrheals are used cautiously because many patients experience abdominal distention, principally attributable to intestinal ileus, which may be aggravated by these medications. The etiology of IL-2–induced diarrhea is not clearly understood; one study observed that gut permeability does not significantly increase after 48 hours of high-dose IL-2 therapy (174). Although the incidence of severe diarrhea (grade 3–4) has diminished to approximately 20% (117), additional studies are needed to understand its cause and develop more effective therapies.

Ascites can develop and is generally not clinically compromising. Glossitis (10,175), xerostomia and stomatitis (118,176) are frequent and treated with mouth washes and nystatin if a yeast infection is suspected (see Table 3.1-5). Gastritis has been largely prevented with antihistamines, which have been used since early studies (11). Ranitidine (or an antihistamine other than cimetidine) is initiated 8 hours before IL-2 administration and continued for 8 to 24 hours after the last dose of IL-2. Gastrointestinal symptoms largely resolve 2 to 3 days after IL-2 discontinuation. Appetite is regained by 5 to 7 days. As a consequence of these side effects, a loss in lean body mass is common. Parenteral nutrition during IL-2 therapy has not been used.

Colonic necrosis and perforation is a rare complication of IL-2, occurring in 1% to 5% of patients in early series (177,178) and has not been reported recently. Bowel perforation, which may be more frequent in patients receiving IL-2 with IFN-α (179), must be addressed promptly and surgically. Small bowel mucosal ulceration and necrosis is extremely rare but must be considered in the differential diagnosis (121,178). Exacerbation of Crohn's disease during IL-2 therapy may prompt surgical intervention as well (180). The diagnosis of bowel perforation can be difficult because the symptoms can be masked by the common side effects of IL-2. Plain abdominal x-rays revealing free intraperitoneal air are diagnostic and should

be performed frequently in patients experiencing abdominal pain. After successful surgical treatment and recovery from bowel perforation, patients can be safely retreated with IL-2. Extreme caution must be used, however, to exclude residual infection with the aid of computed tomography scans and barium studies before initiating therapy. Patients with active Crohn's disease should not receive IL-2 therapy.

A rare cause of abdominal pain has been pancreatitis (181). The diagnosis can be made by computed tomography scan and elevated serum amylase or lipase. The treatment includes discontinuation of IL-2, gastrointestinal rest, and supportive measures. Retreatment with subsequent courses of IL-2 should proceed with caution. Other causes of abdominal pain may include hepatic capsular distention secondary to parenchymal congestion or hemorrhage into metastases. Splenomegaly can occur and is generally not associated with abdominal pain (182). Gastrointestinal hemorrhage is extremely rare (16,118), although occult blood in the stool is not uncommon in patients with severe diarrhea. Frank rectal bleeding during IL-2 should lead to discontinuation of IL-2 and a gastrointestinal evaluation. If bleeding is self-limited, this evaluation may be performed after recovery from IL-2 side effects and before the next cycle of therapy.

Hepatic Toxicity

Hepatic toxicity is primarily manifested as reversible cholestasis (183). Elevations in serum bilirubin and alkaline phosphatase are accompanied by more modest elevations in asparate aminotransferase and alanine aminotransferase (183,184). Only mild elevations in prothrombin time and small decreases in albumin are noted (Fig. 3.1-3). Bilirubin levels return to a normal mean of 5.6 days after stopping high-dose IL-2 (183). In a large series of patients, bilirubin values greater than 2.0 mg per dL occurred in 84% of treatment courses (see Table 3.1-2). In general, IL-2 therapy is not discontinued because of jaundice, unless the bilirubin reaches approximately 8.0 to 10 mg per dL. Hepatitis or long-lasting sequelae have not been reported; one death caused by hepatic necrosis occurred in a patient receiving continuous IL-2 (26). Because of the transient hepatic dysfunction occurring during IL-2 therapy, caution must be used when administering concomitant medications that are metabolized by the liver. Patients with diminished hepatic reserve (i.e., more than 50% of the liver replaced by tumor), are generally not eligible for high-dose IL-2 therapy.
FIGURE 3.1-3. Interleukin-2 (IL-2) treatment is associated with marked increases in bilirubin. Shown for each measured chemical analyte is the normal range, as well as the baseline and peak (or trough) values for the 261 patients receiving IL-2 therapy. (SGOT, serum glutamic-oxaloacetic transaminase; SGPT, serum glutamic-pyruvic transaminase.)

Neurologic Toxicity

High-dose IL-2 therapy may result in disorientation (14% of courses), somnolence (5%), or coma (2%) (15). Symptoms usually occur at the end of treatment and resolve completely within hours or several days of IL-2 discontinuation. Careful cognitive testing has documented full recovery (185).

Behavioral changes range from mild agitation to combativeness, which may require medication with haloperidol and occasional restraints (185). The preferred agent for agitation is haloperidol because it has not been accompanied by the secondary side effects of many other sedatives. IL-2 should be stopped at the first sign of neuropsychiatric toxicity. Premonitory signs include lethargy; impaired memory; responses that are slow, vague, or incoherent; impaired attention; irritability; mild aphasia or paraphrasia; "picking" motion; and insistence on getting out of bed (185). Symptoms of neurologic toxicity generally worsen after stopping IL-2. If severe obtundation develops, endotracheal intubation is advised to protect the airway.

Sleep disturbances and vivid dreams are not uncommon during therapy and may persist for several days after stopping IL-2. IL-2 dosing should be discontinued if these dreams become disturbing or if patients hallucinate. Fatigue is frequent (185) and may be due in part to altered sleep patterns. Paranoia or emotional lability manifested by frequent crying may also occur. Patients and their families must be extensively assured that all neuropsychiatric symptoms are transient. It is important to provide a safe physical environment and increased patient supervision

during periods of altered mental status to prevent accidental injury.

The mechanism of neurologic toxicity is unclear. It is known that IL-2 penetrates the blood-brain barrier (186) and results in increased brain-water content as measured by magnetic resonance imaging (187). Magnetic resonance imaging performed in eight patients with cancer or human immunodeficiency virus infection who experienced severe neurologic toxicity during IL-2 therapy, including coma, ataxia, hemiparesis, seizures, aphasia, apraxia, and cortical blindness, has revealed multiple white- and gray-matter lesions (188). The exact nature of these lesions is unknown, but the lesions resolved as neurologic function improved with the cessation of IL-2. Transient vision loss resembling transient ischemic attacks have been described in two patients (189). Fatal leukoencephalopathy (190) and stroke in one patient (37) have also been reported. The causal relationship of these severe central nervous system toxicities to IL-2 is unclear.

The fear of increased intracranial pressure from edema, as well as the potential for hemorrhage into lesions, has led to the exclusion of patients with brain metastasis from most high-dose IL-2 protocols. Carefully selected patients with small brain metastases and little edema have been treated without added morbidity (191).

Extremity paresthesias (192) and peripheral neuropathy (31) may result from soft tissue edema. Extremity elevation, diuretics, and use of compression garments provides symptomatic relief. Carpal tunnel syndrome requiring surgical decompression (193) and brachial plexopathy (194) are extremely infrequent.

Musculoskeletal Toxicity

Myalgias and arthralgias are frequent during IL-2 therapy (192,195). The shoulder area is a common site of symptoms and can show increased radionuclide activity on bone scan (196). Symptoms are generally controlled with acetaminophen (Tylenol) and nonsteroidal antiinflammatory agents. Symptoms may persist for several weeks, but rarely last for prolonged periods (197). One patient developed severe muscle pain and weakness after IL-2 and tumor-BCG vaccination, leading to a biopsy that revealed necrotizing myositis (198). Reactivation of rheumatoid arthritis has been described (199).

Dermatologic Toxicity

Cutaneous macular erythema begins in the face and neck 1 to 3 days after starting IL-2, and generally progresses to the trunk and extremities (175,200). Erythema is accompanied by generalized skin burning and itching and begins to resolve with mild, dry, scaly desquamation within 1 to 3 days of IL-2 discontinuation. Skin from the palms and soles may exfoliate as confluent sheets in some patients. Petechial purpura may occasionally develop in the extremities and is not clearly associated with thrombocytopenia. Skin biopsies have shown mild dermal papillary edema and perivascular infiltration of T cells expressing HLA-DR (175,200), as well as increased expression of adhesion molecules on endothelial cells (132,200).

Pruritus and desquamation, which may persist for 3 to 6 weeks in some patients, can be treated with a variety of oral or topical agents (see Table 3.1-5). Steroids are rarely required and should be avoided. Patients are advised to protect against heavy sun exposure because of increased skin sensitivity. Infrequently, IL-2 therapy results in skin blisters and moist desquamation (200,201 and 202), which can be treated with silver sulfadiazine and oral antibiotic prophylaxis. One case of fatal pemphigus vulgaris has occurred after IL-2 and IFN-ß (203). Moist desquamation of the intertriginous areas of the perineum requires vigorous local hygiene. Fournier gangrene after high-dose IL-2 (204) is extremely rare and requires prompt surgical débridement and aggressive antibiotic therapy.

Glossitis (10,175), xerostomia, and stomatitis (118,176) frequently occur during therapy and are treated with topical agents (see Table 3.1-5). Angioneurotic edema of the face is extremely rare (205) and may require discontinuation of IL-2 therapy. Diffuse hair loss and thinning may occur (175) but is generally mild and does not require the use of prosthesis. Subcutaneous IL-2 administration commonly results in self-limiting pain and inflammation at the injection site (31). Subcutaneous IL-2 administration has rarely resulted in skin necrosis (33). One patient developed lobular panniculitis at a subcutaneous injection site, which was exacerbated with subsequent intravenous IL-2 (206). IL-2-based regimens have also been implicated in the development of erythema nodosum (207) and exacerbation of preexisting psoriasis (208).

Vitiligo has been noted in 15% to 45% of patients with metastatic melanoma who receive IL-2-based therapy, and has been associated with clinical response (209,210). Vitiligo is manifested as the appearance of white patches of hair on the scalp, mustache, or beard; patches of depigmented skin on the trunk or extremities; and halo depigmentation around nevi or cutaneous tumors.

Endocrine and Metabolic Effects

Intravenous or subcutaneous IL-2 alters the circadian rhythm of stress-related hormones. ß-endorphin, adrenocorticotrophic hormone, cortisol, and corticotrophic-releasing hormone increase 4 to 12 hours after IL-2 is administered (211,212,213 and 214). The magnitude of these changes may be increased on reexposure to IL-2 (214). Epinephrine and norepinephrine levels have increased 2 hours after bolus IL-2 (136). Melatonin decreases acutely, whereas growth hormone, prolactin, follicle-stimulating hormone, and luteinizing hormone are mildly affected or not affected at all (212,213). Men receiving high-dose IL-2 experience transient decreases in plasma testosterone and increases in estradiol levels (215). Serum acute-phase reactants, such as C-reactive protein, increase within 24 hours of IL-2 administration and remain elevated during therapy (113,184,216).

Acute adrenal insufficiency during IL-2 therapy is uncommon but has been reported in one patient after presumed hemorrhage into one of bilateral adrenal metastases (217). This scenario is extremely rare. The fear of adrenal insufficiency should not preclude IL-2 treatment in patients with adrenal metastases. Bilateral adrenalectomy has generally been considered a contraindication for therapy with IL-2 because of the immunosuppressive effects

that may or may not be experienced with replacement doses of steroids. One patient received high-dose IL-2 after bilateral adrenalectomy and experienced the usual side effects of this therapy (218). No series demonstrating the efficacy of therapy in such patients, however, have been performed.

Thyroid dysfunction occurs in 13% to 41% of patients receiving IL-2 alone (219,220 and 221). A similar incidence is seen in patients receiving IL-2 with LAK cells or IFN (219,222,223,224,225,226,227 and 228). Hypothyroidism is the most common abnormality and occurs in 35% of patients receiving high-dose IL-2 alone (221). The majority of these cases are subclinical, which highlights the importance of routine testing of thyroid function during immunotherapy. Nine percent of patients received thyroid hormone replacement for moderate or severe hypothyroidism (221). The incidence of hypothyroidism increases with multiple courses or duration of IL-2 treatment. Contrary to some reports, hypothyroidism is most likely not associated with clinical response (219,220 and 221,224,227). Studies claiming an association with clinical response (222,223,226) have generally not accounted for duration of treatment or the bias that continued therapy is offered to responders. Hyperthyroidism is less frequent than hypothyroidism, occurs in 7% of patients, and is generally transient (221). Most of the time, hyperthyroidism is diagnosed on routine testing and has not resulted in symptoms or alteration of the treatment plan.

Symptoms of thyroid dysfunction may be difficult to distinguish from those of IL-2 when patients are in active treatment; routine screening of thyroid-stimulating hormone and FT4 is necessary with each course of therapy. Routine measurements of T3 and T4 are not necessary because they fluctuate widely in the majority of patients receiving IL-2 and are not useful in making clinical decisions (221). Moderate or severe hypothyroidism should be treated with levothyroxine as soon as the diagnosis is made. IL-2 dosing is generally not interrupted for the diagnosis of hypothyroidism; if the diagnosis is made before initiating IL-2, it is prudent to delay IL-2 therapy for several days while starting hormone replacement. Thyroid dysfunction is reversible but may persist for many months. The current practice is to wean levothyroxine after 1 year of replacement.

Transient decreases in serum cholesterol are common during IL-2 therapy (229,230). The significance of this finding is unknown and no intervention is required. Similarly, transient decreases in serum ferritin and increases in transferrin have been reported (231). Low serum levels of potassium, calcium, magnesium, and phosphorus are frequent (164,165) and should be repleted to achieve serum levels in the lower range of normal (see Table 3.1-5). Transient vitamin C deficiency has been reported (232) and is not commonly treated.

Hematologic Toxicity

Anemia develops with IL-2 therapy, partly because of the frequent blood draws required for treatment monitoring, and partly because of bone marrow suppression. Decreased circulating erythroid and granulocyte and macrophage progenitors have been noted during therapy (97,106). These progenitors rapidly rebound after stopping IL-2. Red blood cell transfusions were required in 14% of treatment courses in 199 patients receiving high-dose IL-2 alone (77), although a majority of patients (>70%) have required transfusions in studies of IL-2 with LAK cells (12,118). For inpatient regimens, the hematocrit is generally maintained above 28% to 30% if the patient is hemodynamically unstable.

Neutrophil counts have generally been little affected by IL-2. Increases in neutrophils are noted in the first 24 hours of IL-2, along with a shift to immature forms (77,98). Severe neutropenia during or shortly after IL-2 therapy is rare (15,16,41,97). Transient declines in neutrophils to less than 500 per μL occur in 3% of patients or less (38,99,233). Transient neutrophil dysfunction occurs as noted by decreased Fc receptor expression and decreased chemotaxis while preserving bacterial phagocytosis (98,99). These findings may explain the occurrence of infections during IL-2 therapy. During IL-2 therapy, evidence of neutrophil activation (hydrogen peroxide and hypochlorous acid production) exists, which may relate to the development of VLS (131).

Eosinophilia is common with various doses and schedules of IL-2 (eosinophil counts may reach 40,000 per μL) (9,38,39,41,77,97,110,234,235). It is progressive with continued or repetitive treatments, and counts return to baseline within 3 to 14 days after discontinuation of IL-2. It is proposed that eosinophilia is mediated by IL-5 (110,236). IL-2 infusion leads to elevated plasma levels of IL-5, which is a growth factor for eosinophils (110). Major basic protein, a product of eosinophil degranulation, increases in the circulation and is deposited in the dermis, suggesting a mechanism for the vascular leak associated with IL-2 (110).

Lymphocytopenia develops rapidly and persists during IL-2 treatment (8,23,38,41,76,77). One to 2 days after discontinuation of IL-2, lymphocytes rebound manyfold above baseline and are elevated for 3 to 7 days before returning to normal levels.

Progressive thrombocytopenia develops with repeated IL-2 infusion (15,16,77,97,237,238) and is dependent on intensity of therapy. Platelet counts may continue to drop for 1 to 2 days after IL-2 discontinuation but then return promptly to baseline. With high-dose IL-2 alone, platelet counts less than 60,000 per μL occurred in one-third of treatment courses and less than 20,000 per μL in 4% of courses (15), resulting in platelet transfusions in 2% of courses (77). Platelet counts less than 25,000 per μL have been seen in as many as 16% of patients receiving constant infusion IL-2 (237). Those patients had increased megakaryocytes observed in bone marrow biopsies, suggesting peripheral platelet loss or sequestration. Thrombocytopenia is more severe when IL-2 is combined with chemotherapy (210,239,240).

Bolus IL-2 dosing is generally discontinued when platelet counts reach 30,000 to 40,000 per μL. Hemorrhage has been extremely rare (77,121), despite low platelet counts, mildly elevated prothrombin time (77,183,241), elevated partial thromboplastin time (77,242), and decreased levels of clotting factors (238,241,242). The remaining platelet pool consists of larger, more viable and activated platelets (243). Patients are generally transfused with platelets when counts fall below 20,000 per μL, or in the presence of bleeding. Vitamin K may be administered prophylactically to patients with significantly prolonged prothrombin time (241).

Infectious Complications

The incidence of infection in patients receiving a variety of IL-2-based therapies has ranged from 0 to 45% when reviewed by Pockaj et al. (244). With high-dose IL-2 therapy, bacterial infections occur in 13% to 19% of treatment courses (244,245) and are primarily venous catheter or urinary associated. The predominant infectious organisms are *Staphylococcus aureus, Staphylococcus epidermidis*, and *E. coli.* Surveillance blood cultures during continuous infusion IL-2 drawn from an implanted central venous catheter port have been positive in as many as 56% of patients, of which nearly one-half were symptomatic (246). Proper treatment of infections includes discontinuation of IL-2, catheter removal or surgical intervention when indicated, and prompt antibiotic coverage. Opportunistic infections have generally not occurred (15), and empiric therapy for such is generally not warranted. Resumption of IL-2 therapy is possible when all evidence of infection is resolved.

Patients receiving IL-2 have experienced more frequent infections than patients receiving IFN-γ (247) or parenteral nutrition (245) in similar environments. The vigilant monitoring for infection, the liberal use of antibiotics for suspected infection, and the use of prophylactic antibiotics have resulted in decreased infectious episodes (117,244). Careful attention to prevention of infections is mandatory because IL-2 induces neutrophil dysfunction (98,99). Peripheral intravenous catheters should be changed routinely every 3 days; prophylactic antibiotics in this setting have not been commonly used. Patients with temporary or indwelling central venous catheters should receive antibiotic prophylaxis during IL-2 therapy. Central catheter sepsis has been almost completely prevented by the concomitant use of oxacillin or a first-generation cephalosporin (117,248,249). Those patients allergic to these antibiotics may be treated with clindamycin (see Table 3.1-5). Ciprofloxacin prophylaxis was not effective in preventing bacteremia in one study (16).

Fevers occurring after the first or second doses of IL-2 can usually be attributed to IL-2. Fevers occurring at other times, however, should prompt a search for an infectious etiology. Empiric broad-spectrum antibiotic therapy should be initiated after blood and urine cultures are obtained. If no source of infection is found and cultures remain negative for 3 days, the antibiotics may be discontinued. Antibiotics selected for use during IL-2 therapy should have low risk of nephrotoxicity.

Perineal hygiene is important during IL-2 therapy to prevent secondary infection. Skin edema and breakdown may have contributed to the development of Fournier's gangrene in one patient (204).

Hypersensitivity Reactions

One manifestation of immunologic "toxicity" is the development of hypersensitivity reactions to radiographic contrast agents (ionic > nonionic) after prior treatment with IL-2. Ten percent to 28% of patients develop reactions that include fever, chills, emesis, diarrhea, rash, wheezing, hypotension, edema, and oliguria within hours of intravenous contrast (59,61,250,251,252 and 253). Hospitalization for these reactions is required in as many as 10% of patients. Patients experiencing these reactions should be treated with supportive measures, including antihistamines. Planned IL-2 administration should be delayed until all clinical and laboratory abnormalities (i.e., elevated creatinine) are resolved. Steroids should be avoided because of the possibility of interfering with the antitumor response. Contrast agents have not generally been used in patients with prior reactions. Five of six patients who previously experienced reactions did not do so, however, with later reexposure to contrast (250).

Allergic reactions to chemotherapy agents in patients receiving high-dose IL-2 have been reported (254). These reactions generally occur after two courses of prior chemoimmunotherapy and 2 to 4 hours after the chemotherapy infusion. They manifest as cutaneous erythema, pruritus, hypotension, oliguria, and edema, and generally resolve in 24 to 48 hours with the aid of antihistamines and intravenous fluids.

Surgery and Immunotherapy

Part of "3.1 - Principles of Administration and Management of Side Effects "

Renal carcinoma patients who present with metastatic disease have traditionally undergone nephrectomy before initiating IL-2 therapy. The role and timing of nephrectomy in patients with metastatic disease is unclear. Forty percent of patients undergoing nephrectomy before IL-2 therapy could not subsequently receive the intended IL-2, because of disease progression (255), highlighting the pitfalls of this approach.

Patients with metastatic melanoma or renal carcinoma who have recurrent disease after achieving a partial or complete response to IL-2 therapy may derive limited benefit from surgical resection (256,257). This treatment option is worthy of consideration because retreatment with IL-2 in this context is unlikely to result in clinical responses (257).

Emergent surgery during or shortly after IL-2 has been performed primarily to treat infectious complications of therapy (177,178,204). After appropriate patient resuscitation, prompt surgical intervention has been safe.

Planned IL-2 treatment at the time of surgery for the purpose of preventing surgically induced immune suppression has also been done in limited studies. Preoperative or perioperative IL-2 has been given to patients undergoing surgery for colorectal cancer (258,259,260 and 261), gastric cancer (261), pancreatic cancer (261), non-small cell lung cancer (262), and hepatic tumors (261,263). Most of these studies have used low doses of IL-2. No major added morbidity has been noted.

Approaches to Reduce Interleukin-2 Side Effects

Part of "3.1 - Principles of Administration and Management of Side Effects "

The side effects of high-dose IL-2 therapy have diminished as experience with its administration has increased (117). Despite the improved safety, less toxic regimens or the discovery of agents that ameliorate side effects and preserve efficacy are needed. Lower doses of IL-2 with reduced side effects are currently being tested in a prospective randomized study in patients with metastatic renal carcinoma (42). Various agents expected to reduce vascular leak or hypotension during IL-2 have been studied. Agents that have not been clearly established

as beneficial in reducing side effects of IL-2 include pentoxifylline and ciprofloxacin (264,265), soluble p75 TNF-receptor IgG chimera (266), lisofylline (267), and C1 esterase inhibitor (268). Melatonin has reduced the incidence of hypotension (while increasing clinical responses) in a randomized study of 91 patients receiving subcutaneous IL-2 (147). Further studies are needed, however, to confirm these findings. *N*-methyl-L-arginine has reversed hypotension in early clinical studies (146,269) and is currently undergoing clinical testing in patients receiving high-dose IL-2. Perhaps the most efficacious approach to reduce IL-2 side effects is the simultaneous use of steroids. Many of the toxicities of IL-2 can be ameliorated with steroids (124,125), but these are not currently used clinically because of the possibility of interfering with therapeutic response.

As new antigens expressed on the surface of tumors are identified, therapies with IL-2 are beginning to focus on its administration in conjunction with vaccines targeted against these antigens (191). It is hoped that as understanding of immune responses to tumors increases, specific therapies can be applied that do not have the undesirable side effects frequently associated with nonspecific immune stimulation.

Introduction

Part of "3.2 - Melanoma "

Melanoma poses an increasingly important health problem. It is estimated that in 2000, 1 in 75 people in the United States will run the risk of developing a malignant melanoma in their lifetimes. Although surgery with or without adjuvant therapy can be curative in early-stage disease, the outlook for patients with distant metastases remains bleak. Median survival in most series ranges from 6 to 9 months with 5-year survival rates of less than 4% (1). An estimated 7,300 Americans are expected to die of

melanoma in 1999 (2). Many of these patients are young (median age, 46 to 50 years); therefore, their loss represents a societal burden in excess of their actual numbers. Although a variety of cytotoxic chemotherapy agents used either alone or in combination possess activity against metastatic melanoma, responses to these agents are usually partial and of short duration. In particular, combination cytotoxic chemotherapy results in 5-year durable responses in only 1% to 2% of patients (3), and has yet to be shown superior to single-agent dacarbazine in a randomized phase 3 trial (4,5 and 6). Similarly, although the addition of either tamoxifen or interferon-α (IFN-α) to cytotoxic chemotherapy has also been reported to improve results in phase 2 and small phase 3 trials (7,8,9,10,11 and 12), such benefits have not borne out in larger phase 3 trials (4,13,14 and 15). Thus, new approaches to the treatment of metastatic melanoma are clearly necessary.

Clinical and laboratory observations have suggested that host immunologic responses may occasionally influence the course of melanoma and have stimulated interest in the use of biologic response modifiers in melanoma. Virtually the entire repertoire of immunotherapeutic approaches have been explored; many have shown some antitumor and/or immunomodulatory activity (16). Areas of active investigation include: recombinant cytokines, either alone or in combination with adoptive immunotherapy, toxicity reduction agents, or cytotoxic chemotherapy; vaccines; monoclonal antibodies or antibody conjugates; and gene therapy. These various approaches are detailed throughout this textbook. This chapter focuses on clinical investigations using the cytokine interleukin-2 (IL-2) in melanoma.

IL-2 was first identified in 1976 as a T-cell growth factor (17); isolation of the complementary DNA clone was described in 1983 (18). Subsequently, recombinant IL-2 was shown to have potent immunomodulatory and antitumor activity in a number of murine tumor models (19). Clinical investigations with recombinant IL-2 showed that this agent possessed significant antitumor activity, producing durable complete responses (CRs) in a small percentage of patients with either metastatic melanoma or renal cell carcinoma. The high-dose intravenous (i.v.) bolus IL-2 regimen, developed at the National Cancer Institute (NCI) Surgery Branch, received U.S. Food and Drug Administration (FDA) approval for the treatment of metastatic renal cell carcinoma in 1992. FDA approval for the treatment of metastatic melanoma was granted in 1998. This section reviews the clinical investigations involving IL-2 administered as a single agent, either by the high-dose i.v. bolus route or by alternative administration schedules in patients with metastatic melanoma. It also describes results of clinical trials using IL-2 in combination with IFN-α, other cytokines, monoclonal antibodies, vaccines, cellular therapy, or chemotherapy in patients with melanoma. Finally, it also details results of various strategies aimed at dissociating the toxicity of IL-2 from its antitumor effects. As in previous reviews, doses of IL-2 are reported as international units (IU) when they are described by authors or when a conversion factor is provided by an author within the same reference. Otherwise, doses are reported in the text and tables as they are described by authors, followed by an annotation that includes the estimated IU to facilitate comparisons between treatment regimens. Per convention (20), the following conversion factors are used: 1.0 Cetus Unit = 6 IU, 1.0 Hoffman-LaRoche (HLR) Unit = 1.0 Biologic Response Modifier Program (BRMP) Unit = 2.6 IU. It must be noted, however, that other differences may exist between these various preparations (21); therefore, these simple conversions may not be entirely valid.

Approaches Using Interleukin-2 Alone

Part of "3.2 - Melanoma "

Interleukin-2 Administered as a High-Dose Intravenous Bolus

The high-dose i.v. bolus IL-2 regimen was developed at the NCI Surgery Branch in the mid-1980s. Its development was based on murine experiments indicating that intraperitoneal administration of IL-2 could induce regression of established pulmonary and hepatic metastases from a variety of tumors, including the B16 melanoma (19,20,21,22 and 23). These studies showed that the tumor response to IL-2 was dose-dependent and was enhanced when the daily dosage of IL-2 was divided over three daily doses, or when IL-2 was combined with syngeneic lymphokine-activated killer (LAK) cells. Early clinical trials performed with natural and recombinant human IL-2 at the NCI Surgery Branch established toxicity and management guidelines and a maximum tolerated dose for the high-dose bolus regimen, administered either alone or in combination with autologous LAK cells (24,25 and 26). In this regimen, IL-2 (Cetus or Chiron) was administered at 600,000 to 720,000 IU per kg intravenously every 8 hours days 1 to 5 and 15 to 19 of a treatment course. A maximum of 28 to 30 IL-2 doses per course was administered; doses were frequently withheld for excessive toxicity, however. Treatment courses were repeated at 8- to 12-week intervals in responding patients. This IL-2 regimen, administered either alone or in combination with LAK cells, produced overall tumor responses in 15% to 20% of patients with metastatic melanoma in clinical trials conducted at the NCI Surgery Branch or within the Cytokine Working Group (CWG) (formerly the Extramural IL-2 and LAK Working Group). CRs were noted in 4% to 6% of patients and were frequently durable (27,28,29 and 30). Even though studies in animal models indicated that antitumor activity was optimal when IL-2 was combined with LAK cells, randomized and sequential clinical trials comparing IL-2 plus LAK with high-dose IL-2 alone failed to show a sufficient benefit for the addition of LAK cells to justify their continued use (31,32 and 33). Studies involving IL-2 and cellular therapy (adoptive immunotherapy) are described in detail in Chapter 13.1 .

Long-term follow-up data on metastatic melanoma patients treated in early high-dose bolus IL-2 trials is now available. This data, which comes from several sources, confirms that IL-2 produces significant clinical benefits for a minority of patients. Atkins and colleagues reported a retrospective analysis of 270 patients treated on all eight trials involving high-dose bolus IL-2 conducted between 1985 and 1993 (34). Data was analyzed through fall 1996 (median follow-up, 62 months; range, 3 to 11 years). Although this population was highly selected for excellent organ function and absence of central nervous system (CNS) metastases or significant comorbidities, it included a large percentage of individuals with poor prognostic features, such as visceral metastases, multiple metastatic sites, previous systemic therapy, or a combination of these. Objective responses were seen in 43 patients (16%) [95% confidence interval (CI): 12% to 21%], including 17 CRs (6%) and 26 partial responses

(PRs) (10%) (Table 3.2-1). Responses occurred in all disease sites, including lung, liver, lymph nodes, soft tissue, adrenal, bone, and subcutaneous nodules and in patients with large tumor burdens or bulky individual lesions (Fig. 3.2-1).The median durationof response for all responders was 8.9 months (range, 2.5 months to more than 96.0 months), with 59% of complete

responders and 28% of all responders remaining long-term progression-free (Fig. 3.2-2). In addition, no patient responding longer than 30 months had progressed, suggesting that some patients actually may be "cured." Responses were less frequent in patients with baseline Eastern Cooperative Oncology Group (ECOG) performance status 1 or greater or in those patients who had received previous systemic therapy; responses were seen in equal frequency in those patients with multiple organ sites involved or visceral metastases. Fifteen responding patients had surgery or radiation therapy after IL-2 treatment; five of these remained long-term disease-free, suggesting a role for regional salvage treatment in patients who develop isolated site relapse after a response to IL-2 therapy. Forty-two patients (15.5%) were alive at last contact; the median Kaplan-Meier survival curve for the entire treated population was 11.4 months (Fig. 3.2-3). Twenty of the responding patients (47%) remained alive; 15 had survived longer than 5 years. Toxicity was typical for high-dose bolus IL-2 regimens and was largely reversible (see Chapter 3.1). Six deaths (2.2%) all were related to infection (35). No treatment-related deaths occurred in the 88 patients treated after 1991, the period when antibiotic prophylaxis became a routine component of the treatment protocol. These encouraging results led to FDA approval of this high-dose IL-2 regimen for patients with metastatic melanoma.

High-dose recombinant interleukin-2 therapy for patients with metastatic melanoma: analysis of 270 patients treated from 1985-1993. *J Clin Oncol* 1999;17:2105-2116, with permission.)

Follow-up data on this population was collected through December 1998 (36). Eighteen responding patients remained alive; 13 were continually disease- or progression-free.

Rosenberg et al. reported long-term follow-up data on 409 patients (182 with metastatic melanoma, 217 with renal cell carcinoma) treated with high-dose i.v. bolus IL-2 alone at the NCI Surgery Branch (37). Patients were treated between September 1985 and November 1996. All patients received 720,000 IU of IL-2

(Cetus or Chiron) every 8 hours, for a maximum of 15 doses per cycle as clinically tolerated. Some patients received polyethylene glycol (PEG)-IL-2 during the second treatment cycle; a randomized comparison showed that these patients fared no differently than those receiving high-dose bolus IL-2 alone, however (38). All but 35 of these patients were included in the 270 patient (34) data set described above (see Table 3.2-1). Complete regression was observed in 12 of the 182 patients (6.6%) with metastatic melanoma; partial regression occurred in 15 patients (8%). Ten patients (6%) with melanoma exhibited ongoing continuous CRs from onset of treatment for 70 to more than 148 months. In this population, CRs were significantly more frequent in patients who had not received previous immunotherapy. Only 2% of previously treated patients exhibited CRs. In addition, the chance of achieving a CR was favorably associated with the amount of IL-2 administered during the first treatment course and the maximal lymphocyte count (rebound lymphocytosis) after the first cycle of IL-2.

Interleukin-2 Administered at Lower Doses or by Alternative Schedules

Due to significant toxicity associated with the high-dose i.v. bolus IL-2 regimen and the expense involved with necessary hospitalization and intensive monitoring, various investigators have attempted to establish active regimens using lower doses of IL-2. In these regimens, IL-2 is administered either by lower-dose i.v. bolus, continuous infusion, or subcutaneous injection in an effort to maintain or enhance antitumor effects while decreasing toxicity. Lower IL-2 doses also enable prolonged IL-2 treatment. Such prolonged treatment schedules were able to further expand the number and enhance the function of circulating natural killer (NK) cells (39,40 and 41). Clinical and experimental evidence demonstrated that antibody-dependent cellular cytotoxicity (ADCC) and NK/LAK cell activity were able to be increased by relatively low and considerably less toxic doses of IL-2 (39,40,41,42 and 43). However, these biologic parameters did not correlate consistently with the observed antitumor effect. The results of these treatment approaches in patients with metastatic melanoma are presented in Table 3.2-2 .

c.i.v., continuous intravenous infusion; CR, complete remission; IL-2, interleukin-2; PR, partial remission.

The most widely used alternative IL-2 regimen was first reported in 1987 by West and colleagues (44). This treatment consists of IL-2 administered at 18 MIU per m^2 per day by continuous i.v. infusion on days l to 5 and 11 to 15, with or without LAK cells. In their first report, this schedule of IL-2 administration together with LAK cells produced tumor responses in 5 of 10 (50%) evaluable patients with melanoma (44). Toxicity was still significant, but generally considered more predictable and manageable than with the high-dose i.v. bolus IL-2 schedule. The National Biotherapy Study Group (NBSG) studied this continuous infusion IL-2 regimen, omitting the LAK cells. Objective responses were seen in 33 of 188 patients (18%) with melanoma (45). Dillman and his colleagues in the NBSG subsequently explored an alternative schedule that combined bolus and continuous infusion IL-2. In this schedule, a total of 90 MIU per m^2 of IL-2 was administered over 3 instead of 5 days (46). Treatment was administered every 2 weeks for 2 months. Twenty-two patients with melanoma were enrolled, of whom 18 had measurable disease. Two CRs and two PRs occurred 22% overall response rate (RR); (6% to 48%; 95% CI). Additional studies of this regimen and long-term follow-up data on these initial patients have not yet been reported. Legha et al. reported their results with a treatment regimen that used a slightly lower dose IL-2 (12 MIU per m^2 per day) administered by continuous infusion for 4 days on 4 consecutive weeks (47). Out of 31 patients, they observed one CR and six PRs, for a 22% RR (10% to 41%; 95% CI). Toxicity was manageable on a general hospital ward. Responses lasted from 4 to more than 18 months. Finally, Dorval et al. investigated a regimen using a slightly higher dose of IL-2. Patients received IL-2 at 20 MIU per m^2 days l to 5, 15 to 18, and 29 to 31. Although significant toxicity occurred, eight responses were reported among 24 patients with metastatic melanoma (48). However, four of these responses were transient, lasting less than a month. Based on available data, the possibility exists that this continuous infusion regimen may possess antitumor activity roughly equivalent to that of high-dose bolus IL-2. The long-term follow-up experience with this regimen, however, raises concerns about the durability of these responses. In one study, only 10 of 175 patients (6%) with melanoma and 25% of the complete responders survived more than 3 years (49).

Several investigators have studied much lower doses of IL-2 that are safely administered in outpatient settings. Vlasveld and colleagues investigated a low-dose outpatient regimen in which

IL-2 was administered at 1.8 MIU per m^2 per day by continuous infusion, 24 hours per day for 21 consecutive days (50). Although toxicity was quite manageable, no responses were observed in the 15 melanoma patients included in their phase 2 study (51). Whitehead explored a weekly bolus regimen of IL-2 in metastatic melanoma within the Southwest Oncology Group (52). This regimen produced significant short-term side effects and virtually no antitumor activity. Together, these results suggest that maximal antitumor activity likely requires dose-intensive IL-2 regimens that necessitate inpatient support. In particular, very low-dose, outpatient IL-2 regimens appear to be largely inactive in metastatic melanoma. Although no randomized comparisons with high-dose bolus IL-2 have been performed, the frequency, durability, and quality of responses to these less intensive regimens make such large-scale phase 3 trials unappealing.

Interleukin-2 Toxicity Reduction Strategies

The utility of high dose IL-2 has been limited by toxicity, many features of which resemble bacterial sepsis. Side effects include hypotension, cardiac arrhythmias, pulmonary edema, fever, increased capillary permeability, catheter-related sepsis, and, rarely, death (34,53,54). These side effects and their management are described in more detail in Chapter 3.1 . Given the limited benefits of regimens that use lower doses of IL-2 in metastatic melanoma, considerable effort has been focused on reducing the toxicity associated with high-dose IL-2 administration.

IL-2 is a potent inducer of proinflammatory cytokines, such as IL-1, tumor necrosis factor–α (TNF-α) and IFN-γ (25,55,56 and 57). These substances and others, including nitric oxide (58), likely play major roles in IL-2 toxicity. Tumor response, however, is thought to be mediated by cellular immune reactions, raising the possibility of enhancing the therapeutic index of IL-2 by dissociating its toxic effects from its antitumor effects.

A number of such toxicity dissociation approaches have been tried with limited success (Fig. 3.2-4). Most of these approaches used the high-dose i.v. bolus IL-2 schedule. The addition of dexamethasone prevented the usual induction of circulating TNF by IL-2 and was shown to significantly reduce treatment-related

toxicity, including fever and hypotension, allowing for a threefold increase in the maximum tolerated dose (59). Potential interference with antitumor efficacy limited this approach, however, (59,60) and highlighted the need for more selective ways of inhibiting the effects of secondary cytokines released in response to IL-2.
FIGURE 3.2-4. Model illustrating how interleukin-2 (IL-2) activates lymphocytes and monocytes. IL-2–activated T and natural killer (NK) cells produce interferon-γ (IFN-γ), which in turn activates monocytes leading to interleukin-12 and -15 production, further stimulating T and NK cells. Monocytes also make nitric oxide (NO) and proinflammatory cytokines, such as interleukin-1, tumor necrosis factor-α (TNF-α), and IL-6, all of which contribute to the toxicity of IL-2. Agents that block IL-1, TNF-α, and NO, such as CNI-1493, may block IL-2 toxic manifestations without interfering with T- and NK-cell activation. (iNOS, inducible nitric oxide synthase; MΦ, macrophage; sIL-1R, soluble interleukin-1 receptor; sTNFR:Fc, soluble TNF receptor Fc chimera.) (From Gollob JA, Atkins MB. Treatment of metastatic RCCA with high-dose IL-2. In: Vogelzang NJ, Scardino PT, Shipley WU, and Coffey DS, eds. *Comprehensive textbook of genitourinary oncology*, 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2000, with permission.)

More recent investigations have involved the coadministration of IL-2 with soluble receptors to TNF (soluble TNF receptor: immunoglobulin Fc), IL-1 (soluble IL-1 receptor), methylxanthine-derived TNF, or IL-1 signal transduction inhibitors (pentoxifylline or CT1501R) (61,62,63 and 64). Several of these approaches showed significant promise in animal models and inhibited some of the biologic effects associated with high-dose IL-2 in patients, without interfering with antitumor effects. In fact, responses (five CRs and four PRs) were seen in 9 out of 45 patients (20%) with metastatic melanoma who were treated as part of these largely phase 1 trials (Table 3.2-3). However, none of these agents were able to significantly block IL-2 toxicity as measured by an ability to administer more therapy with a given toxicity or the induction of less toxicity with a given amount of therapy. These results probably indicate that multiple factors, including a variety of proinflammatory cytokines, nitric oxide, and, perhaps, direct interactions of activated lymphocytes with the vascular endothelium, are responsible for the major side effects of IL-2. If this is the case, the neutralization of just one element is unlikely to abrogate toxicity. Future exploration of this approach requires a combination of cytokine antagonists or use of novel antagonists of secondary cytokines with more pluripotent inhibitory effects.

Table 3.2-3 Interleukin-2 Toxicity Reduction Strategies: Melanoma Response Rate

Trial Design	Regimen IL-2 [a]	Other Agent	N	CR/PR	RR (%)	Author (Reference)
IL-2 + CT 1501R	High-dose bolus	1-5 mg/kg i.v., q6h	12	1/0	8	Margolin et al. (63)

[a]IL-2 (Chiron) 600,000 IU/kg, i.v., every 8 h, d 1-5 and 15-19.

From Atkins MB. Immunotherapy and experimental approaches for metastatic melanoma. *Hematol Oncol Clin North Am* 1998;12:877–902, with permission.

Two potentially promising approaches involve the use of either *N*-methyl-L-arginine or CNI-1493. *N*-methyl-L-arginine is an inhibitor of nitric oxide synthase. Kilbourn and colleagues have shown that its administration is able to rapidly reverse the hypotension associated with high-dose-IL-2 in patients with metastatic renal cell carcinoma (65). Additional clinical trials of this agent in combination with IL-2 are in progress. CNI-1493 is a tetravalent guanylhydrazone compound that blocks the synthesis of proinflammatory cytokines, such as TNF and IL-1, through the inhibition of the p38 MAP kinase signaling pathway. It also has been shown to inhibit lipopolysaccharide and IFN-γ-induced nitric oxide production by blocking the upregulation of L-arginine uptake and inducible nitric oxide synthase activity (66,67). This compound is selectively taken up by monocytes; therefore, it has no effect on lymphocyte function or activation. Preclinical experiments suggest that CNI-1493 can broadly block the byproducts of macrophage activation (which may contribute significantly to the toxicity of IL-2) without interfering directly with lymphocyte activation by IL-2. In a rat hepatoma model, the use of CNI-1493 allowed administration of IL-2 at doses tenfold higher than the maximum tolerated dose and protected the animals from toxicity while enhancing the antitumor effects of IL-2 (68). These findings have formed the basis of an ongoing clinical trial of this agent in conjunction with high-dose i.v. bolus IL-2.

Potential Correlates of Response and Resistance

Various factors possibly contributing to response to IL-2 therapy are listed in Table 3.2-4 . As mentioned in the first section of this chapter, in the 270-patient database presented to the FDA, tumor response was significantly associated with a baseline ECOG performance status of 0 and an absence of previous systemic therapy (34). No association of response with number of metastatic sites or amount of therapy administered was observed. In contrast, in the NCI Surgery Branch database, achievement of CR correlated with the absence of previous immunotherapy, total dose of IL-2 administered, and degree of rebound lymphocytosis after cessation of IL-2 (37). A previous analysis also found tumor response occurred more frequently in patients who developed vitiligo and whose metastases were limited to subcutaneous tissue (69). For the past 9 years, high-dose IL-2 treatment at the NCI Surgery Branch has involved much less IL-2 administration than in previous years. Patients treated after 1991 received an average of seven (rather than 13) doses of IL-2 per cycle (70). Despite a previous observation that tumor response correlated with the amount of IL-2 administered,

no discernible decrement in RR has occurred for patients treated more recently.

Table 3.2-4 Factors Associated with Response to High-Dose Interleukin-2 (IL-2)

Factor	Author (Reference)
Pretreatment	
No prior therapy	
Any	Atkins et al. (34)
Immunotherapy	Rosenberg (37)
Performance status	Atkins et al. (34), Keilholz (72)

HLA-A1	Scheibenbogen et al. (79)
During/post treatment	
Amount of IL-2 during first course	Royal et al. (69), Rosenberg (37)
Rebound lymphocytosis	Rosenberg (37)
Vitiligo	Rosenberg (37)
Autoimmune thyroiditis	Atkins (74)

CRP, cyclic adenosine monophosphate receptor protein; IL-6, interleukin-6; LDH, lactate dehydrogenase.

A French multicenter analysis of 19 patients treated with IL-2 alone, 29 patients treated with IL-2 plus IFN-α, and 30 patients treated with *cis*-diaminedichloroplatinum/IL-2/IFN-α, correlated tumor response with pretreatment levels of IL-6, C-reactive protein (CRP), and lactate dehydrogenase (LDH) (71). In a multivariate analysis, serum CRP levels and diseases confined to skin, subcutaneous tissue, or lymph nodes (Mla or Mlb) were most predictive of response and survival. In another analysis of 65 patients treated with IL-2 and IFN-α, high serum LDH, poor performance status, and large tumor burdens were associated with poor responses to treatment and poor overall survival (72).

Other analyses correlated response with development of vitiligo (73) and other autoimmune phenomenon, such as thyroid dysfunction (Fig. 3.2-5) (74). Vitiligo has been the most extensively studied. Vitiligo was documented in 11 of 74 patients with melanoma who were followed for more than a year after receiving high-dose IL-2 alone (73); it was only seen in patients exhibiting objective tumor responses. None of 27 nonresponding patients with melanoma followed for a year or more developed vitiligo (p = .0002); likewise, vitiligo did not occur in patients receiving IL-2 for metastatic renal cell cancer. This data suggests that specific T-cell immunity may be responsible for the antitumor effects of IL-2, and that the presence of melanoma antigens are necessary to break down existing tolerance to normal host structures, such as melanocytes.
FIGURE 3.2-5. Diffuse goiter **(A)** and hypopigmentation of skin and facial hair surrounding a resolving cutaneous melanoma metastasis **(B)** in a patient exhibiting autoimmune thyroiditis and vitiligo associated with a complete response to high-dose interleukin-2 and lymphokine-activated killer cell therapy. Patient has remained in continuous complete remission since 1986. (From Atkins MB et al. Thyroid dysfunction after high-dose IL-2 therapy: an update. In: Scherbaum WA, Bogner U, Weinheimer B, Bottazzo GF, eds. *Autoimmune thyroiditis: approaches towards its etiobiological differentiation.* Berlin: Springer-Verlag, 1991;271-283, with permission.)

Many groups have attempted to correlate responses with specific host HLA alleles. The NCI Surgery Branch reported an association of tumor response with the HLA-A11 allele, especially in patients receiving tumor-infiltrating lymphocyte (TIL) and IL-2 therapy (75,76). HLA-A19 was also expressed more frequently among those melanoma patients responding to TIL/IL-2 (76). HLA-DR4 expression was associated with increased IL-2 toxicity (76). These associations were not as strong and convincing in later analyses that included larger numbers of patients (77). Another study correlated HLA-DQI expression with tumor response (p = .0017) and survival (p = .026) (78). Finally, Scheibenbogen et al. noted that HLA-CW7 and HLA-A1 phenotypes were more frequent in patients who responded to an IL-2 and IFN regimen (79). However, it has been difficult to confirm the contributions of these various phenotypes to antitumor response or toxicity, or to use such parameters to restrict this toxic therapy to those patients most likely to benefit.

Resistance to IL-2 therapy has been postulated to be owing to a number of factors, including tumor-induced immune suppression via the FAS/fas ligand interactions (80) or T-cell receptor dysfunction mediated via diminished zeta chain expression (81).

Of note, Rabinowich et al. have shown that these T-cell receptor abnormalities can be reversed by IL-2 immunotherapy and that such reversal may correlate with tumor response (82). Additional correlative laboratory studies performed in conjunction with current and future clinical trials are necessary to sort out the significance of these various molecular phenomena to the antitumor effects of IL-2.

Interleukin-2 in Combination with Other Biologic Response Modifiers

Part of "3.2 - Melanoma "

Interleukin-2 in Combination with Interferon-α

Preclinical laboratory and animal studies provide a strong rationale for clinical investigations involving the combination of IL-2 with IFN-α (83,84,85 and 86). In 1989, Rosenberg and colleagues reported promising results from a dose-escalation phase 1/2 trial using high-dose i.v. bolus IL-2 and i.v. IFN-α, both supplied by Hoffman-LaRoche (87). They examined IFN-α at 3-6 MU per m^2 and IL-2 at 2.6-12.0 MIU per m^2 per dose, each administered every 8 hours on days 1 to 5 and 15 to 19. Of 91 evaluable patients, 39 had metastatic melanoma. Tumor responses were seen in 25 patients (seven CRs, 18 PRs), including 13 patients with metastatic melanoma (three CRs, ten PRs). The RR was as high as 41% among the 27 patients treated at the highest doses of IL-2 (12 MIU/m^2) and IFN-α (6 MU). Toxicity was similar to that seen with regimens of high-dose IL-2 alone; a higher than anticipated incidence of cardiac and neurologic toxicity was observed, however. In 1995, Marincola and colleagues published a long-term follow-up of the NCI Surgery Branch experience using the combination of IL-2 and IFN-α. They reported on 189 patients, of whom 82 had melanoma (88). The overall RR was 25% (43/189) and the RR in patients with melanoma was 24% (20/82). Only one patient treated for melanoma was a long-term progression-free survivor, however. They concluded that this combined regimen provided no obvious benefit relative to high-dose bolus IL-2 alone.

The CWG performed a randomized phase 3 comparison of i.v. bolus IL-2 with or without IFN-α. IL-2 was administered either alone at 6 MU per m^2 per dose (16 MIU/m^2) or at 4.5 MU per m^2 per dose (12.6 MIU/m^2) in combination with IFN-α at 3 MU per m^2 per dose (89). As with the NCI Surgery Branch study, both the IL-2 and IFN-α were supplied by Hofmann-LaRoche. The toxicities of these regimens were essentially equivalent and resembled that of high-dose bolus IL-2 alone. Eighty-five patients were enrolled, with 44 patients randomized to IL-2 alone and 41 to IL-2 plus IFN-α, respectively. Responses were seen in only six patients, two of whom (5%) received IL-2 alone and four of whom (10%) received both IL-2 and IFN-α. No complete responses occurred on either arm. The study was terminated early due to disappointing results on both arms and the low likelihood that the addition of IFN-α would result in a meaningful improvement over standard regimens involving IL-2 alone.

Other investigations involving combinations of IL-2 and IFN-α are listed in Table 3.2-5 . Karp combined thrice weekly IFN-α with low-dose IL-2 (60,000 IU/kg) administered as an i.v. bolus injection every 8 hours for up to 14 doses on days 1 to 5 and 15 to 19 (90). He observed six responses (one CR and five PRs) among 38 evaluable patients (15% RR: 4% to 27%, 95% CI). Three of the six responses endured over 12 months, with two responses ongoing more than 26 and 40 months.

c.i.v., continuous intravenous infusion; CR, complete response; IFN-α, interferon-α; IL-2, interleukin-2; PR, partial response.

[a]Total of 53 patients with metastatic malignancy, of which only melanoma is shown.

Keilholz and his colleagues explored two alternative regimens. Patients either received IFN-α 10 MU per m^2 per day subcutaneously for 5 days, followed by IL-2 (18 MIU/m^2/day) administered by continuous infusion for 5 days, or the same schedule of IFN-α followed by a decrescendo schedule of IL-2. This decrescendo schedule required IL-2 to be administered at 18 MIU per m^2 over 6 hours, followed by 18 MIU per m^2 over 12 hours, 18 MIU per m^2 over 24 hours, and, finally, a maintenance dose of 4.5 MIU per m^2 per day for 72 hours (92). This decrescendo regimen was designed to induce optimal IL-2 receptor expression and minimize toxicity by avoiding the induction of high circulating levels of secondary cytokines. The continuous-infusion IL-2 schedule produced five responses in 27 patients (one CR and four PRs; 18% RR; 6% to 36%; 95% CI), whereas the decrescendo IL-2 schedule yielded 11 responses, also in 27 patients (three CRs, eight PRs; 41% RR; 22% to 61%; 95% CI). The decrescendo IL-2 and IFN-α regimen produced tumor responses in 22% of patients whose disease had progressed after (dimethyl-triazeno)imidazole carboxamide (DTIC) chemotherapy, and had an impressive 17-month median survival (91). In addition to encouraging antitumor activity, this regimen had a more favorable toxicity profile than the more conventional schedule. This decrescendo IL-2 and IFN-α schedule has been compared to the same schedule plus cisplatin in a large-scale phase 3 randomized trial conducted within the European Organization for Research on Treatment of Cancer (EORTC) (92). Sixty-six eligible patients were randomized to the IL-2/IFN-α arm, with responses observed in 18% of patients (four CRs and eight PRs). Although the RR was less than that seen with the cisplatin IL-2/IFN-α combination arm, overall and progression-free survival were equivalent (see Interleukin-2-Based Biochemotherapy).

Investigators at the M. D. Anderson Cancer Center added IFN-α to their continuous infusion IL-2 regimen. They observed only two PRs out of 23 patients (8% RR; 1% to 28%; 95% CI) (93). Kruit and his colleagues enrolled 57 patients with melanoma in a phase 2 multicenter Netherlands-based trial of IL-2 at 7.8 MIU per m^2 per day (HLR) by continuous infusion, and IFN-α at 6 MU, administered subcutaneously on days 1 to 4 every 2 weeks. Responses were seen in 16% of the 51 evaluable patients (eight responses; one CR, seven PRs) (94). Whitehead et al. explored a similar regimen, 2 MU per m^2 per day of IL-2 (HLR) plus IFN-α, with no responses occurring in 14 melanoma patients (95). Castello and colleagues also demonstrated no responses among 15 patients with melanoma who were treated with a similar regimen (except IL-2 was administered as a subcutaneous injection) (96).

Despite promising preclinical investigations and encouraging clinical results from a few regimens, there is no convincing evidence supporting the benefit of the IL-2 and IFN-α combination over high-dose IL-2 alone. Nonetheless, because some IL-2 and IFN-α combinations have produced tumor responses at doses of IL-2 that are inactive when used alone, this combination has served as a building block for clinical trials in which other biologic agents or cytotoxic chemotherapies have been added.

Interleukin-2 in Combination with Other Immune-Activating Agents

IL-2 is an attractive agent to combine with other cytokines or immunomodulatory molecules. Its multiple immunomodulatory properties create many opportunities for potential additive or synergistic antitumor effects. A variety of clinical trials with such combinations have been performed (Table 3.2-6).

Table 3.2-6 Interleukin-2 with Other Immune Activating Agents

c.i.v., continuous intravenous infusion; IFN-α, interferon-α; IFN-γ, interferon-γ; IL-2, interleukin-2; IL-4; interleukin-4; FAA, folic acid antagonist; TIL, tumor-infiltrating lymphocyte.

[a]Patients initially received intrasplenic local IL-2 therapy followed by i.v. infusion.

[b]Two sequential randomized dose escalation studies of subcutaneous IL-2, with and without levamisole.

[c]Randomized study with IL-2 and IFN-α, with or without histamine; last two rows represent patients receiving IL-2, IFN-α 2, and histamine.

A few trials have examined combinations of IFN-γ and IL-2. IFN-γ is a cytokine with potent immune-enhancing activity.

It induces macrophage and granulocyte activation, enhancement of major histocompatibility complex (MHC) class I and II, expression and tumor antigen expression. The NCI Surgery Branch studied IFN-γ administration before standard high-dose i.v. bolus IL-2 (97). Some of these patients also received TIL cells. Only 2 of 20 patients exhibited tumor responses; none of the five patients receiving IFN-γ, IL-2, and TIL responded. Other phase 1 trials combined IFN-γ with lower dose, more protracted IL-2 administration schedules but did not produce definitive clinical antitumor activity in any patients with melanoma (98,99).

Several investigators have explored IL-2 in combination with IL-4 (100,101). One rationale for this combination was enhancing tumor-specific T-cell responses and nonspecific NK/LAK cell-mediated cytotoxicities. These studies have been disappointing, however, with few tumor responses and minimal enhancement of IL-2 immunomodulatory effects observed. Although IL-4 continues to be of interest as a potential *ex vivo* dendritic cell (DC) growth factor in combination with granulocyte-macrophage colony-stimulating factor (102), combinations with IL-2 have not been pursued further.

Creagan and his colleagues at the Mayo Clinic investigated the combination of IL-2 and levamisole, an antiparasitic agent purported to have immunostimulatory properties (103). Levamisole has shown some potential benefit as an adjuvant to surgical resection in patients with high-risk melanoma (104,105). Creagan performed a phase 2 trial of subcutaneous IL-2 and levamisole that demonstrated no objective responses in 19 patients with melanoma (103). Ahmed and his colleagues at the Royal Marsden Hospital explored a combination of IL-2 at 3 and 5.4 MIU per m^2 per day, subcutaneously, with or without levamisole (106). Responses were seen only in patients receiving IL-2 alone.

Flavone-8-acetic acid (FAA) potentially enhances NK cell activity and synergizes with IL-2 in animal tumor models (107). Thatcher and colleagues performed a phase 2 trial of IL-2 combined with FAA in patients with metastatic melanoma (108). IL-2 was first administered intrasplenically via femoral catheter, then by i.v. bolus on alternate days; FAA was administered intravenously as a 6-hour infusion before the IL-2. Five responses occurred in 34 patients, including one CR. Responses occurred mainly in nonvisceral sites. Thatcher et al. thought that this RR was not significantly better than that of IL-2 alone. O'Reilly explored FAA combined with continuous infusion IL-2, observing three responses (one CR, two PRs) in 21 patients (overall RR of 14%) (109).

Interest has been generated in the combination of IL-2 with histamine (110). Histamine, a biogenic amine, can inhibit monocyte-derived oxygen-free radical formation. Some investigators believe that monocyte free radical formation inhibits T-cell and NK-cell tumoricidal activity. Randomized trials are currently exploring the value of adding histamine to IL-2 in patients with metastatic melanoma or acute leukemia. One must conclude from the evidence above that no convincing information currently exists that any immunologic agent can add to the antitumor activity of IL-2 alone in metastatic melanoma.

Interleukin-2 and Monoclonal Antibodies

A variety of rationales have been proposed for combining IL-2 with monoclonal antibodies (MAbs) in the treatment of melanoma. Antibodies can bind to relatively unique tumor antigens, making the tumor cells more receptive to clearance by activated immune cells and IL-2 has been shown to enhance such antibody-dependent clearance (ADCC) (42,43,111,112,113 and 114). Alternatively, antibodies may be directed at molecules on the surfaces of host effector cells (e.g., CD3, CD2, CD16), which may activate them or make effector cell populations more receptive to IL-2-mediated expansion, or both (115,116,117 and 118). Furthermore, biotechnology advances have facilitated the creation of bispecific monoclonal antibodies that are capable of binding to effector and tumor cells and antibody:cytokine conjugates. These constructs may facilitate delivery of effector cells or cytokines to tumor cell surfaces (119,120). Clinical trials involving IL-2 and MAbs are displayed in Table 3.2-7 .

[b]Anti-CD3 monoclonal antibody.

[c] Anti-CH 14.18 chimeric monoclonal antibody.

[d]Both groups of patients received IL-2 for 7 wk.

[e]Number of patients with metastatic melanoma: 15 out of 29.

The largest amount of clinical research activity has focused on ganglioside-specific MAbs. Gangliosides are glycolipid molecules composed of oligosaccharide chains linked to ceramide fatty acid cores. Melanoma cells are rich in gangliosides, two of which, GD2 and GD3, appear to be upregulated by the transformation of melanocytes (121,122). Ganglioside structures, which can trigger T-cell activation when bound, are also present on the surface of certain T cells (115). Phase 1 clinical trials of unconjugated ganglioside-specific monoclonal antibodies have shown they can reach tumor sites after systemic administration. Some tumor responses have been observed with R24 (anti-GD3), 3F8 (anti-GD2), and other murine MAbs (122,123,124,125,126 and 127).

The anti-GD3 ganglioside antibody, R24, has been the MAb most actively investigated in combination with IL-2. The initial study was performed by Bajorin and colleagues at the Memorial Sloan-Kettering Cancer Center (128). In this study, IL-2 was administered at 6 MIU per m^2, intravenously, over 6 hours on days 1 to 5 and 8 to 12, whereas R24 was given at one of four dose levels between 1 and 12 mg per m^2 daily on days 8 to 12. T-cell activation and the magnitude of the rebound lymphocytosis seemed to correlate with R24 dose level. Of the 20 treated patients, there was one PR and two minor responses. Human antimouse antibody (HAMA) formation was noted to occur surprisingly early—in less than 7 days—in some patients. In a study by Soiffer et al., R24 MAb was combined with very low dose, continuous-infusion IL-2 (129). IL-2 was administered for the entire 8-week period; R24 was administered during weeks 5 and 6. Twenty-eight patients with metastatic melanoma were enrolled, with only one PR (regression of liver metastases from an ocular primary melanoma) observed. Alpaugh et al. reported the results of a phase 1b trial that used a 5-day continuous infusion of R24 followed by 3 weeks of subcutaneous IL-2 and IFN-α (130). Twenty melanoma patients were enrolled. Tumor biopsies obtained on days 8 (before the initiation of IL-2 and IFN-α) and 29 showed chronic inflammation relative to pretreatment samples; it is difficult to determine to what extent the R24 may have contributed to this inflammatory reaction, however. In any event, no objective responses were seen in the 18 evaluable patients.

In an effort to avoid HAMA responses and potentiate ADCC, Albertini and his colleagues at the University of Wisconsin performed a phase 1 clinical trial using continuous-infusion IL-2 and the chimeric anti-GD2 ganglioside antibody 14.18 (131). This chimeric human/mouse antibody combines the antigen-binding Fab fragment of mouse 3F8 MAb with the heavy and light chains of a human immunoglobulin molecule. The combination of the chimeric 14.18 antibody and IL-2 led to enhanced ADCC and LAK activity and reduced human antichimera antibody (HACA) formation. Antitumor activity was observed in 2 of 24 patients (one CR, one PR). One case of peripheral neuropathy was observed; nerve pain was the dose-limiting toxicity. Concomitant laboratory evaluations suggested that the addition of IL-2 to the 14.18 antibody might have suppressed antiidiotypic antibody formation (132).

Although some tumor responses have been observed with combinations of IL-2 and antibodies directed against gangliosides, the limited antitumor activity seen with this approach does not justify further clinical investigation of this strategy in patients with metastatic melanoma. Either more potent MAbs or additional information on how to optimally combine MAbs with IL-2 are necessary for this approach to be pursued further.

The use of IL-2 in combination with MAbs directed against T-cell antigens also has been explored. Preclinical studies support the concept that anti-CD3 MAb administered at low doses can activate T cells to release cytokines, proliferate, and mediate antitumor effects (116,117 and 118,133). Sosman and colleagues explored doses of anti-CD3 antibody OKT3 from 10 mg to 600 mg, followed by low-dose i.v. infusion of IL-2, subcutaneous IL-2, or high-dose bolus IL-2 (134,135,136 and 137). However, these trials failed to demonstrate that activated T cells (those expressing CD25, the high-affinity IL-2 receptor) could be expanded *in vivo.* Furthermore, when OKT3 was combined with high-dose IL-2, only one objective response was observed in 16 patients with melanoma (137). Although this approach has been disappointing, it is possible that this strategy may produce better results if bispecific MAbs or fusion antibodies that are able to activate effector cells directly at tumor cell surfaces can be developed.

In an effort to enhance ADCC at the tumor site, Gillies et al. linked IL-2 to the carboxy-terminus of the ch14.18 molecule (138). This fusion protein binds to GD2-expressing tumor cells *in vitro* as avidly as the native ch14.18 antibody, mediating ADCC against GD2-expressing melanoma cells by stimulating both cytotoxic T cells and NK cells that express IL-2 receptors, regardless of whether they express Fc receptors. Animal models using this fusion protein show it to be superior to IL-2 or ch14.18 alone (or both combined at comparable doses) (119,139,140). Phase 1 trials of this fusion protein in melanoma patients have recently been initiated.

Interleukin-2 and Tumor Vaccines

It has long been evident that melanomas possess tumor antigens that can be recognized by the host immune system (141); consequently, vaccination therapy with a variety of crude melanoma cell preparations has been pursued since the 1970s. Whereas some of these approaches appear promising, their beneficial effects have yet to be confirmed in phase 3 trials (141,142,143,144,145,146 and 147). Efforts to develop an effective vaccine have been hindered by a combination of poor immunogenicity of relevant antigens, tumor-reinforced tolerance, antigen shedding, and tumor heterogeneity. Nonetheless, any successful induction of T-cell immunity to a tumor through vaccination could be enhanced, theoretically, by subsequent IL-2 administration. As a consequence, several investigators have examined their vaccines in combination with IL-2 (Table 3.2-8).

Table 3.2-8 Interleukin-2 Combined with Vaccines

Author (Reference)	IL-2 Dose	Route	Schedule	Type of Vaccine	No. of Doses	Additional Therapy	N	Response CR	PR	Total Response (%)

CR, complete remission; IL-2, interleukin-2; PR, partial response.

[a]Study included four arms, of which responses were seen only in the IL-2 + vaccine arms.

[b]Only 8 out of 36 patients studied had measurable disease.

Adler and colleagues have investigated an allogeneic liposomal melanoma vaccine with or without systemic or regional low-dose IL-2 administration (148). Nine of 24 patients with melanoma experienced objective responses, including six responses (three CRs, three PRs) in the ten patients who received the vaccine plus low-dose regional IL-2. However, follow-up reports or confirmatory studies on these results have not been forthcoming. Oratz and colleagues encapsulated their polyvalent shed-melanoma-antigen vaccine into liposomes combined with IL-2 in an effort to increase its

immunogenicity (149). Thirty-six patients with stage IV melanoma received this combination vaccine, followed by daily low-dose IL-2 injections (2–5 × 10^5 IU) for 2 weeks. The addition of IL-2 was perceived to induce a marked increase in frequency and duration of vaccine-induced delayed-type hypersensitivity responses relative to historical controls who received the vaccine alone (149). Of 28 patients whose metastatic disease had been completely resected at entry, 12 have been followed up for 2 years, nine of whom (75%) remained alive, compared to only 15% to 30% of "matched" historical controls. Two tumor responses (one CR, one PR) were observed in the eight patients with measurable disease. Longer follow-up and randomized controlled studies are necessary to determine the true value of this combination.

With advances in molecular biology and better understandings of immune recognition, efforts have shifted toward the study of defined-antigen vaccines. A number of melanoma-specific proteins that represent targets for cytotoxic, tumor-specific T cells have been cloned and characterized (150,151 and 152). The protein antigens and peptides include embryonic proteins (MAGE family), as well as tissue-restricted (melanocyte) proteins such as tyrosinase, MART-1, and gp100 (153,154,155,156,157,158 and 159). Rosenberg and colleagues investigated the immunologic and clinical effects of an 9-amino-acid peptide from the gp100 protein (residues 209–217) and a mutated version of this peptide (gp100 peptide 209-2M), which binds HLA-A2.1 more effectively in combination with incomplete Freund's adjuvant (160). Rosenberg also studied the mutant gp100:209-2M peptide in combination with high-dose IL-2 (161). Whereas the mutated peptide (gp100:209-2M) alone was quite effective in inducing specific T-cell responses (10 of 11 patients), few antitumor effects were observed. In contrast, 13 of 31 patients (42%) who received the peptide together with high-dose IL-2 experienced objective tumor responses. A confirmatory trial of this combination is currently under way within the CWG, and a phase 3 trial randomizing patients to either high-dose IL-2 alone or in combination with the gp100:209-2M peptide is contemplated.

Efforts to define additional peptide antigens and antigen-presenting strategies may yield more potent and broad-spectrum vaccines to be tested in combination with IL-2. Mulé diacritical and colleagues, for example, have demonstrated in animal models that low-dose IL-2 can enhance the antitumor effects of DC-based vaccines that utilize tumor lysates as sources of tumor antigens (102). These effects provide a rationale for combining IL-2 with DC-based vaccine approaches in melanoma.

Interleukin-2–Based Biochemotherapy

Part of "3.2 - Melanoma "

Many investigators have studied the effects of combinations of IL-2-based immunotherapy and cytotoxic chemotherapy on melanoma. IL-2 plus DTIC combinations have produced considerable toxicity while yielding RRs of only 13% to 33% (4,20,162,163). More encouraging results have been observed with studies that combine cisplatin-based chemotherapy with high-dose IL-2 alone or lower doses of IL-2 combined with IFN-α (164,165,166,167,168 and 169). Composite results from a variety of inpatient regimens show a RR of approximately 50%, with 10% to 20% CR (Fig. 3.2-6) and a median survival of approximately 11 to 12 months (Table 3.2-9). PRs were frequently of short duration (median, 4 to 6 months in most studies) and were not associated with prolonged survival. In some studies, up to 60% of patients who obtained CRs remained long-term progression-free (169). Overall, approximately 10% of all patients appear to be disease-free for more than 2 years (4). As with high-dose IL-2 alone regimens, relapses beyond 2 years are extremely uncommon (169). In contrast to chemotherapy or immunotherapy alone, responses were seen in all disease sites with equal frequencies and no clear dose–response relationship for IL-2 was apparent. Although some investigators reported partial regressions of preexisting small CNS metastases (164,170), most trials excluded such patients, and the CNS was actually a common

site of initial relapse (167). Responses were seen in patients with previous chemotherapy (168), and appeared to be associated with the frequent development of vitiligo (164). Cisplatin appeared to be required for synergy (168), and activity appeared greatest when chemotherapy was administered first (165). Early studies documented that cytotoxic chemotherapy did not interfere with ongoing responses to immunotherapy, enabling closer integration of these two modalities (166). The apparent higher RR and 10% durable, unmaintained CR rate suggests that these combination regimens may be superior to either chemotherapy or immunotherapy alone, and that synergistic interactions between the IL-2 and cisplatin-based chemotherapy may contribute to these improved results. Furthermore, two compilations of data from large numbers of patients seem to indicate that biochemotherapy produces RRs superior to those of chemotherapy or immunotherapy alone. Keilholz et al. collected data on 631 patients treated with IL-2 alone or in combination with IFN-α or cytotoxic drugs (171). In this analysis, patients receiving IL-2, IFN-α, and chemotherapy experienced an RR of 44.8%, compared with RRs of 20.8% and 14.9%, respectively, for IL-2 and IFN-α and IL-2 alone. Median survival, however, was not significantly improved. Allen et al. performed a metaanalysis of 168 published trials involving 7,711 patients with metastatic melanoma treated with either chemotherapy, IL-2-based immunotherapy, or biochemotherapy (172). Once again, patients treated with a combination of IL-2, IFN-α, and cytotoxic chemotherapy experienced a significantly greater RR (p <.0001). However, these early biochemotherapy regimens (see Table 3.2-9) involved extensive inpatient treatment and substantial toxicity, expense, and patient time commitments, making widespread use or phase 3 investigation impractical.

Inpatient Concurrent Biochemotherapy Regimens

Several investigators have endeavored to enhance the practicality and tolerability of inpatient biochemotherapy. The most promising of these approaches are displayed in Table 3.2-10 . Legha et al. developed a regimen in which cisplatin, vinblastine, and DTIC (CVD) chemotherapy was administered concurrently with IL-2 and IFN-α immunotherapy (169,173). Therapy was administered in an inpatient setting over 5 days every 3 weeks. A maximum of six cycles was administered to responding patients. This regimen produced responses in 34 out of 53 patients (11 CRs, 23 PRs; RR 64%), with a median response duration of 6.5 months. The median time to disease progression and median survival for all patients were 5.0 months and 11.8 months, respectively. Five patients (9%) remained in continuous CR for 50 to 61 or more months. The principal side effects consisted of myelosuppression with 64% incidence of febrile neutropenia and 48% incidence of bacteremia. Other common side effects included nausea, vomiting, and anorexia, fluid retention, and hypotension. Hypotension, infections and severe thrombocytopenia were more common in patients who received three or more cycles of therapy. Neurologic, renal, and cardiopulmonary toxicities were uncommon. Antitumor activity appeared equivalent to the other biochemotherapy combinations, whereas the toxicity was considerably more manageable.

bio, continuous infusion IL-2 + subcutaneous interferon; CNS, central nervous system; CR, complete response; CVD, cisplatin, vinblastine, dacarbazine; HD, high dose; IL-2, interleukin-2; IFN-α, interferon-α; PR, partial response; RR, response rate; tam, tamoxifen.

McDermott et al. completed a phase 2 pilot trial of a version of the Legha concurrent regimen that was modified slightly to further reduce toxicity and enhance convenience (174). Modifications included using antibiotic and granulocyte colony-stimulating factor (G-CSF) prophylaxis and more aggressive antiemetics, prohibiting long-term central venous access, and restricting therapy to a maximum of four cycles. A total of 131 treatment cycles was administered to 44 patients. These patients displayed inordinate amounts of poor prognostic features—82% of patients had visceral metastases and 75% had more than one site of metastasis. In addition, 75% of patients received previous systemic therapy, including 53% who received previous IFN-α. Significant toxicities necessitating dose reductions were limited primarily to gastrointestinal toxicity (nausea and vomiting) and myelosuppression. The frequency of these toxicities was reduced with the incorporation of serotonin receptor-blocking antiemetics and G-CSF into the treatment regimen. Hypotension and renal insufficiency were uncommon, occurring in 11% and 3% of treatment cycles, respectively; significant cardiopulmonary toxicity was not observed. Hypotension was transient; all episodes resolved in less than 24 hours and were not associated with any symptoms or clinical sequelae. Neurotoxicity was only observed in two patients with resected brain metastases who had received previous cranial irradiation. Tumor responses were observed in 19 of 40 (48%) evaluable patients (eight CRs, 11 PRs). Responses occurred in all disease sites, including liver and bones. Responses were seen in 11 of 23 patients (48%) who had previously received IFN-α therapy. The median response duration was 6.5 months (range 2 to more than 22 months), with two patients remaining progression-free. Eleven responders (including four patients who had achieved CRs) had their initial relapses in the CNS. This high frequency of isolated or initial CNS relapse was believed to be the major explanation for the relative lack of durable responses. The observation by Moussieu et al. that small CNS metastases may respond as well as systemic metastases to biochemotherapy (170), however, questions this explanation. The extent to which poor prognostic characteristics of study patients, their heavy previous exposure to IFN-α, or any modification of treatment regimen impacted on the number of durable complete responses observed, remains speculative.

O'Day et al. (175) modified Legha's concurrent biochemotherapy regimen by adding tamoxifen and administering IL-2 in a decrescendo fashion similar to that described by Kielholz et al. (176). G-CSF was also added to prevent febrile neutropenia and infection. They have reported the results of their first 35 patients. Thirty-four percent of patients had received previous chemotherapy, 91% had multiple visceral sites of metastases, and 17% had small brain metastases. Treatment was well tolerated, with the majority of patients being discharged on day 5

and readmission being required in only 6% of cycles. One treatment-related death occurred due to a CNS bleed. Responses were seen in 57% of patients (20% CR) with all CRs confined to 23 patients in the chemotherapy naïve population. Five patients underwent surgical resection of residual low-volume disease. Although these results are encouraging, the median follow-up of 8.7 months was too short to assess either long-term efficacy of this approach or the value of salvage surgery in this population. In a follow-up trial, escalating doses of tamoxifen were added to the regimen. Tumor responses were seen in 12 of 27 patients (177).

Outpatient Biochemotherapy Regimens

The observation that the activity of cisplatin and IL-2-based regimens may be more related to the proximity of biologic and cytotoxic components rather than actual doses of individual agents has raised the possibility of developing regimens suitable for outpatient administration (Table 3.2-11). With this in mind, Flaherty et al. developed a regimen in which patients received cisplatin and DTIC on day 1 and i.v. IL-2 (24 MIU/kg) on days 4 to 8 of a 21-day cycle (178). Responses were seen in 41% of patients. A similar regimen (except that IFN-α was added) was tested by the CWG. In this randomized phase 2 trial, patients were assigned to receive IL-2 either by subcutaneous or i.v. injection (179). Eighty-two patients were enrolled. Forty-four patients were randomized to the i.v. IL-2 arm and 38 to the subcutaneous IL-2 arm. The two arms were well-balanced for performance status, extent of disease, and previous IFN-α therapy. Seventy-six percent of all patients had visceral metastases and 23% had received IFN-α therapy before. Tumor responses were observed in 37% of patients (12% CRs, 25% PRs) on the i.v. IL-2 arm and 19% of patients (3% CRs, 16% PRs) on the subcutaneous IL-2 arm. Toxicity was comparable, except a higher incidence of neutropenia occurred on the i.v. IL-2 arm.

Total		459	50 (11)	107 (23)	34	

CBDT, cisplatin, carmustine, dacarbazine, tamoxifen; CDDP, cisplatin; c.i.v., continuous intravenous infusion; CR, complete response; CWG, Cytokine Working Group; DTIC, dacarbazine; IL-2, interleukin-2; IFN-α, interferon-α; PR, partial response; tam, tamoxifen.

Thompson et al. (180) evaluated a regimen involving cisplatin, carmustine, DTIC, chemotherapy on day 1, daily tamoxifen (CBDT), and subcutaneous IL-2 and IFN-α on days 3 to 9. Grade 3 and 4 nausea occurred in 32% of patients; hospitalization for supplemental i.v. hydration was necessary in 11% of treatment cycles. An overall RR of 42% (ten CRs, twelve PRs) was observed in 53 patients, with a median overall survival of 11 months.

Atzpodien et al. (181) reported on outpatient regimens involving carboplatin and DTIC or cisplatin, carmustine, dacarbazine, and tamoxifen (CBDT) for several cycles, followed by subcutaneous IL-2 and IFN-α. These regimens produced responses in 35% and 55% of patients, respectively, with minimal reported toxicity. Of note, a phase 2 trial of outpatient CBDT chemotherapy (days 1 to 3) with IL-2 administered for 3 days before chemotherapy and IFN-α administered concurrently (days 1 to 3) produced an RR of only 23% and more thrombocytopenia and nausea than were observed with chemotherapy alone (182). Whether these regimens are truly suitable for routine outpatient use and how they compare with either chemotherapy alone or more thoroughly tested inpatient biochemotherapy regimens remains to be determined.

Randomized Trials Involving Interleukin-2-Based Biochemotherapy

Several randomized phase 3 trials comparing biochemotherapy regimens to immunotherapy or chemotherapy alone have been initiated (Table 3.2-12). Initial results have been disappointing, however. The EORTC Melanoma Group has examined the value of adding cisplatin to decrescendo IL-2 and IFN-α in a randomized phase 3 trial. Although the cisplatin-containing

arm produced a significantly higher RR (35%) than IL-2/IFN alone (15%), responses were of shorter duration and no increase in the number of durable CRs or overall survivals occurred (192). The NCI Surgery Branch has pursued a different approach, reporting the results of a study comparing the combination of cisplatin, DTIC, and tamoxifen and high-dose bolus i.v. IL-2 plus subcutaneous IFN-α to cisplatin, DTIC, and tamoxifen alone (183). Chemotherapy was administered on days 2 to 4, and IL-2 and IFN-α were administered on days 5 to 8 on the biochemotherapy arm. Tamoxifen was administered throughout. Cycles were repeated at 21-day intervals, with up to 4 cycles administered to responding patients. One hundred two patients were enrolled, with 52 randomized to receive chemotherapy and 50 randomized to receive biochemotherapy. The two arms were balanced for most parameters, although twice as many patients with performance status 1 or 2 were enrolled on the biochemotherapy arm. The biochemotherapy regimen produced a slightly higher objective RR than the chemotherapy alone (44% vs. 27%, p = .071). Responses were generally of short duration in each treatment group, however; as a consequence, the improved RR did not translate into an improvement in number of durable CRs or overall survival rates for patients on the biochemotherapy arm. A trend toward survival advantage occurred in patients receiving chemotherapy alone (median survival, 15.8 months vs. 10.7 months; p = .052). These discouraging survival results and the low number of durable CRs (especially for a regimen containing high-dose bolus IL-2) raised concerns that chemotherapy may have diminished activity of immunotherapy in this combination. With only approximately 50 patients enrolled in each arm and the slight imbalance in performance status noted, however, this study was too small to definitively eliminate a benefit for biochemotherapy in melanoma.

Table 3.2-12 Phase 3 Interleukin-2/Cisplatin-Based Biochemotherapy Trials

Protocol/Principal Investigator(s) (Reference)	Design	Status
EORTC Kielholz et al. (92)	IL-2 / IFN-α[a] vs. IL-2/IFN-α[a]+ CDDP	Completed: RR higher for IL-2/IFN-α + CDDP, but no overall survival difference
NCI Surgery Branch Rosenberg et al. (183)	CDDP/ DTIC/tam vs. CDDP/DTIC/tam + HD IL-2/IFN-α	Completed: no significant difference in RR or survival between the two groups
EORTC Keilholz et al. (184)	CDDP/DTIC/IFN-α vs. CDDP/DTIC/IFN-α + IL-2[a]	In progress
M. D. Anderson Cancer Center Legha et al. (169)	CVD vs. sequential CVD + IL-2/IFN-α[b]	Completed accrual
ECOG/SWOG 3695 Atkins/Flaherty (185)	CVD vs. concurrent CVD + IL-2/IFN-α[b]	In progress

Although confirmation is required, the lack of survival benefit in these two studies calls into question the value of biochemotherapy combinations relative to chemotherapy or IL-2 alone. Clearly, additional phase 3 trials comparing biochemotherapy to chemotherapy or immunotherapy alone are necessary to clearly establish a role for this approach. Legha and colleagues at the M. D. Anderson Cancer Center have recently completed accrual for a similar study that compares their sequential CVD/IL-2/IFN regimen to CVD alone (169). The EORTC is conducting a study comparing cisplatin, DTIC, and IFN-α to the same regimen with decrescendo IL-2 (184). Finally, a phase 3 Intergroup trial (E3695) comparing the modified concurrent biochemotherapy regimen of McDermott et al. (174) to CVD chemotherapy alone was initiated within ECOG and the Southwest Oncology Group in early 1998.

Potential Mechanisms of Synergy for Biochemotherapy Regimens

Regardless of the overall benefits of biochemotherapy in melanoma, almost all studies have shown a higher RR exists for biochemotherapy than that anticipated for chemotherapy or immunotherapy alone. Mechanisms underlying this apparent synergy have been the focus of active investigation. Schmittel et al. examined T-cell responses to various peptides derived from tyrosinase in serial blood samples obtained from patients receiving cisplatin, DTIC, and IFN-α therapy with or without IL-2 (186). They were able to document the induction of tyrosinase–reactive T cells after therapy in four of seven patients. All four of these patients exhibited tumor responses. T-cell reactivity was lost in two patients at times of relapse. These data suggest that cytotoxic chemotherapy, possibly because it causes tumor cell death and releases apoptotic bodies, may lead to enhanced tumor-antigen presentation to the IL-2-activated immune system. Alternatively, others have suggested a potential role exists for either macrophage products or nitrous oxide in the tumor destruction produced by biochemotherapy regimens. Scheibogen et al. reported a correlation between neopterin (a protein predominantly released by activated macrophages) levels at day 8 of a treatment cycle and response to biochemotherapy (187). Anderson et al., however, were unable to confirm this observation in their biochemotherapy population (188). Anderson did observe, however, a weak correlation between day 5 serum nitrite levels, a product of enzymatic reduction of nitrous oxide, and tumor response. A potential mechanism for nitric oxide may be in

enhancing the amount of DNA damage produced by cytotoxic chemotherapy, either directly or through the depletion of intracellular glutathione levels. In this regard, Buzaid and colleagues investigated the relationship between cisplatin-induced DNA damage *in vitro* and response to biochemotherapy (189). They examined cisplatin-induced damage to the glutathione *S*-transferase-π gene in peripheral blood mononuclear cells (pretreatment) and found a strong correlation between degree of damage and subsequent response to therapy. Attempts to confirm this finding in a larger patient population are currently under way. If confirmed, this observation may provide insight into mechanisms of antitumor responses to biochemotherapy and a tool for selecting the patients most likely to benefit from such treatments. Efforts to determine whether biochemotherapy-induced DNA damage *in vivo* in lymphocytes or tumor cells correlates with tumor response are also under way. These studies, together with an assessment of whether DNA damage is enhanced with biochemotherapy relative to cisplatin-based chemotherapy alone, are critical to our understanding of mechanisms underlying the improved RR observed in biochemotherapy. Understanding such mechanisms will aid the subsequent development of biochemotherapy regimens, including potential applications of biochemotherapy to other cisplatin-sensitive tumors.

Future Applications of Biochemotherapy in Metastatic Melanoma

Efforts to reduce incidences of CNS relapse associated with biochemotherapy combinations have focused on the drug temozolomide. Temozolomide is an oral derivative of DTIC that appears to be able to cross the blood-brain barrier. Phase 2 and 3 trials of temozolomide have shown it to possess systemic antitumor activity similar to that of DTIC (190). In addition, single-agent temozolomide occasionally produced regressions of CNS metastases in patients. The possibility exists, therefore, that a substitution of this agent for DTIC in biochemotherapy regimens may reduce the high incidence of CNS relapses observed in major responders. Studies involving temozolomide-containing biochemotherapy regimens are under way at several institutions.

Other studies have focused on moving biochemotherapy into neoadjuvant or adjuvant settings. In addition to less tumor burden, these earlier disease settings offer the potential advantage of a lowered likelihood of CNS involvement *a priori.* Buzaid et al. at the M. D. Anderson Cancer Center administered their concurrent biochemotherapy regimen neoadjuvantly to patients with bulky local regional metastases (191). Patients received two to four courses of therapy, depending on tumor response assessment after two cycles of therapy, then underwent definitive surgery. Sixty-four patients were enrolled, 63 of whom were evaluable for histologic response. Four patients (6%) experienced a pathologic CR; ten patients (16%) exhibited a major PR (<95% cytoreduction in tumor mass). The overall RR was in excess of 50%. At a median follow-up of 13 months, only 1 of the 14 patients achieving a pathologic CR or major PR recurred, compared with 25 out of 49 patients who achieved less than a major PR. These results highlight the critical need that exists for achieving a major response during or shortly after therapy to receive clinical benefit from biochemotherapy; it also raises concerns about the value of surgery in patients not exhibiting such major responses (192). Miller et al. examined the activity of biochemotherapy in the adjuvant setting (193). They performed a phase 2 trial of subcutaneous IL-2 (9 MIU/day, days 1–4) and i.v. DTIC (750 mg/m^2, day 1) administered every 4 weeks for six cycles to patients with stage IIB and III disease. They observed a promising 2-year relapse-free survival of 62%, a result that compares favorably to that achieved with high-dose IFN-α in a similar patient population. Considering the small patient numbers, short follow-up, and hazards of using historic controls in the adjuvant therapy of metastatic melanoma, however, these results should be viewed with extreme caution. Nonetheless, data such as these lend support to formally examining the role of biochemotherapy relative to IFN-α in the high-risk adjuvant setting.

Conclusions

Part of "3.2 - Melanoma "

Modest progress has been made in the treatment of metastatic melanoma over the past decade. With the advent of high-dose IL-2, a "cure," albeit in a minority of patients, is possible. Combinations of IL-2 and IFN-α along with chemotherapy may produce responses in as many as one-half of the patients treated; it is unclear, however, whether these combinations are going to increase the number of patients who survive long-term disease-free. Strong preclinical rationales for the combination of IL-2 with other cytokines, toxicity blocking agents, or various monoclonal antibodies or vaccines exist; however, these approaches have not been fully tested clinically. The wealth of promising potential treatment strategies that exists offers hope that "cures" for more than the rare patient with metastatic melanoma will be achieved within the near future. Whatever promising approach is developed, the likelihood exists that its activity can be enhanced by coadministration of IL-2.

Introduction

Part of "3.3 - Renal Cell Carcinoma "

Renal cell carcinoma (RCC) was diagnosed in approximately 25,000 patients in the United States in 1999, and its incidence has been increasing since 1994 (1). Metastatic disease develops in approximately 50% of patients (2). Metastatic RCC is a clinical entity that has been notoriously difficult to treat with cytotoxic chemotherapy or hormonal manipulation. In a review by Elson of 610 patients enrolled in Eastern Cooperative Oncology Group (ECOG) trials of therapeutic agents for advanced RCC (3), five prognostic factors that influenced overall patient survival were identified. These factors included number of metastatic sites, previous chemotherapy, performance status, weight loss, and time from diagnosis to study entry. The median survival of these patients was less than 7 months; a subset of 113 patients who possessed a combination of the most favorable prognostic factors had a 2-year survival rate of only 24%. Similar prognostic factors and overall results were described by Maldazys and deKernion (4). In a review of chemotherapy trials by Yagoda in 1989, initial response rates (RRs) [partial responses (PRs) and complete responses (CRs)] for 39 agents studied in more than 70 publications ranged from 0% to 19%, with a median RR of 2% (5). A study of patients treated with paclitaxel (Taxol) who had longer-term follow-ups available demonstrated that the survival of patients at 2 years was 8% (6). Despite these data, which document the poor prognoses of patients with metastatic RCC, this malignancy possesses a highly emphasized reputation for showing spontaneous regression (7). These anecdotes are often associated with major surgery (such as nephrectomy), sepsis, or other possible triggering events. Several series of patients undergoing nephrectomy indicate a spontaneous regression rate of approximately 1% exists. In one series, patients with excellent performance statuses underwent nephrectomy and maintained meticulous and frequent follow-ups; a 4% postnephrectomy rate of tumor regression was observed in the absence of therapy (8). Of the four regressing patients, only two experienced regressions of substantial durations, and the sole patient with an ongoing regression experienced life-threatening postoperative sepsis. The transient nature of these spontaneous regressions was also described in a randomized, placebo-controlled study on the efficacy of interferon-γ (IFN-γ) in RCC (9). Although the 6% response rate of the placebo arm is often cited as evidence of the frequency of spontaneous regression of RCC, this value represents a singularly high frequency for this phenomenon; five of the six regressing patients went on to relapse within 13 months. Thus, although spontaneous regression of RCC undoubtedly occurs, its true incidence is estimated to be between 1% and 4%, and regressions are rarely durable or of real clinical benefit. The fact that such occurrences are observed has led to the presumptions that the immune system is responsible and that RCC is a tumor of high immunogenicity. This idea was supported by early evidence that IFN-α could induce regression of RCC in some patients. However, responses to this agent are often of low frequency and modest duration (10).

In 1976, a glycoprotein with multiple immunostimulatory activities was identified (11). This product of lymphocytes, interleukin-2 (IL-2), included among its actions the generation of nonspecific tumoricidal activity in lymphoid cells [lymphokine-activated killer (LAK) cell activity] and T-cell growth-promoting activity (12,13). In preclinical animal models, this glycoprotein was able to cause the regression of a wide array of established tumors when given alone or with *in vitro*-generated antitumor cells (14,15 and 16). Clinical trials begun in 1983 with purified IL-2 derived from stimulated peripheral blood lymphocytes were restricted by drug supply (17). With the advent of recombinant IL-2 in 1984, clinical trials proceeded to higher doses and more prolonged administration schedules, which animal studies indicated would be more effective. The initial regimen used repeated bolus therapy every 8 hours. Animal experiments also predicted that IL-2 would be most effective when administered with LAK cells generated *in vitro* (18); therefore, after a rapid escalation of IL-2 to maximum-tolerated dose, LAK cells were added to bolus IL-2 therapy. After treating patients with tumors of many different histologic types, those with RCC and melanoma showed more striking and frequent tumor regressions (19). Later, more extensive studies with IL-2 alone indicated that patients with RCC had significant RRs without LAK cells (20). Since then, many confirmatory studies support the conclusions that patients with RCC can attain complete and (what appear to be) permanent regressions of metastatic disease and that RCC is one of the most responsive tumors to IL-2–based immunotherapy (Fig. 3.3-1).
FIGURE 3.3-1. Durable complete responses to interleukin-2 in three patients with metastatic renal carcinoma at various sites. Left figures are pretreatment and right-sided figures are the last follow-up evaluation. Patients have responded with lung metastases, liver metastases, and a local recurrence site, as well as at all sites not shown, and remain in ongoing complete response at last evaluation.

Bolus Intravenous Interleukin-2

Part of "3.3 - Renal Cell Carcinoma "

Initial experiences with IL-2 involved rapidly infused boluses of IL-2 administered every 8 hours to the maximum-tolerated number of doses. This schedule and route resulted in high peak levels of IL-2 that fell to undetectable levels just before they were replenished by subsequent doses (17,21). Phase I dose-escalation studies showed that although large single doses of IL-2 (up to 6,000,000 IU per kg) could be administered once a week, when they were administered every 8 hours, the maximum tolerated dose was 600,000–720,000 IU per kg (with the number of consecutive doses tolerated ranging from seven to ten). This cycle was designated as a cycle of therapy and was repeated after 7–10 days of rest, with a pair of such cycles constituting a course of therapy. Treatment was limited by a host of toxic manifestations. In the initial National Cancer Institute (NCI) Surgery Branch experience (20), 1 of 21 patients with RCC exhibited a CR to treatment (that patient remained an ongoing complete responder 14 years later). An update of this experience (including 149 patients with RCC) shows an RR of 20%, with 7% CRs and 13% PRs (22). A larger experience derived from NCI and the IL-2 Cooperative Study Group reported a 7% CR and 8% PR rate for 255 patients with RCC who were given high-dose bolus IL-2 (23,24). The other striking factor in these studies is durability of the CRs. In the cooperative group study, the median response duration was 54 months for all responders. Patients who achieved CRs exhibited response durations of 7 to 107 or more months with few relapses that occurred doing so within the first 19 months. The NCI Surgery Branch reported that 81% of completely responding patients remained in ongoing CR (with no interval therapy or maintenance therapy) with a median follow-up of 7 years (range, 3 to 11 years) (Fig. 3.3-2) (25). A summary of literature on the treatment of RCC with bolus IL-2 alone is presented in Table 3.3-1 .
FIGURE 3.3-2. Actuarial curve of renal cancer patients completely responding to high-dose interleukin-2. Durations of response are measured from the start of therapy. The majority of completely responding patients have not relapsed (median follow-up is 7 years) and no patients have relapsed after 3 years. (From Rosenberg SA et al. Durability of complete responses in patients with metastatic cancer treated with high-dose interleukin-2. *Ann Surg* 1998;228:307-319, with permission.)

Table 3.3-1 Therapy with Interleukin-2 (IL-2) Alone

Author (Reference)	IL-2 Dose ($\times 10^{6}$ IU/m^2)	Route	n	RR (%)	CR (%)	Comments
Rosenberg (25)	25.2 q8h[a]	Bolus i.v.	227	19	9	81% of CR ongoing at median follow-up of 7 yr

c.i.v., continuous intravenous infusion; CR, complete response; IFN, interferon; RR, response rate.

[a]Administered to patient tolerance.

[b]Fixed dose not adjusted for patient size. For comparison, dose here calculated for 2.0 m^2 pt.

Patients in these studies generally had an ECOG performance status of 0 or 1, were free of central nervous system (CNS) involvement, and were screened for normal hepatic, cardiac, pulmonary, and renal function. During therapy, approximately one-half of these patients required either low-dose dopamine or phenylephrine pressor support for oliguria or hypotension. Although initial reports of high-dose bolus IL-2 described treatment-related mortalities of up to 4%, increasing experience has lowered mortality rates to less than 1%, with one series reporting up to 809 consecutive patients who were treated with high-dose IL-2 with no mortality (27). Only one randomized prospective study has been undertaken to determine whether toxicity incurred during high-dose bolus therapy is necessary to achieve optimal responses (28,29). This study compared 720,000 IU per kg of IL-2 administered every 8 hours by intravenous (i.v.) bolus to 72,000 IU per kg administered by the same route and schedule. The dose of 72,000 IU per kg was chosen as the highest dose that could be administered without inducing the same precipitous toxicities as high-dose IL-2 and avoiding intensive care unit support and use of vasopressors. Intermediate doses allowed the administration of a few more consecutive doses but induced exactly the same range of physiologic changes and side effects as high-dose IL-2. Although this study is scheduled to reach full accrual in 1999, an interim report in 1998 noted that 116 patients given 720,000 IU per kg of IL-2 tolerated a median of 12 total doses of IL-2 per course (compared with 27 total doses for the 112 patients receiving the lower dose). Patients who received low-dose IL-2 also showed significantly less thrombocytopenia, pulmonary toxicity, malaise, disorientation, and hypotension than patients who received high-dose IL-2. Vasopressor support was required in 43% of high-dose courses, compared with 4% of low-dose courses (although no treatment-related mortality was encountered in either arm). With a median follow-up of longer than 4 years, interim analysis shows nine CRs and 13 PRs (19% RR) among patients given high-dose bolus IL-2; five CRs and six PRs (10% RR) occurred among patients given low-dose IL-2 (p = .06). Overall survival and response duration data are not mature and are crucial to the final interpretation of this study.

A simple RR of 20% in patients with RCC treated with bolus IL-2 therapy is not significantly different from RRs of patients treated with various chemotherapeutic agents considered

to be of no benefit in RCC. The value of bolus IL-2 in RCC lies in the quality of some responses. One-third to one-half of patients responding to IL-2 achieve CRs and the majority of these patients have never relapsed. Rosenberg et al. noted that none of their 21 completely responding patients experienced a relapse after 3 years(with 3- to 11-year follow-up). Despite a modest overall RR of IL-2, the long-term CR rate of RCC to bolus IL-2 compares favorably with that of metastatic breast cancer and multiagent chemotherapy (30). PRs to IL-2 can last as long as several years, but nearly all eventually relapse (25). Therefore, efforts to improve the efficacy of IL-2 therapy in RCC must preserve and improve on this durable CR rate that, in the absence of randomized, controlled survival studies, represents the predominant evidence supporting the efficacy of this drug.

Interleukin-2 Administered by Continuous Intravenous Infusion

Part of "3.3 - Renal Cell Carcinoma "

In 1987, a report by West et al. indicated that IL-2 administered by continuous i.v. infusion (c.i.v.) over 3 to 5 days in conjunction with LAK cells, had antitumor activity comparable to high-dose bolus IL-2 and LAK cells but was associated with less toxicity (31). Although only six patients with RCC were included in this initial study, three of them experienced clinical responses. At IL-2 doses ranging from 6 to 42 × 10^6 IU per m^2 per day (7,000-50,000 IU/kg/h), universal fever, fatigue, a 35.0% incidence of hypotension, and 2.5% treatment-related mortality occurred. These results are well within the range of toxicities reported in studies of high-dose bolus IL-2, yet c.i.v. IL-2 has been widely pursued as a means of decreasing IL-2 toxicity. Results of subsequent studies of c.i.v. IL-2 are shown in Table 3.3-1 . These studies indicate that the cumulative maximum tolerated dose (MTD) of IL-2 administered is less when it is delivered by c.i.v. instead of bolus infusion. In addition, despite this difference in MTDs, the array and severity of toxicities seen with c.i.v. were not different from those observed with high-dose bolus IL-2. Therefore, only the relative efficacies of these two regimens (at MTD) have bearing on their clinical utility. Weiss et al. conducted a randomized trial comparing these two regimens in patients receiving LAK cells (36). The 46 patients randomized to LAK cells and c.i.v. IL-2 received 18.0 to 22.5 × 10^6 IU per m^2 per day; those randomized to LAK cells and bolus IL-2 received 600,000 IU per kg per dose every 8 hours (approximately 60 × 10^6 IU/m^2/day). The only significant differences in major toxicities were that more infections occurred in patients receiving c.i.v. IL-2, whereas more thrombocytopenia occurred in patients receiving bolus IL-2. Fifteen percent of patients receiving c.i.v. IL-2 and LAK cells responded (two CRs, five PRs), versus 20% of patients given bolus IL-2 and LAK cells (three CRs, six PRs; difference not significant). If the contribution of LAK cells to clinical response is small, insignificant, or equivalent in the two arm, this study suggests that at their respective MTDs, c.i.v. and bolus IL-2 are similar in toxicity and efficacy. What is unclear is whether the lower doses of c.i.v. IL-2 used in other studies to reduce toxicity preserve the efficacy of higher doses of c.i.v. IL-2. The nonrandomized data in Table 3.3-1 suggest that some of these regimens using low-dose IL-2 may be of inferior therapeutic efficacy.

Subcutaneous Interleukin-2

Part of "3.3 - Renal Cell Carcinoma "

The need for frequent dosing when IL-2 is administered by i.v. delivery route led many investigators to try daily subcutaneous administration to maintain low levels of IL-2 and allow therapy to be administered in outpatient settings. Early dose escalation studies by Atzpodien et al. (37) and Whitehead et al. (38)

described modest toxicity that usually consisted of local injection site inflammation and constitutional symptoms. Mild renal dysfunction and thyroid abnormalities were also observed, as well as the development of anti-IL-2 antibodies of unknown clinical significance (37,38). As doses were escalated between 2 and 30 million IU per m^2 per day in one or two divided doses administered subcutaneously for 5 or 6 days a week, appropriate alterations in peripheral blood phenotypes and natural killer cell activity were seen. The once-a-day, 5-days-per-week dosing used by Whitehead appeared to permit a higher MTD but resulted in no major tumor regressions in the 14 evaluable patients reported. Adzpodien's twice-a-day, 6-days-per-week dose schedule administered over 4 weeks could not deliver as much IL-2 per day or per week as the alternative regimen, but one of the six patients with RCC experienced a PR. Stein et al. (39) used approximately 1.8 million IU once a day for 5 days per week and reported two of nine patients achieving PRs. Lissoni et al. (40) administered IL-2 for 2 days at 9 million IU per m^2 per day followed by one-fifth of that dose 5 days per week for 6 weeks, obtaining four PRs in 14 patients. One regimen adopted by other investigators was first reported by Sleijfer et al. (41) and consisted of once-a-day dosing for 5 days per week (initially at 18 million IU per dose for the first week, followed by 9 million IU per dose for the next 5 weeks, without adjustment for body weight). Toxicity was typically modest, with elderly patients and patients with major cardiovascular disease receiving this regimen. Of 27 patients reported, one 76-year-old patient died of a myocardial infarction and cerebral ischemia. Six of 26 evaluable patients (23%) experienced major tumor regression (two CRs, four PRs) lasting from 2 to 19+ months. An update of this experience abbreviated the regimen to 4 weeks and reported a 19% RR (42) with two CRs and seven PRs among 47 patients. Pharmacokinetic studies of a subcutaneous regimen such as this one demonstrate that detectable levels of IL-2 are maintained throughout most of the day, but peak serum levels of IL-2 rarely exceed 5 ng per mL (in marked contrast to the peak serum levels greater than 300 ng per mL observed with high-dose bolus IL-2) (29). The relative efficacy of this subcutaneous regimen is currently being tested in a randomized prospective comparison to high-dose bolus IL-2, as well as against the low-dose i.v. regimen. Yang and Rosenberg (29) reported that the toxicity of the subcutaneous regimen was substantially less than that of high-dose i.v. IL-2, especially with respect to hypotension, thrombocytopenia, pulmonary toxicity, and disorientation. High-dose IL-2 achieved four CRs and five PRs in 56 patients (16% RR), whereas three CRs and three PRs were observed in 53 patients given subcutaneous IL-2 (11% RR). This difference is not statistically significant, and no difference in survival rates occurred, but this study is ongoing.

Clinical studies of subcutaneous IL-2 show that it can achieve partial and complete regressions of tumors in patients with advanced RCC; for patients with major medical problems, such as cardiovascular disease, it may represent the only option for trying IL-2. Nevertheless, a major condition for using low-dose IL-2 in healthy patients with good performance statuses should be that its efficacy is equal or superior to that of high-dose IL-2. Such assessments should also carefully evaluate completeness and durability of responses, because such responses represent the major reason why IL-2 benefits patients with RCC.

Interleukin-2 Administered with Adoptive Cellular Transfer

Part of "3.3 - Renal Cell Carcinoma "

Preclinical animal studies indicated that the addition of LAK cells to IL-2 markedly improved the antitumor activity over a range of IL-2 doses and against a variety of murine tumors (15,18). *In vitro* studies of human LAK cells indicated that tumors of virtually all histologic types (including RCC) were susceptible to LAK cell lysis (44). Based on these findings, many early clinical protocols included LAK cells administered with IL-2. Although several phase 2 trials suggested a higher RR exists for LAK cells and IL-2 compared with historical controls receiving IL-2 alone, other studies could not confirm this (Table 3.3-2) (45,46,47,48,49 and 50). The largest prospective randomized study involved 87 evaluable patients randomized to receive high-dose bolus IL-2 alone or the same IL-2 dose with LAK cells (45). Despite receiving a median of 10^{11} LAK cells per course, no statistically significant improvement in the RR of patients randomized to receive LAK cells occurred; survival after a median follow-up of 63 months was not different (*p* >.5). An independent smaller study by Law et al. also failed to demonstrate a benefit in RR or overall survival with LAK cell administration (52). No evidence exists to demonstrate that patients with advanced RCC receive significant benefit from the administration of LAK cells; therefore,

due to the expense and complexity of generating LAK cells, their use cannot be recommended.

Table 3.3-2 Therapy with Interleukin-2 (IL-2) and Lymphokine-Activated Killer (LAK) Cells

Author (Reference)	IL-2 Dose (× 10⁶ IU/m²)	Route	Median LAK Cells Administered (× 10⁻¹⁰)	n	RR (%)	CR (%)	Comments
Rosenberg (45)	25.2 q8h	Bolus i.v.	10	72	35	11	—

c.i.v., continuous intravenous infusion; CR, complete response; N/A, not applicable; RR, response rate.

Note: All IL-2 units converted to IU (1.0 Hoffman-LaRoche/Biologic Response Modifier Program unit = 2.6 IU and 1 Cetus unit = 6 IU).

In the treatment of melanoma, nonrandomized studies on the use of adoptive transfer of tumor infiltrating lymphocytes (TILs) expanded from patients' autologous tumors suggest they have benefits over using IL-2 alone (53). That the overall RR when TILs are added to IL-2 is nearly double that of historical RRs to IL-2 alone supports this contention; perhaps more compelling, some responders include patients who had recently received IL-2 alone and failed to respond. Furthermore, T cells with specific reactivity to autologous tumors can be found in the majority of TIL cultures from melanoma. Such data have led to exploration of TILs from RCC in combination therapy with IL-2. However, T cells with specific reactivity to autologous tumors are rare in RCC TIL (54). Figlin and Belldegrun have used RCC TIL in combination with IL-2 (and, in many cases, IFN-α) and report overall RRs that appear higher than IL-2 alone (55). This result has not yet been reproduced, however, and it is not clear if the improvement in RR is attributable to the administration of TIL. These questions should be investigated in randomized clinical trials, which have been undertaken.

Combination Therapy with Interleukin-2 and Interferon-α

Part of "3.3 - Renal Cell Carcinoma "

IL-2 and IFN-α represent the two biologic agents with reproducible activity in the treatment of RCC. Although the response frequency of either agent alone is low, preclinical animal models have suggested that combining these agents could result in synergistic therapeutic effects (56). Early patient studies included several combination regimens that seemed to have impressive RRs in the uncontrolled phase 2 setting. In different studies, IL-2 has been administered by i.v. bolus, continuous infusion, or subcutaneous injection, whereas IFN-α has been administered intravenously, subcutaneously, or intramuscularly. The IFNs selected have included primarily IFN-α-2a and -2b, which are considered together and do not result in significant differences in efficacy or toxicity. The studies cited in Table 3.3-3 include a number of widely differing regimens and display RRs that vary greatly and overlap those reported for similar regimens using only IL-2. The i.v. regimens have been exemplified by a study from the NCI Surgery Branch in which escalating doses of IL-2 and IFN-α were given by periodic bolus dosing to the maximum-tolerated amount. The initial short-term RR for the combination of cytokines was 31% (57); a later report showed that this rate was 28% for a larger group of patients. The combination therapy seemed associated with increased CNS toxicity and myocarditis, and survival was not improved compared with an historical NCI Surgery Branch experience with IL-2 alone (58). Several randomized studies are included in Table 3.3-3 . A large three-arm multiinstitutional trial in France reported by Negrier randomized patients to receive high-dose continuous infusion IL-2, with or without a modest dose of IFN or a greater dose of IFN alone (35). With 425 patients randomized and a median follow-up of 39 months, overall RRs for IL-2, IFN, or both agents were 7%, 7%, and 19%, respectively (*p* = .01, favoring both agents). Event-free survival at 1 year also significantly favored the combination, but an analysis of overall survival revealed no differences existed between any of the groups (*p* = .55). A smaller trial by Jayson using low-dose subcutaneous IL-2 and subcutaneous IFN also failed to demonstrate benefits for the combination by any parameters (63). These studies are notable for RRs for IL-2 alone that appear lower than those described for higher-dose regimens of IL-2. A third randomized study by Henriksson (which included tamoxifen in one arm and IL-2, IFN, and tamoxifen in the other), showed no difference in survival between these two regimens; it did not report overall RRs (64). A fourth randomized trial by Boccardo et al. (68) administered either high-dose, c.i.v. IL-2 for 4 days or low-dose IFN three times per week, or both regimens combined. In 66 randomized patients, the response to IL-2 alone was 23%, the response to IFN alone was 9%, and the RR for the combination of both was 9% (difference was not significant). For any randomized study of IL-2, large numbers of patients and long-term follow-up are needed because only a minority of patients substantially benefit from the therapy, and benefits consist of long-term durable responses. Unlike chemotherapy, no evidence exists that the agent markedly benefitting these few patients is having a lesser benefit on other patients treated. Therefore, one would not expect a change in median survival to occur; furthermore, analyses performed with less than 3-year median follow-ups may not identify that minority of patients who are potentially cured by IL-2-based therapy. This problem has significantly affected interpretations of every randomized trial of IL-2-based therapy performed. Even in the absence of such long-term data, experience with IL-2 and IFN combinations has varied, and results overlap extensively with results attained with IL-2 alone. With a few exceptions, the percentage of completely responding patients attained with this combination does not seem to be increased, and significant uncertainty as to the durability of these responses remains. Therefore, little conclusive data exists documenting synergistic benefits from the use of IL-2 and IFN in patients with advanced RCC; because the potential for increased toxicity exists, more compelling randomized studies are needed to recommend its use.

Table 3.3-3 Therapy with Interleukin-2 (IL-2) and Interferon-α (IFN-α)

Interleukin-2, Interferon, and Chemotherapy

Part of "3.3 - Renal Cell Carcinoma "

In vivo animal data with a variety of chemotherapy agents and IL-2 demonstrated that, rather than antagonizing the activity of IL-2 by immunosuppressing the tumor-bearing host, many of these chemotherapy regimens exhibited (at least) additive or (at best) synergistic therapeutic results (69) when added to IL-2. Chemotherapy agents often had to show direct antitumor activity to be most effective, and candidates for such agents in RCC included 5-fluorouracil (5-FU) and vinblastine. In treatment of colon cancer, the addition of IFN to 5-FU was reported to augment therapeutic results, primarily through effects on the pharmacokinetics of 5-FU; therefore, many investigators combined IL-2, IFN, and 5-FU in exploring chemoimmunotherapeutic strategies in patients with metastatic RCC. Table 3.3-4 illustrates a number of such studies, using many different doses and schedules for all three agents. IL-2 was administered at high and low doses by i.v. bolus, continuous infusion, or subcutaneous injection, and IFN was administered intravenously, subcutaneously, and intramuscularly. Most investigators used 5-FU as a 750 mg per m² infusion once every week or as a 600 mg per m² per day continuous infusion for 5 days every 3 to 4 weeks. The variation in the RRs shown in Table 3.3-4 is quite evident, ranging from overall RRs of 0% to 39% and complete RRs of 0% to 13%. For the 434 patients in Table 3.3-4 who received IL-2, IFN, and 5-FU, the overall RR is 23% and the complete RR is 5%. Even more striking is that the protocols of Joffe (70), Dutcher (65), and Hanninen (75) are similar, patterned after the regimen developed and reported by Atzpodien; however, they exhibit disparate overall RRs of 16%, 16%, and 39% and complete RRs of 0%, 4%, and 11%. That significant toxicities are experienced when these agents are combined (despite the universal utilization of lower doses of IL-2) is evident. Several of the studies cited had treatment-related mortalities of 2% (70,71 and 72). As with the combination of IL-2 and IFN, some concern remains as to whether such combinations are able to achieve the same longevity of response initially reported with high-dose IL-2 alone (65). Again, large, long-term randomized studies are needed to investigate these critical issues. One study with vinblastine showed results similar to the more favorable results of studies with 5-FU, but these results have not been confirmed by others. In the end, it is important to determine whether responses observed are indeed durable and if concurrent administration of IL-2, IFN, and chemotherapy is superior to the sequential administration of these agents.

Table 3.3-4 Interleukin-2 (IL-2) with Interferon-α (IFN-α) and Chemotherapy

Author (Reference)	IL-2 Dose (× 10⁻⁶ U/m²)	IFN-α Dose (× 10⁻⁶ U/m²)	Chemotherapy (mg/m²)	n	RR (%)	CR (%)
Joffe (71)	10 b.i.d. × 3 d/wk, then 5 t.i.w., s.c.	6 qwk, then 6-9 t.i.w., s.c.	5-FU, 750 qwk	55	16	0

Other Combinations with Interleukin-2

Part of "3.3 - Renal Cell Carcinoma "

A multitude of other agents have been combined with IL-2 in the treatment of advanced RCC, largely due to dissatisfaction with low RRs to IL-2 alone. Some combinations were identified as promising by preclinical animal data, others were proposed based on improving awareness of mechanisms of antitumor immune response. IL-4 was discovered to activate NK cells and generate LAK cells in murine systems and had some antitumor activity. Sosman et al. infused IL-4 by continuous infusion in a phase 1 setting and then infused it after IL-2 administration (77).

In the 14 patients who received both components of therapy, only one minor response occurred. Whitehead administered IL-2 and IL-4 by concurrent subcutaneous injections in the phase 1 setting to a group of patients with mixed tumor histologies; one of six patients with RCC appeared to have a transient PR (78). A larger unpublished study conducted by Lotze et al. in the NCI Surgery Branch demonstrated that IL-4 had no significant antitumor activity alone and, when it was combined with high-dose bolus IL-2, did not appear to enhance the RR seen with IL-2 alone *(personal communication).*

Stadler (79) reported a phase 2 study using IL-2 at modest doses via subcutaneous route combined with IFN and *cis*-retinoic acid (reported to potentiate the antiproliferative activities of IFN). He described a 17% overall RR with one completely responding patient. Levamisole, a veterinary antihelminthic reported to have immunostimulatory activity, has also been combined with IL-2 (80), but has only resulted in one partial regression among 22 evaluable patients. Despite the possible role of cyclophosphamide as an immunomodulator, Mitchell reported the use of cyclophosphamide with low-dose bolus IL-2 (without IFN) in 15 patients without observing any clinical responses (81). Other early phase efforts to combine IL-2 with IL-1ß (82) or IFN-γ (83,84 and 85) are of insufficient size or design to determine efficacy against RCC.

These isolated efforts have not identified compounds that enhance responses of patients with RCC to IL-2; in general, reliable preclinical models for predicting effective combinations have not been identified.

Therapy of Disease Relapses after Immunotherapy

Part of "3.3 - Renal Cell Carcinoma "

Patients who experience PRs to immunotherapy with IL-2-based regimens are likely to relapse and develop progressive disease within 2 years. Basic immunologic precepts suggest that an immune response against tumor-associated antigens could induce long-term memory T cells; therefore, the likelihood exists that repeat therapy with IL-2 could reinduce tumor remission. A review by Lee et al. (86) of patients with metastatic RCC who responded to a variety of IL-2-based therapies in the NCI Surgery Branch evaluated the chance that such a population may respond to further IL-2 therapy after disease relapse. These investigators found that this was not the case, however. Of 29 patients who received some form of IL-2 retreatment after relapse, the only one exhibiting a (brief) second response was a patient who had received TIL and IL-2 initially, responded and relapsed, then received only IL-2 afterwards (due to a lack of TIL availability). This experience supports the recommendation that patients who relapse after maximal IL-2 therapy should not be retreated with IL-2, but should instead move on to other modalities (or at least receive other modalities along with further IL-2). One area not adequately investigated is whether patients who respond to low-dose IL-2 and relapse could subsequently respond to a maximal dose of IL-2.

If these post–IL-2 relapses are caused by simple inadequate log-kill of tumor cells by activated immune cells, relapsing sites should be harbingers of multisite failures, and nonsystemic modalities, such as surgical resection, should be inadequate for maintaining a patient's tumor-free status for extended periods. However, Lee et al. found that surgical resections of isolated relapses in selected patients who had responded previously to immunotherapy maintained 30% of them free of progressive disease for 3 years or longer from time of resection. Therefore, surgical resection is recommended for patients who respond to IL-2 but suffer limited relapse. Studies on these resected tumor relapses may provide insights about mechanisms by which tumors escape immunotherapy.

Summary

Part of "3.3 - Renal Cell Carcinoma "

High-dose IL-2 by bolus administration or continuous infusion has endured as a therapy for metastatic RCC. Although RRs are consistently 15% to 20%, nearly one-half of these responses are complete and durable. Although lower doses of IL-2 have demonstrated comparable initial RRs in many series, duration and completeness of these responses remain to be evaluated. Once a caregiver departs from therapy with IL-2 alone, the benefits of regimens combining IL-2 with other agents are much less clear. Besides considering whether initial RRs are actually increased when other agents are added to IL-2, a more significant consideration is whether durability of responses is impaired when these agents are added. Long-term, randomized studies are necessary to address this important issue.

- Summary and Conclusions

Introduction

Part of "3.4 - Hematologic Malignancies "

Several lines of preclinical evidence suggest a potential role for interleukin-2 (IL-2) in the treatment of hematologic malignancies:

1. In animal models, IL-2 eradicated widely disseminated hematologic malignancies (1) and augmented the therapeutic efficacy of adoptively transferred T lymphocytes sensitized to tumor-associated antigens (2).
2. Cells from patients with hematologic malignancies, such as acute myelogenous leukemia (AML), acute lymphoblastic leukemia (ALL), chronic myelogenous leukemia, malignant lymphoma, and multiple myeloma, are susceptible to lysis *in vitro* by human lymphocytes stimulated by IL-2 [i.e., lymphokine-activated killer (LAK) cells] (3,4,5,6,7 and 8).
3. Susceptibility to such lysis is non-cell cycle specific and maintained even in cell lines that demonstrate pleiotropic drug resistance markers, suggesting no cross-resistance between IL-2 and chemotherapy (9).
4. IL-2-activated natural killer (NK) cells can inhibit malignant colony proliferation by clonogenic human leukemic stem cells in colony-forming assays (10).
5. IL-2 can block the *in vivo* growth of human leukemic cells in immunosuppressed nude mice (11).
6. Peripheral blood lymphocytes from patients with acute leukemia at diagnosis or in relapse are defective in their ability to generate LAK activity against autologous leukemic cells in response to IL-2 *in vitro*—a defect that is reversed when the patient enters a complete remission (CR) (12).
7. An apparent correlation has been reported between the ability to respond with LAK cell generation and the clinical course of AML (13).
8. Because T-cell responses can be generated specifically directed against tumor-associated antigens (e.g., the immunoglobulin idiotype of B-cell lymphomas and multiple myeloma, the product of BCR-ABL in chronic myelogenous leukemia and antigens on AML, IL-2 might be clinically useful by augmenting such responses.
9. IL-2 might stimulate or augment an antitumor effect by NK cells, especially against tumors that do not express adequate class I major histocompatibility complex (MHC) antigens.
10. A state of minimal residual disease (MRD)—a setting in which immunotherapy is more likely to be effective—can be readily induced because hematologic malignancies are among the most sensitive to chemotherapy, radiation, or both.

Accordingly, IL-2 is being explored in the treatment of hematologic malignancies. Although the trials conducted involved heterogeneous patient populations and IL-2 regimens, some of the preliminary results are encouraging. Most trials targeted patients with AML or non-Hodgkin's lymphoma (NHL). This chapter briefly reviews the positive, negative, and inconclusive results and current status of such IL-2-based therapy trials.

Clinical Trials of Interleukin-2 for Refractory Hematologic Malignancies

Part of "3.4 - Hematologic Malignancies "

Several phase 1 and 2 trials were performed in patients with hematologic malignancies heavily pretreated with chemotherapy, radiation, or both. The prior exposure to aggressive therapy may influence the toxicity of IL-2 therapy. For example, such patients may be more susceptible than solid tumor patients to IL-2-associated toxicity, such as capillary leak syndrome and thrombocytopenia, a problem that may be exacerbated by marrow involvement in hematologic malignancies. Moreover, heavily pretreated patients may be less able to respond immunologically to IL-2.

Malignant Lymphoma

The patients treated were clinically heterogeneous with respect to disease, grade, stage, prior therapy, and so forth. The IL-2 regimens were empiric and varied in terms of source, dose, route, and schedule. Some of the trials involved infusion of autologous LAK cells.

Table 3.4-1 summarizes the results of eight trials of IL-2 with or without LAK cells in patients with NHL who relapsed after chemotherapy or autologous bone marrow transplantation (ABMT) (14,15,16,17,18,19 and 20). Most patients received high-dose IL-2 by continuous

intravenous infusion (c.i.v.), bolus infusion, or both and often required hospitalization. Overall, 6% of patients had a CR and 11% had a partial response (PR) with an overall response rate of 17%. Although most responses were short, a CR or PR occasionally persisted for longer than 2 or 3 years. Histology was reported for only 79 of the NHL patients. Of the 45 patients with diffuse NHL, three patients had a CR and four patients had a PR with an overall response rate of 16%. Of the 46 patients with follicular histologies, three patients had a CR and nine patients had a PR with an overall response rate of 26%.

Table 3.4-1 Interleukin-2 with or without Lymphokine-Activated Killer Cells Therapy for Non-Hodgkin's Lymphoma

Regimen	Total No. Patients Evaluable	No. CR	No. PR	Overall Response Rate CR + PR (Total %)
IL-2	82	5	9	14/82 (17)
IL-2 + LAK	39	2	5	7/39 (17)
Total	121	7	14	21/121 (17)

CR, complete remission; IL-2, interleukin-2; LAK, lymphokine-activated cells; PR, partial response.

Concern existed that IL-2 might serve as a growth factor *in vivo* for lymphoid malignancies expressing the IL-2 receptor. *In vitro* studies have been contradictory (11,21). In one trial, neither of the two patients with cutaneous T-cell lymphoma responded to IL-2 and LAK cells (17). In the largest reported series of IL-2–treated NHL patients, however, 8 of the 11 responders had T-cell lymphomas (20). The same series included seven patients with refractory mycosis fungoides or Sézary syndrome, five of whom responded to IL-2 (one CR, four PR). Although sparse, these results show that IL-2 can induce clinical regression of T-cell lymphomas in some patients and does not promote tumor growth.

Six reported clinical trials of IL-2 with or without LAK cells included 31 patients with Hodgkin's disease (HD) (16,17 and 18,20,22). All patients were extensively treated and eight had relapsed after ABMT. Of 16 patients who received IL-2 alone, one patient had a PR that lasted 11 months. Of 15 patients who received IL-2 plus LAK cells, three patients had short PRs (all <3 months).

Thus, some regimens of IL-2 with or without LAK cells can induce a PR or even a CR in some patients with malignant lymphoma. The therapies and patients, however, have been extremely heterogeneous. No trials have compared one IL-2 regimen with another, or one IL-2 regimen with and without LAK cells, in comparable patients so as to identify the subset of patients who are more or less likely to benefit from IL-2 therapy and to identify the most effective IL-2 regimen.

Acute Leukemia

Clinical trials of IL-2 for acute leukemia have focused on patients with AML who did not respond to chemotherapy or ABMT or who relapsed after such treatment. The most impressive clinical results were reported (23) and updated (24) by Meloni et al. Patients with AML [refractory, or in the first to fourth relapse (Rel 1–4)], whose marrow had less than 30% blasts (median, 15%) were treated with IL-2.

IL-2 was administered by c.i.v. for 5 days using a daily dose-escalating protocol. After 3 days of rest, IL-2 therapy was repeated at the maximum tolerated dose (MTD) for a total of 4 cycles. The first five patients received IL-2 from Glaxo; all subsequent patients received IL-2 from Chiron at a dose of 8–18 × 10^6 IU per m^2 per day. Responders to IL-2 received maintenance IL-2 as monthly 5-day courses at 4–8 × 10^6 IU per m^2 per day. After the first year, a lower dose of IL-2 was administered every other month.

Of 24 patients treated, 13 entered a CR. Although five of the CRs were of short duration and two were too early for evaluation, six patients remain in CR at 3+ to 9+ (median, 6+ years) years. The long-term disease-free survivors included patients who received IL-2 in Rel 2–4 with M1-, M2-, or M4-type AML. The results are quite encouraging and require confirmation and extension.

In another series (25), ten patients with AML in relapse with more than 30% blasts in their marrow were treated with high-dose IL-2 by i.v. bolus (8 × 10^6 IU per m^2 per 8 hours × 5 days per cycle for 3 cycles, each cycle separated by 9 days of rest). Two patients with 30% and 81% blasts in the marrow had a CR, but of only 3- to 4-months' duration. Finally, a CR of 6 months' duration was induced in one out of six AML patients treated with IL-2 while in "early relapse—partial remission" (26). The dose was largely 3 × 10^6 Cetus U per m^2 per day × 5 days by c.i.v. every other week, after which the dose was administered every month.

Nineteen patients with ALL treated with IL-2 were reported to have no response (27).

Thus, IL-2 induced clinical responses in some patients with refractory AML. Although most responses were of relatively short duration, some responses were quite durable. In patients with refractory disease, however, such clinical activity is significant and warrants further investigation in more favorable clinical settings, namely, in patients with MRD.

Clinical Trials of Interleukin-2 as an Adjunct to Chemotherapy

Part of "3.4 - Hematologic Malignancies "

Theoretically, therapy with IL-2 is more likely to be effective in a setting of MRD [i.e., after chemotherapy or the more aggressive chemotherapy and radiotherapy used for bone marrow

transplantation (BMT)]. Therefore, IL-2 has been administered to patients who were in CR after chemotherapy but at high risk for relapse in the hope of decreasing the relapse rate and prolonging disease-free survival.

Virtually all such trials have been performed in patients with AML in chemotherapy-induced CR1 or CR2. The trials involved small groups of heterogeneous patients and a variety of IL-2 regimens and yielded variable, inconsistent, and inconclusive results. The effects of IL-2 in patients with AML in CR1 can be evaluated retrospectively only by comparing their results with those expected with chemotherapy alone, which, in turn, vary greatly depending on clinical and cytogenetic prognostic indicators. Therefore, large numbers of well-characterized patients must be studied. This has not been done.

In one trial (28), patients with AML in CR1 at high risk for relapse were randomized to receive 4 cycles of IL-2 by c.i.v. at 9×10^6 IU per m^2 per day (n = 10) or 0.9×10^6 IU per m^2 per day (n = 8) for two 5-day cycles. The median CR duration for both groups was approximately 1 year. Another group of nine patients with AML in CR1 received a low dose of IL-2. Six patients in this group relapsed early (29). No benefit from IL-2 therapy was detectable in these small groups.

Several low-dose IL-2 regimens have been used in patients with AML in CR1. Cortes et al. (30) treated 18 consecutive patients with AML in CR1 with IL-2 by c.i.v. (4.5×10^5 IU per m^2 per day) and i.v. bolus (1×10^6 IU per m^2 once a week). For comparison, two historical control groups with similar prognostic factors, including cytogenetics, were selected. These control groups met the eligibility criteria for IL-2 therapy but had not received it. The median CR duration of the IL-2–treated group was 53 weeks. At 4 years, 6 out of 18 (33%) patients in the IL-2 group and 5 out of 36 (14%) patients in the control group (p = .09) were in CR. The results suggest that postremission IL-2 therapy might have reduced the relapse rate.

In a small, multicenter randomized trial (31), 14 patients with AML in CR1 received IL-2 and ten did not. The low-dose IL-2 regimen consisted of 0.2×10^6 IU per m^2 subcutaneously twice a day for 3 months. Eight of the 16 patients who received IL-2 and six of the ten patients who did not relapsed with a median disease-free survival of 52 and 40 weeks. Thus, no significant effect was noted.

A low-dose IL-2 regimen with minor variations developed at Dana Farber/Roswell Park is being studied in a number of clinical settings. In one study (32), patients with AML in CR1 received IL-2 at 4.5×10^5 IU per m^2 per day by c.i.v. (18 patients) or 1.2×10^6 IU per m^2 per day subcutaneously (5 patients) for 90 to 160 days with i.v. boluses of higher doses (i.e., 1, 2, and 3×10^6 IU per m^2 administered on 3 successive days every 14 days). The regimen was well tolerated. Of 23 patients treated, 13 did not complete therapy because of early relapse. The median CR duration for the ten patients who completed IL-2 therapy was 22 months (range, 8+ to 77+ months). No conclusions can be drawn about the clinical benefit of IL-2 therapy.

A phase 2 trial with a similar low-dose IL-2 regimen is in progress by CALGB (protocol 9,621) for AML patients younger than 60 years in CR1 with favorable cytogenetics. The IL-2 regimen consists of 1×10^6 IU per m^2 per day subcutaneously on days 1 to 14, 19 to 28, 33 to 42, 47 to 56, 61 to 70, and 75 to 90 with a high-dose s.c. bolus of 12×10^6 IU per m^2 on days 15 to 17, 29 to 31, 43 to 45, 57 to 59, and 71 to 73. A phase 3 trial is planned. The same IL-2 regimen is being tested in the phase 3 trial of IL-2 versus no IL-2 (CALGB, protocol 9,720) in patients older than 60 years with AML in CR1.

A combination of histamine and low-dose IL-2 is also being explored in patients with AML in CR1. This is based on studies that suggest that IL-2-induced NK-mediated lysis of AML cells is inhibited by a monocyte-derived inhibitory signal that, in turn, is inhibited by histamine. In one reported (33) and updated (34) trial, 26 patients received histamine plus IL-2 (18,000 IU per kg s.c. twice a day) in 21-day cycles with 3- to 6-week rest periods until relapse or 24 months of CR. Fifteen of 26 patients remain in CR with a median follow-up of 26 months. A randomized phase 3 trial of IL-2 and histamine versus no IL-2 or histamine is in progress.

One trial (35) involved a higher dose of IL-2 administered for a shorter period of time. In a trial to assess the feasibility, toxicity, and biologic response of IL-2 administered after consolidation chemotherapy for AML in CR1, the Children's Cancer Group treated 21 patients with an IL-2 regimen that had been identified as an MTD in a phase 1 trial in patients who had undergone ABMT for hematologic malignancies. The regimen, designated as *Seattle Regimen*, is highlighted in Table 3.4-2 because it is being extensively tested in large phase 2 and 3 trials.

Table 3.4-2 Seattle Interleukin-2 Regimen

	IL-2 Dose by c.i.v.
Induction	9×10^6 IU/m^2/d $\times$ 4 d
Rest	4 d
Maintenance	1.6×10^6 IU/m^2/d $\times$ 10 d

c.i.v., continuous i.v. infusion; IL-2, interleukin-2.

From Robinson N et al. Interleukin-2 after autologous stem cell transplantation for hematologic malignancy: a phase I/II study. *Bone Marrow Transplant* 1997;19:425–442, with permission.

This IL-2 regimen was more toxic than the low-dose regimens because of the occurrence of fever (57%), vascular leak (48%), hypotension (38%), rash (29%), septicemia (5%), and thrombocytopenia (29%). The IL-2 regimen was considered tolerable. With a median follow-up of 7 months, seven patients had relapsed. A randomized prospective trial to determine whether this IL-2 regimen will prevent relapses and prolong disease-free survival in such children is in progress (Children's Cancer Group, protocol 2,961).

Because patients with AML in CR2 have a poor prognosis, they, too, have been subjects for IL-2 trials. Shepherd et al. (36) treated patients in CR2 or PR with IL-2 (3×10 IU or 9×10^6 IU per day, 5 days per week for 3 weeks s.c.) with cycles repeated with 1-week rest periods until relapse. Of 29 CR2 patients, two had a CR that was longer than the duration of their CR1 (19 and 20+ months). Three of 21 patients treated in PR achieved a CR2, two of which lasted longer than 2 years. Similarly, of seven patients in CR2 treated with polyethylene glycolated IL-2, three had a CR2 duration substantially longer than their CR1 (37).

Finally, 21 patients with AML were treated in CR2 with 4 cycles of IL-2 at 9×10^6 IU per m^2 per day on days 1 to 5 and 8 to 12 per cycle by a 1-hour infusion every 6 weeks (38). The duration of the CR2 in five patients exceeded that of their CR1. The authors concluded that the IL-2 regimen was feasible and the data sufficiently encouraging to justify a phase 3 trial. Such a trial, however, was never performed. Cumulatively, results of all these studies are inconclusive or, at best, slightly encouraging.

Clinical Trials of Interleukin-2 after Bone Marrow and Stem Cell Transplantation

Part of "3.4 - Hematologic Malignancies "

Autologous

If MRD is truly the setting in which IL-2 therapy is most likely to be effective, then the most suitable patients may be those who have undergone BMT after otherwise lethal doses of chemoradiotherapy but who are at high risk for post-transplant relapse. For example, patients who undergo ABMT for advanced hematologic malignancies (i.e., AML or malignant lymphoma beyond CR1) have more than a 50% probability of relapse, most often within a few months.

BMT as a setting for IL-2 therapy is based on the following rationale, in addition to its setting as an MRD:

1. After BMT, a greater increase in circulating IL-2–responsive lytic CD56+ cells occurs than after conventional chemotherapy (39).
2. IL-2 might induce or augment a graft-versus-leukemia (GVL) or a graft-versus- tumor effect after allogeneic bone marrow transplantation (AlloBMT) or perhaps even after ABMT.
3. IL-2 after ABMT might destroy whatever clonogenic tumor cells might be transplanted with the marrow/stem cells, and, thus, might represent a form of purging tumor cells *in vivo.*

A number of clinical trials have been performed using IL-2 as consolidative immunotherapy after ABMT in the hope of reducing the relapse rate and prolonging disease-free survival. IL-2 has been used in the following ways:

1. In a few trials, IL-2 was administered immediately after marrow infusion.
2. In most trials, IL-2 was administered after some degree of documented hematologic recovery.
3. In some trials based on preclinical data, the marrow or stem cells were incubated with IL-2 before infusion, after which systemic IL-2 was administered.
4. IL-2 is being explored as part of a cocktail of growth factors to mobilize autologous stem cells with potential antitumor killer activity.

The chemoradiotherapy used for BMT is often associated with toxicity, which makes recipients less able to tolerate IL-2 than nontransplant patients with solid tumors. Therefore, several trials have been performed to determine the toxicity and immunomodulatory effects of different sources, schedules, and regimens of IL-2 administered after ABMT. Peripheral blood is increasingly replacing marrow as a source of stem cells for autologous transplantation. Accordingly, ABMT should be used when the source is known to be marrow, and autologous stem-cell transplantation (ASCT) should be used when the source is blood, a combination of blood and marrow, or unknown.

Timing and dosage are important. For example (40), when children with ALL were treated with Roche IL-2 (0.5 to 2.0 × 10^6 IU per m^2 per day × 4 days per week) beginning 1 day after ABMT, unacceptably serious nonhematologic toxicity was observed without any immunomodulatory effects. Severe toxicity was also reported in two patients with AML given high-dose IL-2 beginning 2 days after ABMT; a lower dose of IL-2 administered at a later time was far less toxic (41).

Theoretically, IL-2 should be administered sufficiently early after ABMT before relapses are likely to occur but after the reconstitution of IL-2–responsive lymphocytes in the circulation. Such cells capable of lysing tumor targets *in vitro* with or without incubation with IL-2 have been detected within 2 to 3 weeks after ABMT and ASCT (39,42,43).

A variety of empirically derived IL-2 regimens have been used after ASCT. Although a variety of immunologic changes are induced, none of these changes can serve as proxies or predictors of clinical benefit because none of the regimens has been documented definitively as clinically beneficial. Therefore, the optimal regimen of IL-2 in terms of dose, route, schedule, and duration remains unknown. Although some trials identified and used the MTD for IL-2, it is unknown if the MTD is the optimal dose.

The following three broadly defined types of IL-2 regimens have been used after ASCT:

1. The French-type regimen (44)—This regimen involves a high dose of IL-2 administered for 5 cycles. The first cycle lasts 5 days and the subsequent cycles last 2 days each every other week.
2. The Seattle-type regimen (45,46)—This regimen is a single cycle consisting of a short course of a moderate induction dose of IL-2 for 4 to 5 days, 4 to 6 days of rest, and a low-maintenance dose for 10 days. All doses are administered by c.i.v.
3. The Dana Farber/Roswell Park–type regimen (47)—This regimen involves a low dose of IL-2 chronically administered by c.i.v. or subcutaneously for 3 months or longer. Low-dose regimens are better tolerated than moderate- or high-dose regimens and require no hospitalization.

The immunomodulatory effects induced by the low-dose and moderate- to high-dose regimens differ. Although both types of regimens induce NK expansion with an increase in circulating lymphocytes expressing CD16 and CD56, the moderate- to high-dose regimens also induce increases in circulating CD3+ and CD8+ T cells, as well as increases in cytotoxic reactivity by circulating cells with and without exposure to IL-2 *in vitro* whereas low-dose regimens do not (41,48,49 and 50). For this reason, low-dose regimens have incorporated intermittent administration of moderate- to high-dose IL-2 to enhance cytotoxicity. New regimens are also

being studied that involve low-dose IL-2 immediately after ASCT and higher doses thereafter (51).

Lymphomas

Patients with NHL have been included in a few phase 1 and 2 trials of IL-2 after ASCT. One of the trials was designed to identify the MTD of IL-2 (Roche) and its immunomodulatory effects (48) when administered to 16 patients with advanced hematologic malignancies beginning 33 days (median) after ABMT. Patients were sequentially assigned to escalating IL-2 "induction" doses on days 1 to 5 of the IL-2 protocol and a nonescalating, low IL-2 "maintenance" dose on days 12 to 21. The dose-limiting side effects of induction IL-2 were reversible hypotension and thrombocytopenia. Its MTD was 3×10^6 RU per m^2 per day (equivalent to 9×10^6 IU). The IL-2 regimen induced marked, rebound lymphocytosis with an increase in CD3[+] and CD8[+] cells, as well as an increase in NK cells expressing CD16 and CD56. This IL-2 regimen was associated with an increased ability of cells to lyse NK-resistant tumors with and without IL-2 *in vitro*.

In animal models, the combination of IL-2 plus LAK cells has been therapeutically more effective than IL-2 alone (52,53). Therefore, a trial was performed to determine whether LAK cells could be generated, characterized, and infused with IL-2 in patients after ABMT for advanced hematologic malignancies (54,55 and 56). Beginning 35 days (median) after ABMT, patients received the MTD IL-2 induction course identified above. Patients underwent leukaphereses during the period of maximal lymphocytosis (days 7 to 9 of the IL-2 protocol). The cells were cultured for 5 days in IL-2 (1,000 U per mL) and reinfused on days 12 to 14. Low-dose "maintenance" IL-2 was administered on days 12 to 21. A total of 0.4 to 3.8×10^{11} (median, 1.7×10^{11}) cells were infused per patient.

The LAK cells infused were quite lytic against the Daudi tumor target. The infused cells expressed CD3 (65%), CD8 (61%), and CD56 (43%). The most common toxicities associated with LAK cell infusions were fever, chills, and dyspnea. These toxicities usually resolved within 2 to 4 hours (56). LAK cell infusions induced a thrombocytopenia more severe than that observed with IL-2 alone, however, especially in patients with AML (56). The use of LAK cells was abandoned by the Seattle group primarily for financial reasons.

The clinical end-results of IL-2 with or without LAK cell therapy after ABMT in patients with NHL were encouraging. Of 22 patients at a high risk for relapse thus treated with IL-2 plus LAK cells (16 patients) or IL-2 alone (6 patients), 11 relapsed, two died in CR, and nine remained in CR 27 to 51 (median, 37+) months after BMT (56).

When IL-2 could no longer be obtained from Hoffman LaRoche, a phase 1/2 trial was performed with IL-2 from Chiron Therapeutics, Inc. Patients with advanced hematologic malignancies received IL-2 beginning a median of 46 days after ASCT. The MTD of induction IL-2 administered in the hospital was identified and maintenance IL-2 was administered in the outpatient clinic. The resultant "Seattle regimen" (see Table 3.4-2) was then tested in a phase 2 trial in 52 patients after ASCT for hematologic malignancies (57). Eighty percent of patients completed the induction IL-2. Most patients exhibited some degree of capillary leak. One patient died of cytomegalovirus pneumonia and one patient died of adult respiratory distress syndrome. Maintenance IL-2 was well tolerated. The regimen was well tolerated in the majority of patients.

Lymphocytosis was observed after induction IL-2. It reflected a rise in the number of cells expressing CD3, CD8, CD56, and P75 and was associated with significant cytotoxic activity.

The results in the 25 patients thus treated for high-risk NHL, updated since the report (57) are shown in Figure 3.4-1 . Patients with low-grade NHL numbered three in relapse 1 (Rel 1) or CR2 and nine beyond CR2. Those patients with intermediate or high-grade NHL represented nine in Rel1 or CR2 and four beyond CR2. The results compare favorably with historical controls at our institution. A phase 3 trial of this Seattle IL-2 regimen versus observation after ASCT for NHL in relapse is in progress at Southwest Oncology Group (protocol 9,438) to determine whether IL-2 will decrease the relapse rate and prolong disease-free survival. To date, approximately 230 patients have been entered in the trial.
FIGURE 3.4-1. Interleukin-2 therapy after autologous bone marrow and stem cell transplantation for patients with non-Hodgkin's lymphoma (low or intermediate/high grade) at high risk for relapse. (From Robinson N et al. Interleukin-2 after autologous stem cell transplantation for hematologic malignancy: a phase I/II study. *Bone Marrow Transplant* 1997;19:425–442, with permission.)

A different approach evolved from studies in murine models in which marrow incubated with IL-2 *in vitro* before transplantation and combined with systemic IL-2 was injected into tumor-bearing mice. This approach was reported as more effective against tumors than marrow not incubated with IL-2 (58). Accordingly (59), in the largest trial of NHL patients, marrow or stem cells were incubated with IL-2 for 24 hours and then infused into patients conditioned for ASCT. These patients then received systemic IL-2 at a dose of 1 to 2×10^6 IU per m^2 per day by c.i.v. beginning on day 1 for at least 21 days. Subsequently, all patients received 6 cycles of maintenance IL-2 at a dose of 6×10^6 IU per m^2 per day × 5 days per week in weeks 1 and 2 every 28 days. Hematologic engraftment occurred. Clinically, of 19 patients treated for recurrent or refractory NHL, two died as a result of treatment, eight relapsed a median of 4 months after ASCT, and nine remain disease free with a median follow-up of 8 months. The results show that this approach is feasible and clinically tolerable but more cumbersome than the

use of IL-2 alone. The clinical outcome cannot be evaluated in this group of patients because only a small number of individuals were studied for a short period.

IL-2 administered after ABMT for lymphoma has also been used in combination with interferon-α (IFN-α) (60) in a trial of 32 patients with NHL and 24 patients with HD. Sixty-one patients (NHL, 36; HD, 25) served as historical controls. IL-2 and IFN-α were self-administered in 2 cycles beginning a median of 4 months post-transplant and separated by a 4-week period. Each cycle consisted of IFN-α combined with IL-2 at 3 to 6 × 106 IU per m^2 per day × 5 days per week for 4 weeks administered subcutaneously. After a median follow-up of 34 months, 45 out of 56 (80%) patients treated with IFN-α plus IL-2 are disease free compared with only 32 out of 61 (53%) historical controls. The disease-free survival benefit applied to NHL and HD. The relative contributions of IFN-α or IL-2 are unknown. A phase 3 trial of IFN-α and IL-2 versus no cytokines is in progress.

Acute Lymphoblastic Leukemia

Although patients with ALL have been included in some of the phase 1 and 2 trials after ABMT, only two trials specifically dealt with patients with ALL. In Weisdorf et al.'s study (61), in which IL-2 was administered immediately after ABMT, ALL recurred in nine of ten patients in a median of 3 months. One randomized trial was reported (62) in which adult patients with ALL in CR1 were randomized to receive (n = 30) or not receive (n = 30) IL-2 (the French regimen) after ABMT. The 3-year post-BMT probability of CR was similarly low in both groups (29% and 27%). Thus, no clinical benefit of IL-2 therapy was observed.

Acute Myelogenous Leukemia

AML has been the major target of clinical trials of IL-2 after ASCT. Patients who undergo ASCT while in relapse have a 75% probability of post-transplant relapse and a 20% probability of long-term disease-free survival. The corresponding figures for patients treated in CR2 are 50% to 60% and 30%. The results for patients transplanted for AML in CR1 are far more variable, depending on a number of prognostic indicators, including cytogenetics, but, overall, the probability of post-transplant relapse and disease-free survival is approximately 40% to 50%.

For IL-2 trials, AML patients with a poor prognosis (i.e., beyond CR1) have an advantage because the beneficial effects of IL-2, if any, can be more quickly assessed because the controls are likely to relapse and to do so early. Such studies, however, are logistically difficult to assess because the patients become ill too quickly and require rapid initiation of therapy. Furthermore, only a fraction of the patients who relapse enter a CR2.

The phase 1 trial with Roche IL-2 by Higuchi et al. (48) and the feasibility trial of IL-2 plus LAK cells by Benyunes et al. (55) included 17 such AML patients who were treated with IL-2 alone (12 patients) or IL-2 plus LAK cells (5 patients) beginning a median of 54 days after ABMT. At the time of BMT, 11 patients were in Rel1, three were in CR2, and three were beyond CR2—all associated with poor post-transplant prognosis.

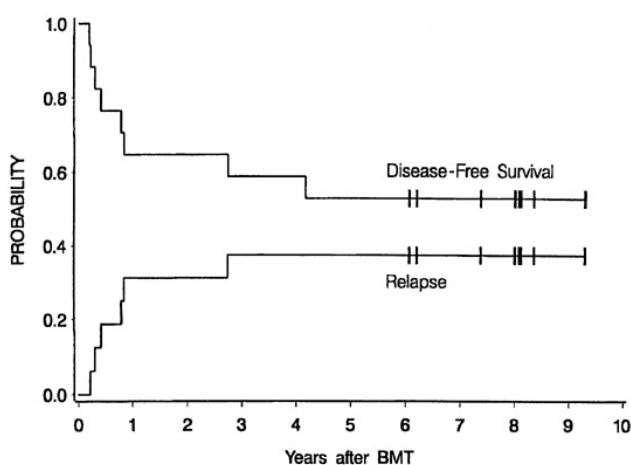
The clinical details of the patients treated have been published (55). The updated results (63) are shown in Figure 3.4-2 . Of 17 patients treated, one died of infection, six relapsed, one died in CR with a secondary malignancy at 5 years, and nine remain in continuous CR beyond 6 years. For comparison, a historical control group was identified that consisted of all patients with comparable clinical characteristics who underwent ABMT at our institution for AML beyond CR1 during the same period. The patients received the same preparative and purging regimens and met the eligibility criteria for IL-2 therapy. These patients did not receive IL-2, however, because they refused treatment or had financial problems, or because IL-2 was temporarily unavailable (54). Of the 15 control patients thus identified, one died of infection, ten relapsed at a median of 4 months, and four (27%) remain in CR beyond 6 years—consistent with results that are expected with ABMT for such patients.


FIGURE 3.4-2. Kaplan-Meier product limit estimates of relapse and disease-free survival of patients treated with autologous bone marrow transplantation (BMT) plus IL-2 ± lymphokine-activated killer cells for acute myelogenous leukemia in first relapse or later (n = 17). (From Benyunes MC et al. Interleukin-2 with or without lymphokine-activated killer cells as consolidative immunotherapy after autologous bone marrow transplantation for acute myelogenous leukemia. *Bone Marrow Transplant* 1993;12:159-163; and Fefer A. Graft-versus-tumor responses. In: Thomas ED, Blume KG, Forman S, eds. *Hematopoietic cell transplantation.* Cambridge, MA: Blackwell, 1999:316-326, with permission.)

A subsequent phase 1 and 2 trial with the Seattle IL-2 regimen (Chiron) after ASCT included 16 patients with AML beyond CR1, some with secondary AML. The published, updated results (57) reveal that one patient with a history of mantle radiation for prior HD died early of adult respiratory distress syndrome, two patients died in CR as a result of cytomegalovirus pneumonia or cardiac fibrosis, nine relapsed at a median of 8 months, and only four remain in CR beyond 6 years. The somewhat discrepant results between two different Seattle trials involving small groups of heterogeneous AML patients highlight the need for a prospective randomized phase 3 trial.

Virtually all other trials reported with IL-2 after ASCT for AML have involved patients in CR1. In the smallest series (64), six patients received high-dose IL-2 after ABMT. Five of these patients were still in CR at 1.5 to 5 years.

The effectiveness of the Seattle IL-2 regimen is being tested after ASCT for AML in CR1 at the City of Hope. To date (65), 46 such patients underwent ASCT after conditioning with total body irradiation,

VP16, and cyclophosphamide (Cytoxan). At a median of 36 days after ASCT, 35 of these patients received IL-2. At 2 years, the disease-free survival for all 46 patients is 82%. The results are sufficiently encouraging to justify a phase 2 trial by SWOG with a view to a subsequent phase 3 trial to determine whether IL-2 will reduce the relapse rate and prolongs disease-free survival.

A small French trial, however, yielded no evidence of benefit (27). Twenty-two patients with AML in CR1 received IL-2 (from Roussel-Uclaf) beginning an average of 72 days after ABMT. Two patients died from toxicity. At 3 years, the probability of relapse was 59%, and leukemia-free survival was only 41%. These results are consistent with those expected without IL-2 therapy. IL-2 was administered later than other trials, and the IL-2 regimen delivered was somewhat unusual. Although a median of 69% of the scheduled dose of IL-2 was administered, the doses that were not tolerated and, therefore, not administered, were probably during the last 2 or 3 days of the first cycle because patients tend to tolerate the first 2 days of most IL-2 doses. If so, then these patients most likely received 2 days of IL-2 every other week for 5 weeks—a regimen not consistent with any of the short-term high-dose or chronic low-dose IL-2 regimens in any murine models.

The low-dose IL-2 regimen of Dana Farber/Roswell Park is being evaluated in a large phase 2 trial (CALGB, protocol 9,621) in patients who undergo ASCT for AML in CR1 with average to poor cytogenetic prognostic features. The IL-2 regimen consists of low-dose chronic s.c. IL-2 with intermittent 3-day periods of intermediate-dose bolus IL-2.

The use of stem cells incubated *in vitro* with IL-2 followed by systemic IL-2 is also being explored (66). Thirty-one patients with AML in CR1 at high risk for relapse underwent ASCT with marrow or stem cells cultured with IL-2 for 8 to 9 days. Beginning right after the infusion, the patients received IL-2 at a s.c. dose of 2 to 10×10^5 IU per m^2 per day for 7 days. Six patients died as a result of complications of ASCT, 12 relapsed, and 13 remain in CR at a median of 4 years. The results demonstrate that this approach is feasible, although probably rather cumbersome, and that incubated cells can reconstitute the patient hematologically. No conclusion can be drawn, however, about clinical benefit. Large phase 2 and 3 trials would have to be performed to determine if this approach is beneficial and to identify the treatment component required (i.e., IL-2, activated cells, or both).

Finally, IL-2 is being studied as part of a cocktail of cytokines and chemotherapy to mobilize stem cells for ASCT for patients with AML in CR1. In one such study (67), the actual leukemia-free survival for the 23 patients who received a systemic s.c. IL-2 dose of 3×10^6 IU per m^2 twice a day × 10 days was 63%. The median follow-up from CR, however, was less than a year. This approach seems feasible, but assessment of its clinical efficacy must await more trials and longer follow-up.

Interleukin-2 after Allogeneic Bone Marrow Transplant

AlloBMT for advanced hematologic malignancies is associated with a high relapse rate (e.g., >50%). The major rationale for using IL-2 as an adjunct to AlloBMT is to induce or augment a GVL effect, because the potential effector mechanisms of GVL (i.e., cytotoxic and noncytotoxic T cells, NK cells, and the secreted cytokines) may be enhanced by IL-2. The major concern, however, is that GVL and graft-versus-host disease (GVHD) share at least some effector mechanisms and targets. Thus, IL-2 therapy might increase the incidence or severity of GVHD.

Rare case reports exist of IL-2, alone or in combination with chemotherapy or IFN-α, inducing clinical antileukemic effects when given to patients whose leukemia relapsed after AlloBMT (68,69,70 and 71). Attempts to use IL-2 after AlloBMT to prevent relapses, however, have been limited by concern that it might induce fatal GVHD. To reduce this possibility, IL-2 was first used only in recipients of marrow depleted of T cells who were less likely to develop GVHD (72). Beginning a median of 67 days after BMT for a variety of hematologic malignancies, low-dose IL-2 was administered by c.i.v. at 2 to 4×10^5 IU per m^2 per day for 3 months. The number of circulating NK cells increased without a significant change in T-cell number. Only one patient developed GVHD. The relapse rate in the 25 patients who completed more than 4 weeks of IL-2 was significantly lower than that of historical controls who were transplanted for the same conditions in the same way without IL-2 and survived disease-free beyond 100 days. The results are interesting and encouraging and call for follow-up trials.

IL-2 therapy after unmodified AlloBMT could theoretically exert a greater GVL effect than after T cell–depleted BMT, but could also present a greater risk for GVHD. The relevant clinical data reported are sparse. Based on a report (73) that IL-2 protected against fatal GVHD in a murine model, seven leukemic patients received IL-2 at 3×10^6 IU per m^2 per day for 5 days by c.i.v. beginning 4 hours after BMT from a 2- to 3-antigen mismatched donor (74). All patients developed severe GVHD. Six patients died; three died as a result of GVHD. Clearly, this regimen of IL-2 administered early to mismatched recipients had unacceptable toxicity and no benefit.

The only reported trial of IL-2 in recipients of non–T cell–depleted allogeneic marrow was a phase 1 trial (75) conducted among 17 children who underwent matched sibling AlloBMT for acute leukemia beyond CR1. They began receiving IL-2 (Roche) by c.i.v. a median of 68 days after BMT. Cohorts of patients received escalating doses of induction IL-2 (0.9, 3.0, or 6.0×10^6 IU per m^2 per day for 5 days, representing levels 1, 2, and 3) as inpatients and were then discharged. After 6 days of rest, they received maintenance IL-2 (0.9×10^6 IU per m^2 per day for 10 days) as outpatients.

Because IL-2 could potentially exacerbate GVHD, and because the immunosuppressive agents used for GVHD prophylaxis could interfere with an immunologically mediated antileukemic effect of IL-2, the IL-2 was administered only to children whose GVHD prophylaxis was withdrawn and who developed no GVHD during the susequent 2 weeks. Three patients received level 1, eight patients received level 2, and six patients received level 3. The MTD of induction IL-2 was determined to be level 2.

All induction doses of IL-2 at levels 1 and 2 were received by all patients. Fever, nausea, vomiting, diarrhea, weight gain, and mild rash were common, reversible, and not dose limiting. Levels 1 and 2 were not associated with any toxicities greater than

grade 2. Most patients exhibited a mild, reversible thrombocytopenia with a nadir during the rest period and a return to baseline during maintenance. Neutropenia did not occur.

Acute GVHD during IL-2 therapy was observed in only two patients—one after completing level 1 and one at level 3. In both patients, GVHD resolved within a week of discontinuing IL-2 without additional therapy. Extensive, chronic GVHD of variable severity occurred in five patients (one out of three patients at level 1, zero out of eight patients at level 2, and four out of five patients at level 3). The immunologic changes induced were comparable to those observed with IL-2 after ABMT with lymphocytosis and increases in cells expressing CD8 and CD56. Thus, level 2 (MTD) induction IL-2 induced immunomodulatory effects, was relatively well tolerated, and was not associated with a high incidence or great severity of acute or chronic GVHD.

The clinical outcomes for the 17 patients reported (75) are updated (63) in Figure 3.4-3 . One patient died early of infection, seven relapsed, and nine remain in CR at 3 to 8 years. These long-term disease-free survivors include four out of six patients with AML and 5 out of 11 patients with ALL—all at high risk for relapse. The results are better than expected for such patients with AlloBMT alone. A multisite phase 2 trial has been initiated.

Summary and Conclusions

Part of "3.4 - Hematologic Malignancies "

The role of IL-2 in the treatment of hematologic malignancies has yet to be defined. The most cogent and relevant observation is that some patients with some refractory hematologic malignancies, especially AML and NHL, have responded to some regimen of IL-2 with or without LAK cells, usually with PRs, but occasionally with durable CRs. These results need to be confirmed, and anecdotal responses in other hematologic malignancies need to be validated. The optimal regimen remains unknown and can be identified only by comparative trials in more homogeneous patients because the trials involved small numbers of clinically heterogeneous patients and different IL-2 regimens.

Theoretically, IL-2 therapy should be more effective in a setting of MRD (e.g., after conventional chemotherapy or high-dose therapy plus blood or marrow stem-cell rescue). Several small phase 2 trials have been performed with IL-2 for AML patients in chemotherapy-induced CR1 with inconclusive results. One randomized phase 3 trial of one regimen of IL-2 for AML in CR1 has been initiated by the Children's Cancer Group. Similar trials are anticipated by other groups with other regimens. Two phase 2 trials are in progress by CALGB and are likely to lead to phase 3 trials.

The post-transplant setting may be preferable to the post-chemotherapy setting for IL-2 therapy. In the post-transplant setting, fewer residual tumor cells exist and more CD56⁺ cells are present with MHC-unrestricted lytic activity against tumors, particularly those hematologic malignancies that express few MHC molecules. Pilot or phase 1 and 2 trials of various IL-2 regimens administered after ABMT yielded some encouraging but inconsistent and inconclusive results. Based on encouraging results of one phase 2 trial, a phase 3 trial of IL-2 versus observation after ASCT for relapsed NHL is in progress by SWOG. Moreover, rigorous phase 2 trials of IL-2 for patients who have undergone ABMT or ASCT for AML in CR1 are in progress or about to be initiated by SWOG and CALGB.

The use of IL-2 after allogeneic transplantation is based on the hope that a donor lymphocyte-mediated GVL effect can be induced or augmented without concomitant exacerbation of GVHD. Trials have been limited by concern that IL-2 might induce severe or fatal GVHD. The encouraging clinical results of two phase 1 and 2 trials of IL-2 administered to recipients of allogeneic T cell-depleted or non-T cell-depleted marrow for leukemia, however, warrant larger phase 2 and, ultimately, phase 3 trials.

The MRD setting is one in which the efficacy of IL-2, or any other immunotherapy, is most difficult to evaluate because it ultimately requires randomized phase 3 trials with large numbers of patients and a long follow-up time. The lower the amount of MRD at initiation of IL-2 therapy (e.g., AML in CR1), the more patients and longer follow-up time is required. Moreover, it is extraordinarily difficult to identify the optimal regimen of IL-2 without measurable disease to follow and without surrogate markers or proxy laboratory assays predictive of clinical efficacy. Thus, the optimal therapeutic dose of IL-2 may or may not be the MTD.

The impact of any additional therapeutic variable, such as exogenously generated LAK cells obtained after chemotherapy, after recovery from BMT, or as part of the infused marrow and stem cells, is even more difficult to assess in an adjuvant clinical setting. It requires phase 2 and 3 trials to determine not only the therapeutic efficacy of the entire combination of IL-2-activated cells and systemic IL-2, but also whether all components are required.

In summary, the role of IL-2 in the treatment of hematologic malignancies remains unknown but deserves continued investigation. The encouraging clinical results reported, however sparse, suggest that its role will be clarified with additional basic research and clinical trials that are in progress or soon to be initiated. Until then, IL-2 should be used for hematologic malignancies only in the investigative setting of a clinical trial.

Biology of Interleukin-4

Part of "4 - Interleukin-4: Clinical Applications "

Molecular Aspects

Interleukin-4 (IL-4) is a glycoprotein with an approximate molecular mass of 15 to 19 kd. A mouse IL-4 complementary DNA (cDNA) was first isolated from a mouse T helper 2 (Th2) cell library as a cDNA encoding for a unique mouse interleukin that expressed B-cell, T-cell, and mast-cell stimulating activities (1). Subsequently, a human IL-4 cDNA was isolated by cross-hybridization from an activated human T-cell clone cDNA library (2). Mouse chromosomal DNA segments for IL-4 were isolated based on homology with the IL-4 cDNA and mapped to chromosome 11 (3). The gene for human IL-4 consists of four exons and three introns located on chromosome 5 at position q23.3-31.2 (4). It is produced mostly by activated Th2 cells (5) and mast cells (6). Multiple stimulatory and regulatory effects on the immune system can be demonstrated (Table 4-1). IL-4 mediates its biologic activity by binding to a high-affinity receptor expressed on B and T lymphocytes, myeloid cells, monocytes, macrophages, mast cells, fibroblasts, endothelial cells, and some cancer cells (7,8 and 9). Initially, it was shown that IL-4 binds to three molecular species of 140-, 70- to 75-, and 65-kd molecular weight (10,11). The 140-kd protein is termed *IL-4 receptor a* (IL-4Rα) (12) and the 65-kd form is termed the *γ common chain* (γ$_c$), which is shared with other cytokine receptors, including IL-2, IL-7, IL-9, and IL-15. The γ$_c$ chain increases by two- to threefold the affinity of IL-4 for gp140 and IL-4Rα in lymphoid cells (13,14). Binding of IL-4 to the IL-4Rα chain induces dimerization of the IL-4Rα chain with the γ$_c$ chain in these cells. It has been demonstrated that two different forms of IL-4R exist: the classical and alternative forms (15) (Fig. 4-1). The classical IL-4Rα form is predominantly expressed in hematopoietic cells and consists of IL-4Rα and γ$_c$ chains. The alternative form of IL-4R is predominantly expressed in nonhematopoietic cells and consists of IL-4Rα and IL-13Rα' chains. Moreover, the alternative form of IL-4R is used as a functional component of the IL-13R complex (15,16). Sanafelt et al. created a mutant form of IL-4 that was substituted in the region of IL-4 implicated in interactions with the γ$_c$ chain. The mutant containing the mutation Arg-121 to Glu (IL-4/R121E) exhibited complete functional and binding selectivity for T cells, B cells, and monocytes. The mutant showed no activity on endothelial cells, which express only alternative forms of IL-4R, suggesting its use in the treatment of certain autoimmune diseases (17). It has been shown that the phosphorylation and activation of Janus tyrosine kinase (Jak)3 is crucial for IL-4-induced activation of signal transducer and activator of transcription (STAT) 6 in hematopoietic cells. It has been demonstrated that nonhematopoietic cells, however, lack Jak3 expression. In these cells, Jak1 and Jak2 mediate activation of STAT6 instead (16). Furthermore, IL-4 and IL-13 signals are transmitted through the alternative form of IL-4R in these cells (18). The structure and signal transduction through IL-4R and IL-13R appear to be different in hematopoietic versus nonhematopoietic cells. The crystal structural analysis of the complex between the human IL-4 and IL-4Rα chain revealed a novel spatial orientation of the two proteins; a small, but unexpected, conformational change in the receptor-bound IL-4 and an interface with separate clusters of transinteracting residues (19). Downstream events involve insulin receptor substrate-2, phosphoinositol-3 kinase activation, and STAT6 translocation (20) to the nucleus.

Table 4-1 Biologic Properties of Interleukin-4

Human IL-4: Glycoprotein with molecular weight of 15-19 kd encoded on chromosome 5 at q23.3-31.2

Mouse IL-4: Molecular weight: 19 kd (EL-4 cells) and 24 kd (COS7-derived recombinant) encoded on chromosome 11

Produced by CD4+ T cells (Th2 subset), basophils, and mast cells

Other names: B-cell growth factor-1, B-cell stimulating factor, mast-cell growth factor, and T-cell growth factor-2

Effects on B Cells

 Increases surface class II major histocompatibility complex antigens in B cells

 Induces Ig isotype switching for IgG1 and IgE production

 Enhances Ig production and expression of CD23 on B cells

Effects on T Cells

 Stimulates the growth of normal helper and cytotoxic T cells, including tumor-infiltrating lymphocytes

 Promotes Th2 cell growth

 Stimulates the growth of normal helper and cytotoxic T cells, including tumor-infiltrating lymphocytes; acts synergistically with IL-2 to enhance proliferation of precursor cytotoxic T lymphocytes and induce their differentiation into active cytotoxic T lymphocytes

 In concert with TGF-ß, promotes the differentiation of naïve CD4+ T cells into Th1-type cells

 Roles in induction of Th1-type response and antitumor-immune response shown in experiments using IL-4 gene knockout mice

Effects on Myeloid Cells

 In combination with GM-CSF, promotes the differentiation of bone marrow precursor cells to DCs

 Drives Th1 response by inducing apoptotic death of lymphoid DCs and mature myeloid DCs

 Decreases macrophage production of IL-1ß, IL-6, and TNF-α

Effects on Other Cells

 Direct growth-inhibitory effect on human cancer cells, including induction of apoptotic cell death

 Inhibits angiogenesis

 Upregulates the expression of vascular cell adhesion molecule 1 on endothelia, allowing enhanced recruitment of VLA-4+ cells (i.e., memory T cells, eosinophils, and DCs)

DCs, dendritic cells; GM-CSF, granulocyte-macrophage colony-stimulating factor; Ig, immunoglobulin; IL, interleukin; TGF-ß, tumor growth factor-ß; Th1, T helper 1; Th2, T helper 2; TNF-α, tumor necrosis factor-α; VLA, very late antigen.
FIGURE 4-1. Interleukin-4 receptor (IL-4R) structure model. The classical IL-4R is predominantly expressed in hematopoietic cells and consists of the 140-kd protein, IL-4Rα, and the 65-kd form of the γ common chain (γ$_c$), which is shared with other cytokine receptors, including IL-2, IL-7, IL-9, and IL-15. An alternative form of IL-4R is predominantly expressed in nonhematopoietic cells, including endothelia, and consists of IL-4Rα and IL-13Rα' chains. IL-4 and IL-13 signal through the alternative IL-4R in nonhematopoietic cells. Thus, the structure and signal transduction through IL-4R and IL-13R appear to be different between hematopoietic and nonhematopoietic cells. IL-4Rα chain is also required in functional type 1 IL-13R. This chain binds to both IL-4 and IL-13 in type I IL-13R system. In this complex, IL-13 binds to all three chains, whereas IL-4 binds to only two chains. (Modified from Murata T, Obiri NI, Debinski W, Puri RK. Structure of IL-13 receptor: analysis of subunit composition in cancer and immune cells. *Biochem Biophys Res Commun* 1997;238:90-94; and Obiri NI, Leland P, Murata T, Debinski W, Puri RK. The IL-13 receptor structure differs on various cell types and may share more than one component with IL-4 receptor. *J Immunol* 1997;158:756-764, with permission.)

Immunology

IL-4 promotes growth and differentiation of B cells (21,22), T cells, and mast cells and mediates profound regulatory effects on macrophages (23). IL-4 increases surface class II major histocompatibility complex (MHC) antigens in B cells (24), low-affinity Fc receptors (CD23), surface immunoglobulin (Ig) M, CD40, and cell adhesion molecules (i.e., leukocyte function-associated antigens 1 and 3) (25). IL-4 induces Ig isotype switching for IgG1 and IgE production (26,27); stimulates the growth of normal helper and cytotoxic T cells (28), including tumor-infiltrating lymphocytes (29); and acts synergistically with IL-2 to enhance proliferation of precursor cytotoxic T lymphocytes, inducing their differentiation into active cytotoxic T lymphocytes (30). IL-4 also upregulates the expression of vascular cell adhesion molecule 1 on activated endothelia (31). IL-4 in combination with granulocyte-macrophage colony-stimulating factor, promotes the differentiation of bone marrow precursor cells to dendritic cells (DC), as described in the section Interleukin-4 in Dendritic Cell Biology and Its Use in Dendritic Cell-Based Therapy (32,33,34,35 and 36).

Interleukin-4 in T-Helper Cell Responses

IL-4 is a Th2-type response mediator. Naïve helper T cells differentiate preferentially to Th2-type cells, which produce predominantly IL-4, IL-5, IL-6, and IL-10; drive isotype switching in the

differentiation of B cells; and enhance CD8[+] T-cell production of IL-4 (i.e., Tc2). The view of IL-4 as solely a Th2 inducer, however, oversimplifies its biology. In the presence of IL-4 and tumor growth factor-ß, both of which are known as Th2 differentiation factors, naïve CD4[+] T cells can differentiate into Th1-type cells, at least *in vitro* (37). Critical roles of IL-4 in the induction of Th1-type responses and antitumor immune responses have been demonstrated in experiments using IL-4 gene knockout mice (38). Initiation of the immune response to otherwise immunogenic tumors is markedly suppressed in these animals. Peritumoral IL-4 expression after transfection with the IL-4 gene, however, restores the Th1-mediated antitumor immune response in these IL-4-deficient mice, suggesting the potent ability of IL-4 to induce a response even in immunologically compromised hosts.

Interleukin-4 in Dendritic Cell Biology and Its Use in Dendritic Cell–Based Therapy

Figdor et al. noted that IL-4 is capable of enhancing the antigen-presenting capacity of human monocytes accompanied by upregulation of MHC class II and reduced secretion of IL-1ß, IL-6, and tumor necrosis factor-α (TNF-α) (39). Later, it was found that IL-4 in combination with granulocyte-macrophage colony-stimulating factor also promotes the acquisition of a DC phenotype and function in mouse bone marrow (34) and human monocyte precursors or CD34[+] cell (32,33,34,35 and 36) cultures. Thus, IL-4 is widely used *ex vivo* in clinical trials of DC-based cancer therapy (40,41 and 42). It has been demonstrated that myeloid DCs produce large amounts of IL-12 and induce Th1 differentiation; in contrast, lymphoid DCs derived from CD4[+], CD3[-], and CD11[-] plasmacytoid cells cause Th2 differentiation. Furthermore, IL-4 has been demonstrated to drive Th1 responses by inducing apoptotic death of lymphoid DCs and maturing myeloid DCs (44). These findings suggest a possible mechanism by which local exogenous IL-4 mediates immune modulation at the level of the antigen-presenting cell.

Other Biologic Functions

Human IL-4 has a direct growth-inhibitory effect on human renal cell carcinoma and malignant melanoma cells (44,45,46,47 and 48). These cells express the high-affinity receptor for IL-4. Lahm et al. examined the effect of IL-4 on the growth of seven human colorectal carcinoma cell lines. In five of seven cell lines, a dose-dependent reduction of proliferation was observed, and those cells expressed functional IL-4R (49). The growth inhibition mediated by IL-4 involves suppression of insulinlike growth factor 2 (50). Similar observations were found in human astrocytes and astrocytic tumors (51). Growth inhibition of glioma cells by IL-4 appears to involve upregulation of p27Kip1, a cyclin-dependent kinase inhibitor (52). One report (53) demonstrated an IL-4R–dependent growth inhibition by IL-4, as well as human breast cancer cell lines. Apoptotic cell death was detected as a mechanism of IL-4-induced growth inhibition. Taken together, the antitumor effect of IL-4 on human cancer cells appears to be mediated, at least in part, by the direct inhibition of tumor growth via IL-4R–mediated signaling. IL-4 may promote the growth of some types of human cancer cells, however, such as squamous cell carcinoma of the head and neck cell lines (54).

Antiangiogenesis is an important strategy to control tumor growth *in vivo*. Murine IL-4 downregulates the expression of vascular endothelial growth factor receptor 2, one of the receptors for vascular endothelial growth factor on endothelial cells *in vitro* (55). The inhibited growth of C6 rat glioma cells engineered to express murine IL-4 in athymic mice is accompanied by reduced levels of vascularization. Volpert et al. (56) demonstrated that IL-4 blocks the basic fibroblast growth factor-mediated neovascularization in rat cornea. No species specificity was observed in the effect. IL-13 inhibited the migration of human or bovine microvascular cells, as well as IL-4.

Recombinant Interleukin-4 in Cancer Therapy

Part of "4 - Interleukin-4: Clinical Applications "

Animal Models

The availability of recombinant IL-4 led investigators to test its antitumor effect *in vivo*. Hillman et al. demonstrated the therapeutic potential of systemic IL-4 administration for the treatment

of pulmonary metastases in a murine RenCa renal adenocarcinoma model (57). A dose-dependent (up to 2 µg per animal per day for 5 consecutive days since day 5) reduction in the number of metastasis and augmented survival was observed. *In vivo* depletion of lymphocyte subpopulations indicated that CD8+ T cells and asialo GM1+ cells were involved in the rejection of tumors. When IL-4 was intralesionally administered to the same RenCa tumors implanted below the renal capsule (6 µg per animal, single injection), marked inhibition of primary tumor growth was observed. Little effect on the progression of distant metastatic sites was detected (58). A unique route of IL-4 administration was tested by Bosco et al. (59). Using BALB/c mice bearing a chemically induced fibrosarcoma or a spontaneous adenocarcinoma (TS/A), IL-4 was administered by daily, local subcutaneous injection at the site of tumor-draining lymph nodes. Small amounts (0.00001 to 1,000 µg per day) of recombinant IL-4 inhibited tumor growth and led to induction of immunologic memory specific for the tumor. Delivery of 0.1 µg per day of IL-4 led to the best survival among the dosages tested, suggesting a dichotomous response to IL-4. IL-4 inhibited tumor growth far better than the direct injection of the most effective doses of IL-2, IL-1, or interferon-γ. Tumor-draining lymph nodes from animals treated in these studies displayed numerous macrophages, activated lymphocytes, and eosinophils. Combination therapy was also tested. Coadministration of IL-1 with IL-4 was much better at eliciting tumor rejection and long-term memory superior to that observed with other cytokines used singly or in combination.

Other trials demonstrated a compromised tumor-rejection response after systemic administration of IL-4. Terres et al. (60) examined the effect of systemic administration of recombinant IL-4, IL-10, or both in mice harboring a syngeneic p815 tumor line transfected with B7.1. In nontreated animals, these tumors were rejected by T cell–mediated responses. Treatment of animals with IL-4 particularly at higher doses when compared with other studies (10 µg per mouse begun on day 7 and ended on day 22 every 3 days) resulted in a compromised rejection response accompanied with splenomegaly characterized by a marked increase in neutrophils and natural killer cell activity. IL-10, in contrast, was not immunosuppressive. When given in combination with IL-4, IL-10 countered the IL-4-suppressive effect. Suppressive effects of systemic IL-4 administration in antitumor immunity were demonstrated in another trial (61). A higher number of pulmonary metastases in the murine melanoma cell line B16F10 was associated with enhanced production of IL-4 and IL-10 by CD4+ T cells in the spleen. Such cells were not detected in animals inoculated with the same number of B16F1, a less metastatic B16 subclone compared with B16F10. When animals were treated with anti-IL-4 antibody, the number of metastases decreased. Animals with B16F1 cells had an increased number of metastases after treatment with 10 µg per kg of recombinant IL-4. This study suggested that IL-4 secreted from tumor-associated Th2 cells enhanced the metastatic ability of tumors *in vivo*, perhaps by activating the endothelium (IL-4 enhances expression of vascular cell adhesion molecule 1 on endothelial cells, enhancing recruitment of memory T cells and DCs). The impact of systemic IL-4 administration in tumor-bearing animals may differ depending on cell line, animal strains, and so forth, as well as timing, dosage, and the duration of administration. IL-4 mimics the immunobiology of other cytokines in which issues such as timing and location are important to function.

Clinical Trials of Recombinant Interleukin-4

Recombinant human IL-4 (rhIL-4) has been tested on various types of human tumors. Possible mechanisms that propagate trafficking of the antitumor effects of IL-4 include induction of

immune responses, antiangiogenenic effects, and induction of apoptotic death or direct growth inhibition of tumor cells or both. Phase 1 clinical trials with rhIL-4 as a single antitumor agent began in 1988. In general, rhIL-4 has been relatively well tolerated at lower doses, but dose-limiting toxicities have been reached with the glycosylated and nonglycosylated forms (61,62,63,64 and 65). Side effects include fatigue, diarrhea, gastric ulceration, arthralgia, dyspnea, headache, sinus congestion, and hyponatremia. The more common side effects are headache, nasal congestion, fever, fluid retention, anorexia, fatigue, nausea and vomiting, and diarrhea. With the exception of some inflammatory reactions at subcutaneous injection sites, no allergic reactions have been reported and no antibodies to rhIL-4 have been described. Pharmacokinetic studies indicate that IL-4 can be detected in the serum 8 to 12 hours after subcutaneous administration but is rapidly cleared after intravenous administration with a half-life of less than 1 hour (65). Elevated liver enzymes (i.e., alkaline phosphatase and transaminase) are frequently reported, especially in patients with hepatic disease. Following are some of the published results from single-agent phase 1 and 2 clinical trials with rhIL-4.

Atkins et al. tested relatively high doses (10 or 15 µg per kg, thrice-daily intravenous bolus injection) in ten patients (63). A dose of 10 µg per kg of IL-4 was found to be the maximum tolerated dose for this schedule. No clinical benefit, however, was observed. Vokes et al. (66) reported our clinical study with 62 patients with advanced non-small-cell lung cancer. A dose of 0.25 µg per kg or 1.0 µg per kg of rIL-4 was administered subcutaneously three times per week. Therapy was well tolerated with no myelosuppression or elevation of liver enzymes, bilirubin, or blood glucose. Symptoms encountered in patients with 1.0 µg per kg included fatigue (18 of 41 patients), fever (14 of 41 patients), and anorexia (12 of 41 patients). Among 55 evaluable patients, one partial response occurred that lasted longer than 5 years. Eight patients had stable disease lasting 106 to 350 days. Leach et al. (67,68) summarized the results of preclinical safety evaluation and found that *Escherichia coli*-derived rhIL-4 is safe and well tolerated in doses up to 5 µg per kg per day and 10 µg per kg when administered three times a week. Diverse effects observed in primates have not been generally observed in human patients.

We initially began phase 1 studies in the fall of 1988 with recombinant IL-4 provided by Sterling Pharmaceuticals (Malvern, PA). Patients were started at 1 µg per kg given as a rapid intravenous infusion once a day for 2 cycles of 7 days separated by a week of rest. This dose was escalated in 12 patients to a final dose of 30 µg per kg administered on the same schedule (61). Toxicities were minimal but included symptoms described previously in this section. Using a biologic assay with the induction of CD23 on a malignant B-cell line (69), we defined an α *phase* as approximately 8 minutes and a β *clearance* as approximately 48 minutes. Ultimately, a total of 100 patients were treated, 99 eligible for analysis. A review of this experience is being prepared for publication. Three patients per cohort were treated with rIL-4 at 1, 3, 10, or 30 µg per kg per day as a single intravenous bolus. Subsequent patients in group 1 (IL-4 alone) were administered IL-4 three times daily for a total of 15 doses at 3, 10, or 20 µg per kg per dose. In group 2, patients received a combination of IL-4 and IL-2 intravenous bolus at low doses of IL-2 (216,000 U per kg) with 2, 6, or 20 µg per kg IL-4 every 8 hours or at high doses of IL-2 (720,000 U per kg) with 2, 6, 10, or 20 µg per kg IL-4 in cohorts of three patients. Twenty-seven and ten patients, respectively, were treated with 20 µg of IL-4 every 8 hours and either 216,000 or 720,000 U per kg of IL-2, respectively. Toxicity of IL-4 was associated with mild hypotension, peripheral swelling, nasal congestion, and headache and was observed in a dose-dependent fashion. No responses were observed in the 48 patients who received IL-4 alone. Partial responses were observed in patients who received the combination therapies, including 51 evaluable patients. Two of 19 melanoma who received the 720,000 U per kg per dose IL-2 with IL-4 had partial responses. Three out of 18 patients with renal cell carcinoma who received 216,000 or 720,000 U per kg per dose IL-2 with IL-4 had partial responses (2) or complete remissions (1). No patient (zero out of eight) with colon cancer responded. One of two patients with breast cancer responded to this therapy. In conclusion, no increases in survival were observed with IL-4 alone. Although responses were observed in combination with IL-2 treatment, the enhanced toxicity precluded effective application, suggesting the need for locoregional therapy with delivery by gene transfer approaches.

Interleukin-4 and Its Use in Gene Therapy

Part of "4 - Interleukin-4: Clinical Applications "

Animal Models

As is true for other cytokines, intrinsic potency and toxicity have complicated application of IL-4 as a therapeutic agent when applied systemically. Many cytokines mediate a variety of antagonistic and synergistic immunologic effects when encountered by immune cells, which are activated during the process of ongoing immune responses, at various stages subsequent to hematopoiesis and lineage commitment. Indeed, one of the major characteristics of most cytokines is their ability to regulate immunity at a local or regional level. Systemic levels provided by most conventional schema fail to mimic the induction of an effective immune response, particularly in the context of an established tumor. Introduction of genetic engineering of cells made it possible to assess the effects of sustained IL-4 production at local tumor sites (Table 4-2). The initial reports of Tepper et al. (70) demonstrated that tumor rejection could be initiated with IL-4 transfection of murine tumors. Tumor rejection was initially thought to be solely mediated by eosinophils and macrophage infiltration. In retrospect, it was almost certainly caused in part by endothelial activation and antiangiogenic effects mediated directly by IL-4 or through recruitment and activation of innate immune effectors, which can regulate the local angiogenic response alone. Transfecting the IL-4-dependent T-cell line with IL-4 led to autocrine growth *in vitro*(71,72). These cells could not grow *in vivo*, however, even in nude mice, presumably because of the local biologic activity of IL-4. Introducing the IL-4 gene into a murine renal cell carcinoma (RenCa) or a colorectal carcinoma (CT26) caused rejection, systemic immunity mediated predominantly by CD8⁺ T cells, and therapeutic effects, even when administered as late as 9 days after establishment of the primary tumor. Macrophages and eosinophils were observed to infiltrate the tumors early. T cells were observed to enter the tumor site mostly during the second week (73).

Table 4-2 Gene Therapy Approaches Using Interleukin-4

Murine Models

Authors	Year	Tumor Type	Effector Type or Mechanisms
Tepper	1989	Plasmacytomas and mammary adenoca	Eosinophils and macrophages
Blankenstein	1990	IL-4-dependent T cell CT4S	Loss of tumorigenicity even in nu/nu mice
Golumbeck	1991	Renal cell carcinoma (RenCa)	CD8⁺ T-cell mediated specific immunity
Pippin	1994	Colorectal (MC-38) and fibrosarcoma (MC-105)	Synergy with IL-2
Pericle	1994	Mammary adenoca (TS/A)	Cellular and humoral immunity
Stoppacciaro	1997	Colon cancer	Influx of dendritic cells
Cayeux	1997	β-galactosidase–expressing MCA-205 and TS/A	Enhancement of cross-printing
Okada	1999	Gliosarcoma (9L)	Effective peripheral vaccine against intracranial tumors
Schüler	1999	Colorectal (CT-26)	Required for antitumor T-cell priming in IL-4 knockout mice

Human Trials

Authors	Year	Tumor Type	Vaccine Formulation	Efficacy and Toxicity
Belli	1998	Melanoma	Transduced allogeneic melanoma cell line	Three out of seven patients with local response
Lotze	1999	Melanoma, etc. (see Table 3)	Transduced autologous fibroblasts	Three out of six melanoma patients and three out of 18 patients with local response

IL, interleukin.

We confirmed such studies in murine models and demonstrated synergy with systemic administration of IL-2 (74). Pericle et al. highlighted an aspect of IL-4 biology as the Th2-type response-inducing factor (75). Although morphologic observation suggested that the rejection of IL-4-transfected TS/A tumors depended on eosinophil cytolysis, lymphocyte depletion experiments showed that this rejection also required CD8+ lymphocytes. The memory response induced by this initial rejection appears to be mediated partially by Th2-type humoral response, as well as antibody-dependent cellular cytotoxicity and other cellular-effector mechanisms. Comparison of these mechanisms mediating memory with those elicited by IL-2 gene-transduced TS/A cells shows that Th2 memory is more efficient in protecting against a subsequent challenge of TS/A-pc than the Th1-type memory elicited by IL-2 gene-transduced TS/A cells. As described in the Interleukin-4 in Dendritic Cell Biology and Its Use in Dendritic Cell–Based Therapy section, IL-4 plays an important role in DC maturation. IL-4-transduced cancer cells increased the influx of DCs to the tumor site relative to other cytokines (76), suggesting that local IL-4 expression at the vaccine site may enhance leukocyte recruitment, including DCs, thereby enhancing tumor-antigen presentation.

Cytokine gene-transfected tumor cells conferred protection against a subsequent lethal tumor challenge that was comparable with a tumor cell/adjuvant vaccine (77). Cayeux et al. (78) reported that IL-4/B7.1 cotransfected cells are clearly superior to a tumor cell/adjuvant vaccine. The mechanism responsible for enhanced antitumor immunity was addressed using the TS/A (H-2d) and MCA-205 (H-2b) tumors transfected with the individual cytokine gene or B7.1, or both (79). ß-galactosidase (ß-gal) was chosen as a surrogate tumor Ag. ß-gal has well-defined MHC class I epitopes in H-2b and H-2d mice. Immunization of (H-2b × d) F1 mice with MCA-205/ß-gal CD80 or IL-4 transfectants enhanced cross-priming and rejection of an otherwise lethal challenge with TS/A/ß-gal. On the other hand, direct antigen presentation was examined using H-2b nu/nu mice reconstituted with F1 lymphocytes in which antigen-presenting cells expressed only the H-2b haplotype. These animals were immunized with H-2d TS/A/ß-gal transfectants and challenged with TS/A/ß-gal. CD80 enhanced direct antigen presentation by tumor cells. Cytokine gene transfection did not. This elegant set of studies demonstrated that combinations of cytokine (e.g., IL-4) and costimulatory molecule (CD80) gene therapy enhanced antitumor immunity by enhancing antigen-presenting cell function and defining effector pathways.

Interleukin-4 Gene Therapy in Central Nervous System Tumors

The central nervous system (CNS) has been regarded as a partly immune-privileged site. CNS tumors are indeed challenging targets for immunotherapy (80). Although cytokine gene therapy for CNS tumors is an attractive approach, inducing considerable inflammation after cytokine gene expression in the CNS may cause life-threatening brain edema or elevation of intracranial pressure (81). In murine brain tumor models, however, accumulating findings demonstrate that IL-4 can be expressed in the CNS as an effective treatment for brain tumors. For example, investigation of a spontaneously generated mouse glioma cell line transduced with a panel of cytokines demonstrated that IL-4-transduced glioma cells conferred antitumor immunity with the least toxic response to surrounding normal brain among the cytokines tested (82). Prolonged survival was observed in animals who received IL-2, TNF-α, or IL-4-secreting tumors. IL-2 and TNF-α, however, seemed to have a detrimental effect on survival in some animals when expressed intracerebrally. IL-4-encoding retroviral vector (83) or its combination with the herpes simplex thymidine kinase (HSV-TK) gene (84) or herpes simplex viruses (85) produces safe and effective antibrain tumor responses in murine brain tumor models.

We explored the potential of IL-4-transduced glioma peripheral vaccine to induce immunoreactivity to CNS tumors (86). As a mechanism for enhancing the safety of vaccine administration, we introduced the HSV-TK gene, a so-called suicide gene, into a

retroviral vector encoding the murine IL-4 and neomycin phosphotransferase genes. By incorporating the HSV-TK gene into IL-4-transduced glioma vaccines and subsequently treating vaccinated patients with ganciclovir, we hope to eliminate the small potential for local tumor growth at the site of vaccination and enhance the delivery of tumor antigens to antigen-presenting cells. Subcutaneous immunization of rats with nonirradiated IL-4 plus HSV-TK-transduced syngeneic rat gliosarcoma 9L (9L-IL-4-Tk) cells followed by treatment with ganciclovir completely protected animals from a subsequent intracranial challenge with wild-type 9L cells. More important, treatment of established (day 3) intracranial 9L tumors with genetically engineered tumor cells resulted in long-term survival (>100 days) for 25% to 43% of 9L-IL-4-Tk-immunized animals using various concentrations of ganciclovir and for 27% of nonirradiated IL-4-transfected 9L (9L-IL-4) immunized animals. These findings support the potential use of tumor cell vaccines expressing the IL-4 and HSV-TK genes for the treatment of malignant gliomas.

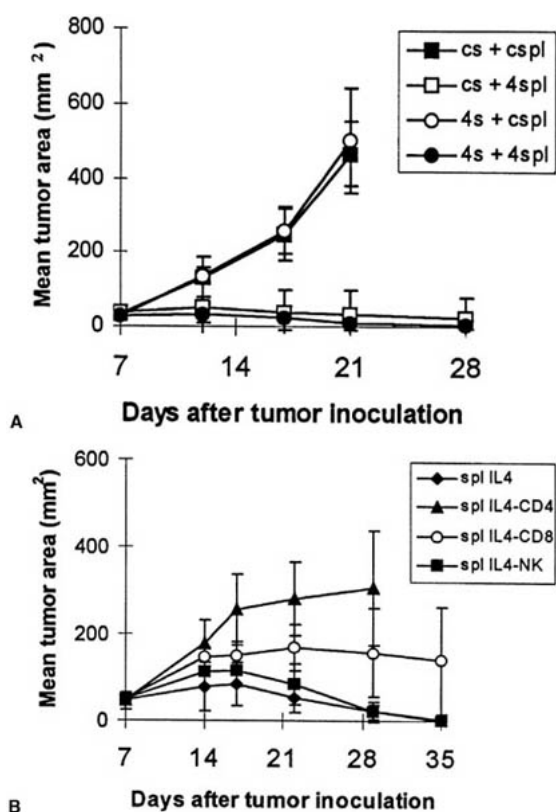
The mechanisms by which IL-4 induces anti-9L immune responses have been evaluated. 9L-IL-4 grew at a rate comparable to sham-transduced 9L (9L-neo) for a period of 10 to 14 days and then regressed. This occurred only in immunocompetent rats. Regression of 9L-IL-4 was not observed in nude athymic rats. These data clearly suggest a role for T cells in the regression of 9L-IL-4 tumors. In addition to evidence supporting T-cell involvement, we also determined that serum concentrations of Ig of the IgG1 isotype were markedly elevated in the sera of rats bearing 9L-IL-4. We were able to take advantage of this enhanced humoral-immune response to isolate tumor-associated antigens by combining IL-4 tumor vaccine and serologic identification of antigens by recombinant expression cloning (87). A series of adoptive transfer experiments were performed to determine whether transfer of humoral or cellular elements from immune to naïve rats were able to mediate protection against 9L because immunization with 9L-IL-4 apparently affects the cellular and humoral immune response (88). Rats were immunized by implanting 2×10^6 9L-IL-4 cells subcutaneously; after 4 weeks, sera and splenocytes were harvested from rats in which 9L-IL-4 regressed. Sera or nylon wool nonadherent splenocytes or both were transferred to naïve, irradiated (1,000 rad) recipient rats. One day after transfer, recipient rats were implanted subcutaneously with 2×10^6 parental 9L cells. As shown in Figure 4-2A, tumor growth was observed in groups where nonimmunized splenocytes or serum from 9L-IL-4-immunized rats were transferred. Only transfer of splenocytes from 9L-IL-4-immunized rats with or without immune serum eradicated tumor growth in recipient rats. Further analysis using specific antibodies to deplete lymphocyte subsets from splenocytes revealed that CD4[+] and CD8[+] T cells play important roles in rejection (Fig. 4-2B). Natural killer cells do not. We are initiating clinical trials of IL-4[+] HSV-TK gene-transduced tumor vaccines for patients with malignant gliomas (89) based on these studies.


FIGURE 4-2. CD4[+] and CD8[+] cells play major roles in memory immune response against 9L gliosarcoma. A: Adoptive transfer of serum, splenocytes, or both, from 9L-IL-4-immunized rats. Four weeks after a single injection of 9L-IL-4, serum and splenocytes were harvested and transferred to irradiated recipient rats. Recipient rats were injected with 9L cells after 1 day. (cs, serum from control rats; cspl, splenocytes from control rats; 4s, serum from 9L-IL-4 immunized rats; 4spl, splenocytes from 9L-IL-4 immunized rats.) B: Depletion of subpopulations of splenocytes (spl) from 9L-IL-4 abrogates anti-9L immunity. Four weeks after a single injection of 9L-IL-4, splenocytes were harvested and depleted for CD4[+], CD8[+], and natural killer cells before being transferred to irradiated recipient rats. Recipient rats were injected with 9L cells after 1 day.

Clinical Trials of Interleukin-4 Gene Therapy

We demonstrated in clinical trials (90,91) that IL-4 expressed from genetically modified fibroblasts could indeed cause local endothelial activation and recruitment of immune effectors. We treated 18 patients in the context of phase 1 and 2 (immunologic end points) trials designed to determine whether IL-4 gene therapy could be administered safely and effectively to patients with cancer. This study was terminated prematurely because of a shortage of the initial vector. The results in the original study still are of considerable interest, revealing antitumor responses in three patients with melanoma (all partial), including extensive vitiligo in one patient with a partial response. A surgical complete remission was realized in one patient who remains disease free 5 years later in spite of pretreatment crescendo recurrences in the skin, small bowel, and brain metastases. Table 4-3 demonstrates IL-4 production in vaccination

in 14 patients. Tissue biopsies of multiple vaccination sites were obtained from the patients to determine the level of gene expression *in situ* for IL-4 and neomycin-resistance gene (91). Two weeks after the first vaccination, both IL-4 and neomycin-resistance transgene transcripts were still detectable. After the second vaccination, expression of the individual transgenes peaked on day 1 after the vaccination but were still detectable on day 14. Immunohistochemical analysis of the injection sites of IL-4-transfected fibroblasts and tumors revealed endothelial activation and recruitment of DC and T cells to the injected site. With vector TFG human IL-4-neo-TK, we will be able to launch our next phase of protocols in the combination with IL-2 administration (melanoma) and alone in the setting of glioma (92). It is likely that the complexity of immune reactivity will preclude the use of a single cytokine to elicit or maintain long-term effective immune reactivity to human tumors.

Table 4-3 Interleukin-4 Gene Therapy at the University of Pittsburgh

Disease	Primary Vaccine			Secondary Vaccine		
	Maximum Dose of IL-4[a]	No. of IL-4–Producing Fibroblasts	No. of Tumor Cells	No. of Tumor Cells	Maximum Dose of IL-4[a]	No. of IL-4–Producing Fibroblasts
Mel	2,073	9.0×10^6	5.0×10^6	—	—
Mel[b]	2,482	1.0×10^7	4.0×10^6	2,472	4.0×10^6

IL-4, interleukin-4; mel, melanoma.

[a]U/24 h.

[b]Patients with partial response.

Belli et al. reported the application of a melanoma vaccine using a HLA A2+ allogeneic cell line transduced with IL-2 or IL-4 (93). Seven patients were given 5×10^7 irradiated IL-4-transduced cells per vaccination, and each patient received at least three vaccinations subcutaneously. Although some patients demonstrated regression of skin nodules, no changes were observed in other lesions. The side effects, including transient fever and erythema, were mild at the site of injection.

Interleukin-4 Toxin Therapy

Part of "4 - Interleukin-4: Clinical Applications "

Debinski et al. and Puri et al. (94,95) investigated the possibility of targeting IL-4R with chimeric proteins composed of human IL-4 and mutant forms of *Pseudomonas* exotoxin A because IL-4Rs are present on a variety of human cancer cells. Administration of chimeric toxin to animals caused regression of established xenografts. To improve the efficacy, the researchers constructed circularly permuted forms of IL-4 that retain proliferative and binding activity (96). A toxin-fused circularly permuted IL-4 was found to have several-fold higher affinity to IL-4R and to be at least several-fold more toxic to human renal cell carcinoma cells (97) and human malignant astrocytomas (98) compared with an original form of nonpermuted IL-4 toxin. Intratumoral administration of the IL-4 toxin into well-established human glioblastoma (99) and acquired immunodeficiency syndrome-associated Kaposis's sarcoma (100) xenografts demonstrated a complete remission of flank tumors in all animals. On the basis of this observation, Debinski et al. have begun a phase 1 trial for glioblastoma patients (101).

Future Directions with Interleukin-4 in Cancer Therapy

Part of "4 - Interleukin-4: Clinical Applications "

Systemic administration of recombinant IL-4 administered alone to cancer patients did not produce apparent benefit. It is clear from the clinical trials performed with rhIL-4 that IL-4 can be repeatedly administered without life-threatening toxicity. The complex regulatory responses after systemic IL-4 administration have been quite apparent in animal models. The results with local IL-4 produced at the tumor site by cells transduced with IL-4 gene, in contrast, are encouraging. IL-4 is capable of inducing Th1-type responses in combination with tumor growth factor-β (37) or by eliminating lymphoid DCs (43). Thus, future applications of the use of IL-4 in cancer therapy should include gene transfection and combination approaches. With regard to gene therapy strategies, we generated substantial evidence demonstrating the efficacy of local delivery of IL-4 by retroviral-transduced fibroblasts when admixed with tumor cells and injected as a tumor vaccine. We (102) demonstrated that IL-12 gene-transduced DCs, however, elicit a more effective immune response against tumors than gene-transduced fibroblasts expressing a comparable amount of cytokine when these cells are injected directly into tumor nodules. Cytokine-transduced DCs are significantly more effective than nontransduced DCs, suggesting a possible role for

IL-12 in the protection of DCs from tumor cell suppressive signals, death signals, or both (103). When considering the efficacy of local cytokine expression delivered at the tumor site, responses induced by other methods of cytokine delivery should be evaluated. Adenoviral vectors, for example, have emerged as effective vehicles for *in vivo* gene delivery for various purposes. Effective local expression of IL-4 mediated by adenoviral vectors may also serve as a signal for migration of DCs into inflammatory sites via upregulation of vascular cell adhesion molecule 1. Gene transfer approaches should be evaluated to determine various strategies of gene delivery. The use of IL-4 in DC-based therapy in combination with granulocyte-macrophage colony-stimulating factor and other cytokines should be pursued extensively. Adding other cytokine genes to DC-based subcutaneous or intradermal vaccines may optimize recruitment of immune cells to the DC-vaccine site by creating a local inflammatory environment. In addition, combination with other antiangiogenic factors may be an attractive strategy for the use of IL-4.

Initial Findings in Interleukin-12 Biology

Part of "5 - Interleukin-12: Clinical Applications "

Interleukin-12 (IL-12) was initially identified as a natural killer (NK) cell stimulatory factor (1) and a cytotoxic-lymphocyte maturation factor (2). IL-12 is a disulfide-linked heterodimeric cytokine composed of a 35-kd light chain (p35) and a 40-kd heavy chain (p40) (1, 2). The complementary DNA encoding the p35 and p40 chains of IL-12 from the mouse and human have been cloned. Unlike most other cytokines, simultaneous transfection of mammalian cells with two different genes is necessary for production of biologically active IL-12 (3, 4). This cytokine exerts a variety of biologic effects *in vitro* and *in vivo* (Table 5-1). These include the ability to synergize with IL-2 in augmenting allogeneic, cytotoxic T-lymphocyte responses (5), lymphokine-activated killer cell activity (2), and interferon-γ (IFN-γ) production from NK and T cells (1, 6). IL-12 also directly stimulates the production of IFN-γ and other cytokines from these cells (1, 2), enhances the lytic activity of T and NK cells (1, 7), and promotes their expansion (8). Under most circumstances, IL-12 induces primarily a T helper 1 (Th1) (cellular immune) response *in vitro* (9). Under conditions of limited IFN-γ production, as seen in IFN-γ gene-disrupted animals or neonates, IL-12 induces and promotes a Th2 (T helper 2) response. Studies of administration of recombinant murine IL-12 (rIL-12) to normal mice revealed that rIL-12 also enhances NK and cytotoxic T-lymphocyte activity and induces IFN-γ production *in vivo* (10). IL-12 is a potent adjuvant in a murine Leishmania model (11). These findings suggest that IL-12 might be an appropriate cytokine for enhancing antitumor immunity.

Table 5-1 Biologic Characteristics of Interleukin-12

Identified as "cytotoxic lymphocyte maturation factor" (CLMF) or "natural killer cell stimulatory factor" (NKSF)

A disulfide-linked heterodimeric cytokine

Simultaneous expression of p35 and p40 subunits required for biologic activity

Produced by professional antigen-presenting cells (macrophages and dendritic cells), lesser amounts by keratinocytes and polymorphonuclear leukocytes

Promotes the expansion of activated T, natural killer, and natural killer-T cells

Enhances natural killer cell and T-cell cytotoxicity

Strongly induces interferon-γ production from T and natural killer cells synergistically with interleukin-2 or interleukin-18

Promotes T helper 1 (Th1)-type response (directly stimulates the production of Th1-type cytokines, including interferon-γ and interleukin-2)

Strongly inhibits angiogenesis (through secondary elaboration of chemokines, including IP-10 induced by interferon-γ)

Production of Interleukin-12

Although IL-12 was originally isolated from B-cell lines, normal B cells do not secrete IL-12 heterodimer (12). Macrophages and dendritic cells appear to be the principal producers of IL-12 (Table 5-2). Macatonia et al. (13) demonstrated that monocytes treated with heat-inactivated *Listeria monocytogenes* produce IL-12 and direct the promotion of cellular immunity of the Th1 type *in vitro* and *in vivo*. Similarly, murine macrophages expressing the CD40 costimulatory molecule and interacting with anti-CD3-activated CD40L⁺ splenic T cells or CD40L⁺ T-cell clones are induced to secrete IL-12 (14). The IL-12 production by antigen-presenting cells (APCs) is believed to be dependent of CD40/CD40L interaction by APCs based on the findings using anti-CD40L antibodies and CD40L gene-disrupted mice. Administration of anti-CD40L antibodies has the ability to block IL-12 production. Activated T cells derived from CD40L gene-disrupted mice are incapable of eliciting IL-12 secretion from splenic monocytes. Activated T cells cannot mount Th1-type immunity (15, 16). In addition, soluble trimeric CD40L promotes the secretion of IL-12 from macrophages at levels lower than those observed in macrophage-activated T-cell cultures (14). Additional stimuli that enhance APC production include microparticulate ingestion (17), IFN-γ plus lipopolysaccharide (18), *Mycobacterium tuberculosis* (19), *Listeria* (9), *Neisseria meningitidis*-derived lipopolysaccharide (20), polyinosinic acid (21), phagocytosis of *Borrelia burgdorferi* (22), lipoteichoic acid preparations of gram-positive bacteria (23), recombinant human immunodeficiency virus gp120 protein (24), and nitric oxide-generating compounds (25). CpG motifs present in hypomethylated oligodeoxynucleotides or bacterial DNA also elicit IL-12 production from human and murine responder APC cells (26, 27). The production of IL-12 by activated APC appears to represent a critical early physiologic event in cellular immunity because dendritic cells appear to represent the principal producers of IL-12 *in situ* in draining lymphoid organs (28).

Table 5-2 Interleukin-12 Producers and Stimuli

IL-12 Producer	Stimuli
DC	Anti-CD40 antibody
	T cells with antigen particulates
	Bacteria
	Bacterial products
Macrophages	Anti-CD40
	LPS
	IFN-γ
	Polyinosidic acid
	Human immunodeficiency virus gp120
	Bacteria
	Bacterial products
Langerhans' cells	Culture *(in vitro)*
B cells	LPS + IFN-γ
	Phorbol esters
	SAC
Neutrophils	LPS
Keratinocytes	UV irradiation
	Phorbol esters
	Culture *(in vitro)*
Microglia	LPS
Astrocytes	LPS

DC, dendritic cell; IFN-γ, interferon-γ; LPS, bacterial lipopolysaccharide; SAC, *Staphylococcus aureus* Cowan A strain.

Receptor and Signaling of Interleukin-12

Initial studies using radiolabeled Scatchard binding assays implementing Iodine-125-labeled IL-12 showed that IL-12 receptors (IL-12R) are expressed on only the cell surface of NK cells and T cells activated with IL-2 or phytohemagglutinin (29). This result confirmed in principle that IL-12 has the ability to promote the secretion of IFN-γ from these two cell types. IFN-γ induced by IL-12 enhances APC functions by increasing the expression of major histocompatibility antigen gene products and antigen-processing functions required for the promotion of primary T-cell immune responsiveness (30). When stimulated for 4 days with phytohemagglutinin, T lymphocytes were found to express approximately 1,000 to 10,000 binding sites per cell with three classes of binding affinities.

They were consistent with low-, intermediate-, and high-affinity IL-12 receptors displaying Kd in the range of 2 to 6, 50 to 200, and 5 to 20 pm, respectively (29). The low-affinity IL-12R was characterized as a multichain complex with an approximate molecular weight of 135 to 210 kd. The low-affinity IL-12R was expressed optimally 2 to 4 days after phytohemagglutinin stimulation on T cells or 7 to 8 days after IL-2 activation of T cells or NK cells.

Expression cloning studies performed by Presky et al. (31) and Wu et al. (32) subsequently showed that the IL-12R is composed of a dimeric complex (ß1ß2) in which the ß1 and ß2 chains confer low to intermediate binding affinity of the complex for IL-12 (Table 5-3, Fig. 5-1). Each subunit was designated as a *ß chain* because of its homology to gp120 molecule, serving as a common ß chain for a number of alternate cytokines (33). The ß chains of murine IL-12R DNA have been isolated and cloned using cross-hybridization techniques (34). In the mouse system, the ß1 chain of IL-12R appears to play the dominant role in binding the IL-12 ligand. The ß1 and ß2 chains appear to play significant roles in binding IL-12 in human cells expressing the high-affinity IL-12R (33, 35). The ß1 chain appears to be principally occupied with binding to the IL-12 p40 chain, whereas the ß chain of IL-12R appears to associate with the p35 chain of IL-12 (35, 36). This mechanism explains the capacity to bind to the IL-12-p40 homodimer, which has the capability to bind to IL-12Rß1, but not to IL-12Rß2, to effectively antagonize the binding of the IL-12 heterodimer to IL-12R. Antibodies directed against the IL-12ß chains efficiently inhibit IL-12-induced IFN-γ production and activated T-cell proliferation. Antibodies have no effect, however, on the ability of other T-cell growth factors, including IL-2, IL-4, or IL-7, to promote T-cell expansion (32).

Table 5-3 Characteristics of Interleukin-12 Receptor Subunits

Subunit	Kd for IL-12	Distribution	Author (Reference)
ß1	2-5 nM	T (Th1, Th2, CD8+), NK, B	Wu et al. (32)
			Rogge et al. (45)
ß2	3-5 nM	Th1 CD4+ T cells	Rogge et al. (45)
ß1 + ß2 (COS)	50 pM	Th1 CD4+ T cells	Presky et al. (31)

IL-12, interleukin-12; NK, natural killer; Th1, T helper 1; Th2, T helper 2.
FIGURE 5-1. Schematic of the high-affinity receptor of interleukin-12.

The IL-12R appears to use intracellular signaling apparatus that distinguish IL-12 from most of the other cytokines. Specifically, functional signaling through the IL-12R results in the phosphorylation of p56[lck], the Janus kinases tyk2 and Jak2, and the signal transducer and activator of transcription (STAT) kinases 3 and 4 (37, 38, 39, 40, 41 and 42). STAT 4 is also similarly used in the signaling mediated by IFN-αR (43). To evaluate the individual and combined signaling capacity mediated by each of the IL-12R subunits, the transmembrane and intracellular domains of

the IL-12Rß1 and IL-12Rß2 subunits were fused to the extracellular domain of the receptor of epidermal growth factor-R, resulting in the production of chimeric molecules (44). Only cells transfected with the fusion protein containing the intracellular domain of the IL-12Rß2 subunit were able to mediate signals on epidermal growth factor-R stimulation, resulting in proliferation and phosphorylation of Jak2 kinase. Although unable to promote proliferation by themselves, cells transfected with IL-12Rß1 alone or with IL-12Rß2 (but not IL-12Rß2 alone) demonstrated association with tyks. Overall, activation through these chimeric receptors resulted in the phosphorylation of Jak2, tyk2, and STAT3 (in STAT4-deficient BaF3 cells). In addition to IL-12 to Th1, CD4+ T cells lead to the rapid phosphorylation of STAT4 kinase (45). Th2 CD4+ T-cell clones do not phosphorylate STAT4 in response to IL-12, despite expressing the low-affinity IL-12R (46). Studies performed in STAT4 gene-disrupted mice support a similar biology to that observed in IL-12–p40 gene-disrupted animals. Th2 immune responses (and IL-4, IL-5, and IL-10 production) were predominant in the absence of functional STAT4 kinase activity (47). Although Th1-associated immune responses do occur, they are generally far weaker that those observed in heterozygous or wild-type control animals in response to IL-12 or pathogenic organisms, such as *L. monocytogenes* (47, 48). IL-12 activation of NK cells does not occur in STAT4 gene-disrupted mice (48). IFN-γ produced as a consequence of IL-12 administration is minimized, and long-term antigen-specific cellular immunity is lessened in these gene-disrupted animals.

Preclinical Tumor Models

Part of "5 - Interleukin-12: Clinical Applications "

Antitumor Effects of Systemic Administration of Recombinant Interleukin-12 Protein

We initiated murine therapeutic studies to investigate the possible antitumor effect of IL-12 (49). These experiments demonstrated that systemic application of IL-12 suppressed tumor growth and prolonged survival of tumor-bearing mice, even when IL-12 treatment was started as late as 14 days after tumor inoculation. Such therapeutic effects were also reported in similar models by Brunda et al. (50). In these studies, therapeutic intervention with systemic administration of IL-12 could be initiated as late as day 28 after injection of tumor cells (M5076 reticulum cell sarcoma), resulting in inhibition of tumor growth, reduction in the number of metastases, and an increase in survival time. Similar findings related to the potent antitumor effects have been reported by other investigators using diverse tumor models (41, 51, 52 and 53). Virtually every murine tumor model carefully studied has demonstrated significant antitumor effects.

Antitumor Effects of Paracrine Administration of Interleukin-12 Using Gene Transfer Technique

Although IL-12 has potent antitumor effects when injected systemically, induction of long-term immunity is less frequent and variable from experiment to experiment (49, 50). Brunda et al. observed that the best results with systemic IL-12 administration (complete regression of the tumor and induction of protective immunity against tumor rechallenge) was observed after peritumoral injections of IL-12 in a subcutaneous (s.c.) renal cell carcinoma (RenCa) tumor model (50). Local administration of IL-12 at the site of tumor may more closely mimic an endogenous immune response because IL-12 is secreted primarily by "professional" antigen-presenting cells (i.e., macrophages and dendritic cells). IL-12 plays a critical costimulatory role with CD80 (B7) on APC in inducing proliferation and IFN-γ production from Th1 clones (54). Thus, IL-12 may be the proximal cytokine for inducing tumor-specific immunity when administered at the tumor site.

Using plasmid or retroviral expression systems, we studied the effects of IL-12 gene therapy in murine tumor models (55, 56). Paracrine secretion of IL-12 using genetic engineering was highly effective in preventing tumor establishment and the induction of protective antitumor immunity. Furthermore, intradermal inoculation of genetically modified tumor cells or intratumoral injection of genetically modified fibroblasts can lead to regression of a nontransfected tumor inoculated at a distant site before therapy (56, 57). Other investigators reported the usefulness of *in vivo* transduction using IL-12 adenoviral vectors (58, 59) in the treatment of established tumors. Such strategies may be appropriate for clinical application and are in the process of being tested.

Combination Therapy with Interleukin-12

Synergy of IL-12 and CD28/CD80 signaling in promoting T-cell responses (54) supported the evaluation of this approach in murine tumor models (60). Zitvogel et al. (61) evaluated the antitumor benefit associated with combined IL-12 and CD80 gene delivery in two poorly immunogenic tumor models (MCA-207 sarcoma and TS/A mammary adenocarcinoma). Coinoculation of tumor cells infected with retroviruses encoding IL-12 induced specific immunity at a significantly higher rate when compared with animals injected with tumor cells transduced to express IL-12 or CD80 alone. The therapeutic efficacy of these vaccines was dependent on the dose of IL-12 delivered by the transduced tumor cells and blocked by the administration of CTLA4-immunoglobulin fusion protein or neutralizing antibodies against murine IFN-γ or murine tumor necrosis factor-α. Similar synergistic effects of IL-12 and CD80 have been noted in C3H mice bearing mCD80-transfected K1735 melanoma, as well as serum creatine kinase mammary carcinomas (62).

Other molecules reported for synergistic effect with IL-12 include IL-2 and IL-18. As initial studies suggested using transfected fibroblasts (63), treatment using IL-2 in combination with IL-12 appears to be associated with potent antitumor effects (64) possibly related to nitric oxide production (65). This combination could be applied in humans if reduction in side effects could be accomplished (66). IL-18 has also been suggested as useful in combination with IL-12. Combination therapy using systemic administration of rIL-12 and rIL-18 induced serious side effects in our mouse models primarily because of the markedly enhanced induction of high levels of IFN-γ (67). Treatment strategies using local expression of IL-12, IL-18, or both have been actively pursued (68, 69).

Mechanism of the Antitumor Effects of Interleukin-12 Administration

Although the precise mechanism of the IL-12–induced antitumor effects are still under investigation, substantial information is already available. IL-12 is an effective antitumor reagent in NK cell–deficient beige mice and in mice depleted of NK cell activity by pretreatment with antiasialo GM1. IL-12 is less effective in nude mice (50). These results suggested that T cells, rather than NK cells, were primarily involved in mediating the antitumor effects of this cytokine. Depletion of CD8+, not CD4+, T cells appears to significantly reduce the efficacy of IL-12 as well. In our mouse models (49), only the coordinate depletion of CD4+ and CD8+ T cells resulted in significant abrogation of the IL-12 antitumor effect. Although some differences in the results of T-cell depletion studies exist between the various tumor models used, these studies clearly demonstrate the critical involvement of T cells in IL-12 antitumor effects. After systemic administration of rIL-12, INF–γ depletion only partially abrogated the antitumor effects of IL-12, suggesting the importance of additional antitumor mechanisms induced by IL-12.

NK T cells are also involved in the antitumor effects of IL-12 (70, 71). NK T cells, the Vα14-expressing murine NK T cells (homologous to the Vα24 human NK T cells), express NK1.1 and a single invariant T-cell receptor encoded by the Vα14 and Jα281 gene segments. Cui et al. (72) have shown that Vα14 NK T cell–deficient mice no longer mediate the IL-12–induced rejection of tumors. These results suggest that Vα14 NK T cells are essential targets of IL-12, especially in the metastatic tumor models. Furthermore, NK T cells mediate their cytotoxicity by an NK-like effector mechanism after activation with IL-12.

These results collectively suggest that IL-12 affects multiple cell populations within immunity to mediate its antitumor effects. Furthermore, IL-12 may affect additional nonimmune events associated with tumor progression. IL-12–induced IFN-γ triggers the subsequent production of a variety of other cytokines and chemokines from a variety of cells, including tumor cells (68). These include the CXC chemokines, IP-10 and Mig, which inhibit angiogenesis. Kanegane et al. (73) showed that local and systemic treatment with IL-12 was associated with expression of IFN-γ, IP-10, and Mig genes and proteins within the tumor. Levels of IP-10 and Mig expression in the tumor, liver, and kidney were inversely correlated with tumor size. Furthermore, administration *in vivo* of neutralizing antibodies to IP-10 and Mig substantially reduced the antitumor effects of IL-12 inoculated locally into the tumors. These results support the notion that IP-10 and Mig contribute to the antitumor effects of IL-12 through their inhibitory effects on tumor angiogenesis.

Clinical Studies of Interleukin-12

Part of "5 - Interleukin-12: Clinical Applications "

Clinical studies to treat cancer patients using IL-12 have been initiated using systemic administration (intravenous or s.c.) or gene therapy strategy. Although it is still in the early stage of clinical development, some information is available from the phase 1 and 2 studies.

Systemic Administration of Recombinant Interleukin-12

We began the first clinical evaluation of rIL-12 in the spring of 1994 (Table 5-4). This phase 1 dose-escalation trial (74) was designed to determine the toxicity, maximum tolerated dose (MTD), pharmacokinetics, and biologic and potential antineoplastic effects of IL-12. Cohorts of four to six patients in sequential doses escalating from 3 ng per kg per day to 1,000 ng per kg per day were treated. Patients with advanced cancer and a performance status of more than 70% received escalating doses of recombinant human IL-12 (rhIL-12) by bolus intravenous injection once as an inpatient and once daily for 5 days every 3 weeks as an outpatient, after a 2-week rest period. After establishment of the MTD as less than 1,000 ng per kg per day (because of stomatitis and liver function test abnormalities), eight more patients were enrolled to further assess the safety, pharmacokinetics, and immunobiology at a dose of 500 ng per kg per day. Forty patients were enrolled, including 20 with renal cancer, 12 with melanoma, and five with colon cancer.

Table 5-4 Clinical Trials Using Systemic Administration of Recombinant Interleukin-12 in Cancer Patients

Author (Reference)	Route	Tumor types	Dose	Schedule	Total no. of pts.	MTD
Atkins et al. (74)	i.v.	Multiple	Dose escalation (0.03–1.0 mg/kg)	Test dose + 5 d injections (1 to 6 cycles)	40	0.5 mg/kg
Motzer et al. (77)	s.c.	Renal cell	Dose escalationª(0.1–1.5 mg/kg)	D 1, 8, and 15(multiple cycles allowed)	51	Fixed dose: 1.0 mg/kg Up-titration: 1.5 mg/kg

MTD, maximum tolerated dose.

ªFixed dose schedule: 24 patients; up-titration schedule: 27 patients.

Mild anemia, leucopenia, thrombocytopenia, lymphopenia, hyperglycemia, and hypoalbuminemia were noted in some patients but were rapidly reversed after discontinuation of therapy. Fever was observed at doses as low as 3 ng per kg and was largely preventable with acetaminophen and nonsteroidal antiinflammatory agents. Other symptoms included fatigue, myalgia, mild nausea and rare emesis, and headache. Oral stomatitis of undetermined etiology was a frequent complaint and limited therapy in some patients at higher doses. Mild elevation of transaminases was observed with 1,000 ng per kg rhIL-2 in three-fourths of patients, causing this dose to be declared as an intolerable daily dose on this schedule. The half-life elimination was 5.3 to 9.6 hours. Biologic effects included dose-dependent

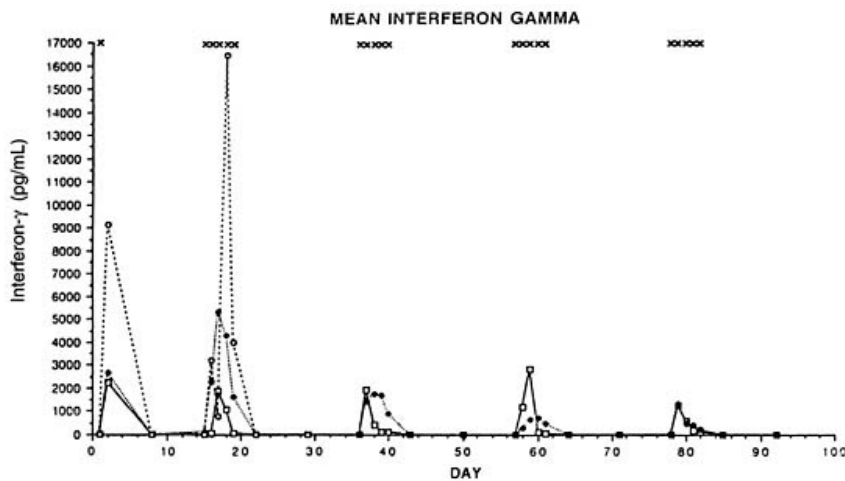
increases in circulating IFN-γ, which decreased with subsequent cycles (Fig. 5-2). Serum neopterin rose in a reproducible fashion regardless of dose or cycle. Tumor necrosis factor–α was not detected by enzyme-linked immunosorbent assay. One of 40 patients developed a low titer antibody to rhIL-12. Lymphopenia was observed at all dose levels with recovery occurring within several days of completing treatment without rebound lymphocytosis. In this phase 1 study, rhIL-12 administered according to this schedule is biologically active at doses tolerable by most patients in an outpatient setting.


FIGURE 5-2. Serial mean serum interferon-γ (IFN-γ) levels for patients treated at the top three recombinant human interleukin-12 dose levels. (□, 250 ng/kg; ♦, 500 ng/kg; ○, 1,000ng/kg.) (From Atkins BA et al. Phase I evaluation of intravenous recombinant human interleukin-12 (rhIL-12) in patients with advanced malignancies. *Clin Cancer Res* 1997;3:409–417, with permission.)

This phase 1 study allowed initiation of treatment in a subsequent phase 2 trial in patients with renal cancer at a dose of 500 ng per kg. The phase 2 study was abbreviated after 17 patients entered the trial because profound neurasthenia required admission in over one-half of the patients. Neurasthenia was associated with two treatment-related deaths, one in a patient with advanced atherosclerotic disease who developed renal failure and subsequent complications of dialysis and one in a patient with a gastrointestinal bleed who did not undergo autopsy evaluation.

A thorough scientific investigation was subsequently initiated to determine the cause of the striking difference between the phase 1 and 2 studies. It failed to identify, however, any difference in the drug products used or the patient populations enrolled, which could have illuminated the difference between the two trials. The difference was attributed to the modification of the administration schedule in the subsequent trial. The phase 2 trial used an administration schedule omitting the initial test dose of IL-12, which was received 2 weeks before the daily dosing schedule applied in the phase 1 study. This suggested that IL-12 "protected" against subsequent IL-12 toxicity. This theory has been lent credence by mouse studies, as described below.

A single injection of rIL-12 administered 2 weeks before subsequent dosing included in the phase 1 study had a profound effect on IL-12–induced IFN-γ, diminishing its production and associated toxicity (75). The schedule-dependent toxicity of IL-12 has been confirmed in primates and mice. Coughlin et al. (76) examined the influence of giving a single dose of rIL-12 a week before (predosing) subsequent, daily, consecutive rIL-12 administration. In C3H/HeN mice, treatment without predosing induced rejection of syngeneic K1735 melanomas in 33% of mice. In A/J mice, treatment induced rejection of syngeneic B8-11·SCK (SCK.B7-1) mammary carcinomas in 63% of mice. Administration of a predose of rIL-12 markedly reduced cytokine toxicity in a dose-dependent manner and allowed safe administration of up to eightfold higher doses of daily rIL-12 in C3H mice and fourfold higher doses of rIL-12 in A/J mice. Predosing followed by either standard or high daily doses of rIL-12, however, did not significantly alter the response to rIL-12 treatment in either tumor type. Predosing desensitizes mice to the toxic effects of rIL-12 and allows much higher doses to be given. Predosing does not improve treatment and, by some criteria, attenuates rIL-12 therapeutic outcome. The use of predosing alone does not enhance the effectiveness of rIL-12 in cancer clinical trials.

A phase 1 trial of escalating doses of s.c. rIL-12 given on days 1, 8, and 15 of each 28-day cycle in patients with advanced renal cell carcinoma was carried out (77). Treatment in the initial dosage scheme consisted of a fixed dose level of 0.1, 0.5, or 1.0 mg per kg given in cohorts of three or six patients. On the basis of the toxicity profile, a second scheme ("up-titration") was undertaken, wherein rhIL-12 was escalated sequentially for each patient from week 1 to week 2, to a target maximum dose given week 3 and thereafter; cohort target dose levels were 0.5, 0.75, 1.0, 1.25, and 1.5 mg per kg. Fifty-one patients were treated. The MTD for the fixed dose scheme was 1.0 mg per kg. Dose-limiting toxicities included increase in transaminase concentration, pulmonary toxicity, and leukopenia. The most severe toxicities occurred with the first injection and were milder during further treatment. With the escalation dose scheme (up-titration), the MTD was reached at 1.5 mg per kg and dose-limiting toxicity consisted of an increase in serum transaminase levels. At the MTD of 1.5 mg per kg, serum IL-12 levels increased to a mean peak level of 706 pg per mL. Serum levels of IFN-γ increased to a mean peak level of approximately 200 pg per mL at 24 hours after achieving a maintenance dose of 1.5 mg per kg. The rIL-12 was relatively well tolerated when administered by s.c. injection. Phase 2 trials of rIL-12 were initiated in previously untreated patients with renal cell carcinoma and in patients with melanoma using the up-titration schedule of rhIL-12 (mg per kg) for phase 2 trials as follows: cycle 1–0.1 (day 1), 0.5 (day 8), 1.25 (day 15); cycle 2–1.25 (fixed).

Antitumor Activity and Immunologic Modulation After Systemic Administration of Recombinant Interleukin-12

In our initial phase 1 study using intravenous administration of rIL-12, four patients were noted to have stable disease, one patient with melanoma had a complete response that was transient, and one patient with renal cell cancer has continued a partial response without progression for almost 2 years (74). In a phase 1 study using s.c. delivery of rIL-12, one patient had a complete response, 34 patients had stable disease, 14 patients progressed, and one patient was not evaluable (77). Although it is premature to draw any conclusions from these phase 1 studies, initiation of succeeding phase 2 studies are warranted to define the antitumor effects of rIL-12.

Limited but interesting results are available on the immunomodulatory effects of rIL-12 in humans as well. Robertson et al. (78) reported the immunologic effects of intravenous rIL-12 during the conduct of a phase 1 clinical trial. Forty patients with advanced cancer received bolus intravenous injections of rIL-12 at doses ranging between 3 and 1,000 ng per kg. Dose-dependent increases in serum IFN-γ levels were observed during rIL-12 therapy. rIL-12–induced lymphopenia involved all major lymphocyte subsets. NK cell numbers were the most profoundly affected and CD4 T-cell numbers were the least affected. CD2, LFA-1, and CD56 were transiently upregulated on the surface of NK cells obtained during rIL-12 treatment. Peripheral blood mononuclear cells obtained from cancer patients before rIL-12 therapy exhibited defective NK-cell cytotoxicity and T-cell proliferative responses. Peripheral blood mononuclear cells obtained after lymphocyte recovery after the administration of a single 500 ng per kg dose of rhIL-12 displayed augmented NK-cell cytolytic activity in four out of four patients tested and enhanced T-cell proliferation in three-fourths of patients tested. These studies confirm that doses of rIL-12 resulting in significant immunologic activity can be administered with acceptable toxicity to cancer patients. Furthermore, rhIL-12 therapy reverses defects in NK and T-cell function that are associated with advanced cancer.

Gollob et al. (79) showed that repeated s.c. injections of IL-12 in patients with cancer resulted in the selective expansion of a subset of peripheral blood CD8⁺ T cells. This T-cell subset expressed high levels of CD18 and further upregulated IL-12 receptor expression after systemic rIL-12 treatment. These CD3⁺CD8⁺CD18⁺⁺ T cells have been identified as well in normal subjects and express IL-12, IL-2R, and other adhesion or costimulatory molecules, or both to a greater degree than other CD8⁺ and CD4⁺ T cells. They appeared morphologically as large granular lymphocytes although they did not express NK cell markers, such as CD56. In addition, CD8⁺CD18⁺⁺ T cells were almost exclusively T-cell receptor αß+ and exhibited a T-cell receptor Vß repertoire that was strikingly oligoclonal, whereas the Vß repertoire of CD18 with or without T cells was polyclonal. Although CD8⁺CD18(bright) T cells demonstrated little functional responsiveness to IL-12 or IL-2 alone *in vitro*, they responded to the combination of IL-2 plus IL-12 with enhanced IFN-γ production and proliferation, as well as non-MHC-restricted cytolytic activity. These CD8⁺CD18⁺⁺ T cells appear to be a unique population of peripheral blood lymphocytes with features of memory or effector cells, or both, which are capable of T-cell receptor–independent activation after combined stimulation with IL-2 plus IL-12. As this activation results in IFN-γ production and enhanced cytolytic activity, these T cells may play a role in innate, as well as acquired, immunity to tumors and infectious pathogens. Additional studies will be necessary to determine whether CD8⁺CD18⁺⁺ T cells mediate some of the antitumor effects of IL-12 or IL-2 administered to cancer patients or whether they have additional biologic roles. IL-12 has been used also at lesser doses as a vaccine adjuvant. We treated 25 melanoma patients of doses up to 300 ng per kg in conjunction with immunization using synthetic peptides (i.e., MART1/MelanA, gp100, tyrosinase) without a single objective response (Lotze et al., *unpublished observation*). Similar studies performed by Rosenberg's group have reported at best a minimal response. IL-12 as an adjuvant seems to have little use based on these findings.

Feasibility and Safety of Phase 1 and 2 Studies of Interleukin-12 Gene Therapy

Clinical studies showed that systemic administration of rIL-12 has significant side effects that were not predicted from the animal models. The MTD of the systemic administration of rIL-12 in humans, 500 ng per kg, was found to be significantly lower by 2 to 3 orders of magnitude than that in the mouse (100 mg per kg in C57BL/6 mice) because of significant dose-dependent toxicities. Although phase 2 studies have not been completely reported, the antitumor effects of systemic administration of

rIL-12 at reported tolerable outpatient doses administered in humans appear to be less potent than those in mice. In contrast, gene therapy strategies can provide high local concentration of IL-12 at the tumor site without the need for attaining high systemic levels of IL-12. In murine tumor models (55, 56 and 57), eradication of locally treated tumors leads to induction of systemic immune responses that are tumor specific.

Phase 2 clinical trials of IL-12 gene therapy were initiated in the summer of 1995 using direct injection of tumors with genetically engineered autologous fibroblasts (Fig. 5-3) (80). Patients with advanced malignancies of any histologic type with tumor lesions accessible from the body surface were eligible for this dose-escalating (10 to 3,000 ng per 24 hours) protocol. Primary fibroblast cultures from the patients were transduced using the retroviral vector carrying human IL-12 genes, p35 and p40, as well as the gene encoding neomycin phosphotransferase (TFG-hIL-12-neo). We used transduced autologous fibroblasts because they are readily available from the patients' dermal skin, can be induced to proliferate in cultures, and be retrovirally transduced. Furthermore, autologous fibroblasts can express cytokines at high levels. Minimal immune response to cultured autologous fibroblasts from individual patients was thought to enable repeated administration, which is not possible with immunogenic viral vectors, including adenoviral vectors or allogeneic cell lines. The results of such clinical studies revealed that these advantages are also present in the clinical setting (Tahara et al., *unpublished observation*). Fibroblast cultures were obtained and retrovirally transduced with a success rate of greater than 90%. The average IL-12 transgene expression after selection was approximately 150 ng per 10^6 per 24 hours, which is higher than what we observed in the mouse. The lack of RCR in the fibroblast preparation and patients' serum also supports the feasibility of this approach. Even though retroviral vector systems generally have modest transgene expression, we achieved 9,000 ng per 24 hours dose level (per injection) and *in vivo* expression of p40 transgene in 57% of the patients examined 7 days after the fourth injection. Thus, local and presumably continuous expression of IL-12 can be maintained for at least 4 weeks with 4 weekly injections.
FIGURE 5-3. Clinical protocol of interleukin-12 (IL-12) gene therapy.

This therapy was associated with minimal side effects in patients treated at dose levels at or below 5,000 ng per 24 hours. Dose-limiting side effects (Shwartzmanlike skin reaction) were observed in some patients who were treated at 7,000 and 9,000 ng per 24-hour dose levels. No systemic toxicities, however, were observed in these patients. The mechanism of inducing this skin reaction is not clear. With rare exception, IL-12 was not detectable in the serum and only marginally increased after treatment, suggesting that high local concentrations of IL-12 can be achieved without detectable systemic levels.

Preliminary Information on the Antitumor Activity of Interleukin-12 Gene Therapy

In several patients with breast cancer, head and neck cancer, and melanoma, objective antitumor effects were observed. Antitumor effects were not limited to the injected tumor. IL-12 alone or other induced cytokines, such as IFN-γ and IL-10, were not detected in these patients. Although the therapeutic effects were transient in most of the patients, sustained systemic antitumor responses were observed in two patients with melanoma. These results suggest that such a local therapy could induce sustained systemic immune responses against tumors in some patients.

Based on these results, phase 2 studies have been initiated in patients with melanoma or head and neck cancer at a dose level of 5,000 ng per 24 hours. Six and three patients have been treated so far on these protocols, respectively. These studies at a fixed dose may confirm some of the favorable findings observed with phase 1 study and provide an opportunity for a more detailed analysis regarding modulation of the local tumor environment.

Conclusions

Part of "5 - Interleukin-12: Clinical Applications "

Clinical application of IL-12 using systemic administration of rIL-12 has been of limited use in part because of the demise to limit systemic toxicity and development as an outpatient regimen.

Gene therapy strategies appear to be more promising at this time. Both strategies have revealed additional unique and unpredicted biologic effects of IL-12. The results obtained in phase 1 studies warrant further investigation of this very interesting molecule in the clinic. Additional efforts to optimize the methods of application in association with optimal antitumor effects and tolerable toxicity are necessary. A more complete understanding of the role of IL-12 in human tumor immunity, especially with dendritic cells or adaptive T-cell responses, will likely lead to successful application of this molecule to cancer and antiviral therapies.

Colony-Stimulating Factors: Basic Principles and Preclinical Studies

Malcolm A. S. Moore

Introduction

Part of "6 - Colony-Stimulating Factors: Basic Principles and Preclinical Studies "

Colony-stimulating factors (CSFs) belong to a large family of cytokines with pleiotropic and frequently overlapping activities that orchestrate steady-state lymphohematopoiesis, as well as mediate acute responses involving specific cell lineages. For historic reasons, hematopoietic growth factors have been named after the lineages they regulate [e.g., erythropoietin (Epo), thrombopoietin (Tpo)] or after the assays that permitted their detection [e.g., CSF, granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor (M-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF)]. Others are termed *interleukins*, numbered consecutively in order of discovery, indicating cytokines produced by and acting on leukocytes. Eighteen interleukins exist, many of which can be produced by nonleukocytic populations. These have actions on cells outside the hematopoietic system, as well as on leukocytes and their progenitors. Interleukin-3 (IL-3) was independently identified as a multilineage CSF and has been termed *multi-CSF.* Due to its close relationship with other members of the CSF family, it is included in this review. Other cytokines are identified by their receptors (c-kit and Flk-2/Flt-3 ligands).

Early attempts to functionally classify hematopoietic growth factors as early-acting, late-acting, or lineage-specific (versus multilineage-stimulating) have not held up to detailed analysis. Apparently, for example, lineage-specific, late-acting factors, such as G-CSF and Tpo, exhibit potent synergistic interactions influencing pluripotential stem-cell proliferation and differentiation. Early-acting, multilineage factors, such as c-kit and Flk-2/Flt-3 ligands, can affect early stem-cell proliferation and differentiation, as well as highly differentiated cells such as mast cells (c-kit ligand-stimulated) or dendritic cells (DCs) (Flk-2/Flt-3 ligand-stimulated).

Macrophage Colony-Stimulating Factor

Part of "6 - Colony-Stimulating Factors: Basic Principles and Preclinical Studies "

Molecular Characterization

In the early 1970s, a CSF that had a restricted ability to stimulate the development of colonies containing only macrophages was identified in serum, urine, and fibroblast cell-line-conditioned media (1, 2). One unit of this M-CSF was defined as the amount of factors required to stimulate a single macrophage colony in a 7-day agar or methylcellulose culture of mouse bone marrow cells in the linear part of the dose-response curve (representing 0.44 fmol of murine M-CSF). This sensitive bioassay permitted detection of activity in human serum, urine, or cell-line conditioned media at concentrations as low as 1 pm and facilitated purification of the factor. Murine M-CSF was isolated from mouse L-cell conditioned medium as a glycoprotein of 70 kd, composed of two 35-kd polypeptide chains with disulfide bonds (3). M-CSF purified from human urine or tumor cell lines is a 44-kd to 86-kd homodimeric glycoprotein (Table 6-1) (3, 4). Oligonucleotide probes predicted from the N-terminal sequence were used to isolate human M-CSF genomic clones. Messenger ribonucleoproteins (mRNAs) of different sizes are produced by alternative splicing of exon 6 (5, 6). Three spliced variants of biologically active M-CSF are produced: a short, or alpha form (α-form), with a leader sequence of 32 amino acids followed by 256 amino acids; a long, or beta form (β-form) of 554 amino acids; and a gamma form (γ-form) of 438 amino acids. The COOH-terminus anchors some forms of M-CSF in an active cell-associated form, with the native secreted form of macrophage colony-stimulating factor-alpha (M-CSF-α) being generated by cotranslational *N*-linked glycosylation and proteolytic cleavage at or near amino acid 158. The 18 cysteines in the homodimeric species form three intermolecular and three intramolecular disulfide bonds, rendering the protein resistant to proteolytic cleavage. The 64-kd homodimer consists of two bundles of four alpha helices laid end-to-end with an interchain disulfide bond, together with mannose-rich asparagine-(*N*)-linked oligosaccharide chains (7). A portion of this molecule is released by proteolysis as a 44-kd extracellular protein. A second soluble form of 86-kd is composed of two identical subunits of 223 amino acids with *O*- and *N*-linked sugar residues. This form is cleared from the membrane within the intracellular secretory compartment before its release from the cell, and does not appear as a surface membrane-bound molecule. A high-molecular-weight proteoglycan form of M-CSF (> 200 kd) with a core protein of 45 kd and a chondroitin sulfate glycosaminoglycan chain has been reported (8). The proteoglycan

form is not a latent form or precursor of the 85-kd M-CSF because it rapidly phosphorylates tyrosine residues of the M-CSF receptor (9). This form is found in bone matrix, suggesting it plays a role in bone metabolism, and because it can bind and neutralize the biologic activity of basic fibroblast growth factor (bFGF), it may regulate fibroblast proliferation (10). The membrane-anchored form of M-CSF expressed by marrow stromal cells has been shown to mediate intercellular adhesion of M-CSF-receptor–expressing hematopoietic cells (11). The soluble, matrix-associated, membrane-bound cell-associated forms of M-CSF play different specific roles on receptor-bearing target cells, with ligand-receptor interactions involving endocrine, paracrine, juxtacrine, or autocrine pathways (12).

Table 6-1 Characteristics of Colony-Stimulating Factors

	M-CSF	G-CSF	GM-CSF	IL-3

Chromosome	1p13-21	17q11-21	5q33	5q31

G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-3, interleukin-3; kb, kilobase; M-CSF, macrophage colony-stimulating factor.

[a]Number of *N-* or *O-*linked glycosylation sites.

The human M-CSF gene maps to the short arm of chromosome 1, bands p13–21 (see Table 6-1) (13).

Macrophage Colony-Stimulating Factor Receptor

High-affinity (kd = 10^{-13} m) M-CSF binding sites are expressed at levels of 1×10^4 to 1×10^5 per cell on mature monocytes, macrophages, and osteoclasts (Table 6-2) (4). During differentiation within the macrophage lineage, the number of receptors increases while proliferative response to M-CSF declines. The M-CSF receptor is encoded by the c-fms oncogene and is a member of the growth-factor receptor family that exhibits ligand-induced tyrosine-specific protein kinase activity (14, 15). C-fms maps on chromosome 5 at band 5q 33.3 in relative proximity to other growth-factor receptors and genes (see Table 6-2) (4). The receptor is an integral membrane glycoprotein of 972 amino acids that include a signal peptide. The extracellular ligand-binding domain has 512 amino acids, with five immunoglobulin-like domains joined to a 435 amino-acid cytoplasmic-protein kinase domain through a single membrane-spanning helix. On ligand binding, the receptor undergoes noncovalent dimerization, rapid autophosphorylation (30 seconds), and signaling, followed by covalent dimerization via disulfide bonds, leading to further modification, tyrosine dephosphorylation, and internalization (15). Specific autophosphorylation sites determine whether the receptor mediates proliferation versus differentiation signals, and whether mutations of mouse fms at Tyr807 totally abrogate differentiation but increase the rate of M-CSF–dependent proliferation and provide a paradigm for fms involvement in leukemogenesis (16). Phosphorylated receptor tyrosine residues are sites of interaction for a number of proteins containing src homology type 2 (SH2) domains. In c-fms, Grb2 interacts with Tyr-697, whereas the p85 subunit of phosphatidylinositol 3¢ (PI3)-kinase interacts with Tyr-721. Tyr-809 is the site of interaction for members of the src kinase family. Signaling involves phosphorylation of many cytosolic proteins, including tyrosine phosphorylation of Tyk2, a protein kinase of the Janus protein tyrosine kinase (Jak) family, and the signal transducers and activators of transcription [STAT (STAT1, STAT3, and STAT5)] proteins (see Table 6-2) (15, 17). Multimeric cytosolic complexes of signaling proteins and cytoskeletal components form in macrophages on M-CSF stimulation; these incorporate the STATs, Cb1, SHP-1, Shc, cytoskeletal, and contractile proteins (e.g., vimentin, actin, myosin regulatory light chain, tropomyosin, and paxillin), Ras family signaling proteins, NnaJ-like proteins, and glyceraldehyde-3-phosphate dehydrogenase (18). STAT5 homodimer or STAT5-α/STAT5-ß heterodimers formed in response to M-CSF signaling bind to the prolactin-inducible element (PIE) forming novel PIE-binding complexes (19). Mitogen-activated protein (MAP) kinases p42 and p44 are phosphorylated and constitutively activated by raf kinase in response to M-CSF binding to fms (20). Persistent activation of the raf-MAP kinase pathway by M-CSF is necessary for Ets-2 expression

and posttranslational activation in macrophages. A novel nonreceptor protein kinase, RAFTK, associates with c-fms in response to M-CSF and participates in signal-transduction pathway (21). RAFTK is involved in focal-adhesion signal-transduction pathways in many cell types; focal adhesions may modulate cytoskeletal functions and thereby alter phagocytosis, cell migration, and adhesion of macrophages.

Table 6-2 Characteristics of the Colony Stimulating-Factor Receptors

	M-CSFR	G-CSFR	IL-3Rα	GM-CSFR-α	GM-CSFR-ßc	GM-CSFR-αß

ßc, beta common; G-CSF, granulocyte colony-stimulating factor receptor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-3, interleukin-3; kb, kilobase; M-CSF, macrophage colony-stimulating factor; PA, pseudoautosomal region of X and Y chromosomes; p13, phosphatidylinositol 3" kinase; STAT, signal transducers and activators of transcription proteins.

Origin of Macrophage Colony-Stimulating Factor and Regulation of Production

M-CSF is present in normal plasma at levels of 100 to 200 units per mL, and most tissues produce M-CSF transcripts of several sizes. This ubiquitous expression may reflect production by cells common to many organs (e.g., macrophages, endothelial cells, fibroblasts, or mesothelial cells) (Table 6-3) (4). Fluctuations in levels of circulating M-CSF reflect a balance between production and excretion, with M-CSF receptors on Kupffer's cells in the liver and on splenic macrophages responsible for significant clearance by specific binding of M-CSF with subsequent endocytosis and intracellular destruction (22). Adherence and bacterial lipopolysaccharides are potent inducing stimuli for monocyte and macrophage M-CSF production, with further enhancement by cyclooxygenase inhibitors and inhibition by prostaglandin-E (PGE), which participates in a negative feed-back loop (4, 12, 23). GM-CSF is a strong inducer of M-CSF mRNA in monocytes, and tumor necrosis factor-α (TNF-α) synergizes with it to induce M-CSF secretion. IL-2 is also an inducer of monocyte M-CSF production and IL-1 strongly augments M-CSF secretion. IL-4 and IL-10 strongly inhibit M-CSF production by repressing M-CSF gene transcription. Constitutive production of M-CSF is found in alveolar macrophages; production is increased after endotoxin treatment of macrophages from individuals who have smoked (but not from nonsmokers). Activated T cells produce M-CSF, as can keratinocytes, endothelial cells and IL-1, IL-6, or TNF-stimulated fibroblasts, and marrow stromal cells (see Table 6-3) (4).

Table 6-3 Cellular Sources of Colony-Stimulating Factors

Cell Type	Stimuli	M-CSF	G-CSF	GM-CSF	IL-3
T lymphocyte	Ag, lectin, IL-2	+	-	++	++
B lymphocyte	Ag, LPS, IL-1	-	-	++	-
Monocyte/Macrophage	LPS, adh, phag	++	++	++	-
Mesothelium	LPS,	+	+	+	-
Keratinocytes	+	+	+	-	
Osteoblasts	PH, LPS	+	+	+	-
Synoviocytes	RA	+	+	+	-

Fibroblasts	IL-1, TNF, IL-17	+	+	+	-
Marrow stroma	IL-1, TNF, IL-17	+	++	++	-
Endothelium	IL-1, TNF, LPS, shear	+	+	+	-
Astrocytes	IL-1, TNF	+	?	+	-
Microglia	IL-1, TNF	+	+	+	-
Placenta	None or IL-1	+	+	+	-
Trophoblast	None or IL-1	+	+	+	-

adh, stimulus of adherence; ag, antigen; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IgE, immunoglobulin E; IL-1, interleukin-1; IL-2, interleukin-2; IL-3, interleukin-3; IL-17, interleukin-17; LPS, lipopolysaccharide; M-CSF, macrophage colony-stimulating factor; phag, phagocytosis; PH, parathyroid hormone; RA, rheumatoid arthritis; shear, hydrodynamic shear forces; TNF, tumor necrosis factor; -, no factor produced; +, low level factor production; ++, high level factor production.

Biologic Activities of Macrophage Colony-Stimulating Factor

Action on Progenitor Cells

Whereas the pathway of differentiation stimulated by M-CSF is restricted to cells of the phagocytic mononuclear lineage, its action is not limited to progenitors restricted to this lineage. At the progenitor level, highly purified populations are stimulated by M-CSF alone, as well as by GM-CSF and IL-3, with a frequency indicating that many oligopotential progenitors have receptors for all three growth factors. Furthermore, cultures of marrow cell initiated with M-CSF, followed by delayed addition of GM-CSF, form colonies of granulocytes and macrophages indistinguishable from those initiated with GM-CSF (24). This indicates that M-CSF sustains a progenitor population with the potential to form granulocytes, although it is responsible only for macrophage-lineage terminal differentiation. In the murine system, M-CSF can act on multipotent high proliferative potential cells, including pluripotent stem cells, but only in synergistic interaction with IL-1, IL-6, IL-3, or KL (25).

Action on Monocytes and Macrophages

Insight into the physiologic importance of M-CSF has come from studies of the osteopetrotic (op/op) mouse characterized by an autosomal recessive inactivating mutation of the M-CSF gene, resulting in absence of M-CSF (26). Quantitative defects in macrophage populations characterize op/op mice with marrow macrophages 1% of numbers in normal mice and with no splenic marginal zone macrophages. Strong evidence exists that M-CSF is involved in survival, proliferation, and differentiation on at least some monocyte-macrophage populations; evidence

that the factor functions as a macrophage activator as part of an inflammatory host defense response also exists. Acute events after M-CSF interaction with monocytes include increased cell spreading, membrane ruffling, and receptor turnover, as well as induction of a variety of cytokines (IL-1, G-CSF, TNF, IL-6). The latter response may be observed only with adherent cells. M-CSF activation enhances macrophage phagocytosis, bacteriocidal and amebicidal capacity, and upregulates Fc receptor gamma (FcR-γ) and antibody-dependent cell-mediated cytotoxicity (ADCC) (4). Nitric oxide is also produced by macrophages after synergistic stimulation by M-CSF and endotoxin or interferon-gamma (IFN-γ). M-CSF induces the transcriptional activation of heat shock genes (*HSP60, HSP70*, and *HSP90*); these may play important roles in macrophage activation by functioning as molecular chaperones and protecting cells against autooxidative damage associated with respiratory burst (27). M-CSF activation of monocytes and macrophages enhances their capacity to kill or inactivate a wide range of pathogens, including *Mycobacterium, Leishmania, Candida albicans, Histoplasma* and *Entamoeba histolytica, Staphylococcus aureus*, and *Cryptococcus neoformans* (4, 28, 29). M-CSF inhibits macrophage metalloelastase production, whereas GM-CSF induces it, suggesting that these molecules may control degradation of elastin fibers in lung or blood vessels (30). Differences in functional states of macrophages mediated by M-CSF include downregulation (perhaps irreversibly) of IL-12 production (31); upregulation of CD14 (a receptor for endotoxin, rendering monocytes more sensitive to this agent) (32), and release of immunoglobulin E (IgE)–dependent histamine, releasing M-CSF primes elicited-peritoneal macrophages for differential expression of adhesion molecules, enhancing very late antigens-5 (VLA-5) expression, adhesion to extracellular matrix components, and subsequent secretion of IL-6 (34). Transwell migration studies have shown that M-CSF is a chemotactic and chemokinetic agent for macrophages (35). Human macrophages express chemokine receptors (CCR5, CXCR4) that act as coreceptors for human immunodeficiency virus type 1 (HIV-1) and are major targets for HIV-1 infection *in vivo.* M-CSF and GM-CSF markedly increase the extent of HIV-1 entry and replication, as well as expression of CCR5 on macrophages (36).

M-CSF activates antibody-dependent (ADCC) and -independent tumor cell cytolysis. Human macrophages cultured with IL-2 and M-CSF show high tumoricidal activity against human and murine leukemic cell lines; the effector mechanism involves production of cytotoxic molecules (37). Synergy between M-CSF and IFN-γ also induces tumoricidal macrophages (38). Monocytes and macrophages exposed to M-CSF for 48 hours exhibit enhanced FcR-γ expression and mediate ADCC killing of tumor cells with phagocytosis of intact cells as the principal mechanism of antitumor cytotoxicity (37, 38).

Action on Osteoclasts

M-CSF–deficient op/op mice are toothless, and marrow cavities are occluded by bone overgrowth owing to an osteoclast deficit (26). This defect in osteoclastogenesis can be cured by M-CSF treatment (39). Whereas a specific osteoclast CSF supports the proliferation of osteoclast progenitors and formation of colonies of tartrate-resistant acid phosphatase–positive osteoclasts, M-CSF plays a role in later development of osteoclasts, inducing osteoclast fusion and stimulating their motility (chemotaxis), spread, and survival (40, 41). Bone stromal cells produce M-CSF in response to IL-1 and TNF, cytokines produced locally by bone marrow mononuclear cells that are recognized for their ability to promote osteoclast formation and bone resorption (41).

Role of Macrophage Colony-Stimulating Factor in Pregnancy

Impaired fertility is observed in op/op mice and a marked pregnancy-associated increase in serum levels of M-CSF suggests a role exists for M-CSF in blastocyst attachment, trophoblast outgrowth, implantation, and proliferation of placental tissue (42). The major effect of M-CSF on female reproductive function is on frequency and rate of ovulation, indicating a major role for the factor in regulating follicular development and ovulation (43). In male op/op mice, a greatly reduced serum testosterone level owing to reduced testicular Leydig cell steroidogenesis exists, indicating M-CSF plays a novel role in the development or regulation, or both, of male hypothalamic-pituitary-gonadal axis (44). The expression of c-fms and M-CSF by normal human first trimester–invasive extravillous trophoblast cells, and evidence of the role of M-CSF in stimulation of proliferation of this tissue, suggests an autocrine and possibly paracrine role exists for M-CSF in invasive trophoblast *in situ* (see Table 6-3) (45). M-CSF may also have a role in mammary gland development during pregnancy; in mid-gestation op/op mice, ductal branching is impaired, and after parturition, a failure to switch to lactation occurs (46).

Role of Macrophage Colony-Stimulating Factor in the Central Nervous System

The numeric density of microglia, resident brain macrophages, is significantly reduced in op/op mice; cells are smaller and have shorter cytoplasmic processes (47). The relative failure of op/op mice to respond to external stimuli also suggests a role for M-CSF in the brain. M-CSF mRNA is expressed in a regional-specific manner in the brain throughout development, whereas *c-fms* is expressed throughout the brain in the microglia (46, 48). M-CSF is neurotrophic in embryonal neuronal cultures; its absence in op/op mice results in severe electrophysiologic abnormalities in the cortex that can be corrected by M-CSF therapy (48). M-CSF is a neurotrophic factor that acts through microglia. M-CSF dramatically augmented β-amyloid peptide-induced microglial production of inflammatory cytokines (IL-1 and IL-6) and nitric oxide (NO) (49). These mediators, in turn, could intensify cerebral inflammatory states by activating astrocytes and additional microglia, as well as by directly injuring neurones. These pathways may be involved in Alzheimer's disease, a chronic cerebral inflammatory state that leads to neuronal injury. Intraparenchymal migration of macrophages occurs in the central nervous system (CNS) during development or as a consequence of tissue injury. Astrocytes, through

their ability to secrete M-CSF, can trigger polarized migration of brain macrophages (see Table 6-3) (50).

Role of Macrophage Colony-Stimulating Factor in Atherosclerosis

Macrophages serve as the principal inflammatory cell in the atheromatous plaque microenvironment. Their localization within the artery wall is probably determined by M-CSF produced locally by endothelial and smooth muscle cells after activation by inflammatory cytokines or modified low-density lipoprotein (LDL) (4, 51, 52). Lipid-laden "foamy" macrophages that develop in plaques produce M-CSF and express acetyl-LDL receptors. These scavenger receptors mediate uptake of modified lipoprotein-cholesterol with subsequent cholesterol ester accumulation and foam cell formation (4, 51, 52). The influence of M-CSF on atherogenesis was studied in an atherogenesis-induction model involving feeding op/op or control mice a high-fat, high-cholesterol diet, or crossing op/op mice with apolipoprotein-E knockout mice (53). Crossing of op/op mice with LDL receptor-deficient mice (an animal model of familial hypercholesterolemia) significantly reduced atherosclerosis, producing a 100-fold decrease in lesion size (54). Absence of M-CSF was associated with complete protection from atherosclerosis, an effect that may have resulted due to decreased circulating monocytes, reduced tissue macrophages, or diminished arterial M-CSF.

Role of Macrophage Colony-Stimulating Factor in Adipose Tissue Growth

Adipose tissue growth results from *de novo* adipocyte recruitment (hyperplasias) and increased size of preexisting adipocytes. M-CSF mRNA and protein are expressed in human adipocytes, and expression is upregulated in rapidly growing adipose tissue. Localized overexpression of M-CSF resulting from an adenovector gene transfer was associated with a 16-fold increase in adipose tissue growth owing to proliferation rather than hypertrophy (55). The proximity of the chromosomal locus for M-CSF (1p21) to sites linked with obesity and insulin action heightens the potential importance of M-CSF in the biology of adipose tissue growth and pathogenesis of obesity.

Preclinical In Vivo Studies of Macrophage Colony-Stimulating Factor

Treatment of mice, rats, rabbits, and primates with recombinant human M-CSF for 7 to 14 days at doses of 10 to 300 µg per kg per day leads to an increase in circulating monocytes (up to tenfold), promonocytes, and macrophagelike cells that can comprise up to 30% to 70% of circulating nucleated cells (4, 56, 57 and 58). The FcR-γ III (CD16 receptor) is found on tissue macrophages, but its expression is restricted to a small subset of circulating monocytes. This CD16$^+$ monocyte population is selectively expanded by administration of recombinant human (rh) M-CSF in primates, with a 50-fold increase in numbers (58). This increase was paralleled by the emergence of a population of circulating CD16$^+$ cells morphologically resembling large granular lymphocytes. The number of natural killer (NK) cells is increased in mouse spleen and blood after M-CSF treatment; the cells are activated as indicated by their higher cytotoxic activity against NK-sensitive tumor targets, enhanced proliferative response to IL-2, and a greater production of IFN-γ in response to IL-2 and IL-12 (59). M-CSF treatment of mice also produces a redistribution of myeloid progenitors with an initial decrease in marrow colony forming unit M, -GM, and -G, with a progressive increase in these populations occurring in the spleen, peaking at levels of four- to 15-fold of baseline by day 3 or 4 (60). Splenic macrophages are also increased in number and activation state in M-CSF–treated mice, being primed for heightened response to endotoxin, as indicated by a tenfold higher level of serum IL-6 (61). Dose-dependent delayed thrombocytopenia, seen in all species after M-CSF treatment, is usually transient and resolves rapidly on cessation of treatment; it resolves on prolonged treatment in mice (62). This thrombocytopenia is not caused by suppressed thrombopoiesis, but by increased activity of the monocyte/macrophage system, which causes hemophagocytosis and shortened platelet survival with increased platelet production, compensating for ongoing platelet destruction with restoration of normal platelet levels (62). M-CSF and IL-1 interact synergistically to enhance restoration of stem and progenitor populations in murine marrow and accelerate hematopoietic recovery in 5-fluorouracil (5-FU) myelosuppressed mice (63). Monocyte ADCC and tumoricidal capacity are enhanced by *in vivo* M-CSF therapy; this is correlated with a significant reduction in metastasis in an experimental melanoma tumor system (64, 65). Treatment of mice bearing melanoma or lung carcinoma with fractionated radiation therapy and M-CSF resulted in an M-CSF dose-dependent increase in tumor killing (65). The combination of IL-12 and M-CSF was most effective with radiation therapy in the clinically relevant dosage of 2 and 2 Gy per fraction with a synergistic antitumor action.

In normal rabbits and young Watanabe hyperlipidemic rabbits deficient in LDL receptors, M-CSF reduced cholesterol levels by one-third (66).

The cholesterol-lowering effect may be attributed to enhanced macrophage activities of neutral and acidic cholesteryl ester hydrolases, enhancing net hydrolysis of acidic cholesterol ester (67).

Granulocyte Colony-Stimulating Factor

Part of "6 - Colony-Stimulating Factors: Basic Principles and Preclinical Studies "

Isolation of Granulocyte Colony-Stimulating Factor Gene and Protein Structure

G-CSF was first identified in the serum of endotoxin-treated mice as a neutrophil G-CSF with the capacity to induce granulocyte differentiation of a murine myelomonocytic leukemic cell line (68, 69). The purification and molecular cloning of human G-CSF was performed between 1984 and 1986 (70, 71), and clinical development commenced in 1986 with approval for clinical use in cancer patients treated with chemotherapy (72). Human G-CSF is glycoprotein of 19,600 d with threonine at amino-acid position 133 being O-glycosylated; structurally, it has four antiparallel α helices arranged to form a helic bundle

(see Table 6-1) (73). G-CSF is encoded by a single gene on chromosome 17q21-22 that is comprised of five exons and four introns (see Table 6-1) (74). Alternative use of the two donor splice sites nine nucleotides apart at the 5" end of intron 2 leads to production of two different mRNAs, encoding one G-CSF of 174 amino acids (71) and one of 177 amino acids (75), which is less active in stimulating granulocyte colony formation. Murine G-CSF has a nucleotide sequence that is 69% homologous, and a deduced amino acid sequence that is 73% homologous to the corresponding sequence of human factor (76). This close homology accounts for species cross-reactivity of the molecules.

Granulocyte Colony-Stimulating Factor Receptor

The expression of the specific transmembrane receptor for G-CSF is largely confined to the hematopoietic system—predominantly, it is confined to mature neutrophils and their morphologically recognizable precursors, with some expression on monocytes. Mature human neutrophils possess 500 to 3,000 high-affinity receptors that bind G-CSF with an affinity of 60 to 300 pm (see Table 6-2) (77). Intermediate myeloid precursors in the marrow express 300 to 500 receptors; receptor expression is found on purified stem-cell populations (78). Receptors are also found on endothelial cells and placenta and trophoblastic cells (77). Receptors are rapidly internalized after ligand binding, and are also rapidly "trans-down-modulated" after exposure of receptor-bearing neutrophils to GM-CSF, TNF-α, lipopolysaccharide (LPS), and chemotactic peptide f-Met-leu-phe (fMLP-$t_{1/2}$ 15 minutes) (79).

The murine G-CSF receptor (G-CSFR) is an 812 amino-acid polypeptide (Mr 90, 814) with a single transmembrane domain. The extracellular domain consists of 601 amino acids with a region of 220 amino acids that shows remarkable similarity to the rat prolactin receptor (80). The cytoplasmic domain shows significant homology with the murine IL-4 receptor. Two human complementary deoxyribonucleic acids (cDNAs) have been identified that encode integral membrane proteins of 759 and 812 amino acids with identical extracellular and membrane spanning sequences, but which differ at the COOH termini (with one alternative spliced form with 24 residues and the other with 87) (81). The predicted molecular masses of these G-CSFRs, 86 and 92 kd, are substantially less than the 150 kd demonstrated by cross-linking, suggesting that some (or all) of the nine potential glycosylation sites contain carbohydrate. The long form of the receptor is predominantly expressed on hematopoietic cells, whereas the short form is expressed in tissues such as placenta (81, 82). The alternative cytoplasmic domains may confer functional differences, with the smaller form possibly functioning in ligand transport or sequestration in the placenta. Alternatively, the two forms may differ in signal transduction properties because the long form contains one potential C-kinase phosphorylation site.

The extracellular region of the G-CSFR is composed of four distinct types of structural domain. Two domains are identified by the presence of highly conserved cysteine residues and a WSXWS motif with a less well-conserved 100 amino-acid stretch that characterizes a hematopoietin receptor superfamily (17). The receptor also incorporates one amino terminal immunoglobulinlike domain characteristic of the Ig superfamily of receptors. Three additional repeats of fibronectin type III domains are present and are also found in the leukemia inhibitory factor (LIF) receptor, gp130 (the common subunit of IL-6, LIF, ciliary neutropic factor, oncostatin-M, and IL-11 receptors), and the alpha chain of IL-3, IL-5, and GM-CSF. Two G-CSF-R domains make direct contact with one G-CSF molecule, leading to dimerization of the receptor (so that the two C-terminal receptor domains interact with each other, probably extending to the transmembrane and cytoplasmic domains, leading to signal transduction).

The gene for G-CSFR is localized on the p32-34 region of human chromosome 1 (see Table 6-2) (82). It consists of 17 exons, is 165 kilobase (kb) in length, and is present as a single copy per haploid human genome. Exons 3-17 code for G-CSFR protein; each subdomain of the receptor is encoded by a set of exons. Approximately 110 nucleotides upstream of the transcription initiation site of the gene an element of 18 nucleotides homologous to the sequences found in the promoter of human myeloperoxidase and neutrophil elastase genes exist (83).

The G-CSFR does not have a catalytic domain; nevertheless, it induces tyrosine phosphorylation of multiple cellular substrates (77). Structure-function studies have demonstrated that different regions of the cytoplasmic domain of the G-CSFR are responsible for distinct signals driving proliferation versus differentiation. Using murine cell lines transfected with deletion-mutant and chimeric-mutant receptors showed that the region responsible for transduction of growth signals lies within the cytoplasmic region of 100 amino acids proximal to the cell membrane. Indeed, the region homologous to the conserved box-domains of other receptors, lying within the first 57 residues, is absolutely required and sufficient to deliver the proliferative signal (84, 85). Additional sequences in the first 96 amino acids are required for a maximal proliferative response. The membrane proximal and the COOH-terminal region are required to transduce a differentiation signal, as measured by induction of expression of the myeloperoxidase gene (85). Because multiple hematopoietic cytokines can stimulate granulopoiesis, the relative importance of the G-CSFR to the process was evaluated in receptor-deficient mice. These mice have severe quantitative defects in granulopoiesis but phenotypically normal neutrophils are still detectable (86). In IL-6 × G-CSFR doubly deficient mice, the additional loss of IL-6 worsened the neutropenia; near normal numbers of myeloid progenitors were detected in the marrow, however, and could terminally differentiate into mature neutrophils (86). Thus, neither G-CSFR nor IL-6 signaling is required for the commitment of multipotent progenitors to the myeloid lineage or their terminal differentiation. In further studies, retroviral transduction of wild-type G-CSFR allowed ectopic expression in hematopoietic progenitors of G-CSFR-deficient mice, resulting in their G-CSF-dependent differentiation into mature granulocytes, macrophages, megakaryocytes, and erythroid cells. Furthermore, two mutant G-CSFR proteins, a truncated mutant that deletes the carboxy-terminal 96 amino acids and a chimeric receptor containing the extracellular and transmembrane domain of G-CSFR fused to the cytoplasmic domain of the erythropoietin receptor, are able

to support the production of morphologically mature, chloracetate esterase and Gr-/Mac-1–positive neutrophils in response to G-CSF (87). This indicates that unique signals generated by the cytoplasmic domain of the G-CSFR are not required for G-CSF–dependent granulocytic differentiation.

Possible defects in the G-CSF receptor or its downstream signaling pathway, or both, have been proposed to explain the pathophysiology of severe congenital neutropenia (SCN) or Kostmann's syndrome. SCN is a rare autosomal recessive disorder characterized by severe neutropenia present from birth with maturation arrest of the myeloid series in marrow at the promyelocyte/myelocyte stage. G-CSF levels are normal to elevated in these patients, but treatment with G-CSF leads to an increase in neutrophils to greater than 1,000 cells per mm^3 in 90% of patients, resulting in significant improvement in survival and quality of life (88, 89). G-CSFR is present at normal or increased levels on patient cells; these receptors bind and internalize G-CSF normally. In approximately 25% of patients with SCN, mutations in one allele of the G-CSFR have been detected (89, 90). These mutations are invariably single nucleotide substitutions that introduce premature stop codons, leading to truncation of the distal cytoplasmic portion of the G-CSFR, the region implicated in generating maturation signals. Patients with G-CSFR mutations appear at greatest risk of developing acute myeloid leukemia (AML) or myelodysplastic syndrome, with one-half of patients with receptor mutations developing leukemia (88, 89 and 90). Conversely, no SCN patient has developed leukemia without this receptor mutation. Mice have been generated that carry a targeted mutation of G-CSFR that reproduces the mutation found in patients with SCN and AML (91). These mice have normal levels of neutrophils and no evidence of a block in neutrophil maturation. In response to G-CSF, however, they show an enhanced neutrophil leukocytosis indicative of an enhanced proliferative response (91). To date, no case of AML or myelodysplastic syndrome has been found in these mice.

Signal Transduction

In common with all members of the cytokine receptor superfamily, ligand binding to G-CSFR induces tyrosine phosphorylation and activation of members of the Jak family. G-CSF induces tyrosine phosphorylation and activation of Jak1, Jak2, and Tyk2 (89, 92, 93). In addition, G-CSF induces the tyrosine phosphorylation of the receptor and members of the STAT family, including STAT3, as well as STAT1 and STAT5, depending on the cells involved. Jak1 is critical for G-CSF-mediated STAT activation, whereas Jak2 or Tyk2 are either not required or play redundant or ancillary roles (see Table 6-2) (93). Because the requirement for Jak1 is similar to that previously shown for IL-6 signaling, data supports the concept that G-CSFR and gp130 are structurally and functionally similar. Activation of the Jak/STAT pathway correlates with proliferative signals by the G-CSFR and requires the membrane-proximal box 1 and box 2 proline X proline motifs for STAT1 and STAT5 phosphorylation, whereas STAT3 phosphorylation requires a region distal to box 2 that contains four tyrosines (93, 94 and 95). Although the membrane-proximal 55 amino acids of the G-CSF receptor are sufficient for activation of STAT5, the maximal rate of STAT5 activation requires an additional 30 amino acids of the cytoplasmic domain. In contrast, the distal carboxyl-terminal region of the receptor appears to downregulate STAT5 activation, in that deletion of this region results in increased amplitude and prolonged duration of STAT5 activation by G-CSF (93, 94). The role of tyrosines in the cytoplasmic region of G-CSFR in STAT3 activation has been evaluated using mutant receptors either completely lacking tyrosines or retaining just one of the four cytoplasmic tyrosines (95). At saturating G-CSF concentrations, STAT3 activation occurred in the absence of tyrosines. In contrast, at low G-CSF concentrations, Tyr704 and Tyr744 of G-CSFR play major roles in STAT3 activation (95). This suggests that G-CSF–induced STAT3 activation during basal granulopoiesis (low G-CSF) and "emergency" granulopoiesis (high G-CSF) are controlled differentially. Furthermore, this establishes the importance of the G-CSFR C-terminus for STAT3 in activation, with implications for understanding of the defective signaling seen with the truncated G-CSFR observed in some SCN patients. Three isoforms of STAT3 have been identified, -α (p92), -ß (p83), and -γ (p72), each derived from a single gene. STAT3-α is the predominant isoform expressed in most cells. STAT3-ß is derived from STAT3-α by alternative splicing, whereas STAT3-γ is derived from STAT3-α by limited proteolysis (96). Mapping of STAT3-α and STAT3-ß activation in murine myeloid cells shows that their optimal activation requires G-CSFR constructs containing Tyr704 and Tyr744. Tyr744 is followed at the +3 position by Cys; the sequence YXXC represents a novel motif implicated in the recruitment and activation of STAT3-α, -ß, and -γ (95, 96). In immature myeloid cells, G-CSF activates STAT3-ß but not STAT3α, suggesting the ß form may be more critical for G-CSF–mediated differentiation. In mature, nondividing neutrophils, no activation of Jak1, Jak2, Tyk2, STAT3, or Jak3 kinase was observed after G-CSF stimulation (92). This suggests utilization in mature neutrophils of alternative signal transduction pathways is distinct from those in proliferating cells. In other studies, however, activation of STAT3-γ has been shown to occur predominantly in terminally differentiated neutrophils, suggesting that it may be part of a controlled proteolytic mechanism modulating pro-proliferative proteins in mature myeloid cells (96, 97). Hematopoietic cell kinase (Hck) is a member of the Src-family of kinases and is known to be expressed in cells of granulocytic lineages. It interacts with the gp130 subunit of the LIF/IL-6 receptor, directly binding via its SH2 domain to multiple phosphotyrosines of G-CSFR (98). Hck becomes activated on G-CSF treatment and is, in turn, able to phosphorylate G-CSFR, indicating a clear functional and physical involvement in G-CSF signaling. The G-CSFR proliferative stimulus also leads to rapid activation of the p21 ras and p42, p44 MAP kinase signaling pathway (99). G-CSF–induced differentiation can occur in the absence of p42 MAP kinase activation, however (52).

Role of Myeloid Transcription Factors in Development of Granulocyte Colony-Stimulating Factor Responsiveness

The Ets factor PU-1, and the CCAAT/enhancer binding protein-alpha (C/EBPα) are master transcription factors that regulate myeloid development (101, 102 and 103). C/EBPα is a basic leucine

zipper transcription factor that regulates a number of myeloid-specific genes and acts as a myeloid differentiation switch on bipotent granulocyte-macrophage (GM) progenitors and directing them to mature to granulocytes (100, 101). Analysis of C/EBPα knockout mice has shown these animals to be absolutely deficient in granulopoiesis (102), a phenotype different from that of G-CSFR -/- mice, which have quantitative defects in granulopoiesis but mature granulocytes detected at reduced levels (approximately 12% of wild type) (86). C/EBPα -/- mice have greatly reduced mRNA levels and no detectable G-CSFR or IL-6 receptor (IL-6R) proteins. Restoration of either receptor in C/EBPα -/- hematopoietic cells by retroviral transduction restores cytokine response and granulocytic differentiation (103).

Hematopoiesis in Granulocyte Colony-Stimulating Factor and Granulocyte Colony-Stimulating Factor Receptor Knockout Mice

Homozygous inactivation of G-CSF (104) or G-CSFR (86) genes leads to a quantitative impairment of granulopoiesis with an approximately 80% to 90% reduction in neutrophils and a 50% reduction in granulocyte-macrophage progenitor cells, maturing granulocytes, and macrophages in marrow. These mice have reduced ability to mobilize neutrophils on challenge, and impaired resistance to challenge infections with *Listeria monocytogenes* (105). Peritoneal macrophage tumoricidal activity and phagocytosis of *Listeria*, together with bactericidal NO production, were reduced in -/- mice; these reductions were associated with expansion of a poorly differentiated population of cells, morphologically intermediate between typical macrophages and typical lymphocytes (105). G-CSF-deficient animals have marked predispositions to spontaneous infection, reduced long-term survival, and high incidences of reactive type-AA amyloidosis. Mice lacking G-CSF and GM-CSF are more severely neutropenic (up to 2 weeks of age) than those with additive features of the constituent genotypes lacking G-CSF alone. In addition, three novel features are present: greater degrees of neutropenia in neonates, increased neonatal mortality, and a dominant influence of lack of G-CSF on splenic hematopoiesis, resulting in significantly reduced numbers of splenic progenitors (106).

Production of Granulocyte Colony-Stimulating Factor: Cell Sources and Regulation of Production

G-CSF can be produced by a variety of organs and tissues on stimulation; constitutive production is normally low or absent (see Table 6-1). G-CSF production is highly inducible and can be elicited by exposure of cells to bacterial cell wall products (e.g., LPS) and proinflammatory cytokines (e.g., IL-1, TNF, or IL-17). Specific cellular sources of G-CSF include monocytes and macrophages, endothelial cells, fibroblasts and related mesenchymal cells, and bone marrow stromal cells (77). With the latter, a 6-hour *in vitro* pulse exposure to IL-1 was necessary to induce G-CSF production, which continued for 48 hours; thereafter, stromal cells could not be restimulated by IL-1, although IL-4 was able to promote further production (107). Primitive CD34+ hematopoietic cells may be capable of conditioning their own hematopoietic microenvironments because they can induce four- to fivefold increases in marrow stromal cell production of G-CSF and IL-6 on coculture (108). IL-1 beta (IL-1β) serves as a potent primary stimulus for endothelial cell release of G-CSF, IL-6, and IL-8; a further increase in G-CSF was observed when IL-1-primed cells were exposed to *Staphylococcus aureus* and *Staphylococcus* exotoxins (109). IL-17, a cytokine produced by activated memory CD4+ T cells, stimulates epithelial, endothelial, and fibroblastic cells to secret G-CSF, IL-6, IL-8, and PGE (110, 111). The action on fibroblasts results in increased steady-state G-CSF mRNA levels within 2 to 4 hours, due to message stabilization with augmented protein production (110). An additive effect on G-CSF production was observed when IL-17 and LPS were combined. When stimulated with IL-17, fibroblasts can sustain proliferation of CD34+ progenitor cells and their preferential maturation to neutrophils (111). Serum levels of G-CSF are low to undetectable in normal mice or humans; in response to LPS treatment or significant infection, however, serum levels are rapidly and markedly elevated (77). A number of studies have demonstrated that the plasma half-life of G-CSF is inversely related to absolute neutrophil count (112). Mature neutrophils and immature myeloid cells in marrow negatively regulate neutropoiesis—at least in part—by decreasing G-CSF levels through receptor-mediated continual absorption, internalization, and destruction. Inhibitors of exocytosis of ligand receptor complexes abrogated the ability of neutrophils to reduce G-CSF levels (113).

Granulocyte Colony-Stimulating Factor Action on Progenitor Cells

The functional characterization of murine and human G-CSF was undertaken in clonogenic assays in semisolid medium, using either normal bone marrow colony-forming unit (CFU)-granulocyte assay, or murine myeloid leukemic cells inducible to differentiate (WEHI-3 colony differentiation assay). Murine marrow progenitors form small colonies of up to 200 cells within 5 to 6 days in the presence of G-CSF in mice or humans. These colonies contain mature neutrophils; with higher concentrations of G-CSF in serum-containing cultures, however, monocyte-macrophage populations develop. The frequency of G-CSF-stimulated colonies in murine marrow is always two- to tenfold lower than the frequency of colonies stimulated by IL-3, GM-CSF, and M-CSF. In human marrow cultures, G-CSF-stimulated colonies outnumber GM-CSF or IL-3 colonies by day 7 (although the reverse is the case by day 14, when human cultures are normally scored). Pluripotent stem cells express G-CSFR (78) but are not stimulated by G-CSF alone. The factor does, however, synergize in the murine system with IL-3, GM-CSF, M-CSF, and KL in accelerating cell-cycle entry of primitive cells detected in the CFU-blast assay and stimulating subsequent proliferation (114). Synergy is also seen with IL-1, IL-3, GM-CSF, and KL in the murine high proliferative potential (HPP) assay, and in *ex vivo* expansion cultures of primitive progenitors (Delta assay) (115, 116). In suspension cultures of

human CD34+ cells, or of more purified primitive progenitors in the CD38-ve fraction, G-CSF synergizes with multiple other cytokines [e.g., GM-CSF, IL-3, IL-1, IL-6, KL, Flk-2 ligand, Epo, and Tpo], resulting in extensive expansion of total cells, progenitors, and, to a much lesser degree, stem cells (116, 117, 118 and 119). Such expanded populations have been used for autologous transplantation (119).

Action of Granulocyte Colony-Stimulating Factor on Neutrophils

G-CSF is a potent activator of neutrophils (PMN), mobilizing secretory vesicles (leukocyte alkaline phosphatase, CD11b) and inducing the release of specific granules (lactoferrin, CD11b, and CD66b) and azurophil granules (elastase, alpha$_1$-antitrypsin complexes) (77, 120). G-CSF enhances PMN–superoxide anion release, enhancing respiratory burst metabolism (120). Amounts as small as 0.1 ng per mL of G-CSF increase binding of the chemotactic peptide fMLP to neutrophils; increase *in vitro* response to this agent, with enhanced superoxide release and upregulation of C3b receptors; and enhance phagocytosis of opsonized microspheres (77, 121). G-CSF enhances neutrophil antibody–dependent cell-mediated cytotoxicity against antibody-coated leukemic cells. Immunoglobulin A (IgA)-mediated phagocytosis is upregulated by G-CSF induction of increased FcR affinity for IgA (77). Anti-*Candida albicans* activity of human PMN *in vitro* is also shown to be stimulated by G-CSF *in vitro* (122). IL-6 mRNA and protein are upregulated in neutrophils after G-CSF treatment *in vivo* or *in vitro* and may contribute to a clinical engraftment syndrome occurring during periods of rapid increase in PMN numbers in patients receiving G-CSF (123). G-CSF has been reported to stimulate PMN production of IFN-α, is chemotactic for neutrophils and monocytes, and induces neutrophil adhesion (124, 125). The leukocyte adhesion molecule-1, which plays a central role in neutrophil localization at inflammatory sites, is rapidly downregulated on neutrophils by G-CSF (77). G-CSF enhances vitamin C uptake in neutrophils by promoting the conversion of ascorbic acid to dehydroascorbic acid as a result of enhanced oxidation in the pericellular milieu and increasing transport of dehydroascorbic acid through facilitative glucose transporters at the cell membrane (126).

In Vivo Preclinical Studies of Granulocyte Colony-Stimulating Factor

Because G-CSF has been in extensive clinical use since 1988, a review of preclinical studies for other than historic reasons may seem redundant. Nevertheless, a number of lessons learned from animal model systems have yet to be applied in clinical practice. The first *in vivo* studies of rhG-CSF were carried out by Moore in 1986. Species cross-reactivity and relatively low immunogenicity of rhG-CSF permitted extensive studies in mice, primates, and dogs. In various mouse strains, 50 µg to 100 µg rhG-CSF per kg per day induced a rapid neutrophil leukocytosis with PMN counts elevated approximately 50-fold, remaining elevated up to 5 weeks with daily G-CSF treatment (127). This is associated with mild monocytosis and lymphocytosis. Although marrow cellularity does not change, a marked transition to myelopoiesis exists to the exclusion of erythropoiesis; spleen cellularity increases three- to fivefold within 2 weeks, with extensive extramedullary granulopoiesis and compensatory erythropoiesis and megakaryopoiesis. Myeloid, erythroid, megakaryocyte, and pluripotent progenitors increase markedly in the spleen, with total numbers per mouse increasing three- to sixfold. G-CSF also increases numbers of circulating progenitors in a dose-dependent manner, increasing levels of CFU-spleen (CFU-s) four- to 32-fold but not altering their self-renewal capacities (128). Genetic marking studies have shown that mobilization includes cells with long-term lymphomyeloid reconstituting capacity (129). A tenfold range in progenitor mobilization response to G-CSF that does not correlate with white blood cell count (WBC) increase is reported among different mouse strains, and F2 intercrosses of low-responding C57BL/6 and intermediate-responding SJL mice indicate that regulation of progenitor mobilization is a complex genetic trait (130). The mechanism by which G-CSF mobilizes stem and progenitors into the peripheral blood may be related in part to its ability to downmodulate endothelial intercellular adhesion molecule 1 (ICAM-1), induced by IL-1, and upmodulate vascular cell adhesion molecule-1 on IL-1–treated endothelium (131). Transendothelial migration of granulocytes (lacking vascular cell adhesion molecule-1 receptor VLA-4) through IL-1–activated endothelium is inhibited by G-CSF in a concentration-dependent manner (131). Additive or synergistic elevation of progenitors and stem cells in mouse peripheral blood is reported when G-CSF is combined with other cytokines, including IL-6, KL, and FL (132, 133 and 134). A population of cells that facilitate engraftment of highly purified stem cells across major histocompatibility complex barriers without causing graft-versus-host disease is mobilized after treatment of mice with G-CSF and FL (136). Comparison of allogeneic engraftment potential of mobilized cells indicates that day 10 of treatment coincides with maximum mobilization of repopulating stem cells and facilitator cells.

Transgenic mice expressing hG-CSF produced approximately 1,000 pg per mL of G-CSF in sera, associated with an expected granulocytosis, elevation of hematopoietic progenitor numbers, and mobilized stem cells; unexpectedly, however, a lymphocytosis occurred, as well as a fivefold increase in peripheral blood and a twofold increase in spleen cellularity (137). Transgenic mice developed osteoporosis due to increased osteoclastic activity. Retroviral gene transfer of the G-CSF gene into vascular smooth muscle or primary myoblasts in rat models resulted in prolonged granulocytosis (7 to 26 weeks, two- to 15-fold increase), suggesting this strategy has potential for treating congenital and cyclic neutropenic disorders in humans (138, 139). Chronic exposure of mice to G-CSF resulting from transplantation of bone marrow infected with a retroviral vector bearing a G-CSF cDNA produced a nonneoplastic granulocytic and progenitor cell hyperplasia (140). Most animals remained healthy despite dramatic neutrophil leukocytosis with neutrophil infiltration of many organs. Progenitors of all lineages were raised ten- to 100-fold in the spleen, blood, and peritoneal cavity but remained unaffected, or slightly depressed, in the marrow. No tumors developed, and no evidence of tissue damage over a 30-week period was observed.

G-CSF protected a significant number of mice from lethal effects of lethal-dose 100/30 total body irradiation, and a single intraperitoneal injection of 1 mg per kg 2 hours after a dose of lethal-dose 95/30 irradiation significantly improved survival (141, 142). G-CSF was effective in reducing chemotherapy-induced myelosuppression in mice treated with single or multiple doses of cyclophosphamide, doxorubicin, vinblastine, mitomycin-c, busulphan, or 5-FU (115, 143). Repeated treatment with cyclophosphamide, followed by G-CSF treatment to accelerate neutrophil recovery, induced stem cell damage as measured by serial bone marrow transplantation (144). Mice treated with etoposide plus chlorambucil, bischloroethyl-nitrosourea, or total body irradiation (80c Gy) also experienced greater long-term damage to primitive stem cell populations when chemotherapy was combined with G-CSF (145). This toxicity can be abrogated using a suitable delay between the end of G-CSF treatment and the beginning of the next cycle of chemotherapy, to ensure rebound quiescence occurs in the stem-cell pool. Other protective strategies include administration of IL-1 24 hours before each chemotherapy cycle (145) or treatment with negative regulators, such as transforming growth factor-ß or macrophage inflammatory protein-1α, to actively place stem cells into a noncycling state (146). In primates, G-CSF shortened the time to recovery of WBCs after cyclophosphamide treatment to 1 week, compared to greater than 4 weeks in controls (147).

In murine and primate models of bone marrow transplantation, G-CSF has been shown to markedly accelerate recovery of neutrophils, marrow, and spleen hematopoietic progenitor cells and stem cells (77). Autologous bone marrow transplantation in monkeys after myeloablative TBI (100 Gy) was enhanced by G-CSF treatment with neutrophil counts of control animals taking 3 weeks to reach 1,000 per mm^3, whereas animals receiving 100 mg per kg per day of rhG-CSF achieved an equivalent neutrophil count 9 days earlier (77).

G-CSF has been shown to prevent progression of systemic nonresponsiveness in various animal models of systemic inflammatory response syndrome (SIRS) and sepsis (148). SIRS constitutes the primary host response to a variety of severe insults such as trauma, burns, pancreatitis, or major surgical intervention. Distinct from SIRS, the term *sepsis* is applied to the state when bacterial infections cause a systemic hyperinflammatory immune response. Rodent models in which G-CSF has been shown efficacious include rodent LPS or fecal septic shock (149, 150) or cecal perforation models (151), dog intraperitoneal *Escherichia coli* infection (152), and a porcine *Pseudomonas* sepsis (153). In all cases, G-CSF improved survival and reduced endotoxemia, bacterial count, and TNF release. G-CSF attenuated the proinflammatory cytokines that would otherwise predominate. Upregulation of the endotoxin-binding protein CD14 on neutrophils may be responsible for enhanced endotoxin binding and accelerated clearance. In a rat intraabdominal sepsis model, G-CSF increased microvascular flow and prevented neutrophil-mediated damage by downmodulating the potent vasoconstrictor endothelin-1 (151). Hemoconcentration and lactic acidosis were also attenuated, which is consistent with reduced endothelial damage and plasma leakage. In a rat pneumonia model (154), all control animals died but more than 90% of G-CSF treated animals survived. Exogenous G-CSF has improved survival in a number of models of pneumonia induced by *Klebsiella pneumoniae, Streptococcus pneumoniae*, and *Pseudomonas aeruginosa* (148). It has also protected mice against T-cell-mediated lethal shock triggered by superantigen, decreasing LPS-induced pulmonary edema and alveolar capillary leakage (155). G-CSF treatment of rats with visceral ischemia or reperfusion injury, or both, resulted in increased survival and reduced TNF release (156). G-CSF stimulates hemoxygenase-1 expression in microvascular endothelial cells *in vitro;* this may be an important response against oxidative damage (148). In a rabbit model of immune complex colitis, treatment with G-CSF markedly decreased production of proinflammatory mediators such as LTB4 and thromboxane B$_2$; mucosal generation of protective PGE, however, was preserved (157). Inflammatory bowel disease is associated with mucosal neutrophil recruitment and activation mediated in part by arachidonic acid metabolites. The potential of G-CSF for treatment of SIRS and sepsis is suggested by these animal models, in which improved survival is observed with evidence of functional activation (CD64 expression, phagocytic activity, decreased apoptosis), decreased neutrophil L-selectin expression, increased serum IL-1 receptor antagonist (IL-1ra), and decreased serum proinflammatory cytokine concentrations (IL-1, TNF, IL-8) (148).

Granulocyte-Macrophage Colony-Stimulating Factor

Part of "6 - Colony-Stimulating Factors: Basic Principles and Preclinical Studies "

Molecular Characterization

Murine GM-CSF was first purified from lung-conditioned medium and shown to be a heavily *N*-glycosylated polypeptide of 124 amino acids and a molecular weight of 23,000 to 29,000 d (see Table 6-1) (158). Subsequent cloning of the murine gene revealed a polypeptide of 142 amino acids with an 18 amino-acid leader sequence (159, 160). Human GM-CSF was first purified from a T-lymphoblastoid cell line as a glycoprotein of 22,000 Da (161). Human GM-CSF cDNA encodes a polypeptide of 144 amino acids with a 17 amino-acid leader sequence (162). The primary GM-CSF transcript expressed from four exons in mouse and humans is processed to a mature mRNA of approximately 780 nucleotides (160). Despite a 60% homology at the nucleotide level and 54% identity at the amino acid level, murine and human GM-CSFs are species restricted in their actions. The crystal structure has been determined at 2.8 A (163). The main structural feature is a four-alpha-helix bundle that represents approximately 42% of the structure. The helices are arranged in a left-handed, antiparallel bundle with two overhead connections. Within these connections is a two-stranded antiparallel beta-sheet. Most of the critical regions for receptor binding are located on a continuous surface at one end of the molecule that includes the C-terminus. Structure-function analysis using monoclonal antibodies (164, 165) or scanning deletion (166) has shown four critical regions, residues 18 to 21, 34 to 41, 52 to 56, and 94 to 115. The disulfide bridge between cysteines 51 and 93 (but not that between cysteines 85 and 118) is essential for activity. Two N-glycosylation sites are present, and mature GM-CSF is also modified by O-glycosylation. Variations

in the molecular weight of mature GM-CSF from 14 kd to 30 kd result from variable glycosylation; up to 50% of the molecule is carbohydrate (see Table 6-1). rhGM-CSF produced commercially from yeast (sargramostim) or baculovirus is glycosylated, although differently from the native molecule; in the former, proline at position 23 is replaced by valine. In contrast, *E. coli*-derived rhGM-CSF (molgramostim) is not glycosylated and contains six fewer residues and an extra initial methionine (167, 168). *E. coli*-derived rhGM-CSF has a significantly faster elimination phase *in vivo* compared to mammalian Chinese hamster ovary cell–derived rhGM-CSF (regramostim), yet it retains high biologic activity and is tenfold more active in stimulating myeloid proliferation and binding to the GM-CSFR than the fully glycosylated form (169).

The GM-CSF gene is located on chromosome 5q23-31 in close proximity to the IL-3 gene (9 kbp downstream) (see Table 6-1) (170). The long arm of chromosome 5 contains a clustering of hematopoietic regulatory genes that include GM-CSF, IL-3, IL-4, IL-5, IL-9, IL-13, and M-CSF and the receptors for platelet-derived growth factor and M-CSFR *(c-fms)* (171). Deletion of the long arm of chromosome 5 from 5q11-21 to 5q22-34 is associated with primary and familial myelodysplastic syndrome and therapy-related leukemia, but it is more likely that the candidate for pathogenesis of 5q is the interferon regulatory factor-1 gene mapping to 5q31.1 (172).

Granulocyte-Macrophage Colony-Stimulating Receptor

The GM-CSFR is a member of the hematopoietin receptor superfamily and is comprised of an 85-kd α-chain that binds GM-CSF with a low affinity (kd = 1 to 10 nm) and a 130-kd β-chain with no intrinsic binding affinity for GM-CSF alone, but converts the GM-CSF α-chain complex to a high affinity state (kd = 30 pm to 100 pm) (see Table 6-2) (167, 173). The α-chain exhibits rapid dissociation kinetics, whereas the α/β GM-CSFR displays slow dissociation kinetics. Both chains share a common conserved ˜200–amino-acid hematopoietin extracellular domain common to members of the superfamily (167, 173). This domain has four conserved cysteine residues that form two internal disulfide loops: a Pro-Pro pair that divides the domain into two subdomains, each of which adopt a seven-stranded beta-barrel structure similar to the immunoglobulin constant chain; and a largely conserved membrane proximal WSXWS motif. The β-chain is shared by the IL-3 and IL-5 receptor α-chains (174). GM-CSF, IL-3, and IL-5 bind to their specific α-chains with absolute specificity, followed by signaling in association with the common compatible β-chain. This cross-competition accounts for much of the redundancy of these cytokines and their homologous actions (observed, for example, in eosinophil development and effector function). It is distinct from receptor trans-downmodulation of GM-CSFR, observed under conditions permitting receptor internalization when cells are exposed to IL-3 or TNF (175). Three isoforms of the GM-CSFR-α chain have been described and are generated by alternative splicing (167). Two forms of 400 and 401 amino acids are identical except for the terminal 54 and 64 amino acids of the cytoplasmic domain. The third form has a transmembrane deletion and can occur as a soluble form. The GM-CSF receptor α-chain is encoded by a gene situated within the pseudoautonomous region, an area of homology between the ends of the human sex chromosomes that undergo obligatory exchange during meiosis, thereby behaving "pseudo-autosomally" (176). The common β-subunit of GM-CSF is encoded by a gene located on chromosome 22q12-13 (177).

GM-CSF receptors are expressed on neutrophils as a single class of high-affinity receptor (kd of 99 pm, 300 to 2,800 receptors per cell) (see Table 6-2). This receptor is expressed at levels of 50 to 500 receptors per cell on myeloid progenitors, monocytes, eosinophils, and DCs (but not on lymphoid or erythroid populations) (167). On monocytes and myeloid leukemic cells, a high-affinity (kd 10 to 40 pm) and more frequent low-affinity (kd less than 2 pm) class of receptor is expressed (178). Primitive progenitor/stem-cell populations (CD34[+], CD38[-]) express receptors for GM-CSF at levels 20% to 30% of more committed granulomonocytic progenitors (179).

Granulocyte-Macrophage Colony-Stimulating Receptor Signal Transduction

The GM-CSFR exists as an inducible and preformed complex, unlike the IL-3 receptor (or any other member of the cytokine receptor superfamily) (180). This complex of the GM-CSFR-α and -β common chains required only the extracellular domains, and the β common component of the complex was phosphorylated by GM-CSF binding and IL-3 and IL-5. Analysis of cytoplasmic truncation mutants of β common showed that the residues to amino acid 783 (numbering from the first amino acid of the leader sequence) were sufficient for GM-CSF–dependent induction of all aspects of myeloid differentiation (181). Shorter truncations selectively lost (in a cell-specific manner) the capacity to induce macrophage migration and cell-surface differentiation antigens and clonal suppression of proliferative potential, however (181). This suggests that different aspects of the differentiation phenotype require signaling pathways that originate from distinct regions of the receptor cytoplasmic domain. The GM-CSFR-α subunit is essential for GM-CSF–mediated growth and differentiation. The membrane proximal proline-rich domain and adjacent 16 residues are necessary for cell proliferation and differentiation and Jak2 activation (182). In contrast, the C-terminal region was not necessary for differentiation, but removal of this region severely impaired the ability of GM-CSF to support cell survival.

Jak2 is the primary kinase regulating GM-CSF activities and inducing c-fos activation through receptor phosphorylation (183). The importance of c-fos and related AP-1 activity in GM-CSF signaling is suggested by the tight correlation between GM-CSF–dependent activation of the c-fos promoter and cell proliferation, and by the inhibitory effect of a transdominant c-fos mutation on the growth of GM-CSF–dependent cells (184). Activation of Jak2, Shc, Erk, and STAT5 proteins correlates with GM-CSF–mediated cell growth. In myeloid leukemic cells, GM-CSF enhances DNA binding and tyrosine phosphorylation of STAT3, which is directly activated by c-fes tyrosine kinase (185). In early stages of GM-CSF–induced proliferation of CD34[+] cells, the 94 kd STAT5-β protein

is activated at later stages of differentiation and increased expression of the 80 kd STAT5 isoform is observed, resulting in heterodimeric DNA binding (186). CrkL, an adaptor protein comprising Src homology (SH)2 and SH3 domains participates in the GM-CSF activated Jak-STAT pathway by directly associating with STAT5 (187). In mature neutrophils, GM-CSF activation is reported to result solely in Jak2, STAT3, and STAT5-ß phosphorylation (not involving other members of the Jak/STAT family) (188). However, earlier reports indicate that STAT1, STAT3, and the product of the c-fps/fes protooncogene become tyrosine phosphorylated and physically associate with the GM-CSFR-ß common chain and Jak2 (189). Jak2 phosphorylation of the p85 subunit of p13-kinase in neutrophils is mediated by an as-yet-unidentified adaptor protein (190). In neutrophils, GM-CSF stimulation leads to phosphorylation of MKK3/MKK6 (upstream kinases of p38 MAPK), and the upstream kinase of Erk. Phosphorylation of MAPK and Erk occur within 1 to 5 minutes after stimulation; inhibitors of p35 MAPK inhibit GM-CSF–induced neutrophil superoxide release (191). In monocytes and macrophages activated directly by GM-CSF—or indirectly by LPS-inducing autocrine GM-CSF production—Cox-2 gene activation occurs after STAT5 is activated (192, 193). In DCs, GM-CSF induces a broad complex of STAT isoforms (STAT1, STAT3, STAT5-α, STAT5-ß, and STAT6) not seen in any other type of GM-CSF–responsive cell (193). Other known intermediates that are phosphorylated and activated as a consequence of GM-CSF include SH collagen (SCH) protein, GRB2, Ras, p21, pp100, pim-1 kinase, raf-1 kinase, p92c-fps/fes kinase, p53/p56 lyn kinase, and p62 yes kinase (167). The signaling pathway ultimately involves transcriptional activation of nuclear factors, such as c-fos, c-jun, c-myc and, possibly, p53, important in the cell cycle. GM-CSF has been shown to abrogate transforming growth factor-ß1–mediated cell-cycle arrest of a myeloid cell line by constitutively overexpressing cdk4 and cyclin D2, which had been downregulated by TGF-ß1 (194).

Origin of Granulocyte-Macrophage Colony-Stimulating Factor and Regulation of Production

GM-CSF is an inducible product of a variety of cell types (see Table 6-3). GM-CSF is not detectable in normal resting cells, although transcription of the GM-CSF gene can be detected using sensitive nuclear run-on assays (195). It is produced by antigen or lectin; or IL-2–stimulated T lymphocytes, antigen, or LPS; or IL-1–stimulated B lymphocytes and macrophages activated by LPS, phagocytosis, or adherence. In these various inducible cells, the accumulation of GM-CSF mRNA is due to increased transcription rate and posttranscriptional stabilization of mRNA. IL-1 or TNF stimulates fibroblast and endothelial cell GM-CSF expression by predominantly posttranscriptional mechanisms. The A/T-rich region at the 3" end of GM-CSF is important in determining mRNA stability, and similar AT-rich sequences are located at the 3" end of a variety of genes that must be turned on and off quickly (195). A variety of transcriptional regulatory elements in the 5" flanking region of the GM-CSF gene control its expression. Contained within the GM-CSF promoter region is the repeated sequence CATT (A/T) located in the region bp -48 to -37 relative to the GM-CSF mRNA initiation site, which is a recognition site for cellular transcription factors. Other regulatory elements, including negative regulatory elements located at 5" in these sequences, modulate transcription of GM-CSF (195). *Cis*-acting elements with NF-kappa-beta (NFκß), AP1, and ETS-like binding motifs in the promoter region of the GM-CSF gene are important for transcriptional activity after T-helper-cell activation. ETS1 can transactivate GM-CSF in T cells, but only after these cells have been stimulated by phorbol esters or ionomycin, agents that mimic T-cell activation (196). ETS1, NFκB and Ap1 synergistically transactivate the human GM-CSF promoter. IL-1–induced GM-CSF production in endothelium was associated with increased GM-CSF mRNA levels (which, in turn, are linked to nuclear-protein kinase-C and low-molecular-weight G-protein activation) (197). Neither activity alone was sufficient to increase levels of mRNA (197). Production of GM-CSF by vascular endothelium may be regulated by hemodynamic force because elevated GM-CSF mRNA and protein production are observed when vascular endothelium is exposed to a shear stress of 15 to 25 dyne per cm^2. This response depends on protein synthesis and results from mRNA stabilization (198). GM-CSF is released from lung mast cells after cross-linkage of their high-affinity Fc epsilon receptors by IgE (199). In turn, GM-CSF in mast cell supernatant can release eosinophil cationic protein from eosinophils, contributing to chronic eosinophil-mediated inflammation (199). In the brain, GM-CSF may be released by infiltrating cells of the immune system or by resident cells, such as microglia and astrocytes (200). Astrocyte-secreted GM-CSF may play an important role in enhancing local inflammatory response to CNS injury and recruiting microglia and activated macrophages. Astrocytes express the α-subunit of the GM-CSF receptor and proliferate in response to GM-CSF (200). Autocrine astrocyte production of and response to GM-CSF may be involved in astrocytosis, a hallmark of various neurologic injuries, and in inflammatory processes.

Granulocyte-Macrophage Colony-Stimulating Factor Action at the Progenitor Level

The biologic effects of GM-CSF were initially related to its ability to stimulate proliferation and differentiation of myeloid-committed progenitors (CFU-GM) at concentrations of 2 to 80 pg per mL. In the murine system, higher concentrations of GM-CSF can stimulate eosinophil colony formation, and tenfold higher concentrations stimulate CFU, megakaryocyte (CFU-Meg); burst-forming unit, erythroid (BFU-E); and mixed (CFU-granulocyte, erythroid, megakaryocyte, macrophage) progenitor colony formation (200). Dose-dependency is less evident in human colony assays, and synergy is observed with a variety of other hematopoietic growth factors (IL-3, M-CSF, KL, and Epo). Although GM-CSF has minimal effects on survival or proliferation of primitive progenitor/stem-cell populations when added alone, cytokine-enhanced

KL induced cell-cycle entry, an effect not observed when cells were incubated sequentially with KL and GM-CSF (179).

Action of Granulocyte-Macrophage Colony-Stimulating Factor on Mature Leukocytes

GM-CSF has a direct action on random migration of neutrophils; a 1-minute exposure is sufficient (201). *In vitro*, GM-CSF increases PMN half-life threefold and protects the cells from ultraviolet or x-irradiation-induced apoptosis (202, 203). Increased viability and longevity of neutrophils is achieved with approximately $1/100$ the concentration of GM-CSF required to stimulate cell proliferation. The Erk-signaling pathway plays an important role in protection and rescue of PMN from apoptosis but appears to be a proximal event in the process (202). GM-CSF also suppresses anti-Fas antibody-induced neutrophil apoptosis with retention of superoxide production and enzyme release (204). GM-CSF induces neutrophil degranulation with release of primary and secondary granules (205). Neutrophils exposed to fMLP or its complement (C5a) produce much higher levels (sixfold) of reactive oxygen products when primed by GM-CSF (206). One mechanism of GM-CSF priming of the fMLP-induced respiratory burst is the synergistic activation of PI3 kinase by heterotrimeric Gi proteins in the presence of tyrosine-phosphorylated proteins, and phosphorylation of p47 phox (207). GM-CSF also rapidly upregulates fMLP receptors on neutrophils (208). GM-CSF primes neutrophils for arachidonic acid release and leukotriene B4 synthesis elicited by fMLP, IL-8, or platelet-activating factor (PAF) (209) by a mechanism involving rapid upregulation of 5-lipoxygenase, a key enzyme in the leukotriene synthetic pathway (210). GM-CSF and IL-8 synergistically interact to enhance PMN synthesis of PAF and LTB4 (211).

Antimicrobial effects of GM-CSF include enhanced bactericidal activity of neutrophils against *S. aureus* (120) and enhanced phagocytosis and intracellular killing of *C. albicans* (212, 213). GM-CSF enhances killing of *Trypanosoma cruzi* (214) and opsonized *Torulopsis glabrata* (215). IgA FcR is induced by GM-CSF (216) and enhanced ADCC toward tumor cells involves upregulation of FcR II (217). This tumor lysis involves an increased release of lytic granular molecules, including defensins and cathepsin-G, a neutrophil protease that mediates tumor lysis (218). GM-CSF increases the expression of class I heavy and light chains and beta$_2$-microglobulin (219) and class II mixed leukocyte culture antigens (220). GM-CSF increases neutrophils' vitamin C uptake by enhancing oxidation in the pericellular milieu and increasing transport through facilitative glucose transporters in the cell membrane (126).

The leukocyte adhesion molecule, which plays a crucial role in neutrophil localization at inflammatory sites and endothelial interaction, is rapidly downregulated by GM-CSF (221), whereas the beta$_2$-integrin molecules CD11b/CD18 and CD11c/CD18 are upregulated (208). Integrins mediate PMN adhesion to endothelium, homeotypic adhesion, chemotaxis and phagocytosis, and respiratory burst. GM-CSF-enhanced neutrophil migration across a nonactivated endothelium independent of concentration gradients, but inhibited migration across IL-1-activated endothelium (i.e., inflamed endothelium) (222).

Eosinophils are potent inflammatory cells involved in allergic reactions, and GM-CSF (and IL-3 and IL-5) can prolong eosinophil survival *in vitro* and *in vivo*, providing an important mechanism for causing tissue eosinophilia (223, 224). Spontaneous eosinophil apoptosis is associated with a decrease in Bcl-xL mRNA and protein levels, and the antiapoptotic action of GM-CSF involves maintenance or upregulation of Bcl-xL (but not Bcl-2) (225). Glucocorticoids inhibit this survival-promoting effect, suggesting a mechanism for their efficiency exists in the treatment of eosinophilia-associated disorders (224). GM-CSF enhances the eosinophil respiratory burst induced by opsonized particles (226). Eosinophil degranulation and release of toxic granular proteins is induced by IgA cross-linking of Ig receptors; this is enhanced by GM-CSF (227), which also upregulates FcR-γ II and CR3 (228). GM-CSF upregulates CD11b adhesion molecules on eosinophils after fMLP or PAF treatment (229), which may facilitate their adherence to endothelium and subsequent migration to inflammatory sites. Enhancement of eosinophil ADCC (230) and enhanced phagocytosis of *C. albicans* and *Staphylococcus* killing is observed after GM-CSF treatment (231). GM-CSF enhances the generation of leukotriene C4 induced by calcium ionophore and the release of arylsulfatase and beta-glucuronidase from specific and small granules of eosinophils (231). Release of eosinophil cationic protein after GM-CSF treatment may contribute to chronic eosinophil inflammation (199).

GM-CSF prevents the apoptotic death of macrophages and enhances their differentiation into macrophages (232). It is chemotactic for monocytes and macrophages (233), and induces M-CSF (234) and TNF-α (235) production by these cells. Synergy between GM-CSF and IFN-γ increases TNF-α release from the surface of monocytic cells by a protease cleavage mechanism (236). IL-1β and IL-receptor (IL-R) antagonist protein are induced in macrophages by GM-CSF; this factor primes monocytes for enhanced reactive oxygen release after fMLP or C5a treatment (237, 238 and 239) and plasminogen activator secretion (340). Activation of monocytes and macrophages by GM-CSF is associated with upregulation of CR3 and IFN-γ receptors (42), the fMLP receptor (241) and the FcR-γ II, which are largely responsible for immune clearance of IgG-sensitized cells (242). The delta integrin Vβ3 is induced on monocytes by GM-CSF (243), as are CD1 (a, b, and c) molecules, thereby enhancing macrophages' roles as accessories to T cells (244). GM-CSF, in synergy with glucocorticoids, upregulates class I and II antigens on monocytes, and enhances macrophage ADCC (245, 246). Significant growth inhibition of *Mycobacterium avium* was observed in human macrophages treated with GM-CSF (247, 248). GM-CSF-activated monocytes and macrophages inhibit replication of *Leishmania* (249), *L. monocytogenes* (247), *C. albicans* (250), *Histoplasma capsulatum* (251), and *T. cruzi* (252) by mechanisms involving augmented superoxide, NO production, and elevation of mannose receptors. Monocytes from septic patients had depressed membrane expression of CD71 and HLA-DR, enhanced apoptosis and priming of such cells with GM-CSF-abrogated apoptosis, and restored LPS responsiveness and cytokine secretion (253). GM-CSF-enhanced LPS or IFN-γ-induced monocyte production of endothelin, a potent vasoconstrictor molecule with immune modulating properties (254).

Human macrophages express chemokine receptors (CCR5, CXCR4) that act as coreceptors for HIV-1. CCR5 is virtually undetectable on freshly isolated monocytes; on exposure to GM-CSF (or M-CSF), however, CCR5 is upregulated, and entry and replication of HIV-1 is markedly increased (35).

Morphogenesis and remodeling of bone involves the synthesis of bone matrix by osteoblasts and coordinated resorption of bone by osteoclasts. Osteoblasts arise from mesenchymal stem cells; osteoclasts differentiate from hematopoietic monocyte and macrophage precursors. CD14$^+$ adherent human monocytes differentiate into tartrate-resistant acid phosphatase (TRAP)–positive osteoclast-like multinucleate giant cells in the presence of GM-CSF and IL-4 (255). Endogenous GM-CSF is an autocrine growth factor for human osteoblastic cells; such cells express GM-CSF and the α and ß chains of GM-CSFR (256). Exogenous GM-CSF induced a dose-dependent proliferation of osteoblasts. Antibody or antisense to GM-CSF inhibited proliferation (256).

The tumoricidal capacity of monocytes is enhanced by GM-CSF, and ADCC activity with tumor-specific antibody has been demonstrated *in vitro* (257) and *in vivo* on transfer of activated human cells to nude mice bearing human tumors (246). GM-CSF also enhances IL-2–mediated LAK cell function (258). In tumor-infiltrating macrophages, it also increases secretion of matrix metalloelastase with subsequent production of angiotensin, inhibiting angiogenesis and suppressing growth of lung metastases (259). GM-CSF may also facilitate tumor antigen presentation and enhance immunogenicity of tumor cells (168).

Granulocyte-Macrophage Colony-Stimulating Factor and Dendritic Cells

DCs are irregularly shaped with numerous cell membrane processes, including spiny dendrites, bulbous pseudopods, and lamellipodia or veils. Mature DCs lack phagocytic capacity and are nonadherent. They express high levels of class II major histocompatibility complex, CD40, CD83, and CD1a, lacking the monocyte/macrophage marker CD14 (260). These cells are professional antigen presenters, stimulating primary T-cell responses and autologous mixed lymphocyte response, which probably relates to the primary response to exogenous antigen. DCs are heterogeneous in lineage, and origin can arise from lymphoid or myeloid precursors. CD34$^+$ precursors in normal marrow generate dendritic colonies when stimulated with GM-CSF and TNF (260, 261). Large numbers of functionally mature DCs can also be generated over 12 to 14 days in suspension cultures of CD34$^+$ cells with the same cytokines; absolute recovery is enhanced by addition of c-kit or flt3 ligands (probably by expanding production of CFU-GM progenitors) (262). Development of DCs in this system occurs via development of an intermediate CD14$^+$, HLA-DR$^+$, or c-fms$^+$ cell that lacks myeloperoxidase and nonspecific esterase. These cells possess substantial phagocytic capacities and are bipotential, generating typical adherent CD14$^+$ phagocytic macrophages in the presence of M-CSF, and CD14-ve, c-fms-ve, CD1a$^+$, CD83$^+$, HLA-DR^{+++} DC in the presence of GM-CSF and TNF (263). Blood monocytes also differentiate into DC without proliferation; in the presence of GM-CSF, this pathway is reversible. Exposure to proinflammatory cytokines, such as TNF, however, induces an apparently irreversible maturation to DC with downmodulation of *c-fms* (255, 260). GM-CSF, TNF, and IL-4 are widely used to induce DC development from blood monocytes (264). CD40 to CD40 ligand interactions play central roles in antigen presentation and T-cell–dependent effector function; CD40 is upregulated by GM-CSF (264). Physiologic conditions inducing monocyte differentiation to DC include a combination of phagocytosis and transendothelial migration. In one *in vitro* model, monocytes first cross a layer of endothelial cells and lodge in an underlying collagen matrix, mimicking entry of monocytes into tissues from circulation (265). A proportion of these cells then "reverse transmigrate" and become DCs, mimicking the migration of DCs out of tissues into lymphatics. Those cells that remain in the collagen "tissue" become macrophages. The phagocytosis process provides a strong stimulus for DC maturation, and the endothelium may be a source of GM-CSF and proinflammatory cytokines (265).

Action of Granulocyte-Macrophage Colony-Stimulating Factor on Leukemic Cells

In vitro analysis of most human leukemias at diagnosis reveals their dependences on exogenous CSFs for *in vitro* proliferation when cultured at low cell densities. At high cell densities, however, autonomous proliferation is seen (266). Genuine cases of autocrine GM-CSF production have been documented in B-lineage acute lymphoblastic leukemia (267) and acute myeloid leukemia, some cases expressing large transcripts from rearranged GM-CSF loci (167). The nontumorigenic FDC-P1 factor-dependent hematopoietic cell line becomes leukemogenic when transplanted into irradiated recipients; in many cases, factor-independent lines that were producing GM-CSF or IL-3 due to rearrangements associated with transposition of intracisternal A-particles can be isolated (268). Enforced expression of GM-CSF by FDC-P1 cells gave rise to autocrine leukemogenic variants (167). The *bcr-abl* oncogene plays a critical role in chronic myeloid leukemia (CML). Retroviral transduction of human Bcr-Abl/p210 into mouse bone marrow cells induced a transplantable myeloproliferative CML-like disease in 100% of mice in approximately 3 weeks; this was associated with excess production of IL-3 and GM-CSF, suggesting that autocrine cytokine production is a component of the pathophysiology of CML (269). The recruitment of chemoresistant leukemic cells into sensitive phases of the cell cycle by GM-CSF may enhance the antileukemic effect of chemotherapy. GM-CSF–induced increases in leukemic cells in S-phase and intracellular phosphorylation of cytarabine have been shown to promote drug-induced cell kill (270).

Mice with Targeted Deletions of Granulocyte-Macrophage Colony-Stimulating Factor, Granulocyte-Macrophage Colony-Stimulating Factor Receptor-Alpha, or Granulocyte-Macrophage Colony-Stimulating Factor Receptor-Beta Common Chains

Mice in which the GM-CSF gene is knocked-out exhibit normal steady-state hematopoiesis, suggesting either functional

redundancy of the myeloid regulatory factors or lack of a role for the factor in normal hematopoiesis (271). A universal abnormality in these mice is a pulmonary pathology with similarities to human alveolar proteinosis that involves accumulation of pulmonary surfactant protein and associated opportunistic infection. After *L. monocytogenes* infection, these mice showed 50-fold more organisms in spleen and liver than similarly infected wild-type mice, accompanied by severe depletion of bone marrow hematopoietic cells and defective inflammatory response (106). Mice lacking GM-CSF and G-CSF have greater degrees of neutropenia at birth and higher mortality than those lacking G-CSF only; in adult mice, however, neutrophil levels are comparable (107). The cellular delayed hypersensitivity response to type II chick collagen was significantly reduced in GM-CSF–deficient mice, supporting the view that GM-CSF is required for the development of collagen-induced arthritis (272). Defects in T-cell function involving generation of cytotoxic CD8 T cells, impaired CD4⁺ T-cell proliferation, and cytokine production has been reported in GM-CSF -/- mice (273). In GM-CSF -/- and GM-CSFRßc -/- mice, DCs of all surface phenotypes were still present in all lymphoid organs (only small decreases occurred in most sites, but a threefold decrease occurred in the lymph nodes of receptor-null mice) (274). In GM-CSF transgenic mice, a threefold increase in lymph node DCs occurred (274). More surprising is the normality of hematopoiesis in GM-CSFRßc/IL-3 double-mutant mice lacking entire GM-CSF, IL-3, and IL-5 functions (275). These mice showed normal hematopoietic parameters except for reduced numbers of eosinophils and lack of an eosinophil response to *L. monocytogenes*. Hematopoietic recovery after administration of the myelosuppressive drug 5-FU was unimpaired, indicating that these three cytokines were dispensable for hematopoiesis in an emergency, as well as in steady state. On injection of endotoxin or casein, ßc -/- mice showed much greater elevations of serum GM-CSF than wild-type mice, indicating that receptor-mediated clearance for normal regulation of local and systemic levels of the cytokine is important (276).

Preclinical In Vivo Studies of Granulocyte-Macrophage Colony-Stimulating Factor

In mice, chronic intraperitoneal administration of murine GM-CSF caused a local peritoneal accumulation of macrophages, eosinophils, and neutrophils, with little systemic changes in hematopoiesis occurring elsewhere (227, 228). Transgenic mice expressing GM-CSF under control of a retroviral promoter exhibited chronic elevation of GM-CSF associated with an abnormal accumulation of macrophages in pleural, peritoneal, and ocular cavities (279). The transgenic mice exhibited a frequently fatal syndrome involving blindness, muscle wasting, and tissue destruction, probably related to GM-CSF induction of various inflammatory mediators. A similar lethal myeloproliferative syndrome was associated with introduction of the GM-CSF gene via retrovirally transduced bone marrow stem-cell transplantation (280).

Continuous infusion, or multiple injections of GM-CSF in mice before sublethal irradiation or chemotherapy, led to accelerated reconstitution of hematopoiesis (167, 168). It is also effective in accelerating hematopoietic recovery after chemotherapy, although greater long-term damage to the stem-cell population is found to occur with repeated cycles of cyclophosphamide plus GM-CSF than with the drug alone (144).

GM-CSF protected neonatal rats from morbidity and death produced by *Streptococcus* infection and *Salmonella typhimurium*-sensitive mouse strains from infectious challenge (315, 316). Protection of rodents from mortality was also observed in otherwise lethal infections with *P. aeruginosa, M. avium, C. albicans*, and aspergillosis (167, 168).

In primates, continuous GM-CSF administration induces a dose-dependent leukocytosis, which can be maintained at 50,000 WBCs per mm³ for up to 1 month (283). The leukocytosis involved neutrophils, band forms, eosinophils, monocytes, lymphocytes, and reticulocytes. WBCs fell to near pretreatment levels within a few days of discontinuation of therapy. GM-CSF also stimulated recovery of neutrophils in monkeys receiving autologous bone marrow transplantation with recovery of neutrophils at least 1 week earlier than in nontreated controls (284). Coadministration of GM-CSF and thrombopoietin in sublethally irradiated primates augmented platelet, red blood cell, and neutrophil recovery to a greater degree than either cytokine alone (285).

In vivo preclinical studies have shown that GM-CSF has an antitumor effect owing to enhancement of LAK and monocyte/neutrophil ADCC (168). Based on its enhancement of functional effects on macrophages and DCs, GM-CSF has been studied for its potential to enhance immune responses to antitumor immunotherapies. GM-CSF in rats elicited a delayed hypersensitivity response to tetanus toxoid similar to that seen with standard Freund's adjuvant (286). Retroviral (287) and adenoviral (288) gene delivery systems have been used to transduce GM-CSF into tumor cells and demonstrate, in syngeneic mouse transplantation models, protective antitumor immunity.

An interesting cholesterol-lowering effect of GM-CSF has been reported in rabbits and may be mediated by enhancement of macrophage functions in lipid metabolism and an increase in very-low-density lipoprotein receptor expression (289).

Interleukin-3

Part of "6 - Colony-Stimulating Factors: Basic Principles and Preclinical Studies "

Molecular Characterization

In the early 1980s, a murine factor purified from a conditioned medium of a murine myelomonocytic leukemic cell line (WEHI-3) was shown to stimulate multiple different murine hematopoietic lineages. The factor, an extensively glycosylated molecule of 28,000 d, was initially termed *multi-CSF* but subsequently renamed *IL-3* (290). A cDNA clone from this cell line encoded a molecule of 266 amino acids with a 27 amino acid signal peptide (see Table 6-1) (291). Mature processed IL-3 has a molecular weight of 15,102, with four potential glycosylation sites. Human IL-3, which is species-restricted in its activity, is a glycoprotein of 25 to 30 kd, with a core protein of 14.6 kd consisting of 152 amino acids with a 19 amino-acid signal peptide (292). Murine and human IL-3 coding sequences show 45% identity at the nucleotide level and 29% at the amino acid level. The protein consists of four α-helix bundles and two ß-sheets.

Structure-function relation studies have shown that two noncontiguous helic domains located near the NH$_2$ terminus and the COOH-terminus of the molecule are responsible for receptor binding (293). Two contiguous residues (Asp-21 and Glu-22) in the NH$_2$-terminal region of human IL-3 mediate binding to the two different chains of the IL-3 receptor; this emphasizes the functional significance of the conserved glutamic acid residue in the first helix of the IL-3, GM-CSF, IL-5 subfamily (294). The gene encoding IL-3 is located on the long arm of chromosome 5 (5q23-32), only 9 kb from the gene for GM-CSF (see Table 6-1) (17).

Interleukin-3 Receptor Complex and Signal Transduction

The receptor for IL-3 consists of two subunits, a 70-kd ligand-binding subunit [IL-3 receptor alpha (IL-3Rα)], which binds IL-3 with low affinity, and a 120-kd signal transducing chain (ßc), which is shared by GM-CSF and IL-3 (see Table 6-2) (293, 295). The cytoplasmic portion of ßc is believed to contain most of the domains responsible for ligand-induced proliferation. Additionally, in murine cells, a highly related protein [beta IL-3 (ß-IL-3)] can form a functional subunit with IL-3Rα (296). Ligand binding is believed to activate the receptor by inducing the formation of heterodimers. Synergy occurs between IL-3 and Epo in stimulation of erythropoiesis. A molecular explanation for this synergy is provided by the observation that the ßc chain functionally and physically associates with the Epo receptor, and these receptors exist as a large supercomplex in erythroid progenitor cells (297). The IL-3α chain gene has been mapped to the pseudoautosomal region of the sex chromosomes (298); the common ß chain gene has been mapped to chromosome 22q31 (see Table 6-2) (177).

Signal Transduction by the Interleukin-3 Receptor Complex

Because the 120-kd signal transducer ßc is a common signaling pathway for IL-3 and GM-CSF, then the Jak/STAT pathways activated by cytokines are common and have been reviewed in the section Granulocyte-Macrophage Colony-Stimulating Factor . The Src family of tyrosine kinases participate in the signal transduction pathway of many cytokines. On binding to its receptor, IL-3 activates c-Src kinase activity, which, in turn, facilitates binding of c-Src to STAT3, activated via phosphorylation of Tyr701 (translocated to the nucleus and signaling myeloid cell proliferation) (299). IL-3 stimulates rapid and transient phosphorylation of SHC protein, Jak2 and MAPK kinase, and isoforms Erk1 and Erk2, which provide antiapoptotic signals (299, 300). In multipotent hematopoietic progenitor cells, synergy is observed between c-kit ligand and IL-3 in the activation of Erk1, possibly representing a point where the two cytokine signaling pathways interact to generate synergistic enhancement of proliferation (300). It has been proposed that IL-3 inhibits G-CSF–induced neutrophil differentiation of the 32D IL-3-dependent murine myeloblast cell line by blocking G-CSF–induced activation of STAT3-DNA binding (301). Such cross-modulation of STAT pathway signaling could be a physiologic mechanism for establishing a hierarchy of growth factor effects on cells exposed to multiple cytokines. The addition of proteosome inhibitors to IL-3-stimulated cells leads to a prolongation of activation of Jak1 and Jak2, and SHC and MAPK kinase phosphorylation (consistent with the hypothesis that proteosome-mediated protein degradation can modulate the activity of the Jak/STAT pathway by regulating the deactivation of Jak) (302). IL-3 activates PI3-kinase, leading to phosphorylation of BAD, a distant member of the Bcl-2 family that promotes cell death (at least in part) through heterodimerization with the survival proteins Bcl-2 and Bcl-x (303). Akt, a survival-promoting serine-threonine protein kinase, is activated by IL-3 in a PI3-kinase-dependent manner; in its active form, it is able to phosphorylate BAD, thus mediating antiapoptosis signaling (304). Bcl-2 and related protein Bax regulate the effector stage of apoptosis and can modulate the entry of quiescent cells into cell cycle. In the presence of IL-3, constitutively expressed Bcl-2 is phosphorylated on serine, losing its capacity to heteodimerize with Bax; therefore, IL-3–induced phosphorylation of a distinct pool of Bcl-2 may contribute to the inactivation of its antiproliferative function (305). The activation of Ras, followed by the activation of the kinase cascade of Raf-1, MAPK kinase, and MAPK that leads to induction of c-fos and c-jun, has been well documented in the human IL-3 system (293). Many adaptor proteins, such as SHC, Grb2 and the c-vav oncogene, have been linked to this pathway and phosphorylated after IL-3 stimulation (293). The Ras-guanine nucleotide exchange factor mSos is indispensable for activation of the Ras pathway and downstream enhancement of kinase activity of cRaf-1, Erk2, and Jnk1 in IL-3 treated cells (306).

NFκß plays an important role in maintaining cell survival in response to IL-3; c-Myc may be a downstream effector mediating this effect (307). Activation of p38 MAP kinase and amino terminal kinase Jnk stress-activated protein kinase has been described as being induced by a variety of environmental stresses, such as ultraviolet radiation, heat shock, or proinflammatory cytokines; IL-3 and Epo activate these cascades in murine hematopoietic progenitors, however (308). IL-3 stimulation results in the induction of c-myc, c-fos, c-jun, and pim-1 (293).

Origin of Interleukin-3 and Regulation of Production

IL-3 mRNA is not detectable in unstimulated T cells but is produced by activated T cells, NK cells, and mast cells after transient increase in gene transcription and mRNA stabilization (see Table 6-3) (293). It is probably a local-acting factor because it does not normally circulate at detectable levels in blood. Measurable amounts of IL-3 are produced in a subgroup of patients experiencing extensive graft-versus-host disease (293). In activated T lymphocytes, positive and negative elements control expression of the IL-3 gene. Two positive control sequences and an interposed repressor sequence reside within 315 nucleotides upstream from the transcriptional start site (309, 310 and 311). The proximal regulatory region is specific to IL-3, binds an inducible T-cell-specific factor and Oct-1, and is essential for its efficient transcription. Transcriptional activation of this region can be

enhanced by a second, more distal activating site consisting of AP-1 and Ef1-binding sites, conferring some specificity (310). A transcription silencer that represses in the absence of the AP-1 site lies between the two activator sites (309).

Action on Progenitor Cells

IL-3 stimulates colony formation by a spectrum of progenitors, including CFU-GEMM, CFU-GM, neutrophil-, eosinophil-, and basophil-restricted progenitors, and, in synergy with other factors, CFU-Meg and BFU-E (293). In marrow culture, approximately one-third of colonies stimulated are granulocyte-macrophage; the remainder is approximately equal numbers of pure neutrophil or macrophage colonies with low numbers (5%) of eosinophil colonies in mice and significantly more (30%) in humans (130). In cultures of highly enriched progenitors, or after serum or monocyte depletion, neutrophil and macrophage colonies are greatly reduced in number (312). Although IL-3 supports the survival and initial proliferation of unipotent neutrophil progenitors, G-CSF is necessary for terminal neutrophil proliferation and differentiation (312). IL-3 acts optimally in a concatenate manner with IL-5 to stimulate eosinophil development (313). Erythroid progenitors (BFU-E and CFU-GEMM) are stimulated by IL-3, with erythropoietin necessary for terminal differentiation and synergistic enhancement seen with c-kit ligand. IL-3 increases the numbers of subcolonies in each erythroid burst, whereas KL increases the size of the subcolonies themselves (314). Experiments involving combinations of IL-3, KL, and Epo (with delayed addition of one or more factors) indicated that the actions of IL-3 and KL were largely independent of one another in the BFU-E assay, and IL-3 acted at an earlier stage of erythroid differentiation than KL (314). Human and murine megakaryocyte progenitors (CFU-Meg) can be stimulated by IL-3 or Tpo alone, but number and size of colonies is greatly augmented by the combination of IL-3, Tpo, and KL (315). In CD34$^+$ suspension cultures, although IL-3 and Tpo stimulate CD41$^+$ megakaryocyte-lineage cells and IL-3 plays an important role early in megakaryocyte development *in vitro*, it appears to inhibit further maturation after endoreduplication begins (315). In assays of more primitive blast-cell colonies and HPP-CFU, IL-3 stimulates in synergy with factors like IL-1, IL-6, IL-11, G-CSF, KL, and FL (25). In addition to growth stimulation, shortening the "go" period, and doubling time of early hematopoietic cells, IL-3 also has an antiapoptotic action on progenitor populations at concentrations lower than necessary to initiate proliferation.

IL-3 can induce integrin expression in a dose-dependent manner, upregulating VLA-4 and VLA-5 on the murine Baf3 murine precursor B-cell line by an inside-out pathway involving H-Ras (316). Conflicting reports on the effects of brief cytokine exposure on marrow-repopulating ability exist. Brief 2- to 3-hour preincubations of mouse bone marrow with IL-3 have been reported to enhance repopulating ability, possibly due to upregulation of homing receptors (317). In contrast, other studies have found that a similar preincubation with IL-3 alone or IL-3, IL-12, and KL led to sustained decreases in marrow and spleen seeding of early and late CAFC, cobblestone area–forming cell and an 11.4% to 7.3% reduction in day 12 CFU-s seeding, together with a decrease in long-term repopulation, occurred (318). IL-3 reduced the α4ß1 integrin-mediated adhesion of human CD34$^+$ cells to fibronectin-coated surfaces in a 30-minute adhesion assay while enhancing migration of progenitor cells through fibronectin-coated transwell filters (318). IL-3 addition can lead to reduction in long-term repopulating ability of cultured marrow (320, 321 and 322). Its addition to combinations of FL and Tpo inhibited long-term generation of long-term culture–initiating cells in cord blood cultures (323). This negative regulation by IL-3 acts at the level of stem-cell self-renewal versus differentiation-decision; it appears to be mediated by the common receptor-signaling subunit ßc and the additional IL-3 signaling protein ß-IL-3, which is specific to IL-3 and is found in mice but not in humans (322). In apparent contradiction to the inhibitory effects of IL-3 on stem cells *in vitro, in vivo* treatment of nonobese diabetic/severe combined immunodeficiency disease mice engrafted with human CD34$^+$ cells with human IL-3 resulted in substantial expansion of the most primitive stem-cell population (323).

Action of Interleukin-3 on Leukocyte Subpopulations

In addition to being an eosinopoietic factor, IL-3 has effects on mature eosinophil functions, many of which are also mediated by GM-CSF. These effects include prolongation of survival (325, 326 and 327), enhanced respiratory burst activity induced by opsonized particles (328), and enhanced FcR-γ II- and CR3-binding activity (329, 330). Eosinophil degranulation induced by cross-linking of IgA receptors is enhanced by IL-3 (331). The intracellular cytoadhesion molecule ICAM-1 is expressed on eosinophils after IL-3 exposure; synergistic upregulation is observed with TNF-α, resulting in enhanced eosinophil capacity for interaction with leukotactic factor activity-1–expressing inflammatory leukocytes (332). IL-3 enhances leukotriene C4 production induced by calcium ionophore and the release of arylsulfatase and beta-glucuronidase from specific and small granules of eosinophils (327, 333).

IL-3 was originally identified as a murine mast cell growth factor, allowing long-term proliferation of mast cells from bone marrow (334). IL-3 enhances the viability of human basophils *in vitro* and may modulate delayed-type hypersensitivity *in vivo* by prolonging basophil survival (335). IL-3 induces basophil chemotaxis (336, 337) and homotypic aggregation of basophils mediated by ß2 integrins (338), features associated with basophil accumulation in late-phase allergic responses. IL-3 induces basophil adhesion to endothelium (339); local production of IL-3 during allergic reactions may selectively promote basophil CD11b upregulation, with recruitment of these cells to extravascular sites of inflammation. IL-3 induces histamine release from basophils and mast cells (340). Pretreatment with the cytokine causes a modest release of histamine; subsequent stimulation with IgE or fMLP, however, causes marked increase (341). IL-3 induces the release of an IgE–dependent histamine-releasing factor, which stimulates histamine release from other basophils, in a dose-dependent manner (342). Secretory IgA mediates basophil granulation and histamine release that is totally dependent on IL-3 pretreatment (343). IL-3 induces secretion of several mediators from basophils. The combination

of C5a with IL-3 induces basophil leukotriene release (344). IL-4, normally a T-cell product, is produced by human basophils on IgE-receptor activation in the presence of IL-3 (345).

IL-3 directly induces the expression of class II antigens and members of the ß2 integrin family (e.g., leukotactic factor activity-1) on macrophages, thereby altering the function of mature phagocytes (345, 346). IL-3 acts as a survival factor for monocytes and induces macrophage secretion of TNF-α, IL-1ß, and IL-6 (347, 348). CD40, a member of the TNF-receptor family and a facilitator of T-cell stimulation and antigen presentation, is upregulated on monocytes by IL-3 (349). IL-3 stimulates phagocytic activity, DNA synthesis, and endotoxin uptake by alveolar macrophages, facilitating their roles in host defense (350). IL-3 can prime monocytes for enhanced respiratory burst activity to a greater extent than either IFN-γ or TNF-α, and stimulates TNF-α release from macrophages; it may decrease IL-2–induced macrophage activation, however (351). As members of the phagocytic mononuclear phagocyte family, osteoclasts are responsive to IL-3. IL-3 administration to op mutant mice significantly increased numbers of macrophages and osteoclasts in these M-CSF-deficient mice (352).

Interleukin-3 and Leukemic Cells

Murine IL-3 was first identified as an autocrine product of a murine myeloid leukemia (293), and the initial identification and cloning of human IL-3 was based on its ability to stimulate proliferation of human CML cells. Extensive subsequent studies have shown the responsiveness of primary blast cells from patients with AML (293, 353). Pretreatment of leukemic cells with IL-3 increases their sensitivity to cycle-specific chemotherapeutic agents (e.g., cytarabine) (354), nonspecific drugs (e.g., daunorubicin), or alkylating agents (e.g., 4-hydroxyperoxycyclophosphamide) (293). Pretreatment also increases AML cell susceptibility to lymphokine-activated killer (LAK) cells, possibly mediated through expression of the cell adhesion molecule LFA-3 (355). Oncogene-transformed murine hematopoietic cells and factor-dependent cell lines show enhanced glucose uptake on IL-3 stimulation due to increased glucose transporter expression (356); in Ras transformed cells, this was associated with an increased affinity of the glucose transporter. Autocrine production of IL-3 and GM-CSF is associated with expression of the bcr-abl oncogene in hematopoietic stem cells, and raises the possibility that excess production of these hematopoietic growth factors may contribute to the clinical phenotype of CML (262).

Interleukin-3 Action on Nonhematopoietic Cells

IL-3 receptors are expressed on certain nonhematopoietic cells (e.g., umbilical vein endothelium constitutively expresses functional high-affinity receptors) (293). Functional activation of endothelium by IL-3 induced endothelial-leukocyte adhesion molecule-1 and enhanced endothelial adhesion of neutrophils and CD4+ T cells (357). TNF-α- or IL-1-induced expression of IL-3 receptors on endothelium primes cells for enhanced IL-8 production, E-selectin expression, and neutrophil transmigration in response to IL-3 (358). Cholinergic neurons in the CNS express the IL-3Rα and ßc subunits; choline acetyltransferase and vesicular acetylcholine transporter mRNA were significantly increased in a central cholinergic neuronal cell line, indicating a potential role of IL-3 exists in differentiating and maintaining these neurons (359).

Preclinical In Vivo Studies of Interleukin-3

Mice lacking IL-3 (IL-3 -/-) mice produced by gene targeting are healthy and fertile (360), as are mice that carry an inactivating mutant in heterodimeric IL-3Rα (361) or lack IL-3 and the ßc-subunit of receptors for IL-3, IL-5, and GM-CSF (275), with no detectable abnormalities in multiple aspects of hematopoiesis *in vivo* and *in vitro* (360). Studies in these mice indicated that IL-3 is not necessary for the generation of mast cells or basophils under physiologic conditions, but it does contribute to increased numbers of tissue mast cells, enhanced basophil production, and immunity in mice infected with nematodes, indicating a role for IL-3 exists in host defense against infection (360). In IL-3 -/- mice, contact hypersensitivity reactions were compromised; IL-3 was shown to be required for efficient priming of hapten-specific contact hypersensitivity responses but was dispensable for T-cell–dependent sensitization to tumor cells (362).

In mice, recombinant murine IL-3 produced a modest elevation in circulating neutrophils, eosinophils, and monocytes, with increased splenic myelopoiesis, mast cell content, and CFU-S, CFU-GM, and a greater than tenfold increase in BFU-E incidence (363, 364). Chronic elevation of IL-3 levels after transplantation of marrow cells transduced with an IL-3-expressing vector was associated with 80% mortality in mice within 5 weeks (365). This was associated with a nonneoplastic, myeloproliferative syndrome involving multiorgan neutrophil and eosinophil infiltration.

In preclinical studies in cynomolgus monkeys, IL-3 administration produced a modest leukocytosis, with increases in neutrophils, eosinophils, basophils, and lymphocytes (366). In rhesus monkeys, IL-3 slightly raised leukocyte counts and substantially expanded (nine- to 13-fold) numbers of circulating progenitors (367). Synergistic increases in numbers of circulating progenitors were observed when IL-3 was administered sequentially with either GM-CSF or IL-1.

In sublethally irradiated primates, IL-3 administered for 7 days, followed by GM-CSF administered for 7 to 21 days, was optimally effective in promoting neutrophil and platelet recovery (368). A GM-CSF/IL-3 fusion protein (PIXY) produced enhanced rates of platelet and neutrophil recovery in irradiated monkeys (369). IL-3 treatment of primates after intensive myelosuppressive chemotherapy with 5-FU or cyclophosphamide dramatically enhanced myeloid recovery and reduced duration of neutropenia (370). Enhanced recovery of thymocytes and splenic T and B cells were observed after IL-3 treatment of sublethally irradiated mice; synergy was observed with IL-11 enhancing immune reconstitution (371). IL-3 *in vivo* appears to be capable of regulating extrathymic T-cell development and augments alloreactive bone marrow-derived

suppressor activity *in vitro* and *in vivo.* Administration of IL-3 to autoimmune diabetic NOD mice delayed the onset and overall incidence of diabetes via enhanced generation of T cells capable of suppressing cyclophosphamide-induced diabetes (372).

Conclusions

Part of "6 - Colony-Stimulating Factors: Basic Principles and Preclinical Studies "

Hematopoiesis is a complex process encompassing the continuous generation of a spectrum of highly specialized, differentiated cell types whose life spans can be measured in hours or years. What is particularly remarkable is the continual generation of these multiple lineages from a population of rare pluripotent, self-renewing stem cells under steady-state conditions and conditions of increased demand for one or a number of lineages. In adult humans, for example, bone marrow produces approximately 10^{10} erythrocytes and 4×10^8 leukocytes every hour. In the 1990s, a remarkable revolution occurred in the understanding of hematopoiesis at molecular levels. Indeed, hematopoiesis is close to being defined as the consequence of a pattern of expression of more than 50 gene products variously defined as hematopoietic growth factors, cytokines, and chemokines, produced within hematopoietic tissues and orchestrating a complex process of multilineage proliferation and differentiation. Furthermore, dysregulation of the complex pattern of autocrine, paracrine, and endocrine regulation provides a molecular basis for understanding malignant hematopoiesis.

The four hematopoietic growth factors reviewed have many overlapping functional activities in hematopoiesis, and considerable redundancy is seen in knockout models. In the cases of GM-CSF and IL-3, this can be explained in part by their sharing of a common receptor signaling chain, whereas sharing common downstream signaling pathways (such as Jak/STAT) can explain much additional functional overlap. The Jak/STAT signaling cascade that ultimately results in the appropriate cellular response to an initial stimulus is under strict regulatory control. A growing family of cytokine-inducible SH2 proteins (CISs), also termed *suppressors of cytokine signaling* (SOCS) have been identified (373, 374). These molecules are negative regulators of Jak/STAT signaling. CIS1 is induced by EpoR, IL-3R, or IL-2R signaling via STAT5, binding to receptors and thereby inhibiting further activation of STAT5 (375). SOCS1 is an inhibitor of IL-6 signaling induced via gp130 and STAT3 that inhibits Jak–tyrosine kinase activity (376). CIS3 is strongly induced by IFN-γ, probably via STAT1, and inhibits signaling via binding to Jaks (373). Growing awareness exists that these negative regulators are critical in self-limiting the signaling mediated by most, if not all, members of the hematopoietin receptor superfamily. Potential dysregulation of these negative regulators of signaling may be expected to lead or predispose subjects to leukemic transformation.

An increased understanding of the role of certain key regulatory proteins in regulation of myelopoiesis exists. The Ets factor PU-1, and the C/EBPα are master transcription factors that regulate myeloid development (102). PU-1 is a unique protein that functions exclusively in a cell-intrinsic matter to control development of granulocytes, macrophages, and B and T lymphocytes. PU-1 -/- progenitors can proliferate in response to IL-3 but not G-CSF, GM-CSF, or M-CSF (377). The failure of PU -/- progenitors to respond to G-CSF is bypassed by transient signaling with IL-3 because, in the presence of factors, progenitors differentiate to myeloperoxidase-positive cells, indicating that PU-1 is not essential for specification of granulocyte precursors (although it is required for further differentiation) (377). The defect in M-CSF proliferative response is due to lack of expression of the M-CSF receptor *c-fms;* even if this is bypassed by fms transduction, however, a persisting defect in macrophage differentiation in PU-1 -/- cells exists. Another important myeloid regulatory gene is C/EBPα, a basic leucine zipper transcription factor that regulates a number of myeloid-specific genes and acts as a myeloid differentiation switch on bipotent GM progenitors, directing them to mature to granulocytes (102). C/EBPα knockout mice have no detectable G-CSFRs and are absolutely deficient in granulopoiesis (103). Increased understanding of the control of myelopoiesis at this level may also provide insight into the nature of lineage commitment and permissive role of CSFs on the expression of the differentiated phenotype in normal and malignant hematopoiesis.

Introduction

Part of "7.1 - Colony-Stimulating Factors in Oncology "

The purification and cloning of several cytokines involved in the regulation of neutrophil production or function in the 1980s was a watershed event in experimental hematology and cancer medicine. These cytokines included granulocyte-macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor, and interleukin-3. The availability of recombinant preparations of these molecules facilitated rapid advances in the understanding of basal hematopoiesis and the systemic and local responses to infection. Later, their clinical application led to new approaches for the supportive care of patients undergoing myelosuppressive chemotherapy and chemotherapy dose intensification. The availability of these factors also transformed the practice of bone marrow transplantation. More than a decade after the first patients were treated with recombinant myeloid growth factors, the refinement of these applications continues and new applications are being explored in the fields of cancer immunotherapy and gene therapy.

Biology of Granulocyte-Macrophage Colony-Stimulating Factor and Granulocyte Colony-Stimulating Factor

Part of "7.1 - Colony-Stimulating Factors in Oncology "

Although several other cytokines influence neutrophil production, survival, and function, two of these molecules, GM-CSF and G-CSF, have been shown to have clear clinical value and are used in most countries in the management of cancer patients. These two cytokines have been the subject of previous review (1, 2) and are the focus of this chapter. Although G-CSF and GM-CSF were originally discovered, purified, and cloned based on the ability of conditioned media containing them to support myeloid differentiation and development *in vitro*, the roles played by these factors in the regulation of *in vivo* hematopoiesis and inflammation are distinct. Preclinical and clinical data are reviewed separately because GM-CSF and G-CSF differ in biology and clinical effects.

Human GM-CSF is a 127-amino acid glycoprotein product of a gene located on chromosome 5. GM-CSF acts on a specific receptor complex present on hematopoietic progenitor cells, as well as mature neutrophils, macrophages, and eosinophils. When exposed to GM-CSF *in vitro*, mature macrophages are activated and release secondary cytokines, including G-CSF and interferon-α (3). *In vitro*, GM-CSF acts on mature neutrophils to prime them to enhance activity in a variety of neutrophil function assays, including bacterial killing and antibody-dependent cellular cytotoxicity. When recombinant GM-CSF is administered *in vivo*, a transient decrease in neutrophil, eosinophil, and monocyte counts is observed, followed by an increase in the number of these cells circulating (4, 5 and 6). Neutrophil adhesion to vascular endothelium is enhanced (7), and migration to sites of injury may be inhibited (8). Therapy with GM-CSF results in a prolongation of the circulating half-life of neutrophils and a modest increase in the neutrophil production rate in the marrow (9).

The constitutive role, if any, of GM-CSF in basal hematopoiesis or in the increased neutrophil production rate observed in response to infection ("emergency hematopoiesis") is unclear. Gene knockout studies have shown that mice deficient in GM-CSF have normal numbers of hematopoietic progenitor cells and mature circulating leukocytes but develop alveolar proteinosis and infections in the lung (10). GM-CSF is usually not detectable in the serum of animals or humans, even during neutropenia, active infection, or both. These observations suggest that natural GM-CSF may be produced locally in the tissues as part of the regulation of the inflammatory response and acts in part to immobilize and prime local neutrophils.

Human G-CSF is a 174-amino acid glycoprotein product of a gene located on chromosome 17. G-CSF acts on a specific receptor complex present on hematopoietic progenitor cells, as well as mature neutrophils. G-CSF acts on mature neutrophils to prime them to enhanced activity in a variety of neutrophil function assays, including bacterial killing and antibody-dependent cellular cytotoxicity. The administration of G-CSF results in a

rapid increase in circulating neutrophils without increases in the numbers of monocytes or eosinophils (11). This increase in neutrophil counts is caused by a significant increase in neutrophil release and production by the marrow and not an increase in the survival of neutrophils in the circulation.

G-CSF appears to be central to basal and emergency hematopoiesis. A nonsense mutation of the G-CSF receptor has been identified in a patient with severe congenital neutropenia. Serum levels of G-CSF are measurable and increase with infection in neutropenic individuals, normal adults, and neonates (12, 13 and 14), suggesting a systemic role for G-CSF in the regulation of neutrophil numbers and function.

Recombinant Molecules

Part of "7.1 - Colony-Stimulating Factors in Oncology "

Recombinant human G-CSF (rhG-CSF) is produced in bacteria. Worldwide, two preparations are available: filgrastim and lenograstim. The clinical data regarding their effects are pooled for presentation in this chapter as rhG-CSF because no comparative studies have demonstrated a difference between the biologic or clinical qualities of these two preparations. Three preparations of rhGM-CSF have been introduced into clinical trials, one produced in bacteria, one produced in Chinese hamster ovary cells, and one produced in yeast. Results are pooled for presentation in this chapter as rhGM-CSF because no comparative studies exist that demonstrate a significant difference between these preparations in terms of biology, efficacy, or toxicity. Most of the data available was obtained with the glycosylated proteins (Chinese hamster ovary and yeast-derived) (15, 16).

Clinical Applications of Recombinant Human Granulocyte-Macrophage Colony-Stimulating Factor and Recombinant Human Granulocyte Colony-Stimulating Factor

Part of "7.1 - Colony-Stimulating Factors in Oncology "

The risk of infection during myelosuppressive cancer chemotherapy is directly related to the duration and severity of neutropenia. When the myeloid growth factors were introduced into clinical practice in the early 1990s, the chemotherapy regimens in use for the treatment of most common cancers used doses and intertreatment intervals chosen to provide the maximum dose intensity with acceptable risks of complicating myelosuppression. Therefore, three distinct possible goals for the integration of myeloid growth factors into clinical practice were developed:

1. Decrease the infection risk associated with chemotherapy.
2. Increase the dose intensity of chemotherapy.
3. Decrease the severity of the established infections in neutropenic patients.

Each approach implies an appropriate design for controlled clinical trials of efficacy and a logical perspective for cost-benefit analysis (Table 7.1-1).

Table 7.1-1 Goals of Myeloid Growth Factor Use during Myelosuppressive Chemotherapy and Appropriate Clinical Efficacy and Cost Evaluations

	Goal		
	Decrease Infection Risk during Chemotherapy	Increased Dose Intensity of Chemotherapy	Treatment of Infection with Neutropenia
Appropriate randomized clinical trial	Same chemotherapy regimen in both groups, one group treated with CSF	"Standard" dose chemotherapy vs. higher dose intensity regimen with CSF	Patients with established febrile neutropenia treated with antibiotics with or without CSF
Appropriate clinical end point	Incidence of infection in the treated and untreated groups	Response rate, time to progression, and survival in the two groups	Duration of antibiotic use and hospitalization in the two groups
Appropriate cost-benefit analysis	Cost of CSF treatment balanced against cost of prevented infections and impact of infections on quality of life	Cost of higher chemotherapy doses, toxicity, and CSF balanced against improvement in survival outcomes	Cost of CSF treatment balanced against cost savings in resource use and any quality of life improvements

CSF, colony-stimulating factor.

Prevention of Infection during Chemotherapy for Nonmyeloid Malignancies

The best-studied application of the myeloid growth factors is their use to decrease the risk of infection associated with a given regimen of myelosuppressive chemotherapy. In evaluating these studies, it is important to recognize that the duration of neutropenia is only an adequate surrogate end point for infection risk to patients if the neutrophils produced during growth factor therapy function normally and the growth factor has no other effects that increase infection risk, such as impairment of migration of otherwise normally functioning neutrophils to sites of tissue injury. This is the rationale underlying the emphasis on randomized trials with a measure of infection rather than the duration or severity of neutropenia as the end point for definitive demonstration of efficacy.

In nonrandomized clinical trials in patients receiving myelosuppressive chemotherapy, treatment with rhG-CSF in doses of 5 to 60 µg per kg per day beginning 24 hours after the chemotherapy was given was associated with a significant shortening of the duration of neutropenia (17, 18, 19 and 20). In these studies, patients received rhG-CSF during one of two chemotherapy cycles. The duration of neutropenia and incidence of infections observed during treated cycles were compared with earlier or subsequent cycles of the same chemotherapy given without growth factor support. The neutrophils produced during rhG-CSF therapy

functioned normally in *in vitro* testing (11, 21, 22). Fewer febrile episodes were observed during rhG-CSF–protected chemotherapy cycles. Although these studies demonstrated that rhG-CSF therapy was associated with a shorter duration of neutropenia after chemotherapy and that the neutrophils produced in response to rhG-CSF appeared to function normally, they did not demonstrate conclusively that rhG-CSF was associated with a reduction in the incidence of infection.

In randomized clinical trials of rhG-CSF for the prevention of infection during chemotherapy, the incidence of febrile neutropenia has been the most commonly used end point for estimating overall infection risk. Eight randomized, placebo-controlled clinical trials of rhG-CSF for the prevention of infection during myelosuppressive chemotherapy have been conducted (23, 24, 25, 26, 27, 28, 29 and 30). These trials are summarized in Table 7.1-2 . In these studies, rhG-CSF therapy was initiated 24 hours after the completion of chemotherapy and continued until the nadir in the absolute neutrophil count had resolved. In all instances, rhG-CSF therapy was associated with a decrease in the duration of severe neutropenia. In all but one study (28), the incidence of infectious complications of chemotherapy as measured by the incidence of febrile neutropenia (23, 24 and 25, 27) or hospitalization for infectious complications (26, 29) was reduced in patients receiving rhG-CSF. The two small-cell lung cancer studies used the same chemotherapy regimen and were designed in a complementary fashion (23, 24). In the Crawford study, patients in the two comparison groups received the same chemotherapy throughout the study; if a patient developed febrile neutropenia, he or she was withdrawn from blinded study medication and offered open-label rhG-CSF if he or she received placebo. This design permitted insight into the impact of therapy with rhG-CSF on the risk of infection without the complicating factor of differences between study groups in chemotherapy dose intensity. The open-label data also demonstrated the efficacy of rhG-CSF when used as secondary prophylaxis. In the Trillet-Lenoir study, chemotherapy doses were reduced in patients experiencing febrile neutropenia, and patients were removed from study medication. This design facilitated understanding of the impact of rhG-CSF on overall chemotherapy dose intensity and of this dose intensity on other hematologic toxicities and survival outcomes. In the study of children undergoing induction chemotherapy for acute lymphoblastic leukemia, which reported no statistically significant reduction in the incidence of febrile neutropenia associated with rhG-CSF therapy, significant reductions in days of hospitalization and culture-confirmed infections in the treated patients (28) were found. One small randomized, but not placebo-controlled, study of rhG-CSF administered during chemotherapy for Hodgkin's disease did not show a difference in infection outcomes but was substantially underpowered (31). Overall, the large randomized trials of rhG-CSF demonstrated that the use of this agent at doses of 5 to 10 µg per kg per day beginning 24 hours after the last dose of chemotherapy

and continuing until hematologic recovery has occurred is associated with a reduction in infectious complications.

Table 7.1-2 Randomized Clinical Trials of Recombinant Human Granulocyte Colony-Stimulating Factor for the Prevention of Infection during Myelosuppressive Chemotherapy

Clinical Setting (Reference)	Design Features	FN Incidence	Other Observations
Small-cell lung cancer in adults (23)	n = 199	77% vs. 40% over six cycles of chemotherapy[a]	Decreased hospitalization,[a] antibiotic use,[a] and confirmed infections[a] in treated group
	Dose = 230 µg/m²/d		
	Off study if FN event occurred		
	Crossover		
Small-cell lung cancer in adults (24)	n = 130	53% vs. 26% over all cycles[a]	Decreased hospitalization,[a] antibiotic use,[a] dose reduction, and dose delay[a] in the treated group
	Dose = 230 µg/m²/d		
	Dose reduction if FN event occurred		
	No crossover		
Advanced cancer in adults (25)	n = 100	64% vs. 22%[a]	—
	Dose = 5 µg/kg/d rhG-CSF ± thymopentin vs. thymopentin vs. placebo	No rhG-CSF vs. rhG-CSF groups[a]	
Inflammatory breast cancer, neoadjuvant (26)	n = 120	Decreased need for hospitalization[a]	Decreased culture-confirmed infections[a] and antibiotic use[a] in the treated group
	Dose = 5 µg/kg/d		
Acute lymphoblastic leukemia in children, up to nine cycles (27)	n = 34	40% vs. 17% over all cycles[a]	Decreased duration of FN,[a] antibiotic use,[a] and culture-confirmed infections[a] in the treated group
	Dose = 5 µg/kg/d		
Acute lymphoblastic leukemia in children, induction cycle only (28)	n = 148	Not significantly different	Shorter hospital stays,[a] fewer culture-confirmed infections[a] in the treated group
	Dose = 10 µg/kg/d		
Acute lymphoblastic leukemia in adults, induction, and consolidation (29)	n = 198		Fewer days in hospital during induction only,[a] fewer deaths during induction[a] in the treated group
	Dose = 5 µg/kg/d		
Neuroblastoma in children, four cycles of therapy (30)	n = 59	Not significantly different	Shorter duration of neutropenia,[a] decreased antibiotic use,[a] higher dose intensity,[a] and improved event-free survival[a] in the treated group
	Dose = 5 µg/kg/d		
	No placebo		

FN, febrile neutropenia; rhG-CSF, recombinant human granulocyte colony-stimulating factor.

[a]p <.05.

In nonrandomized trials in patients undergoing myelosuppressive chemotherapy, therapy with rhGM-CSF was associated with reduction in the duration of neutropenia (32). In these studies, the duration of neutropenia after a first cycle of chemotherapy during which patients received rhGM-CSF was compared with the duration during a subsequent untreated cycle. Although the neutrophils produced in response to rhGM-CSF functioned normally in *ex vivo* functional assays, some data suggested that rhGM-CSF therapy may inhibit neutrophil migration to sites of tissue injury (33, 34).

Eight randomized controlled trials of rhGM-CSF during myelosuppressive chemotherapy have been published (35, 36, 37, 38, 39, 40, 41, 42 and 43). They are summarized in Table 7.1-3 . In addition to these studies, a randomized clinical trial of rhGM-CSF administered at a dose of 5 mcg per kg per day compared with observation during chemotherapy for breast cancer showed no difference in the rate of febrile neutropenia but was underpowered (n = 20) to detect a difference if present (44). Another small but nonrandomized, historically controlled trial of rhGM-CSF during intensive chemotherapy for solid tumors in children showed no impact of the factor on the incidence of febrile neutropenia (45).

Table 7.1-3 Randomized Controlled Clinical Trials of Recombinant Human Granulocyte-Macrophage Colony-Stimulating Factor for the Prevention of Infection during Myelosuppressive Chemotherapy

Clinical Setting (Reference)	Design Features	Infection Incidence	Other Observations
Lymphoma in adults (35,36)	n = 125	Fewer clinically relevant infections	Fewer patients with infection[a] and days of hospitalization for infection[a]
	Dose = 400 µg/d for 7 d	70% vs. 48%[a]	
Small-cell lung cancer in adults (38)	n = 290	Fewer patients receiving 10 µg/kg/d required i.v. antibiotics in cycle 1 (29% vs. 11%)[a]	Fever more common in 10- and 20-µg/kg cohorts than observation arm
	No placebo		
	Dose = 5, 10, or 20 µg/kg/d for 9 d		
	Chemotherapy dose intensity higher in the rhGM-CSF after cycle 1		
Acute lymphoblastic leukemia in children, induction and intensification cycles (37)	n = 40	Not significantly different	No difference in number of days of fever, days of neutropenia, days in hospital or infections
	Dose = 5.5 µg/kg/d for 6 d		
Germ cell tumors in adults (39)	n = 104	Fewer clinically relevant infections in cycle 1, 45% vs. 24%[a]	Fewer infections during neutropenia,[a] infections requiring antibiotics[a] and infections[a] in cycle 1
	No placebo	No difference in cycle 2	14% of cycles of rhGM-CSF discontinued for toxicity
	Dose = 10 µg/kg/d for 9 d		
	Randomized to rhGM-CSF on cycles 1 and 2 vs. 3 and 4		
Non-small-cell lung cancer in adults (40)	n = 230	Higher incidence of intravenous antibiotic use with rhGM-CSF	Increased thrombocytopenia[a] and days in hospital[a] with rhGM-CSF[a]
	No placebo		
	Patients received concurrent radiotherapy and chemotherapy		
Lymphoma or breast cancer in adults (41)	n = 56	Not significantly different	Shorter duration of FN in cycle 1[a] not subsequent cycles, possible worsening of thrombocytopenia in the rhGM-CSF group
	Dose = 500 µg/m²/d		
Sarcoma in children and young adults (42)	n = 37	Not significantly different	More severe thrombocytopenia with rhGM-CSF
	No placebo		
	Dose = 5-15 µg/kg/d, begun in cycle 3		
Breast cancer, adjuvant treatment (43)	n = 142	Not significantly different	Higher dose intensity and more thrombocytopenia in the rhGM-CSF group
	Dose = 250 µg/m²/d for 12 days		
	All patients received ciprofloxacin		

FN, febrile neutropenia; rhGM-CSF, recombinant human granulocyte-macrophage colony-stimulating factor.

[a]p <.05.

The results of these studies are less consistent than those observed with rhG-CSF, and their interpretation is more problematic. None of the studies were designed in the same fashion as the Crawford rhG-CSF study with patients meeting the primary infection end point removed from the study drug (23). Hence, an imbalance in chemotherapy dose intensity over multiple chemotherapy cycles between the study arms in some studies complicates the analysis of the impact of rhGM-CSF on infection risk. The lack of double-blinding in several of the studies complicates the analysis of efficacy and toxicity (38, 39 and 40, 42). The analysis and reporting of alpha error estimates for multiple secondary end points for measuring infection incidence in several of the studies introduced statistical issues that were not addressed in study design or compensated for in the reported analyses. The intensity of surveillance for infection end points, coadministration of prophylactic antibiotics, and incidence of infection in the control group were too low in one study for it to have the power to detect an impact of rhGM-CSF on infection risk because of the choice of chemotherapy regimen (43). The use of fixed durations of rhGM-CSF therapy rather than treatment until neutropenia had resolved may have resulted in underestimates of the efficacy and toxicity of rhGM-CSF in several studies (35, 37, 39, 43, 46).

Three potential explanations exist for the differences observed in these randomized trials of rhG-CSF and rhGM-CSF, each of which is consistent with the data available to date. First, it is possible that rhGM-CSF does not decrease the risk of

infection in patients undergoing myelosuppressive chemotherapy. This may be because of its relatively modest impact on neutrophil production rate or a deleterious effect on neutrophil migration into tissues. Second, it is possible that rhGM-CSF does lower infection risk, but fevers induced by the drug have obscured the benefit in randomized trials. Finally, rhGM-CSF given at doses of 5 to 10 µg per kg per day may reduce the risk of infection in this setting, and one or all of the available preparations may not produce fever in a proportion of patients large enough to obscure this effect (35, 43). It is possible that some of the randomized trials have failed to detect this benefit because of design and power issues. It will be possible to design future clinical trials to further clarify the efficacy of rhGM-CSF.

The efficacy of rhGM-CSF therapy for decreasing infection risks in patients undergoing myelosuppressive chemotherapy remains controversial. The American Society of Clinical Oncology guidelines for myeloid growth factor use do not distinguish between rhGM-CSF and rhG-CSF (47, 48); rhG-CSF, not rhGM-CSF, is approved for this indication by the U.S. Food and Drug Administration. No adequate randomized trials comparing the efficacy of the two factors for the prevention of infection during chemotherapy have been conducted. One randomized study compared rhG-CSF and rhGM-CSF for the treatment of patients who were afebrile but neutropenic after myelosuppressive chemotherapy, a setting in which neither factor has been clearly shown to alter infection risk (49). This study showed no difference in infection end points between the two groups. It was substantially underpowered to demonstrate equivalence and did not include a placebo group.

In randomized trials, therapy with a myeloid growth factor has not been shown to increase survival in any group of patients undergoing myelosuppressive chemotherapy. Indirect evidence exists, particularly in studies of patients receiving chemotherapy for Hodgkin's disease or early stage breast cancer, that chemotherapy dose reductions or delays may compromise survival outcomes. These observations may be relevant to secondary prophylaxis with myeloid growth factors after an episode of febrile neutropenia during a prior cycle of chemotherapy in patients undergoing chemotherapy with curative intent. Similarly, randomized trials have not demonstrated that myeloid growth factor therapy is associated with an improvement in quality of life, although evidence exists that a reduction in mucositis may occur (43, 50). It seems plausible that a serious infection would, if measured, be shown to compromise quality of life more than daily growth factor injections.

The lack of definitive demonstration in randomized trials of a survival or quality of life advantage of myeloid growth factors given to patients during myelosuppressive chemotherapy has resulted in an intense focus on the costs associated with their use. The cost impact of the myeloid factors used in this setting depends on the cost of treating the patients with myeloid growth factors and the cost savings realized through prevented infections. Using the clinical data from the randomized trial of rhG-CSF, which served as the registration trial in the United States (23), coupled with additional cost data, two studies examined these cost offsets (51, 52). In both analyses, the cost offsets were found to depend on several variables but were most sensitive to the risk of febrile neutropenia if the growth factor was not given (53). Both studies estimated that, in most situations, the cost of administering the growth factor to all patients would be completely offset by the cost savings in prevented infections if the risk of febrile neutropenia without growth factor was approximately 40% or greater. These models predicted that at lower risks of febrile neutropenia, myeloid growth factor use is associated with an increase in overall cost, the magnitude of this increase dependent on the magnitude of the risk. These increased costs must be justified by an improvement in survival or quality of life outcomes (54, 55 and 56).

It is hoped that additional data clarifying the survival or quality of life benefits of myeloid growth factors will be forthcoming. It is reasonable to use myeloid growth factors as primary prophylaxis in patients in whom the risk of serious infection approaches 40% and as secondary prophylaxis in patients in whom the goal of therapy is cure or prolonged survival. Evidence exists that dose delay or dose reduction compromises that outcome (57).

Treatment of Febrile Neutropenia

Although patients with febrile neutropenia usually have increased serum levels of endogenous G-CSF by the time they present clinically, pharmacologic doses of myeloid growth factors might increase the rate of their recovery and benefit these patients. The myeloid growth factors have been used in the treatment of patients in whom febrile neutropenia has developed in the absence of prophylactic growth factor use. In this setting, the evaluation of efficacy can only be made in randomized trials comparing antibiotic therapy alone with antibiotics with growth factor. Such trials have been published using rhGM-CSF in adults (58, 59 and 60) and children (61) or rhG-CSF in adults (58, 62). They are summarized in Table 7.1-4 . For adults with established febrile neutropenia, the routine use of myeloid growth factor therapy is not supported by this group of studies and is probably not cost effective, although some evidence to the contrary exists (58). It is reasonable to use myeloid growth factor therapy in the occasional ill patient in whom a 1- to 3-day reduction in the duration of neutropenia may favorably impact outcome, because both growth factors have been shown to increase the rate of neutrophil recovery. This approach is consistent with the American Society of Clinical Oncology guidelines. The duration of neutropenia is longer after many pediatric chemotherapy regimens, and this may explain the efficacy of myeloid growth factor therapy for febrile neutropenia in these patients. In this setting, the use of rhGM-CSF is supported by the current data, although confirmatory studies and cost analyses are desirable.

Table 7.1-4 Randomized Clinical Trials of Recombinant Human Granulocyte-Macrophage Colony-Stimulating Factor or Recombinant Human Colony-Stimulating Factor for the Treatment of Febrile Neutropenia

Growth Factor and Dose (Reference)	Design Features	Impact on Hospital or Antibiotic Days	Other Observations
rhGM-CSF 5 µg/kg/d (61)	n = 58 children Double-blind Placebo-controlled	Decreased days of hospitalization[a] and of antibiotics[a] in the treated patients	Decreased number of patients requiring antibiotics for 10 d or more[a]
rhGM-CSF, 5 µg/kg/d (59)	n = 134 adults Placebo-controlled	No significant difference	Decreased duration of neutropenia[a] and quality of life[a] in treated group
rhGM-CSF, 5 µg/kg/d (60)	n = 68 adults Randomized No placebo control	Decreased days of hospitalization[a] and antibiotics[a] (only in "low risk" chemotherapy cycles)	Decreased duration of neutropenia,[a] no effect with "high risk" chemotherapy
rhG-CSF, 12 µg/kg/d (126)	n = 218 adults Randomized Double-blind Placebo-controlled	No significant difference	Decreased duration of neutropenia[a] and risk of prolonged hospitalization[a] in treated group
rhG-CSF, or rhGM-CSF, both at 5 µg/kg/d (58)	n = 121 Randomized (rhG-CSF vs. rhGM-CSF vs. placebo)	Decreased days of hospitalization[a] (5 vs. 7 days) for the rhG-CSF or rhGM-CSF groups compared with placebo	Decreased duration of neutropenia in the treated groups[a]

Use in Patients with Acute Nonlymphocytic Leukemia

Early concerns existed regarding the safety of myeloid growth factor therapy for patients with acute nonlymphocytic leukemia (ANL) because ANL cells frequently bear receptors for G-CSF and GM-CSF. Four randomized trials have been published (63, 64, 65 and 66). These trials are summarized in Table 7.1-5 . These data indicate that

myeloid growth factor therapy is probably safe during induction chemotherapy for ANL, but the benefit in this setting is unclear. Issues that require clarification include the identification of a subset of patients who benefit consistently, the best schedule for their use during induction therapy, the safety of these factors during consolidation therapy, and the cost impacts of myeloid growth factors during therapy for ANL.

Table 7.1-5 Randomized Clinical Trials of Recombinant Human Granulocyte-Macrophage Colony-Stimulating Factor or Recombinant Human Granulocyte Colony-Stimulating Factor Patients with Acute Nonlymphocytic Leukemia

Growth Factor and Dose (Reference)	Design Features	Impact on Remission or Survival	Other Observations
rhG-CSF, 200 μg/m²/d beginning on d 2 (63)	n = 67	No significant difference in remission frequency or duration	Fewer documented infections[a] in treated patients
	Refractory or relapsed ANL		
	Induction chemotherapy		
	Randomized		
rhG-CSF, 5 μg/kg/d beginning on d 9 of induction	n = 173	Higher remission rate[a] (70% vs. 47%) in the treated group	Shorter duration of neutropenia[a] in treated patients
Adults, 65 yr and older (64)	Newly diagnosed ANL undergoing induction	No difference in survival	No difference in leukemic regrowth
	Randomized, placebo-controlled		
rhGM-CSF, 5 μg/kg/d beginning on d 8 of induction	n = 388	No difference in remission or survival in the treated group	Shorter duration of neutropenia[a] in treated patients
Adults 60 yr and older (65)	Newly diagnosed ANL undergoing induction		No difference in leukemic regrowth
	Randomized, placebo-controlled		
rhGM-CSF, 5 μg/kg/d beginning on d 10 of induction if marrow hypoplastic	n = 124	No significant difference in remission rate in the treated group	Shorter duration of neutropenia[a] and decreased infectious toxicity[a] in treated patients
Adults 55–70 yr old (66)	Newly diagnosed ANL undergoing induction	Median survival longer[a] in the treated group (10.6 vs. 4.8 months)	No difference in leukemic regrowth
	Randomized, placebo-controlled		

ANL, acute nonlymphocytic leukemia; rhG-CSF, recombinant human granulocyte colony-stimulating factor, rhGM-CSF, recombinant human granulocyte-macrophage colony-stimulating factor.

[a] $p < .05$.

A second strategy for treating patients with ANL is the use of myeloid growth factors for priming before or during induction chemotherapy. The goal of this approach is to recruit leukemic cells into more chemotherapy-sensitive phases of the cell cycle by appropriately timed administration of growth factor. This approach has been explored and has not been shown to benefit patients (67, 68, 69, 70 and 71).

Chemotherapy Dose Intensification without Progenitor Cell Support

In this approach, the myeloid growth factors are used to enhance anticancer therapy by increasing the dose intensity of the chemotherapy that can be administered with acceptable toxicity. In randomized clinical trials, the appropriate control group would receive the same chemotherapy drugs without growth factor support and both groups would receive maximal dose intensity within established safety guidelines. The appropriate measure of a successful outcome would be increased dose intensity coupled with an increased complete response rate, time to tumor progression, survival, or quality of life. No randomized studies meeting these criteria have been reported, and the use of myeloid growth factors to support routine chemotherapy dose escalation cannot be supported.

Studies demonstrate that therapy with rhG-CSF or rhGM-CSF is associated with a more rapid recovery of neutrophil counts after dose-intensive chemotherapy. These studies suggest that patients receiving rhG-CSF or rhGM-CSF during chemotherapy adjusted for each cycle based on neutrophil counts can receive 1.3- to twofold greater dose intensity compared with patients who are not receiving a cytokine (72, 73, 74, 75, 76 and 77). At higher dose intensities, thrombocytopenia and nonmyeloid toxicities occur. The clinical benefit of this degree of dose intensification remains unclear. In one randomized trial in patients with myeloid growth factor–facilitated dose intensification of chemotherapy for germ cell tumors, the increased dose intensity was not associated with improvement in survival outcomes (77).

A closely related but distinct approach is the use of myeloid growth factors to maintain full-planned chemotherapy dose intensity in as many patients as possible over all cycles of chemotherapy. Retrospective analyses of survival outcomes in several studies of chemotherapy given with curative intent have suggested that patients who received lower dose intensity caused by dose delays or reductions have a significantly lower rate of survival. It is not clear whether this observed inferior survival is caused by the lower chemotherapy dose intensity received or whether the decreased tolerance of chemotherapy and the inferior survival are caused by more aggressive cancer or comorbidities. These issues can only be addressed in randomized clinical trials that are difficult to carry out. It is encouraging that in a randomized study in patients with neuroblastoma, the higher chemotherapy doses achieved in conjunction with growth factor therapy were associated with improved cancer outcomes (30).

Hematopoietic Recovery after Hematopoietic Progenitor Cell Transplantation

One of the first applications of the myeloid growth factors was their administration after autologous bone marrow transplantation (78). Subsequently, controlled trials of rhGM-CSF (79, 80 and 81) and rhG-CSF (82, 83) demonstrated that therapy with these factors is associated with an acceleration of neutrophil engraftment. The myeloid growth factors have been administered to patients after allogeneic marrow transplant. This therapy has been associated with accelerated neutrophil recovery without a change in the incidence of graft rejection or graft-versus-host disease (84, 85 and 86). The results of myeloid growth factor therapy for patients with graft failure after marrow transplantation have been disappointing (87). Some indication exists that therapy with rhG-CSF may be efficacious in the management of patients with myeloid malignancies who relapse after allogeneic transplantation (88). It is unclear what role G-CSF plays in these patients who are also undergoing cyclosporin withdrawal, which may contribute to the remissions observed.

Mobilization of Peripheral Blood Progenitor Cells

The most significant impact of myeloid growth factors in the field of marrow transplantation followed the observation that, during therapy with these factors, particularly when patients are recovering from myelosuppressive chemotherapy, hematopoietic progenitor cells circulate in increased numbers. These peripheral blood progenitor cells (PBPC) can be harvested and used as an alternative to marrow in the support of myeloablative chemotherapy. The use of autologous PBPC mobilized during therapy with rhG-CSF or rhGM-CSF has been associated with durable engraftment and a more rapid recovery of platelet production compared with traditional bone marrow (89, 90). PBPC are a superior and more flexible source of progenitor cells and multiple cycles of high-dose therapy are feasible and under study (91, 92). Despite concerns about graft failure or graft-versus-host disease, PBPC appear to be safe and effective in allogeneic transplantation (93, 94).

Although they are usually used, the benefit of therapy with myeloid growth factors after the infusion of cytokine-mobilized PBPC has not been fully established. In one study, the combination of rhG-CSF and rhGM-CSF after PBPC infusion was associated with accelerated neutrophil engraftment and shorter hospital stay (95). In another study, rhG-CSF administered after PBPC was not associated with more rapid engraftment (96).

The optimal approach to the mobilization of PBPC is a subject of current investigation. While doses of rhG-CSF or rhGM-CSF of 5 to 10 µg per kg per day given alone or after a mobilizing dose of chemotherapy are effective in mobilizing PBPC, one comparative study has been published that suggests that rhG-CSF is a superior mobilizing agent (97). Further comparative studies are warranted. Moreover, better quality grafts may be obtainable with higher doses of myeloid growth factors or with newer cytokine combinations (98, 99 and 100).

Myelodysplasia

In early nonrandomized studies, therapy with rhGM-CSF or rhG-CSF was shown to produce transient increases in circulating neutrophil counts in neutropenic patients with myelodysplastic syndromes (101, 102, 103 and 104). No randomized clinical trials have been published establishing the safety or efficacy of chronic myeloid growth factor therapy. Outside the setting of a clinical trial, these agents are best used for short-term therapy of the neutropenic-infected patient (105). Some evidence exists that combinations of cytokines may have synergy in patients with myelodysplastic syndromes (106, 107).

Future Applications in Cancer Therapy

Part of "7.1 - Colony-Stimulating Factors in Oncology "

Interest is growing in the application of the myeloid growth factors, particularly rhGM-CSF, to cancer immunotherapy because of their effect on mature effector cell function. In early phase 1 and 2 studies in patients with cancer, therapy with these factors alone was not associated with tumor regression (108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120 and 121). Studies have explored the potential of rhGM-CSF administered to the patient or produced by transfected vaccine cells to enhance the effects of monoclonal antibody or tumor vaccines strategies. PBPC mobilized by myeloid growth factors can be used to generate dendritic cells used in immunotherapy (122, 123, 124 and 125). *Ex vivo* application of the myeloid growth factors enhances transduction efficiency in gene therapy strategies in which PBPC or dendritic cells are the target (122).

Conclusion

Part of "7.1 - Colony-Stimulating Factors in Oncology "

Since the early 1990s, the myeloid growth factors have become established tools in the treatment of cancer patients. The availability of rhGM-CSF and rhG-CSF have improved the supportive care of cancer patients and transformed the field of bone marrow transplantation. Although these advances are important, therapy with the myeloid factors has not been shown to improve survival and the effects of the supportive care advances on the quality of life for patients remains largely unstudied. The next generation of myeloid growth factor studies should focus on the following goals:

1. Characterize the patient benefits associated with the use of myeloid growth factor in supportive care. Focus their use on patients in whom a benefit is demonstrable.
2. Explore the effect of maintaining chemotherapy dose intensity and chemotherapy dose escalation on cancer outcomes.
3. Refine PBPC technology and its clinical applications.
4. Pursue the potential of the mature effector cell activation effects of rhGM-CSF in cancer immunotherapy.

Introduction

Part of "7.2 - Platelet-Stimulating Factors "

Thrombocytopenia is a major problem facing clinicians. In the United States, approximately 8,000,000 units of platelets are transfused yearly into patients to reduce their risks of severe bleeding (1). Platelet transfusion therapy is less than ideal, however. At least 30% are complicated (2), usually by cytokine-mediated febrile reactions but occasionally by bacteremia, graft-versus-host disease, or acute pulmonary injury. Moreover, an inadequate platelet response due to HLA alloimmunization occurs in a number of patients who require repeated platelet transfusions, the frequency ranging from 10% to 30% of individuals, depending on a patient's underlying disease (3, 4). Platelet transfusions are expensive; the approximate cost of a standard six units of platelets (usually sufficient to raise the platelet count 30,000 to 50,000 per mm³) is $300, rising substantially if a single donor pheresis, removal of leukocytes, or HLA matching is required. The distinguished physician and teacher Dr. William Osler stated, "We are still without a trustworthy medicine which can always be relied upon to control purpura." In many ways, Osler's dilemma is as true today as it was when it was first penned in 1892 (5). Clearly, stimulation of marrow platelet production will prove superior to transfusion of allogeneic platelets. The understanding of thrombopoiesis, however, was for a long time inadequate to allow therapeutic intervention.

Generation of platelets from their marrow progenitors is an enormous and complex process. Each day, an adult produces 1×10^{11} platelets, a number that can easily increase tenfold in times of increased demand for platelet production. Megakaryocyte (MK) and platelet formation are dependent on the productive interaction of hematopoietic stem and progenitor cells, marrow stromal elements, and multiple protein growth and survival factors. The evolving understanding of the humoral regulation of MK development—and how this process may be manipulated (and already has been manipulated) for therapeutic benefit—forms the basis of this chapter.

Several cytokines and hormones have been reported to influence the development of the megakaryocytic lineage. Classically, these have been divided into MK colony-stimulating factors (MK-CSFs) and potentiators of MK differentiation (6). Several investigators have shown that interleukin-3 (IL-3), granulocyte-macrophage CSF (GM-CSF), and stem-cell factor (SCF) all display colony-stimulating activity for MKs (7, 8, 9, 10 and 11). MK potentiators, initially defined by their capacity to augment colony numbers when added to marrow cultures containing MK-CSFs and to induce terminal maturation of developing cells, include IL-6, IL-11, and leukocyte inhibitory factor (12, 13). None of these cytokines can support MK colony growth when added to marrow cells alone. In contrast, thrombopoietin (Tpo) was initially defined as the substance in blood responsible for platelet recovery after thrombocytopenic insults (14, 15); with the recent cloning of the molecule, however, it was found to stimulate all aspects of MK development (16).

Molecular and Cellular Biology of the Megakaryopoietic and Thrombopoietic Cytokines and Hormones

Part of "7.2 - Platelet-Stimulating Factors "

Interleukin-3

The human IL-3 gene was cloned in 1986 and encodes a 152-amino acid polypeptide processed to a mature 133-residue cytokine (17). The 25- to 30-kd monomeric polypeptide is produced almost exclusively by stimulated T lymphocytes, natural killer cells, and mast cells. Like many of the other hematopoietic cytokines, significant amounts of *N*-linked carbohydrate modification account for approximately 40% of its apparent molecular weight (M_r).

Although initially defined as an activity that stimulates lymphocyte-20 α-steroid dehydrogenase (18), IL-3 has been shown to possess a number of hematopoietic activities. Cultures of marrow cells containing IL-3 develop colonies composed of basophils, eosinophils, neutrophils, monocytes, and MKs, alone and in combination; if erythropoietin (Epo) is added, large erythroid bursts and small erythroid colonies also develop (12, 19, 20, 21, 22 and 23).

Colony formation is significantly enhanced when other cytokines and hormones are added to IL-3. This appears to be particularly important for MK development, because although the cytokine alone can promote the expansion of immature MKs (i.e., diploid CD41+ cells), blockade of thrombopoietin action in IL-3–containing cultures prevents the development of mature polyploid cells (16). Like many other hematopoietic cytokines, IL-3 primes the mature cells it helps produce to become functionally activated (24). These findings have clinical repercussions. The administration of IL-3 to humans has been associated with toxicities related to its activation of multiple types of mature leukocytes.

Although one of the most pleiotropic and potent of CSFs *in vitro*, the physiologic role of IL-3 has been called into question. For example, minimal hematopoietic effects are noted in animals in which the IL-3 gene has been genetically eliminated (25); the sole phenotype is a loss in delayed-type hypersensitivity reaction (26). Moreover, other than a mild eosinophilia, administration of large amounts of the cytokine (in animals and in patients) fails to substantially alter steady-state or stimulated hematopoiesis (27, 28 and 29). As such, further discussion of IL-3 is limited to a brief review of the clinical trials that have been conducted.

Granulocyte-Macrophage Colony-Stimulating Factor

GM-CSF, an 18- to 30-kd monomeric protein, is produced by activated T lymphocytes, endothelial cells, monocytes, and fibroblasts; like IL-3, it is highly modified with *N*- and *O*-linked carbohydrates. The human GM-CSF gene predicts a polypeptide of 144 amino acids, including a 17-residue secretory leader (30). As its name implies, GM-CSF can support the growth of colonies containing all types of granulocytes and monocytes, alone and in combination. This polypeptide can also act in synergy with Epo to support the development of erythroid bursts or with serum or plasma (presumably with the Tpo in these sources) to stimulate the production of MK-containing colonies (7, 31). It is often commented that IL-3 and GM-CSF are not physiologically relevant, as plasma levels of the cytokines are almost never detectable. When examined in mice made deficient in the ß-subunit of its receptor, however, GM-CSF becomes detectable in plasma, suggesting the receptor plays an important role in GM-CSF clearance. GM-CSF has been shown to prime neutrophils, eosinophils, and monocytes for functional activity (32). This role appears to be its most important—or at least its only unique—physiologic function. Although genetic elimination of the GM-CSF gene in mice fails to affect granulocyte or monocyte production, it is associated with pulmonary alveolar proteinosis (33), thought to be related to inadequate pulmonary alveolar number or function. In addition, approximately one-half of humans with this disease harbor a mutation in the ß$_c$ subunit of the GM-CSF receptor (34). Neither deficiency of GM-CSF nor of its receptor, however, led to any defects in platelet numbers or function.

As preclinical trials of IL-3 and GM-CSF were beginning, a novel fusion protein was designed and constructed in an attempt to capitalize on the beneficial effects of cytokines, including their effects on MK development. PIXI321, as it was termed, joined full-length IL-3 and GM-CSF proteins, together with a flexible polyglycine linker. The recombinant protein was produced in yeast and has shown pronounced effects on hematopoiesis *in vitro* (35) and *in vivo* in preclinical trials (36).

Interleukin-6

IL-6, cloned using several different end points (assays for IL-6 include antiviral activity, myeloma cell growth, hepatocyte growth, and immunoglobulin secretion), was found to affect primitive hematopoietic cells and megakaryocytic development (37). The IL-6 gene encodes a 26-kd polypeptide produced in almost all tissues from activated T cells, fibroblasts, macrophages, and stromal cells (37). The mature protein is composed of 184 amino acids and displays *N*- and *O*-linked carbohydrate modification. IL-6 is normally produced in response to inflammatory stimuli, including IL-1 and tumor necrosis factor. The production of these inflammatory cytokines is induced by IL-6, contributing to a positive feedback loop designed to maintain or amplify inflammatory responses. As such, the administration of IL-6 has met with considerable toxicity.

Alone, IL-6 does not exert any significant hematopoietic effects *in vitro.* However, it acts in synergy with SCF or IL-3 to induce primitive hematopoietic cells into the cell cycle (12, 38), to augment myelopoiesis (39, 40), and to modestly enhance MK development (22, 41, 42). The role of IL-6 in steady-state hematopoiesis is uncertain. The predominant phenotype of IL-6-deficient mice is liver failure and defective hepatic regeneration (43), but these animals also display modest reductions in number of T lymphocytes. In contrast, myeloid cell numbers are normal (44). The combined genetic elimination of G-CSF and IL-6, however, was shown to produce a more severe neutropenia than was found in the absence of G-CSF alone (45). Combined elimination of the IL-6- and Tpo-receptor genes has not been found to reduce platelet production below that found in Tpo receptor–deficient animals alone (W. Alexander and C. G. Begley, *personal communication*, January 1999). Combined genetic elimination of IL-6 and the signaling subunit of the IL-6 receptor leads to modest thrombocytopenia, however, suggesting the cytokine and its receptor play some role in normal MK production.

Interleukin-11

IL-11 was cloned as a marrow stromal cell-derived activity that induces differentiation of an IL-6–responsive myeloma cell line (46). IL-11 was also shown to act in synergy with IL-3 to stimulate MK colony formation (23, 46, 47), however, enlisting it in the ranks of hematopoietic cytokines.

The human IL-11 gene encodes a mature protein containing 199 amino acids. The cytokine is produced constitutively from cells of the marrow stroma, especially fibroblasts, and production increases when these cells are exposed to inflammatory stimuli (48). This appears to occur *in vivo,* as high levels of this cytokine have been found in rheumatoid synovial fluid (49). Blood levels of IL-11 are thought to react to other stimuli; some (50, 51) but not all investigators (52) have found increased IL-11 blood levels in thrombocytopenic patients, suggesting IL-11

possibly plays a role in steady-state thrombopoiesis. Studies conducted on mice that are genetically deficient in the IL-11 receptor, however, have failed to demonstrate any role for the cytokine in baseline or in stimulated platelet production (53).

IL-11 is a pleiotropic cytokine that exerts a multitude of growth stimulatory effects on hepatic, osteoclastic, intestinal, neural and adipocytic cells (54). However, hematopoietic effects of this cytokine have been the most well studied. Like IL-6, IL-11 acts in synergy with IL-3, SCF, or Flt-3 ligand to induce primitive hematopoietic cells into the cell cycle (55) resulting in expansion in the subsequent numbers of committed progenitor cells (38, 56, 57). IL-11 acts together with IL-3 or SCF to enhance erythropoiesis (58), with SCF and G-CSF to augment myelopoiesis (54) and with IL-3, SCF, or Tpo to promote MK development (13, 16, 23, 46, 47, 59, 60). The hematopoietic effects of combining IL-3 and IL-11 are similar to that reported for IL-3 and IL-6 (55), a finding that can be readily explained by the common receptor signaling components of the complete IL-6 and IL-11 receptors (61). One exception to this general rule may be the differential effects of IL-6 and IL-11 on platelet function; when administered to animals, IL-6 activates platelets and enhances their sensitivity to aggregation in the presence of several platelet agonists (62), effects not reported for IL-11. The explanation for this apparent discrepancy may be the differential expression of the two receptors; IL-11 receptors are not found on platelets (63).

Thrombopoietin

The human Tpo gene encodes a mature polypeptide of 332 amino acids (64, 65, 66 and 67), considerably longer than any other member of the hematopoietic growth factor family. This polypeptide can be conveniently divided into two domains. The amino-terminal-154 residues of the mature polypeptide bears striking primary sequence homology with Epo and secondary sequence homology with all the other hematopoietic cytokines, and acts by binding to the MPL receptor (66). In contrast, the carboxyl-terminal domain of Tpo bears no resemblance to any known proteins and contains multiple sites of *N-* and *O-*linked carbohydrates, accounting for the large discrepancy between predicted and actual M_r of the protein. Nearly 50% of the 70-kd thrombopoietin molecule is carbohydrate. Functions for the carbohydrate-containing carboxyl-terminal domain include increased circulatory survival and improved secretory efficiency in cells that produce the hormone (68).

The biologic activities of Tpo have been rapidly identified in the short time since its cloning; the hormone is the major regulator of MK maturation (16). In suspension cultures of murine or human marrow cells, Tpo increases size and number of MKs, leads to their expression of platelet-specific markers, such as CD41 and CD61, and is a potent stimulus of MK endomitosis and polyploidy (64, 66, 69). Tpo is a potent MK-CSF, capable of inducing colony formation from up to two-thirds of all megakaryocytic progenitors (60, 69); it acts in synergy with other molecules that influence MK growth (IL-3, IL-11, SCF, and Epo) (60), with Epo to stimulate the growth of primitive erythroid progenitor cells (70, 71), and with IL-3 or SCF to support survival and stimulate proliferation of hematopoietic stem cells and primitive progenitors (72, 73).

Like many of the hematopoietic cytokines that affect cellular production and the state of activation of corresponding mature cells, Tpo was predicted to activate, or at least enhance, platelet response to activating substances. Initial reports suggested that although Tpo does not cause platelets to aggregate in the absence of well-established agonists (e.g., thrombin, adenosine 5"-diphosphate, collagen), it does sensitize the cells to the aggregatory effects of these agents (74). Such "priming" has also been documented *in vivo;* platelets derived from Tpo-treated animals have heightened sensitivity to standard platelet agonists (75). Thus, the potential to aggravate thrombogenic conditions in Tpo recipients exists, and should be carefully evaluated when it is administered to patients.

Finally, additional attempts have been made to combine two megakaryopoietic cytokines to provide a more effective stimulus of MK growth than that seen with either single agent alone. Investigators have combined optimized versions of IL-3 and Tpo (initial studies identified several amino acid substitutions that increased their individual biologic activities) to produce a protein termed *promegapoietin.* Although no published reports of its effects have appeared, several presented abstracts have indicated its capacity to expand immature CD41+ cells from marrow or peripheral blood progenitor cells (76, 77) and to prevent thrombocytopenia in a nonhuman primate model of radiation-induced myelosuppression (78). In most of these studies, promegapoietin was compared to the combination of IL-3 plus Tpo; it has been claimed by the same investigators that the combination molecule is more active than the combination of the two native sequence recombinant cytokines. Data should be evaluated in a peer-reviewed setting, however, and the potential for immunogenicity of the combination molecule must be carefully monitored.

Pharmacology of Platelet-Producing Agents

Part of "7.2 - Platelet-Stimulating Factors "

Unlike most polypeptide endocrine hormones, such as insulin or growth hormone, a major route of elimination of exogenously administered hematopoietic growth factors is specific receptor-mediated clearance. Although postulated to account for the metabolism of Epo in the 1950s, Stanley and colleagues were the first to show that this mechanism plays a major role in the removal of CSFs, demonstrating that macrophages account for much of the M-CSF clearance from circulation (79).

IL-3 is rapidly cleared from blood after an intravenous (i.v.) bolus infusion, with an equilibration phase of 17 minutes and a 59-minute β-phase elimination (80). As a result, the cytokine is usually administered as an extended i.v. infusion (i.e., greater than or equal to 2 hours per day) or by subcutaneous injection. The elimination of GM-CSF follows similar kinetics; an α-phase of 7 to 20 minutes and a β-phase of 68 to 75 minutes (bacterial versus mammalian cell–derived material, respectively) (81). Although it has not been extensively studied, reports suggest that specific receptor-mediated uptake by leukocytes is responsible for this finding.

IL-6 has been tested in a number of patients with cancer. Half-life of elimination is approximately 4.2 hours after a single

subcutaneous dose (82). The pharmacokinetics of IL-11 are similar, with a half-life of 1.8 to 2.4 hours after a single i.v. infusion (83). Subcutaneous administration results in a slightly longer circulatory life of 8 hours (84). However, unlike the cases of M-CSF, G-CSF, or Tpo, radiolabeled IL-11 localized primarily to the liver and kidneys after injection into mice, suggesting that hematopoietic cells are not the most common sites of cytokine metabolism (85). Thrombopoietic effects of IL-11 administration begin 5 to 9 days after initiation of therapy (Fig. 7.2-1), and are maximal for approximately 1 week after discontinuation of the drug (84).
FIGURE 7.2-1. Platelet response to graded doses of interleukin-11 (IL-11). Cancer patients just before chemotherapy were administered from 10 to 75 mg per kg recombinant human IL-11 (rhIL-11) subcutaneously for 14 consecutive days. The data represent the mean platelet counts of three patients at each dose level. [From Gordon MS et al. A phase I trial of recombinant interleukin-11 (Neumega rhIL-11 growth factor) in women with breast cancer receiving chemotherapy. *Blood* 1996;87:3615–3624, with permission.]

The survival of Tpo in circulation is longer than any other hematopoietic growth factor, with an elimination half-life approaching 30 hours (86). The molecule's carboxyl-terminal region appears responsible for this property. Although a truncated form of Tpo that contains only the amino-terminal region retains full activity *in vitro*, it has little *in vivo* thrombopoietic action. The addition of a single polyethylene glycol moiety (which increases its plasma half-life tenfold) increases its biologic activity in animals substantially, however (87, 88). The long half-life of elimination also makes it possible to administer the drug less frequently than other thrombopoietic agents and to provide full efficacy.

The effects of exogenous cytokines on the kinetics of platelet production have been studied extensively (Fig. 7.2-2). Unlike the immediate release of reticulocytes prompted by Epo and the immediate release of marrow storage pool neutrophils prompted by G-CSF, none of the thrombopoietic cytokines trigger a rapid release of platelets. Instead, the rise in platelets appears on average 3 to 4 days after the onset of cytokine administration (86, 89), strongly suggesting that all platelet-producing effects of these proteins are due to enhanced MK production. This conclusion is consistent with the failure of Tpo or other cytokines to accelerate fragmentation of proplatelet processes, long evaginations of MK cytoplasm considered to represent the most immediate platelet precursor *in vitro* (90). Once size and numbers of MKs increase, platelet count begins to rise until a new steady-state level is reached, the height of which depends on a log-linear relationship with administered dose, at least for Tpo (88). For IL-6 and IL-11, peak platelet count occurs within several days after administration of the cytokine is begun (91, 92). Due to a prolonged biologic effect (the result of its action on primitive and mature hematopoietic cells) and slow plasma clearance, however, enhanced platelet production resulting from parenteral administration of Tpo for 7 to 10 days occurs 6 to 16 days later (86, 89). Thus, careful attention to the pharmacokinetics of Tpo administration is necessary to ensure that excessive thrombocytosis is avoided.
FIGURE 7.2-2. Platelet response to graded doses of thrombopoietin. Just before chemotherapy, cancer patients were administered 0.03–1.00 mg/kg of polyethylene-glycol–modified recombinant human MK growth and differentiation factor (PEG-rhMGDF) daily for 10 consecutive days. The data represent the mean platelet counts of three to four patients and four control patients. [From Basser RL et al. Thrombopoietic effects of pegylated recombinant human MK growth and development factor (PEG-rHuMGDF) in patients with advanced cancer. *Lancet* 1996;348:1279-1281, with permission.]

Preclinical Trials of Thrombopoietic Agents in States of Marrow Failure

Part of "7.2 - Platelet-Stimulating Factors "

IL-3 effectively promotes MK colony growth *in vitro* (9, 46), leading to testing of its capacity to accelerate platelet recovery after chemotherapy-induced myelosuppression. Results from preclinical trials have been mixed, however. Gillio and coworkers administered IL-3 to primates after 5-fluorouracil treatment, finding earlier recovery of neutrophils and platelets (93). In contrast, the same group reported that IL-3 failed to affect recovery from cyclophosphamide-induced marrow suppression (94).

Although GM-CSF was initially found to promote MK colony growth *in vitro* (7, 8), most animal studies failed to demonstrate any significant effect on cells other than leukocytes. In contrast, human IL-6 has been administered to normal mice in a number of preclinical trials designed to test its thrombopoietic potential. Most studies report a 30% to 60% rise in platelet counts of normal mice owing to enhanced MK maturation (41, 42, 95). Although not found by all investigators (96), the administration of IL-6 to irradiated mice hastened the recovery of all types of hematopoietic progenitors and was associated with a modest improvement in erythrocyte, leukocyte, and platelet levels (97). Irradiated and control dogs were treated with graded

doses of human IL-6. Platelet counts rose in a dose-dependent fashion to 220% of baseline values in the control animals; platelet recovery was enhanced in irradiated dogs receiving the cytokine (98). Low doses of IL-6 increased platelet production two- to threefold in normal cynomolgus macaques, and although much higher doses were required, administration of the cytokine improved platelet recoveries in irradiated animals (91, 99).

The preclinical effects of IL-11 have been evaluated in mice, rats, and subhuman primates. In normal rodents, administration of human IL-11 leads to a modest rise in marrow progenitor cells and peripheral blood platelet levels (92, 100, 101). Moreover, administration of IL-11 accelerates recovery of progenitors and mature cells after myelosuppressive therapies. For example, platelet recovery to 50% of baseline values occurred 5 days earlier in mice that were administered IL-11 after combined radiation and chemotherapy than it did in control animals (102). Favorable effects were also noted on red cell recovery, owing, at least in part, to accelerated red cell production. IL-11 appears to accelerate platelet recovery after stem-cell transplantation (54).

More pronounced effects on thrombopoiesis have been noted in primates administered IL-11, likely due to incomplete cross-reactivity of the human cytokine in rodents. For example, its administration to cynomolgus monkeys doubled platelet counts (compared to 17% to 38% in rodents) and prevented severe thrombocytopenia when administered after carboplatinum-induced myelosuppression (103).

Toxicity and therapeutic efficacy of Tpo have been tested in mice, rats, dogs, and nonhuman primates. In all studies, administration of Tpo has been safe; no signs of hepatic, renal, or pulmonary toxicity, capillary leak, coagulopathy, or hematopoietic toxicity have appeared. As would be expected from its profound megakaryopoietic effects *in vitro*, the administration of Tpo to mice or nonhuman primates increases marrow MK numbers up to tenfold, and peripheral blood platelet counts by an equal degree (64, 65 and 66, 75). Moreover, the panhematopoietic *in vitro* effects of Tpo were also found to correlate with its *in vivo* properties; administration of Tpo to control or myelosuppressed animals increased numbers of all types of hematopoietic progenitor cells (104). Genetic elimination of Tpo or its receptor resulted in a 65% to 95% reduction in numbers of transplantable stem cells and hematopoietic precursors of multiple lineages (105, 106 and 107).

When administered to animals treated with nonablative myelosuppressive regimens, the use of Tpo has resulted in higher nadir platelet counts and 7- to 14-day accelerations of platelet recovery (104, 108, 109, 110, 111 and 112). It also has favorable effects on erythrocyte and granulocyte recovery in these animals, consistent with its *in vitro* stimulatory effects on cells of these hematopoietic lineages (72, 73, 104). In one study of nonhuman primates, administration of Tpo after sublethal irradiation resulted in functional iron deficiency (112), confirming its profound effect on erythropoiesis, and arguing for prophylactic use of iron supplementation in patients receiving Tpo.

In contrast to the near-universal preclinical success of Tpo in ameliorating thrombocytopenia (and often pancytopenia) associated with myelosuppressive therapy, its effectiveness after stem-cell transplantation has been less impressive. The administration of Tpo to lethally irradiated mice receiving bone marrow cells accelerated platelet recovery by 2 to 4 days in two studies (113, 114) but did not augment hematopoietic recovery when fewer bone marrow cells were administered (115). In mice receiving peripheral blood stem-cell transplants compared with mice receiving transplants but no Tpo, the hormone accelerated platelet recovery by only 1 or 2 days (113). Tpo also did not facilitate hematopoietic reconstitution in nonhuman primates undergoing autologous bone marrow or peripheral blood stem-cell transplantations (116). Two studies suggest its use in stem-cell donors might improve the quality of the transplantation product, however, leading to enhanced hematopoietic recovery (113, 115).

Clinical Trials of Thrombopoietic Agents

Part of "7.2 - Platelet-Stimulating Factors "

Before discussing results of studies testing therapeutic efficacy of thrombopoietic agents, the goals of such therapy should be considered. In clinical practice, even severe treatment-related thrombocytopenia only rarely induces life-threatening morbidity or mortality; the availability of platelet transfusions has ensured that few thrombocytopenic patients die due to hemorrhage. Most of the adverse effects of thrombocytopenia are mucosal or petechial bleeding, which are not easily quantified, and are thus unlikely to serve as convenient markers of therapeutic efficacy. Rather, as platelet transfusions are associated with multiple adverse reactions, refractoriness to repeated therapy and high cost, a more suitable end point for judging the efficacy of any thrombopoietic agent is reduction in the need for platelet transfusions or earlier release from hospital after episodes of iatrogenic or naturally occurring thrombocytopenia. Alternately, because dose intensities of many forms of chemotherapy are important determinants of success, the ability to administer repeated cycles of chemotherapy on schedule might also serve as an important marker of therapeutic advance.

Recombinant human IL-3 was approved for use in human clinical trials in the late 1980s. Initial reports in individuals with normal hematopoiesis were modestly encouraging (117, 118). In general, its use was well tolerated, with toxicity limited to mild fever, flulike symptoms, myalgias, malaise, and headache. In some patients undergoing autologous marrow transplantation, however, its use leads to intolerable side effects (119).

A number of clinical trials using IL-3 to attempt to accelerate platelet recovery from combination chemotherapy have been reported. Four studies in patients being treated for small cell lung or ovarian cancers have suggested that its use accelerates platelet recovery (120, 121, 122 and 123). In contrast, its use in patients undergoing chemotherapy for non-small-cell lung cancers, relapsed non-Hodgkin's lymphoma, or those undergoing autologous bone marrow transplantation for lymphoma did not significantly affect platelet recovery (119, 124, 125). Similar results were reported for the use of IL-3 in various states of naturally occurring thrombocytopenia (28, 126) with one exception (127). Overall, these studies demonstrate that in selected clinical settings, IL-3 can modestly accelerate platelet recovery and may reduce some of the complications and costs of prolonged thrombocytopenia. As most of the beneficial effects on platelet recovery have been noted at higher doses and are associated with

more profound side effects, however, its clinical utility as a single agent appears to be limited.

Although GM-CSF has proven useful in alleviating neutropenia after moderately aggressive myelosuppressive therapy (128) the weight of available evidence suggests that this cytokine fails to significantly impact thrombocytopenia in the same patients (129, 130 and 131). Similar results have been reported in naturally occurring states of thrombocytopenia (132, 133). One of the few exceptions has occurred in patients undergoing autologous transplantation for Hodgkin's disease, in which patients receiving GM-CSF became platelet transfusion-independent approximately 8 days sooner than a control group (134). Altogether, however, these data suggest that if GM-CSF has an effect on platelet recovery, it is not striking; studies to investigate the efficacy of the cytokine in patients with thrombocytopenia have been abandoned.

When administered to cancer patients before chemotherapy, PIXY321 induced a modest increase in neutrophil and platelet levels (135). In general, toxicity has been tolerable in the majority of the trials of this fusion protein; most patients experience fever, rash, and injection-site erythema. The vast majority of studies have failed to reveal any beneficial effects of the drug on platelet recovery, however (136, 137). On the basis of these and other negative studies, clinical development of PIXY321 for thrombocytopenia has been abandoned.

In contrast to the minimal effects of IL-3, GM-CSF, and PIXY321 on platelet production in individuals with normal hematopoiesis, IL-6 appears to increase platelet counts by 80 to 100% when administered before chemotherapy to cancer patients (138, 139 and 140). This level of thrombocytosis is remarkably similar to that observed in patients with inflammation, in whom the overwhelming majority display elevated endogenous levels of IL-6 (141). Its therapeutic efficacy in patients undergoing chemotherapy for malignancy has been mixed, however, even within seemingly homogeneous patient groups. In studies using apparently identical patient populations undergoing identical chemotherapeutic regimens, for example, the drug showed a promising elevation in mean platelet nadirs in one study (55,000 versus 30,000 in IL-6 and control patients, respectively) (142) but no apparent effect in another report (143). Adding further complexity to the interpretation of effects of IL-6 on platelet recovery, D'Hondt reported favorable effects of IL-6 administration only 17 days after the start of chemotherapy (140). As a result, patients were able to receive subsequent cycles of chemotherapy on schedule more often than only after control chemotherapy cycles. Despite the modest therapeutic efficacy in some of these early clinical trials, however, toxicity of IL-6 has been substantial. In all reported studies, patients receiving IL-6 (compared to control patients) developed modest to significant levels of anemia and mild to modest constitutional symptoms; some studies have been marked by severe complications, such as venoocclusive liver disease. As such, the usefulness of IL-6 in alleviating thrombocytopenia is limited.

Unlike IL-3, IL-6, GM-CSF, and PIXY321, recombinant IL-11 has proven effective and relatively safe in clinical trials. The major side effects of IL-11 are related to sodium and fluid retention, causing generalized edema, dilutional anemia, dyspnea, and secondary atrial tachyarrhythmias (144, 145). Use of diuretics with IL-11 has been recommended, but dangerous degrees of hypokalemia have also been noted even without diuretic use. Approximately 1% of patients develops antibodies to the cytokine that appear to be of no clinical importance. Two major clinical trials of IL-11 have been published, the results of which are shown in Table 7.2-1 . In a phase 1/2 randomized trial of 93 cancer patients who required at least one platelet transfusion during their previous cycle of chemotherapy, administration of IL-11 reduced the need for platelet transfusions during a subsequent cycle of the same chemotherapy (146). In a second intent to treat study of 77 patients with breast cancer who needed one or more platelet transfusions during their first cycle of intensive chemotherapy, the use of IL-11 reduced the need for a platelet transfusion from 68% to 41% in the subsequent treatment cycle, a statistically significant difference if based on intent-to-treat analysis (147). Most of the reduction in transfusional needs occurred during the second cycle of chemotherapy. These studies led to recent FDA approval of the drug for the secondary prophylaxis of thrombocytopenia after chemotherapy.

Table 7.2-1 Effects of Interleukin-11 after Chemotherapy in Two Clinical Trials

Reference	n	Percent of patients requiring platelet transfusion
Tepler et al. (146)		
Placebo	27	96
rhIL-11; 25 µg/kg/d	28	82[b]
rhIL-11; 50 µg/kg/d	27	70[c]
Isaacs et al. (147)[a]		
Placebo	37	60
rhIL-11; 50 µg/kg/d	40	33[d]

n, number of evaluable patients.

[a]Intent-to-treat analysis.

[b]p = .23.

[c]p <.05.

[d]p = .02.

Note: Patients received many different chemotherapeutic regimens in the study of Tepler et al. and cyclophosphamide/doxorubicin in the Isaacs et al. study.

Results of several clinical trials of Tpo therapy are summarized in Table 7.2-2 . In all studies, the administration of either of two forms of recombinant human Tpo was safe and, when administered before chemotherapy, resulted in profound stimulation of platelet production (86, 89, 148). Specifically, no significant changes in vital signs or weight occurred, and the frequency of symptoms or signs of bone pain, organ dysfunction, superficial or deep venous thrombosis, and platelet activation were similar in treatment and placebo groups. It must be noted, however, that patients with histories of cardiac, pulmonary, vascular, or thrombotic disease were excluded from all studies. Only a rare patient in any of the reported trials developed antibodies to Tpo (85, 148). Few patients have been given more than a single course of treatment in these trials, however, making any conclusions on the immunogenicity of the two products premature.

Table 7.2-2 Effects of Thrombopoietin after Chemotherapy in Five Clinical Trials

Reference	n	Nadir plt count (× 10⁻³/mm³) (range)	Days for plt recovery to baseline	Percent plt >50,000/mm³	Percent requiring platelet transfusion
Fanucchi et al. (148)					
Placebo	12	111 (21-307)	>21	N.S.	8
MGDF	38	188 (68-373)	14	N.S.	0
Crawford et al. (149)					
Placebo	10	27	N.S.	N.S.	64
MGDF, 2.5 µg/kg/d	12	21	N.S.	N.S.	50
MGDF, 5 µg/kg/d	18	89	N.S.	N.S.	17
Basser et al. (150)					
Placebo	10	50	22	N.S.	20
MGDF[a]	41	55	17[c]	N.S.	23[d]
Vadhan-Raj et al. (151)[b]					
First cycle without rhTpo	22	N.S.	N.S.	N.S.	50
Second cycle with rhTpo	22	N.S.	N.S.	N.S.	23
Moskowitz et al. (152)					
Placebo	15	36 (8-118)	N.S.	47	20
MGDF, 2.5 µg/kg/d	15	105 (11-438)	N.S.	87	0
MGDF, 5 µg/kg/d	21	147 (31-491)	N.S.	95	0

MGDF, pegylated recombinant human megakaryocyte growth and development factor; N.S., not stated; plt, platelet; rhTpo, recombinant human thrombopoietin.

[a]All doses from 0.03 to 5.00 mg/kg/d are included.

[b]Study designed to hold thrombopoietin during first cycle, and administer thrombopoietin after the second cycle of therapy.

[c]p = .014.

[d]p = .7.

Note: Patients received carboplatin/paclitaxel (148,149), carboplatin/cyclophosphamide (150), high-dose carboplatin alone (151), or ifosfamide/carboplatin/etoposide (152) for their malignancies.

Results from several clinical trials of Tpo in patients with cancer treated with carboplatin-based chemotherapeutic regimens have been reported (148, 149, 150, 151 and 152). In all studies, platelet counts returned to baseline significantly faster; in four studies, nadir platelet counts were higher in the patients receiving Tpo (compared

with either those patients receiving placebos or the same patients during their first cycles of chemotherapy). Chemotherapy regimens administered in the first two of these trials induced only modest thrombocytopenia (mean nadir platelet counts in the placebo groups of 60,000 per mm^3 to 111,000 per mm^3); in neither study was hospital discharge delayed due to thrombocytopenia, nor were significant numbers of platelet transfusions required. In the other three studies (149, 151, 152), nadir platelet values (the number of days with less than or equal to 20,000 or 50,000 platelets per µl) and the number of patients requiring platelet transfusions were all improved compared to cycles of therapy without Tpo. As these studies had accrued small numbers of patients at the time of writing, additional results from these and additional trials enrolling greater numbers of patients is required to confirm the beneficial effects of the use of Tpo to alleviate chemotherapy-induced thrombocytopenia, the need to use platelet transfusions, and to ensure the timely return of platelet counts to safe levels to allow the on-time administration of subsequent cycles of chemotherapy.

Tpo increases the number of megakaryocytic and other hematopoietic progenitors *in vitro* and *in vivo* (72, 73, 104), properties that may benefit patients receiving stem-cell transplants. Although the hormone was of only marginal benefit in several preclinical trials, Tpo has now been tested in several clinical trials of bone marrow or peripheral blood stem-cell transplantation. In 40 patients with breast cancer undergoing autologous bone marrow transplantation, administration of pegylated (MGDF) recombinant human MK growth and development factor led to a 5 to 6 day earlier rise in platelet count (20,000 per mm^3) and a 48% reduction in use of platelet transfusions (as compared with placebo) (152). It has not been effective in patients undergoing autologous peripheral blood stem-cell transplants, however. In a total of 75 patients with breast cancer undergoing autologous peripheral blood stem-cell transplantation, the use of Tpo (either before conditioning chemotherapy or after stem-cell infusion) did not alter platelet recovery or need for platelet transfusion (153, 154 and 155). In a study of 38 patients with delayed platelet recovery after peripheral blood stem-cell or bone marrow transplantation, the use of recombinant human Tpo led to platelet transfusion independence in only two individuals (156).

Because of the dynamics of modern platelet pheresis technology, relatively small increments in peripheral blood platelet counts result in large increases in the numbers of platelets that can be recovered. A single dose of Tpo administered to subjects with normal hematopoietic functions increased yield of platelets threefold and was associated with a fourfold improvement in platelet counts in recipients of the pheresed platelets (157). When this study was expanded to include more than 1,000 normal platelet donors, however, approximately 1% developed antirecombinant Tpo antibodies that cross-reacted with endogenous hormones, leading to donor thrombocytopenia. Although most of these individual platelet donors have recovered, the form of recombinant Tpo used in this study has been withdrawn from further clinical testing in this setting.

Conclusion

Part of "7.2 - Platelet-Stimulating Factors "

Erythropoietin, GM-CSF, and G-CSF have proven effective in many—but not all—patients with anemia and neutropenia. These successes provide the bases for optimism that thrombopoietic

agents can be similarly identified. Although many cytokines and hormones affect MK development *in vivo*, only two, IL-11 and Tpo, and an engineered molecule that combines sequences from IL-3 and Tpo, continue to be tested for efficacy in clinical trials. Initial trials suggest that one or more of these agents prove effective in ameliorating thrombocytopenia in some—but not all—clinical settings. On the basis of its ability to reduce need for platelet transfusions in secondary prophylaxis settings, IL-11 has been approved by the U.S. Food and Drug Administration for use, and it is likely that one or more forms of Tpo will also be approved for use. Promegapoietin, the combination molecule, has been effective in preclinical trials; its toxicity and immunogenicity profile will determine its usefulness. Clearly, applying physiology-based biotechnologic strategies to Osler's dilemma is yielding therapeutic dividends.

- Conclusion

Introduction

Part of "7.3 - Erythropoietin Therapy for the Cancer Patient "

Patients with cancer are frequently anemic (1). In some clinical settings, this anemia is attributable to specific complications of a particular malignancy, including hemolytic anemias associated with B-cell malignancies; blood loss or iron deficiency associated with cancers of the gastrointestinal tract, uterus, uterine cervix, or urothelium; bone marrow infiltration by breast cancer, prostate cancer, or hematologic malignancies; and red blood cell aplasia associated with thymoma. In addition, some patients with cancer develop anemia related to nutritional deficiencies or the cytotoxic effects of cancer chemotherapy. It is important to recognize and, when possible, treat these causes of the anemia of cancer.

A frequent and often dominant pathophysiologic factor in the anemia associated with cancers of all sites is the anemia of chronic disease. This entity was first described in association with chronic inflammatory disorders and was attributed to demonstrable alterations in iron metabolism with increased reticuloendothelial retention of recycled iron, coupled with decreased survival of endogenous and transfused red blood cells (2, 3). This anemia is usually characterized by normocytic or microcytic and normochromic or hyperchromic red blood cell indices and an inappropriately low reticulocyte count. Iron studies, particularly serum ferritin levels, frequently suggest normal or increased iron stores. The anemia of chronic disease is usually mild to moderate in severity with hemoglobin concentrations of 7.5 to 11.0 g per dL. It has been recognized that the anemia of chronic disease is characterized by a diminished erythropoietin response to the decreased hemoglobin levels. This blunting of the erythropoietin response axis has been specifically demonstrated in patients with cancer (4). These studies have also shown that endogenous erythropoietin levels are further diminished when cancer patients are treated with cytotoxic chemotherapy.

Erythropoietin is the major regulator of red blood cell production in mammalian species and is produced in the kidney with the quantity of erythropoietin released related to the tissue partial pressure of oxygen in the oxygen sensor. A high degree of species-to-species homology exists in the sequence and structure of erythropoietin. Human erythropoietin is a 193-amino acid protein with two disulfide bonds and four sites of glycosylation. Recombinant human erythropoietin for clinical use is produced in Chinese hamster ovary cells and bears four linked oligosaccharide chains because removal of the linked oligosaccharide moieties results in decreased biologic activity and complete deglycosylation in a biologically inactive molecule. Glycosylated erythropoietin binds to a specific receptor complex that lacks a tyrosine kinase domain and has sequence homology to receptors for other hematopoietic cytokines, including granulocyte-macrophage colony-stimulating factor, interleukin-3, interleukin-6, and thrombopoietin. The erythropoietin-receptor complex is internalized after binding, inducing proliferation, differentiation, and enhanced survival of erythroid progenitors in the bone marrow. Two recombinant human erythropoietin (rhEpo) preparations are available for clinical application—epoetin-α and epoetin-β. In the United States, only epoetin-α is marketed; in other parts of the world, both preparations

are available. The biologic properties and clinical effects of epoetin-α and epoetin-ß are similar, although some differences may exist in isoform composition, glycosylation, and pharmacokinetics (5, 6). Their clinical data are pooled for discussion as rhEpo in this chapter because a comparative clinical trial demonstrating a significant difference in potency per unit or in safety or efficacy between the two preparations has not been conducted.

rhEpo became available for clinical testing in 1985. The first clinical trials were in patients with chronic renal failure. Chronic renal failure is the clinical setting in which the erythropoietin response to anemia is the most deficient. In these studies, therapy with rhEpo was shown to be effective in increasing hemoglobin levels and decreasing red blood cell transfusion requirements and iron overload. The initial studies were carried out with intravenously administered rhEpo; subsequent studies demonstrated that subcutaneous dosing was more efficient and permitted a one-third reduction in the intravenous dose. The toxicities observed included local injection-site pain when the drug was administered subcutaneously, an increase in diastolic blood pressure in as many as one-third of patients treated with rhEpo, and seizures in 4% of patients, the latter attributable to rapid increases in blood pressure. Iron deficiency developed in the majority of patients because of an increase in iron use, decrease in transfusions, and the chronic blood loss of hemodialysis. An increased frequency of thromboembolic events were not observed in patients receiving rhEpo, and neutralizing antibodies were not detected. The clinical benefits and safety profile of rhEpo therapy observed in hemodialysis patients were subsequently observed in predialysis patients with chronic renal insufficiency and those undergoing chronic ambulatory peritoneal dialysis.

One aspect of these studies was particularly relevant to the current evolution of thought regarding the role of rhEpo in the management of the cancer patient. In these clinical trials, rhEpo therapy was associated with an increased hemoglobin level despite a decrease in red blood cell transfusion requirement, the primary study end point. It was therefore logical to ask whether this increase in hemoglobin level was associated with any benefit to the patients in terms of symptom status. In the hemodialysis patient population, rhEpo therapy was associated with significant improvements in functional ability, health status, life satisfaction, social and sexual functioning, appetite, affect, and happiness (7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17 and 18). These quality of life (QOL) questionnaire-based observations were supported by studies documenting objective improvements in peak oxygen consumption and ventilatory anaerobic threshold in rhEpo–treated patients (19). Similar effects on QOL outcomes were reported in predialysis patients (20, 21, 22 and 23) and in patients undergoing peritoneal dialysis (24). These improvements were observed in pediatric (25) and elderly (26) subsets of renal failure patients. Analogous findings were reported in patients with acquired immunodeficiency syndrome treated with rhEpo (27, 28). The demonstrations of increased energy level, functional capacity, and QOL associated with rhEpo therapy were consistent across different clinical settings, age groups, and countries. This had important implications for the palliative management of anemic cancer patients (29).

The insights into the frequency and pathophysiology of anemia in cancer patients summarized above, coupled with the clinical experience with rhEpo in chronic renal failure and, later, in patients with acquired immunodeficiency syndrome provided the rationale for the initiation and design of clinical trials of rhEpo in patients with cancer.

Effects of Recombinant Human Erythropoietin on the Anemia of Cancer

Part of "7.3 - Erythropoietin Therapy for the Cancer Patient "

For obvious reasons, cancer patients with anemia caused by bleeding, nutritional deficiencies, or hemolysis have been excluded from clinical trials of rhEpo. rhEpo therapy may be associated with enhanced proliferation or survival of immature myeloid cells because these cells bear erythropoietin receptors. Patients with myeloid malignancies have therefore been excluded, and safety in these patients has not been established. Treatment of patients with myelodysplastic syndromes, however, has not been associated with a higher risk of progression to acute leukemia.

Some aspects of rhEpo clinical trials have made a full understanding of this agent's potential in cancer treatment more elusive. In many clinical trials, rhEpo has been given to all patients at a predefined dose with one or two dose escalations permitted in unresponsive patients. These studies have reported a "response rate" for the dose and schedule used, usually indicating the proportion of patients in whom an increase of hemoglobin concentration by 2 g per dL or an increase in hematocrit of 6% was observed during a defined period of rhEpo therapy. Although this approach is frequently taken in the development of cytotoxic chemotherapeutic agents, it may not be the most biologically sound design for clinical trials of a protein hormone, such as rhEpo. This approach in rhEpo development has not fully elucidated the dose-response relationship in patients with cancer and has left the impression, perhaps mistakenly, that 25% to 50% of patients with cancer will be biologically unresponsive to the drug. The results of rhEpo therapy for patients with cancer-associated anemia and patients with anemia associated with cancer during chemotherapy have been analyzed separately because of differences in the degree of relative erythropoietin deficiency and pathophysiology of the anemia. Studies in cancer patients not receiving chemotherapy have included fewer patients treated with lower rhEpo doses or for shorter durations of time before response assessment. Moreover, fewer patients requiring red blood cell transfusions have been included in these studies. This has made the determination of the clinical benefits to this group of patients more problematic.

Clinical Trials of Recombinant Human Erythropoietin for the Anemia of Cancer

Until recently, most rhEpo clinical trials used at least thrice-weekly dosing. In phase 2 studies, therapy with rhEpo with divided weekly doses of 66 to 450 U per kg was associated with an increase in hemoglobin concentration in some patients with cancer-associated anemia (30, 31 and 32). The proportion of patients identified as hematologic responders in these small studies varied from 33% to 83% with the higher response rates generally observed with higher weekly rhEpo doses. In one study, which also included patients receiving chemotherapy, the results suggested that patients not receiving chemotherapy were more

responsive to rhEpo; slightly higher response rates were achieved with somewhat lower weekly doses (32).

Osterborg studied the relationship of rhEpo dose and schedule to hematologic response in transfusion-dependent patients with multiple myeloma or low-grade lymphoma (33). In this study, 126 patients were randomized to receive subcutaneous rhEpo at a fixed dose of 10,000 U per day, 7 days a week, or at an initial dose of 2,000 U per day for 8 weeks followed by stepwise titration of dose or no rhEpo therapy at all. The response rate, defined as transfusion independence and a 2 g per dL increase in hemoglobin concentration, was 60% in the two rhEpo groups and 24% in the untreated patients. Maximal rhEpo efficacy was observed more rapidly in the high fixed-dose group; only 14% of patients responded to the initial dose in the titration group. The authors suggested a starting dose of 5,000 U per day (35,000 U per week, approximately 500 U per kg per week). In a second dose study, similar findings were reported, and 5,000 U per day was also the suggested dose (34). In a small study, 16 patients with gastrointestinal malignancies were randomized to receive subcutaneous rhEpo at 2,000 or 10,000 U three times weekly (35). Five of eight patients receiving 30,000 U per week met the criteria for a hematologic response; one of eight patients in the low-dose group responded.

In the phase 3 registration trial of rhEpo in the United States, 124 patients with the anemia of cancer were randomized to placebo or rhEpo, 100 U per kg subcutaneously thrice weekly, a somewhat lower dose than that suggested in the later dose-finding studies (36, 37). Although transfusion dependence was not an entry criteria, the clinical end point was a decrease in the proportion of patients requiring transfusion or in the number of transfusions administered to the treated population compared with control. The response assessment was made after only 8 weeks of therapy. Although a significant increase occurred in the hematocrit level in the rhEpo–treated group compared with placebo, the response rate in the treated group was only 40%, and a statistically significant reduction in transfusions was not observed. This failure to achieve the clinical end point was probably related to the relatively low dose and short duration of rhEpo therapy and to the study being statistically underpowered to identify a true difference in transfusions between the two groups. Nevertheless, rhEpo is not registered for this indication in the United States. In contrast to the experience in patients with renal failure, serious adverse events were not observed with increased frequency in the rhEpo group.

Therapy with rhEpo has been shown to decrease perioperative transfusion requirements in patients undergoing abdominal surgery for cancer (38). Twenty patients were randomized to receive rhEpo, 300 U per kg 12 days before surgery, then 100 U per kg 4 and 8 days later, or no preoperative rhEpo therapy. Significantly fewer patients in the rhEpo group required allogeneic red blood cell transfusion. In two randomized studies, rhEpo was shown to facilitate preoperative autologous blood donation in cancer patients (39, 40).

Clinical Trials of Recombinant Human Erythropoietin for the Anemia Occurring during Cancer Chemotherapy

The first clinical trials of rhEpo in cancer treatment were carried out in patients undergoing chemotherapy. In phase 1 and 2 clinical trials, intravenous rhEpo doses of 25, 50, 100, 200, or 300 U per kg per day, all 5 times weekly for 5 weeks, were given to patients undergoing cancer chemotherapy (41, 42). No dose-related toxicities were encountered. An apparent dose-response effect occurred with the majority of hematologic responses noted in patients receiving 100 U per kg per day (500 U per kg per week) or higher doses and response rates of 83% in patients receiving 200 or 300 U per kg per day (1,000 or 1,500 U per kg per week). Several series have been published confirming the safety and efficacy of rhEpo in the setting of cancer chemotherapy, usually using subcutaneous doses of 450 U per kg per week given in three divided doses (43, 44, 45, 46 and 47). The efficacy and safety of rhEpo therapy given during chemotherapy also has been confirmed in studies of elderly patients. Therapy with rhEpo has been safe in pediatric chemotherapy patients, but efficacy studies have yielded mixed results (49, 50 and 51).

After the initial dose-ranging studies, several trials explored the effects of rhEpo dose on its hematologic efficacy. Tsuda et al. compared the hematologic effects of rhEpo in 12 patients treated with 3,000 U three times weekly with those in 14 patients treated with twice that dose, concluding that the 6,000 U dose (approximately 250 U per kg per week) was superior in terms of hemoglobin response (52). Glimelius et al. randomized 84 patients with gastrointestinal cancers to receive subcutaneous rhEpo at 2,000 U or 10,000 U given thrice weekly (35). Responses, defined as an increase of 1 g per dL in hemoglobin concentration, occurred more rapidly and in a significantly greater proportion of patients in the higher dose group with a 73% response rate at 4 weeks compared with 30% of responders at 10 weeks in the lower dose group. Mantovani et al. randomized 20 patients receiving cisplatin-based chemotherapy to receive subcutaneous rhEpo at a dose of 150 U per kg thrice weekly (nine evaluable patients) or 50 U per kg daily (eight evaluable patients). Both groups were treated for 12 weeks (53). This small study was relatively underpowered to detect a difference between the 350 and 450 U per kg per week groups; no significant difference between the groups in hematologic response or transfusion requirements was observed.

Cisplatin therapy results in erythropoietin deficiency and is frequently complicated by anemia because of its direct renal effects (54). Some studies have therefore focused on the use of rhEpo therapy for patients receiving cisplatin (42, 47, 53, 55). Others have randomized or analyzed patients receiving cisplatin-based chemotherapy separately from those treated with other regimens (36, 37, 44, 46, 52, 56). In some studies, the data have suggested that patients receiving cisplatin are most likely to respond or respond more rapidly to rhEpo therapy than patients receiving non–cisplatin-containing regimens. Anemic patients receiving non–cisplatin-containing chemotherapy, however, have also responded to rhEpo. Taken in aggregate, the studies do not demonstrate that rhEpo is more effective or requires a different dosing regimen in either group.

Two randomized, placebo-controlled clinical trials of rhEpo for patients undergoing cytotoxic chemotherapy have been reported. Cassinu et al. randomized 100 anemic patients receiving cisplatin-based chemotherapy to receive subcutaneous rhEpo, 100 U per kg thrice weekly, or placebo (55). Significantly higher hemoglobin concentrations were observed in the rhEpo arm

within 3 weeks of beginning the study drug. A significantly smaller proportion of patients in the rhEpo group required red blood cell transfusions (20% vs. 56%) and significantly fewer red blood cell transfusions were given per patient in the rhEpo group over the 9 weeks of the trial. In a large, multicenter, randomized, placebo-controlled study that served as the U.S. registration trial for rhEpo, 289 patients receiving chemotherapy, 132 patients receiving cisplatin, and 157 patients receiving non–cisplatin-based regimens were randomized separately to receive rhEpo 150 U per kg subcutaneously thrice weekly or placebo for 12 weeks (37, 57, 58). The clinical end point of the study was the number of red blood cell transfusions received by the two groups. The data from these two groups were pooled for the final efficacy analysis because no significant differences existed between the cisplatin and noncisplatin subsets in terms of hematologic response (58% vs. 56%, response defined as at least a 6% increase in hematocrit). In the second and third months of study drug treatment, a statistically significant smaller proportion of transfused patients and a significantly lower number of transfused red blood cell units in rhEpo–treated group existed. After the blinded portion of the study, patients receiving placebo were permitted to cross over and receive rhEpo; these patients responded similarly to those initially randomized to rhEpo. Patients who had been receiving rhEpo but had not responded were permitted dose increases to 300 U per kg thrice weekly. Some patients did not respond to 150 U per kg but responded to a higher dose, demonstrating a link between dose and the proportion of patients with a hematologic response. This observation was supported by the study of Ludwig et al. in which patients receiving chemotherapy were treated initially with rhEpo 150 U per kg thrice weekly for 6 weeks, at which point the dose was increased to 300 U per kg in patients in whom the hemoglobin concentration did not increase by at least 2 g per dL (43). In this study, 52% of patients ultimately responded to rhEpo, and the mean dose required was 570 U per kg per week.

Therapy with rhEpo has been studied as a strategy to prevent rather than treat anemia and red blood cell transfusion dependence in patients receiving chemotherapy. In a study of small-cell lung cancer patients receiving intensive non–cisplatin-containing chemotherapy, de Campos et al. randomized 36 patients to receive either rhEpo 150 U per kg thrice weekly, rhEpo 300 U per kg thrice weekly, or no rhEpo for the duration of chemotherapy (59). Hemoglobin levels decreased in all patients, but significantly fewer red blood cell transfusions were administered to the rhEpo-treated groups. No differences were observed between the two dose cohorts. In another study, 62 patients with breast cancer undergoing intensive adjuvant chemotherapy were randomized to receive rhEpo 150 U per kg thrice weekly or no rhEpo treatment (60). In the rhEpo–treated patients, hemoglobin levels were maintained over 6 cycles of chemotherapy; a progressive decrease in hemoglobin was observed in the control group.

The results of phase 2 and 3 studies of rhEpo demonstrate that, when administered to anemic cancer patients receiving cytotoxic chemotherapy, rhEpo therapy is associated with an increase in hemoglobin level and a decrease in the proportion of patients who require red blood cell transfusion. The data available strongly suggest that the proportion of patients who benefit and, perhaps, the rapidity with which they realize that benefit are related to the dose of rhEpo administered, at least up to doses of 500 to 900 U per week when the drug is administered subcutaneously and three times weekly. At these higher doses, 50% to 75% of these patients respond to rhEpo with an increase in hemoglobin levels and a 50% or greater decrease in transfusion risk. Relatively little is known about the benefits of rhEpo doses higher than 1,000 U per week; doses of 1,500 U per week have been administered without encountering dose-limiting toxicities. The proportion of cancer patients who are unresponsive to rhEpo at any dose is unknown. When administered at doses of 450 U per kg per week, rhEpo therapy can prevent the progressive decline in hemoglobin levels observed during chemotherapy. When rhEpo is used to prevent anemia, a significant decrease in transfusion risk has been demonstrated only for patients at high risk for transfusion, such as those receiving carboplatin and ifosfamide chemotherapy. In the setting of cancer chemotherapy, rhEpo therapy is safe. Acute, serious, adverse events and longer-range toxicities, such as stem-cell exhaustion, lineage steal, and increased rates of acute leukemia have not been reported with increased frequency in rhEpo-treated patients.

Clinical Trials in Myelodysplasia

Patients with myelodysplastic syndromes most frequently present with anemia and often become red blood cell transfusion-dependent and alloimmunized. Several uncontrolled clinical trials of rhEpo intravenously at doses of 210 to 3,200 U per kg per week (61, 62, 63, 64, 65, 66 and 67) or subcutaneously at doses of 150 to 2,100 U per kg per week (68, 69, 70, 71, 72, 73, 74, 75 and 76) have been reported with improvement in anemia, decrease in transfusion requirements, or both, observed in zero to 50% of treated patients with an average response rate of approximately 30% in pooled data. Clinical trials of cytokine combinations have suggested that erythropoietic synergy may exist between granulocyte-macrophage colony-stimulating factor (77) or granulocyte colony-stimulating factor (78) and rhEpo in some patients with myelodysplasia, although these findings have not been consistent (79, 80), and the safety of routine use of myeloid growth factors in these patients has not been established.

In a randomized, placebo-controlled clinical trial, rhEpo given subcutaneously at a dose of 150 U per kg per day for 8 weeks was compared with placebo in 87 patients with myelodysplasia (81). The overall hematologic response rate was 37% with a higher frequency of response in patients in the refractory anemia group compared with refractory anemia with excess blasts subset. Serious toxicities or progression to leukemia were not observed with increased frequency in the rhEpo group. Small studies in patients selected for refractory anemia, normal platelet counts and lactate dehydrogenase levels, and a short duration of disease have suggested that, in this subset of patients with myelodysplasia, rhEpo may have hematologic responses and dose requirements similar to patients with cancer-receiving chemotherapy (82, 83).

The available data support the conclusion that rhEpo is safe in patients with myelodysplasia. For the whole population of patients, however, doses of at least 450 U per kg per week or greater are required to achieve hematologic improvement in one-third of patients. Some studies have reported that baseline serum erythropoietin or other cytokine levels can be used to select patients more likely to respond but this has not been a

consistent finding. Data suggest that it may be possible to select a subset of patients, such as those with refractory anemia without excess blasts, in whom lower doses will be required and higher response rates observed.

Practical Aspects of Recombinant Human Erythropoietin Therapy in Cancer

Part of "7.3 - Erythropoietin Therapy for the Cancer Patient "

Iron

Some patients with cancer are iron deficient before the initiation of rhEpo therapy. Any patient with a low serum ferritin or a transferrin iron saturation of less than 20% should be treated with iron during the first 1 to 2 months after the initiation of rhEpo therapy. Many more patients develop iron deficiency during rhEpo therapy. Any patient in whom a response to rhEpo is observed initially but who later begins to become anemic despite continued treatment should be evaluated for iron deficiency and treated. Interest is increasing in the use of intravenous iron repletion in conjunction with rhEpo to prevent and treat iron deficiency. This is a result of the small quantities of orally administered iron that can be absorbed daily, the gastrointestinal toxicity and resultant noncompliance associated with oral iron supplementation, and the improved safety profile of currently available paternal iron preparations.

Recognition is emerging that patients treated with rhEpo frequently develop functional iron deficiency (84, 85). In this syndrome, total body stores of iron, as assessed by iron studies, serum ferritin, or bone marrow-stainable iron, may be normal or increased while erythropoiesis is iron deficient, because demand by the stimulated erythron exceeds supply from body iron stores and oral absorption. Functional iron deficiency has been described in patients treated with rhEpo undergoing hemodialysis, as well as in normal autologous blood donors (86). Given the abnormalities of iron metabolism that accompany chronic diseases with avid retention of body iron stores in the reticuloendothelial system, it is likely that functional iron deficiency is more common in the setting of cancer than in healthy individuals or hemodialysis patients (87). Physicians are learning that parenteral iron administered during rhEpo therapy in patients with renal failure frequently improves the efficacy of a given rhEpo dose. Clinical trials of cotherapy with parenteral iron and rhEpo in cancer patients with normal or increased iron body stores are in progress. The goal of these studies is to determine whether cotherapy with iron improves rhEpo response rates or decreases the dose required to obtain a hematologic response.

Dose and Schedule of rhEpo

As discussed previously, the dose-response relationship for rhEpo in cancer patients is incompletely understood with respect to the overall hematologic response and the rapidity of response. It is reasonable to begin therapy with 10,000 U subcutaneously three times weekly with the dose doubled if an increase in hemoglobin concentration is not observed within 4 weeks in an iron-replete patient.

Studies of less frequent dosing have been carried out because thrice-weekly dosing is inconvenient, particularly for patients who must be treated in a physician's office. It appears that once-weekly subcutaneous dosing with 40,000 U is equivalent to 10,000 U thrice weekly in terms of hematologic response in patients receiving cancer chemotherapy.

Prediction of Response to rhEpo

Interest is growing in identifying patients who will not respond to a given dose of rhEpo. Because rhEpo is expensive, inefficient use of the drug should be minimized. Although some studies have suggested that higher baseline serum erythropoietin levels are predictive of a failure to respond, this has not been a consistent observation. Moreover, most patients with cancer and many patients with myelodysplastic syndromes have low erythropoietin; some of these patients do not respond to the customarily used doses of rhEpo. One approach has been to calculate the erythropoietin level that would be predicted in the absence of chronic disease (log Epo = 3.420-0.056 × hematocrit) and divide this figure into the observed level to generate the observed:predicted ratio (88). Ratios of less than .83 are associated with an increased proportion of responders to rhEpo, although some patients with higher ratios respond.

No pretreatment response-prediction strategy has emerged that can be used to consistently predict a less than 30% chance of nonresponse or a greater than 75% chance of response to the usual starting doses of rhEpo. Newer approaches have focused on evaluating patients after 4 weeks of rhEpo therapy and coupling the hematologic response observed with pretreatment assessments to generate a prediction of response (88, 89 and 90). Patients in whom an increase of 1 g per dL in hemoglobin concentration is observed after 4 weeks of rhEpo therapy who also have an observed:predicted ratio of less than .82 have approximately an 85% chance of responding satisfactorily to that dose of rhEpo. Future work on prediction of rhEpo response and early identification of nonresponders will be important to maximize the cost-effectiveness of this drug in cancer patients.

Cost-Effectiveness

Several studies have examined the cost-effectiveness of rhEpo in the treatment of anemia in cancer patients (91, 92, 93 and 94). In general, these studies have compared the cost of rhEpo therapy for the whole population of treated patients with the cost of the prevented transfusions. These studies have concluded that routine rhEpo therapy adds to overall health care costs. If the only benefit derived from rhEpo therapy is the prevention of some red blood cell transfusions, the prevented transfusions may be less expensive than the rhEpo. As more is learned about the most efficient uses of rhEpo, the balance of costs in these analyses will change to some extent. More important, these analyses have focused on the prevention of red blood cell transfusion effects of rhEpo therapy and have not included the increase in hemoglobin level seen in treated patients compared with controls. These increased hemoglobin levels have been associated with improvements in QOL (see Relationship of Anemia to Quality of Life) and these benefits, if confirmed in randomized trials, should be incorporated into future cost-utility studies.

Relationship of Anemia to Outcomes in Cancer Treatment

Part of "7.3 - Erythropoietin Therapy for the Cancer Patient "

Fatigue in Cancer Patients

Fatigue is the most frequent symptom of cancer patients. In a study of 419 cancer patients, 78% stated that they had fatigue, defined as debilitating tiredness, and 32% reported this symptom to be present and affecting their lives on a daily basis (95). Although the oncologists questioned believed that pain was more important than fatigue to cancer patients, 61% of the patients in this study reported that fatigue affected their lives more than pain. Fatigue is prevalent and important to patients and their caregivers; its importance may be underappreciated by physicians.

Several causes of fatigue exist in cancer patients. It is likely that alterations in endogenous cytokine levels, depression, the effects of therapy, poor nutritional status, and the direct effects of the cancer all play a role. Although the earlier experience in patients with renal failure indicated that anemia not believed to be severe enough to warrant transfusion still impacts functional status and QOL, the anemia of chronic disease associated with cancer has not been recognized as a factor in the debilitating tiredness reported by these patients.

Relationship of Anemia to Quality of Life

Most physicians have been trained to refrain from treating mild and moderate degrees of anemia with red blood cell transfusions unless potentially life-threatening complications exist. This mindset has resulted in an assumption on the part of many physicians that mild and moderate degrees of anemia are asymptotic and unimportant. In most practices, patients with mild and moderate anemias have been left untreated, and patients with severe anemia (hemoglobin concentration <7.5 g per dL) have been transfused and maintained in a state of mild or moderate anemia. In the early studies of rhEpo therapy for cancer patients, some investigators reported improvements in functional status, energy level, or overall QOL in responding patients (36, 43, 96, 97). These studies were not designed or statistically powered to define the QOL benefits of increasing hemoglobin levels above that usually achieved with current red blood cell transfusion practices. Nevertheless, they indicated that a palliative benefit to cancer patients associated with increased hemoglobin levels may exist.

The results of two large, open-label phase 4 studies of rhEpo therapy in cancer patients undergoing chemotherapy in community oncology practices in the United States, each including more than 2,000 patients, have been reported (98, 99). In both studies, therapy with rhEpo was effective in increasing hemoglobin levels and decreasing red blood cell transfusion requirements without severe adverse events. In these studies, physicians remained at liberty to transfuse patients whenever it was deemed appropriate. In neither study was the anemia before rhEpo therapy severe; mean baseline hemoglobin levels were 9.2 and 9.3 g per dL. The rhEpo was administered subcutaneously three times weekly for 4 months in one study at a dose of 150 U per kg per dose and in the other study at a fixed 10,000 U per dose.

In the first study, rhEpo therapy was associated with an increase in mean hemoglobin level to 11.2 g per dL (98). QOL was assessed at the initiation of rhEpo therapy and when the drug was discontinued. The QOL tool used was a three-question linear analog scale that provided a self-assessment, on a scale of 0 to 100, of the patient's energy level, activity level, and overall QOL over the previous week. Statistically significant increases in mean scores for all three questions were found ($p <.001$). The magnitude of the effective size of each of these changes was similar to those reported in other studies of cancer pain control. The increases in scores for each patient correlated with the magnitude of the increase in hemoglobin level ($p <.001$) (Fig. 7.3-1). Tumor response data was collected retrospectively for more than 600 patients. The correlation between

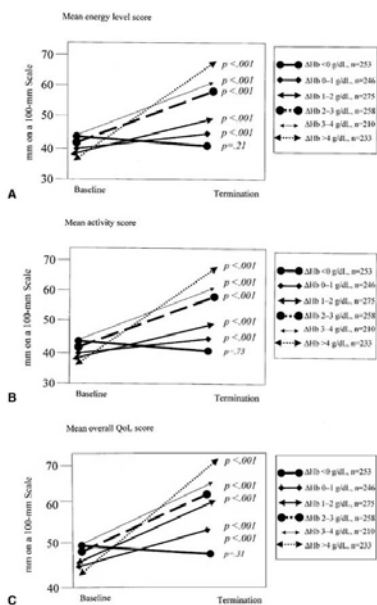
hemoglobin increase and QOL scores were seen within each tumor response category (Fig. 7.3-2).


FIGURE 7.3-1. Changes in mean linear analog scale score for patients at the beginning and termination of recombinant human erythropoietin therapy. The results for different hemoglobin (Hb) response cohorts are shown. The p values shown for each cohort were by paired tests. The mean energy level scores (A), mean activity level scores (B), and mean overall quality of life scores (C) are shown. (Adapted from Glaspy J et al. Impact of therapy with epoetin-α on clinical outcomes in patients with nonmyeloid malignancies during cancer chemotherapy in community oncology practice. *J Clin Oncol* 1997;15:1218-1234, with permission.)
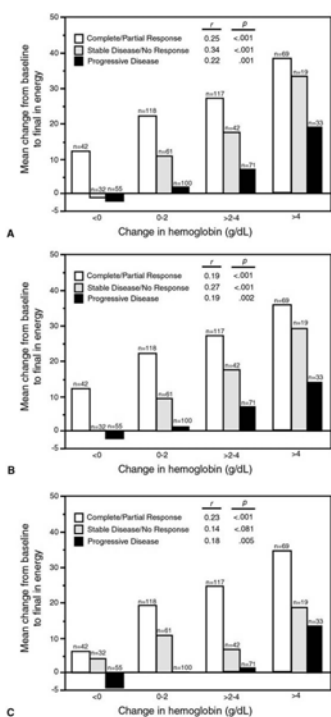

FIGURE 7.3-2. The relationship of changes in mean linear analog scale score during recombinant human erythropoietin therapy to the increase in hemoglobin level for patients with cancer undergoing chemotherapy. Patients were segregated into three chemotherapy response groups, based on the physician's assessment of their tumor response. The correlation between increase in hemoglobin and the increase in score was assessed using a simple linear regression model and the corresponding p values shown. The results for questions regarding energy level (A), ability to carry out daily activities (B), and overall quality of life (C) are shown. (Adapted from Glaspy J. The impact of epoetin alfa on quality of life during cancer chemotherapy. A fresh look at an old problem. *Semin Hematol* 1998;34:20-26, with permission.)

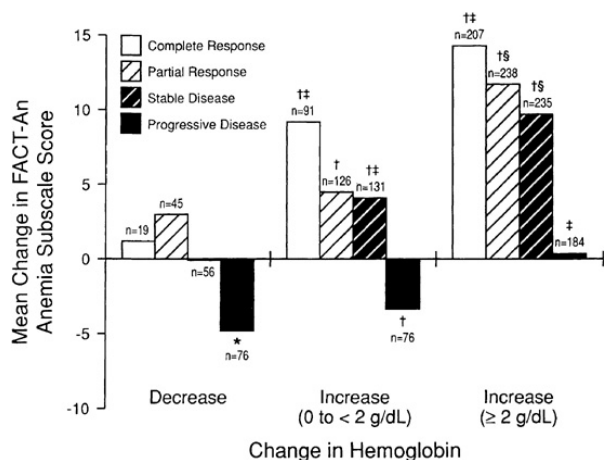
In the second study, the mean hemoglobin level increased to 11.3 g per dL (99). In this study, tumor response data were collected prospectively, and the Functional Assessment of Cancer Therapies anemia QOL tool was added to the linear analog scale as a more validated measure of the impact of rhEpo. In this study, significant increases in QOL as assessed by the linear analog scale were observed. In addition, for each tumor response category, an increase in QOL as measured by the Functional Assessment of Cancer Therapies anemia scale was observed with the magnitude of the increase related to the magnitude of the hemoglobin rise (Fig. 7.3-3). Taken together, these two phase 4 studies strongly suggest that mild and moderate anemia in cancer patients negatively impacts functional status and overall QOL. The negative effects of anemia on QOL were observed despite continued red blood cell transfusion administered whenever clinically indicated. Similar findings have been observed in a third phase 4 study that used weekly rhEpo dosing (100) and in a randomized, placebo-controlled trial in Europe (101).


FIGURE 7.3-3. The relationship of change in quality of life (QOL) score during recombinant human erythropoietin therapy, as measured by the Functional Assessment of Cancer Therapies tool to the observed change in hemoglobin level. Patients are divided into cohorts based on tumor chemotherapy response. (Adapted from Demetri GD et al. Quality-of-life benefit in chemotherapy patients treated with epoetin-α is independent of disease response or tumor type. Results from a prospective community oncology study. Procrit Study Group. *J Clin Oncol* 1998;16:3412-3425, with permission.)

This raises the question as to what is the minimum hemoglobin level requisite for optimal palliation in cancer patients. The data from the two phase 4 studies have been pooled in an incremental analysis (102). The results suggest a nonlinear relationship of hemoglobin level to QOL with QOL improving with each hemoglobin increase of 1 g per dL between 8 and 14 g per dL. The greatest improvement was observed between 11 and 12 g per dL. These data are provocative and have important implications for the palliation of cancer patients. Nevertheless, it is still possible that these results reflect a placebo effect of the rhEpo and not a true biologic effect of increased hemoglobin level. The results of one randomized placebo-controlled trial have been reported in abstract form and suggest that the improved QOL observed in the rhEpo-treated patients is not a placebo effect (101). Moreover, rhEpo therapy in advanced cancer patients has been shown to be associated with the objective improvements in measured metabolic efficiency and exercise capacity (103).

It is important to note that these data relate to the relationship of hemoglobin level to QOL. It is possible that similar improvements could be achieved by restructuring our approach to red blood cell transfusion treatment for cancer patients. No data exist regarding the effect of red blood cell transfusion for mild and moderate anemia on QOL. In addition to the risks associated with transfusions, some properties of transfused red blood cells, specifically decreased 2- and 3-diphosphoglycerate levels, may compromise tissue oxygen delivery and render them less effective than red blood cells produced in response to rhEpo (104).

Potential Effects of Anemia on Survival Outcomes

It has long been recognized that anemia or red blood cell transfusion dependence, or both, correlated with a poor prognosis for a variety of solid tumors. This has been attributed to the anemia being a reflection of the advanced stage of the malignancy, although the immunosuppressive effects of red blood cell transfusions or radioresistance conferred by decreased tissue oxygen levels have also been postulated. It is possible that clinical settings will be identified in which rhEpo therapy is associated with improved survival outcomes. The focus of this research has been on the use of rhEpo to increase hemoglobin levels in patients scheduled to undergo or undergoing radiotherapy, with the goal of increasing the efficacy of radiation. Several studies have demonstrated the safety and hematologic efficacy of rhEpo in patients undergoing radiotherapy (52, 105, 106, 107 and 108). Randomized clinical trials designed to study the survival impact of rhEpo administered to correct anemia and maintain hemoglobin levels in cervical cancer patients undergoing radiotherapy are under way.

Conclusion

Part of "7.3 - Erythropoietin Therapy for the Cancer Patient "

Therapy with rhEpo is well established as an adjunct to cancer treatment; however, the role of this factor continues to evolve. The focus of rhEpo treatment is moving from the prevention of red blood cell transfusions to the maintenance of maximal performance status, comfort level, and QOL in patients with cancer. The importance of iron supplementation, including its potential role in rhEpo-treated patients with normal body iron stores, is being recognized. Future developments in the field are likely to include the following:

1. Further refinements in rhEpo iron supplementation, dosing and response prediction, and improvements in the efficiency of its use
2. Better definition of the cost-utility of rhEpo in cancer patients, including its effects on functional status and QOL
3. Exploration of the potential of rhEpo to improve survival outcomes
4. The introduction of additional erythropoietic agents into clinical trials

- Application of Tumor Necrosis Factor in Isolation Perfusion
- Summary

Introduction

Part of "8 - Tumor Necrosis Factor: Basic Principles and Clinical Applications in Systemic and Regional Cancer Treatment "

Tumor necrosis factor (TNF) has had a long and fascinating history as a potential antitumor agent (Table 8-1). TNF became available in recombinant form in the mid-1980s after dramatic antitumor effects were observed in experimental models. High expectations existed for its clinical use. It was found, however, that humans are sensitive to the toxic effects of systemically administered TNF. Therefore, its clinical use was largely abandoned until 1992, when the initial results of its remarkable efficacy when given via isolated limb perfusion (ILP) were reported. The words of Emil Frei hold true today, as they did in 1989: "Our task is to learn to use TNF… appropriately." (1)

Table 8-1 History of the Study of Tumor Necrosis Factor as an Anticancer Agent

Date	Event
1891–1906	Coley reports use of bacterial toxins in patients with cancer
1936–1944	Shear and others purify LPS from *Serratia marcescens*
1962	O'Malley et al. discover factor in LPS-treated animal that causes tumor necrosis
1975	Carswell and Old coin the term *TNF* and show antitumor activity *in vitro* and *in vivo* in mice
1984	TNF gene cloned
1985	Recombinant TNF first available
1985–1987	Preclinical studies show impressive antitumor effect of recombinant TNF in mice
1987–1991	Phase 1 and 2 human trials of systemic TNF show unacceptable toxicity at therapeutic doses
1992	Liénard and Lejeune report success of TNF and melphalan in isolated limb perfusion
1993	Uses of high-dose TNF in liver and lung perfusions

LPS, lipopolysaccharide; TNF, tumor necrosis factor.

William Coley, a surgeon practicing in New York City in the late 1800s, was the first to investigate the therapeutic potential of inducing tumor necrosis using a crude extract of bacteria (2). Although the phenomenon of tumor necrosis in the presence of an infection was well known at the time, Coley administered preparations of gram-positive and gram-negative bacteria or bacterial products to humans with inoperable cancer and claimed success in some patients (3,4). The side effects of *Coley's toxins*, as these preparations were called, were unacceptable. For this and other reasons, their use was largely abandoned.

In the 1940s, Shear et al. (5) sought to isolate an active agent from Coley's toxins and purified bacterial polysaccharide from *Serratia marcescens*, known as *lipopolysaccharide* (LPS). It was shown that LPS, like Coley's original preparations, induced hemorrhagic necrosis of transplantable tumors in mice, although its toxicity profile also was similar (6). In 1962, O'Malley et al. (7) reported identifying an endogenous factor present in the serum of LPS-treated animals that induced hemorrhagic necrosis of tumors in naïve animals. Further characterization of this factor and the name *tumor necrosis factor* awaited the reports of Carswell and Old in 1975 (8). These authors showed that TNF was produced in mice pretreated with bacillus Calmette-Guérin and then given LPS. This caused hemorrhagic necrosis of methylcholanthrene-induced tumors when administered to naïve mice. In addition, TNF was recognized to cause lysis of various neoplastic cells *in vitro*(9).

It was not until 1984 that the TNF gene was cloned (10). Recombinant TNF became available in 1985 (11), spurring a large number of preclinical murine studies. Prominent antitumor activity at doses associated with minimal toxicity in mice prompted multiple phase 1 and 2 trials of systemic and regional TNF between 1987 and 1991. These trials produced disappointing results.

In 1992, however, Liénard and Lejeune (12) published their first report of the efficacy of ILP using melphalan and high-dose TNF, sparking renewed interest in clinical TNF application. Reports on the use of isolated perfusion to treat tumors in the lung, liver, and kidney soon followed. This chapter reviews the biologic properties of TNF, its use in early clinical trials, and, particularly, its current use in regional administration via isolation perfusion.

Biologic Properties of Tumor Necrosis Factor

Part of "8 - Tumor Necrosis Factor: Basic Principles and Clinical Applications in Systemic and Regional Cancer Treatment "

Tumor Necrosis Factor Gene, Protein, and Biosynthesis

The term *TNF*, as used in this chapter, refers to *TNF*-α, also known previously as *cachectin* (13). TNF-β or lymphotoxin bears sequence homology to TNF but differs functionally (14,15). The human TNF (hTNF) gene has been localized to the short arm of chromosome 6 (chromosome 17 in mice) in the middle of the major histocompatibility complex (16).

hTNF messenger RNA codes for a 76-amino acid presequence and a 157-amino acid mature protein (11). In addition to the 17-kd secreted form of the protein, TNF can exist as an uncleaved 26-kd cell surface protein, which is biologically active, as measured by *in vitro* cytotoxicity (17). The tertiary structure of TNF is maintained by a disulfide bridge and the

molecule has a tendency to form noncovalently linked trimers held together by hydrophobic forces (18).

TNF is a cytokine produced mainly by macrophages and monocytes but can be secreted by various other cell types, including natural killer cells and lymphocytes (19,20). Although LPS is the best-characterized inducer of TNF (21), many other agents increase TNF synthesis *in vivo*, including tumor promoters and mitogens; viruses; and cytokines, such as interleukin (IL)-1, interferon (IFN)-γ, and granulocyte-macrophage colony-stimulating factor (22). Multiple inhibitors of TNF synthesis also are known, including glucocorticoids (21); phosphodiesterase inhibitors; and cyclic adenosine monophosphate analogues, such as pentoxifylline (23), tumor growth factor–ß (24), and IL-4 (25).

Tumor Necrosis Factor Receptors

Two TNF receptors (TNF-R) have been characterized (26,27) and are generally known as *TNF-R1* and *TNF-R2.* These receptors previously have been termed *TNF-R55* and *TNF-R75*, respectively, based on their molecular weights. TNF-Rs are present on the surfaces of almost all cell types with the exception of red blood cells and unstimulated lymphocytes (28,29). Preclinical studies showed that a marked cross-reactivity exists between murine and hTNF and the murine receptors and hTNF-Rs, except that hTNF does not bind to murine TNF-R2 (30,31).

Although TNF-R1 is present on nearly all nucleated cells, it is maintained in relatively low concentrations on cell surfaces and is relatively refractory to upregulation or downregulation (32). Several inducers of TNF-R1 expression, however, have been identified, including IL-1ß and a newly described cytokine, endothelial-monocyte–activating polypeptide II, which is capable of rendering TNF-resistant tumors TNF-sensitive *in vivo* (33,34 and 35). IFN-γ also may induce TNF-R1 expression, but this effect appears less consistent (32,33). TNF-R2 expression is widely variable and is induced by IFN-γ, IL-2 activation of T-cell lymphocytes, and increased intracellular levels of cyclic adenosine monophosphate and protein kinase A (36,37 and 38). Protein kinase C activation downregulates expression of TNF-R2 (38).

TNF-R1 and TNF-R2 are transmembrane glycoproteins with similar extracellular domains but markedly differing intracellular domains (39). TNF-R1 appears chiefly responsible for TNF-induced cytotoxicity, activation of nuclear factor (NF)-κB, and possibly induction of nitric oxide synthetase (40,41 and 42). The intracellular effects of TNF-R2 have been observed mainly in T-cell lymphocytes, where TNF-R2 can mediate TNF-induced cytotoxicity (43). An extracellular role of TNF-R2 in "ligand passing" of TNF from TNF-R2 to TNF-R1, however, also has been proposed (44).

Both TNF receptors are known to be shed from cell surfaces, resulting in circulating levels of soluble receptors (45,46 and 47). This phenomenon may have major clinical consequences and potential therapeutic applications because soluble TNF-R has been shown to block TNF bioactivity *in vitro* and *in vivo* (48). Low concentrations of soluble TNF-R, however, also appear to stabilize the structure of TNF, prolonging its bioactivity and, thus, potentially enhancing its effect (49).

Biologic Actions of Tumor Necrosis Factor

The major actions of TNF on cells *in vitro* are cytotoxicity (8,9,50) and induction of gene expression, including the release of soluble factors (51). Occasionally, TNF can induce cellular proliferation (i.e., fibroblasts) (52,53). Soluble mediators released in the presence of TNF include PGE_2, leukotrienes, platelet-activating factor, nitric oxide, and reactive oxygen intermediates. The list of proteins induced by TNF has become voluminous but includes (1) nuclear factors, such as c-fos and c-jun; (2) cytosolic proteins, including nitric oxide synthetase; (3) mitochondrial manganese superoxide dismutase; (4) cell surface molecules, including intercellular adhesion molecule-1, IL-2 receptor-α, and class I and II major histocompatibility complex molecules; and (5) secreted proteins, including IL-1, IL-6, IL-8, IFN-ß, granulocyte-macrophage colony-stimulating factor, platelet-derived growth factor, u-PA, and TNF itself (54,55,56,57,58 and 59).

The *in vitro* cytotoxic activity of TNF has been best characterized using L929 fibrosarcoma cells, the cell line in which this effect was first documented by Carswell and Old (8). Since then, the TNF sensitivity of many cell lines has been studied. Although no single mechanism for cytotoxicity emerges as the predominant one, traditional apoptosis and directly induced cellular necrosis contribute to this process (60). After TNF binds to its receptors, these complexes are internalized and phospholipase A_2 is activated (61,62). This releases arachidonic acid, prostaglandins, or both, and other eicosanoids (63). The result is the formation of reactive oxygen intermediates by the mitochondria, leading to cellular damage, as well as a chain of intracellular events triggered by the activation of transcription factors, such as NF-κB (64,65 and 66). Cells subsequently develop increased permeability and undergo "cellular collapse" (67). Hyperthermia increases sensitivity to the cytotoxic effects of TNF (68).

In vivo, high concentrations of TNF produce a toxicity syndrome similar to septic shock (69). In various laboratory

mammals, TNF causes hypotension, acidosis, transient hyperglycemia followed by hypoglycemia, oliguria and renal failure, hemorrhagic infarction of the gastrointestinal tract, disseminated intravascular coagulopathy, and death by respiratory arrest (70,71). In addition, chronic administration of TNF (cachectin) causes cachexia in mice, and TNF is at least partially responsible for cancer-associated cachexia (72,73). In smaller doses, human subjects experience fever, headache, and a broad range of constitutional symptoms (74). Most of these effects are attributed to the TNF-induced release of multiple cytokines and other mediators, including IL-1, prostaglandins, and nitric oxide (75,76 and 77).

Antitumor Activity of Tumor Necrosis Factor

In addition to the direct cytotoxicity on malignant cell lines *in vitro*, as described in the Biologic Actions of Tumor Necrosis Factor section, TNF clearly has other antitumor activity. This was well documented by Carswell and Old, who discovered that TNF causes hemorrhagic necrosis in methylcholanthrene-induced fibrosarcomas in mice, despite the fact that these cells are resistant to the cytotoxic action *in vitro* (8). Further study of this phenomenon led to the understanding that TNF induces effects of the tumor microvasculature, ultimately resulting in necrosis in the central portion of the tumor. Specifically, TNF induces tissue factor expression by endothelial cells, promoting fibrin deposition and clot formation (78,79). This induction is enhanced by tumor-derived factors, such as endothelial-monocyte activating polypeptide II, which upregulates endothelial cell expression of TNF-R1 (35,78). In addition, TNF increases vascular permeability and induces expression of various adhesion molecules by endothelial cells, contributing to neutrophil invasion (80,81). The importance of the vascular effects of TNF on tumors is supported by the normalization of the hypervascular angiographic findings after treatment of sarcomas by ILP with TNF and melphalan (82).

Evidence exists that T-cell lymphocytes play a role in the antitumor effects of TNF (83). Tumor regression also has been documented after treatment of nude mice bearing transplantable human tumors with TNF (84,85). Although the degree of necrosis was less in this model than in immune-competent models, necrosis was still present, implicating a complex antitumor mechanism with multiple effectors. Some of this antitumor activity may be caused by synergy between TNF and IFN-γ (84). A large number of conventional chemotherapeutic agents have been screened for potential synergy with TNF with some success (86,87). This research, along with the known synergy between TNF and hyperthermia, has yielded the current combination of melphalan and hyperthermia as the most common agents used in conjunction with TNF in isolated perfusion (12).

Early Clinical Studies Using Tumor Necrosis Factor

Part of "8 - Tumor Necrosis Factor: Basic Principles and Clinical Applications in Systemic and Regional Cancer Treatment "

Preclinical studies demonstrated that single-bolus intravenous (i.v.) administration of recombinant TNF could induce antitumor activity in a variety of murine tumor models (88,89). These findings led to a concerted effort to identify clinical applications of TNF to treat cancer in humans. The majority of phase 1 and phase 2 trials indicated that systemic administration of TNF yielded unacceptable toxicity at subtherapeutic doses. The pharmacokinetic data obtained in these trials, however, paved the way for the refinement of regional applications of TNF and the current use of TNF in isolation perfusion.

Phase 1 Studies of Systemic Tumor Necrosis Factor

Early phase 1 trials were instrumental in defining the pharmacokinetics of bolus i.v. TNF (90,91,92,93,94 and 95). The rate of clearance of TNF from the circulation is highly dose dependent. At doses up to 100 μg per m^2, peak serum levels ranged from undetectable to 8 ng per mL, a half-life ranging from 10 to 17 minutes, and a high volume of distribution and rapid clearance (90,92,94,95). At higher dose levels (150 to 727 μg per m^2), however, the half-life ranged from 27 to 80 minutes (91,92,93,94 and 95), and a single study reported a half-life of 144 minutes using a high dose of 1,667 μg per m^2 (93). In addition, the ratio of peak serum level to dose level was found to increase dramatically as higher doses were given. For example, in one study, a dose of 45 mg per m^2 yielded a peak serum level of 2.2 ng per mL, whereas a 16-fold dose escalation (727 μg per m^2) yielded a 185-fold increase in the peak serum level (407 ng per mL) (91).

Two mechanisms for the nonlinear pharmacokinetics of i.v. TNF have been proposed. First, clearance of circulating TNF appears to exhibit saturation kinetics with preclinical studies, demonstrating enhanced tissue distribution to the liver and kidney (96) and increased clearance time in nephrectomized mice (97). Second, the binding of circulating TNF to soluble TNF-Rs represents a saturable system with complex implications because levels of bioactive TNF and immunologically detectable TNF appear to be different (97).

Phase 1 trials using continuous infusion of TNF demonstrated a pattern of high early circulating levels with a subsequent decrease and failure to reach a steady serum level (98,99). For example, one study measured serum TNF levels ranging from 90 to 900 pg per mL up to 3 hours after initiating the infusion but reported subsequent undetectable serum levels despite continued infusion at the same dose (98). Again, the presence and possible increased production of soluble TNF-Rs receptors may contribute to this phenomenon (100).

Attempts to deliver systemic TNF via intramuscular or subcutaneous (s.c.) injection yielded measurable serum levels only at high-dose levels (>150 μg per m^2) with peak circulating levels occurring 4 to 12 hours after s.c. injection, and somewhat higher peak levels occurring 12 to 24 hours after intramuscular injection (101,102,103 and 104).

The majority of phase 1 trials of systemic recombinant TNF used single- or repetitive-dose i.v. bolus TNF or continuous i.v. TNF. Maximum tolerated doses achieved with repetitive-dose bolus TNF (150 to 300 μg per m^2) (94,105,106,107,108,109 and 110) were no higher than those achieved with single-dose treatment (218 to 410 μg per m^2), except for one trial that delivered 818 μg per m^2 (91,92,111,112). Preclinical rodent studies have demonstrated a tachyphylactic or tolerant effect to repetitive TNF dosing,

which may explain the findings of these phase 1 human trials (113,114).

All phase 1 trials produced single or multiple dose-limiting toxicities with hypotension being by far the most common toxicity (Table 8-2). Hypotension was the most prominent side effect in 11 of 12 bolus i.v. trials that defined a dose-limiting toxicity (91,92,93,94 and 95,106,107,108,109,110,111 and 112). The incidence and severity of hypotension was dose related and occurred in 30% to 60% of patients. Other common grade III and IV toxicities included hepatotoxicity (elevated hepatic transaminases, 10% to 50% of patients), constitutional symptoms, and thrombocytopenia or leukopenia (0% to 40% of patients). Between 15 and 30 minutes after bolus administration of TNF, most patients experienced rigors, followed by hypertension and tachycardia. Between 60 and 90 minutes after infusion, almost all patients developed fever. These sequelae did not appear to be dose related. Hypotension was seen 6 to 12 hours after administration and clearly was dose related, requiring vigorous resuscitation, including vasopressors, in all patients at the highest dose level (1,667 μg per m^2) (93). Nadir platelet counts generally occurred 1 to 2 days after infusion, but few patients had counts less than 100,000 per mm^3. Leukocyte counts generally decreased 30 to 60 minutes after infusion of TNF, after which a return to normal or mildly elevated levels was followed by a gradual decrease; significant neutropenia was seen only rarely.

Table 8-2 Dose-Limiting Toxicities in Phase 1 Trials of Intravenous Tumor Necrosis Factor

Dose-Limiting Toxicity	Number of Trials (%) Bolus i.v. (n = 12)	Continuous i.v. Infusion (n = 6)	Total (n = 18)
Hypotension	11 (92)	2 (33)	13 (72)
Hepatotoxicity	5 (42)	1 (17)	6 (33)
Malaise, myalgia, fatigue	2 (17)	2 (33)	4 (22)
Thrombocytopenia	1 (8)	3 (50)	4 (22)
CNS toxicity, confusion	1 (8)	2 (33)	3 (17)
Leukopenia	1 (8)	1 (17)	2 (11)
Headache	—	2 (33)	2 (11)
Nausea	1 (8)	—	1 (6)
Fever, chills	—	1 (17)	1 (6)

CNS, central nervous system.

Constitutional and hematologic side effects were more frequently dose limiting in phase 1 trials of continuous i.v. TNF than in the bolus i.v. trials (see Table 8-2) (98,99,115,116,117 and 118). With maximum tolerated doses as low as 40 to 160 μg per m^2 per day, however (99,115,118), it is likely that the doses necessary to cause the more severe side effect of hypotension never were reached. Phase 1 trials of s.c. or intramuscular TNF (101,102,103 and 104) yielded similar maximum tolerated doses and side-effect profiles as the i.v. trials, with the addition of severe inflammation at the site of injection as a dose-limiting toxicity in two studies (101,104). Most phase 1 studies reported no evidence of antitumor activity. The occasional responses in these trials are discussed in the following section.

Phase 2 Studies of Systemic Tumor Necrosis Factor

The results of nine phase 2 studies using intermittent bolus i.v. administration of TNF were reported between 1989 and 1992 (Table 8-3) (119,120,121,122,123,124,125,126 and 127). These studies represented treatment of 168 patients (156 evaluable) with tumors of various histologies. The majority of patients were part of a series of Southwest Oncology Group trials in which the TNF administration schedule was 150 μg per m^2 daily for 5 days given every other week for 8 weeks; experience with 127 of these patients was reported in 1991 (128). Seventeen percent of patients were removed from this study because of drug toxicity. Grade III toxicity consisted mostly of constitutional symptoms and was seen in 47% of patients. Grade IV toxicity was seen in 13% of patients and, in addition to the toxicities seen in phase 1 studies, included a subset of patients with disseminated intravascular coagulation, most of whom had pancreatic cancer.

Table 8-3 Phase 2 Trials of Intravenous Tumor Necrosis Factor

CR, complete response; MR, minimal or mixed response; PD, progressive disease; PR, partial response; SD, stable disease.

The therapeutic outcome of the phase 2 trials was disappointing (see Table 8-3). Only 2 of the 156 patients summarized in Table 8-3, both with renal cell cancer, achieved an objective response (126). Similarly, among 410 patients in phase 1 trials whose responses were recorded, only 11 had an objective response (93,95,105,106,107 and 108,110). The only complete response within this group was in a patient with renal cell cancer (110).

Duration of response likewise was disappointing, lasting no longer than 9 months in all but one patient (renal cell cancer, ongoing partial response at 2 years) (93,95,98,105,106,107 and 108,110,126).

Systemic Tumor Necrosis Factor Combined with Other Agents

Several studies sought to demonstrate a synergistic effect between TNF and other biologic agents because of the disappointing results in the phase 1 and 2 trials using systemic TNF alone. Such synergism previously had been demonstrated in mice using IL-2 (129,130), IFN-γ and IFN-α (84), standard chemotherapeutic agents (131,87), and hyperthermia (132). A human phase 1 and 2 trial of TNF and IL-2 yielded four objective responses in 38 patients (10.5%), a response rate somewhat lower than that seen with IL-2 alone (133). Other studies with this therapeutic combination demonstrated low maximum tolerated doses of TNF and similarly low response rates (134,135). Several trials combined TNF with IFN-γ and also demonstrated enhanced TNF toxicity without therapeutic benefit (136,137 and 138). The combination of TNF and IFN-α has shown occasional objective responses in humans (94,139,140). At this time, however, too few patients have been treated to draw any definitive conclusions. No evidence exists to suggest that TNF enhances the effectiveness of systemic chemotherapy in humans. One phase 3 study randomized patients to bischloromethyl-nitrosourea or bischloromethyl-nitrosourea and TNF. The response rate for bischloromethyl-nitrosourea was almost double that for the combined therapy with less systemic toxicity (141). Finally, although anecdotal reports exist of systemic TNF-inducing responses when combined with regional hyperthermia (142), by far the most widely used application of TNF and hyperthermia is in isolated perfusion, which is discussed in the section on Application of Tumor Necrosis Factor in Isolation Perfusion .

Early Trials of Regional Administration of Tumor Necrosis Factor

Because of the promising results of TNF in preclinical studies but disappointing outcome of phase 1 and 2 studies resulting from unacceptable systemic toxicity, the strategy of regional administration of TNF became increasingly attractive. Isolated perfusion with TNF is discussed in the section on Application of Tumor Necrosis Factor in Isolation Perfusion . Several other techniques of regional administration of TNF have been investigated (Table 8-4).

GI, gastrointestinal.

Several phase 1 trials have been conducted using intratumoral injection (see Table 8-4) (93,143,144,145,146 and 147). Although the applicability of this technique to patients with metastatic cancer is limited, these studies did show that TNF has antitumor effects in humans when sufficiently high local concentrations can be achieved. Response rates ranged from 0% to 50%. Even in nonresponders, however, hemorrhagic necrosis has been noted (93), and growth arrest has been documented in injected lesions while noninjected lesions in the same patient progressed (143). In addition, these studies showed that TNF could be injected locally without systemic toxicity, even to the liver or brain under radiologic guidance (143,147).

Murine studies that suggested that TNF demonstrated less toxicity when delivered intraperitoneally rather than intravenously (148) prompted several human trials treating peritoneal carcinomatosis or malignant ascites with intraperitoneal TNF (see Table 8-4) (149,150,151 and 152). In two of these studies that used TNF prepared by Knoll AG, response rates of 76% and 100% were achieved in patients with malignant ascites (150,152). Despite mild constitutional and gastrointestinal symptoms, no dose-limiting toxicity was reached. In two other studies using other commercial preparations of TNF (Genentech and Asahi), however, no objective responses were achieved, and dose-limiting abdominal pain and infectious complications were observed (149,151). These studies suggest some pharmacokinetic advantage may exist to using intraperitoneal TNF, but poorly understood

differences in commercial preparations warrant further investigation of this route of administration.

The use of intravesical TNF has been studied as an adjuvant and a therapeutic agent because of the high rate of local recurrence after transurethral resection of superficial bladder cancer (see Table 8-4) (153,154). Objective response rates of 22% and 23% have been reported. Even at high-dose levels (1,800 µg per m²), neither systemic toxicity nor measurable TNF in the systemic circulation was observed. Although few patients achieved complete responses in these trials, the results emphasize the potential benefits of regional application of TNF.

Finally, direct intraarterial infusion has been attempted to deliver TNF regionally (155,156). Mavligit et al. have reported a 14% partial response rate in patients with hepatic metastases refractory to standard therapies using a continuous 5-day infusion of TNF into the hepatic artery (155). The maximum tolerated dose (150 µg per m²) was similar to that achieved in trials using continuous i.v. infusion with grade IV hypophosphatemia as the dose-limiting toxicity and a notable absence of hypotensive episodes (155,157). Intraarterial TNF also has been used in patients with gliomas with objective responses in 20% of patients, symptomatic improvement in 47% of patients despite absence of tumor shrinkage, and radiographic evidence of necrosis in 70% of patients (156). Therefore, traditional radiographic follow-up may underestimate tumor response to TNF. These studies again support the concept of regional administration of TNF, which is discussed further in the section on Application of Tumor Necrosis Factor in Isolation Perfusion .

Gene Therapy with Tumor Necrosis Factor

The safe administration to patients with tumor-infiltrating lymphocytes retrovirally transduced with a marker gene by Rosenberg et al. established the feasibility of gene therapy in humans (158). The first potentially therapeutic gene investigated for use in cancer patients was TNF, based on the hypothesis that trafficking of transduced tumor-infiltrating lymphocytes to tumor would produce high local concentrations of TNF while avoiding systemic toxicity (159). Although some patients experienced tumor regression after such therapy (160), lymphocytes proved to have transcriptional and secretory limitations that precluded the widespread clinical use of this approach (161). These studies, however, encouraged the development of multiple strategies for the gene therapy of cancer with TNF and other cytokines.

Intratumoral injection of retroviral or adenoviral vectors carrying the TNF gene have demonstrated reliable TNF production and significant antitumor effects in mice (162,163), although systemic toxicity remains a significant concern (164). Studies using a membrane-bound mutant of TNF demonstrated greater safety (165). The use of conditional gene-expression systems may represent another means to control systemic toxicity (166). TNF gene therapy also may be synergistic with other forms of cancer therapy, including ionizing radiation (167,168), chemotherapy (169), and suicide gene therapy (170). Intraarterial injection of liposomes encapsulating the TNF gene has been shown to lead to an antitumor immune response and tumor regression in mice (171). These findings, along with the clinical use of TNF in the isolation perfusion setting, raise the possibility of regional administration of TNF gene therapy in humans.

Application of Tumor Necrosis Factor in Isolation Perfusion

Part of "8 - Tumor Necrosis Factor: Basic Principles and Clinical Applications in Systemic and Regional Cancer Treatment "

Background

Interest in the use of TNF as an anticancer agent was rekindled in 1992 with the initial report of Liénard and Lejeune regarding 23 patients who were treated with a combination of IFN-γ, TNF, and melphalan administered as a hyperthermic ILP for intransit extremity melanoma or unresectable high-grade extremity sarcoma (12). In this initial report, the overall response rate was 100% in 23 assessable patients with a complete response rate of 89%. Subsequently, a number of institutions have been evaluating the use of TNF applied via isolation perfusion using ILP for the treatment of intransit melanoma or unresectable extremity sarcoma and isolated organ perfusion of the liver, lung, or kidney for primary or metastatic unresectable cancers confined to these organs.

Rationale for the Use of Tumor Necrosis Factor in Isolation Perfusion

Isolation perfusion is a specialized surgical technique in which the vascular supply to a cancer-bearing region (extremity) or organ (i.e., liver, lung) is isolated, cannulated, and connected to an extracorporeal bypass machine consisting of an oxygenator, reservoir, heat exchanger, and roller pump similar to that used in cardiac surgical procedures. The organ or region of the body can then be perfused with therapeutic agents added into a solution that is composed of 1 U of packed red blood cells diluted in 700 mL of a balanced salt solution containing heparin. At the completion of treatment, the perfused organ or region is flushed with saline and colloid solution to remove the residual therapeutic agents before reestablishing the native vascular blood flow.

One advantage of isolation perfusion is that complete or near complete separation of the regional and systemic circulation should be theoretically possible in virtually all circumstances, so that leak of perfusate into the systemic circulation can be eliminated or minimized, thereby reducing systemic exposure and toxicity. Another advantage is that dose escalation of the therapeutic agents is limited largely by the tissue tolerance of the perfused organ or limb. Finally, the use of isolation perfusion allows delivery of hyperthermia to the perfused tissues, which has known synergistic tumoricidal effect with TNF (172,173) and chemotherapeutic agents (174,175), as well as direct tumoricidal effects in experimental models (176).

When using TNF via isolation perfusion, continuous monitoring of potential perfusate leak into the systemic circulation is an essential component of treatment because the 3- to 4-mg dose of TNF that is typically used in ILP is approximately tenfold higher than the maximum systemic tolerated dose of TNF in previous phase 1 trials (90,91,94,106). Several leak monitoring techniques using radiolabeled iodine-131–radiolabeled albumin (177,178) or technetium-99-labeled red blood cells (179,180) have been used and have been shown to be sensitive and reliable methods of detecting leak rates less than 1%. Leak rates greater

than 1% occur in 10% to 12% of patients undergoing ILP (177), due to the fact that, despite careful dissection of the iliac artery and vein and the use of a tourniquet at the root of the extremity, it is impossible to completely control small collateral blood vessels present in the pelvis. Control of perfusate leaks during ILP can be improved using various technical maneuvers, such as repositioning of the cannulae, tightening of the tourniquet, placing a partial occluding clamp on the venous outflow line to increase venous pressure within the perfusion circuit, or changing flow rates, which secondarily increases or decreases arterial pressures within the circuit (181). Thom and colleagues have shown that systemic perfusate leak during ILP with TNF, melphalan, and IFN as small as 1% result in significantly higher systemic levels of TNF and other inflammatory cytokines, such as IL-6 and IL-8, compared with patients with no leak (182). Leak of perfusate during liver perfusion does not typically occur because of the unique vascular anatomy of the liver.

TNF appears to be an ideally suited agent for isolation perfusion because sustained high perfusate concentrations of the protein can be routinely achieved during isolation organ or extremity perfusion (182,183). In fact, the perfusate doses of TNF initially measured at the beginning of treatment in the perfusate are approximately equal to the calculated concentration based on the dose of TNF administered into a fixed volume consisting of 1 L of perfusate and 300 to 400 mL of existing blood volume in the liver or extremity. Over the course of isolated limb or other perfusion, TNF concentrations stay largely stable, indicating little degradation or tissue absorption of the protein. Other factors that support the rationale for TNF applied via isolation perfusion are shown in Table 8-5 . Data from experimental models (78,79 and 80) and clinical reports (81,82) exist that support the notion that TNF exerts its antitumor effects primarily via actions on tumor-associated neovasculature and explain, in some part, the observation that TNF-based therapy administered via isolation perfusion is effective against a wide range of different tumor histologies.

Table 8-5 Rationale for Tumor Necrosis Factor Use in Isolation Perfusion

Can achieve high and sustained perfusate concentrations

Limited or no systemic exposure

Efficacy with single-dose administration

Synergy with chemotherapy and hyperthermia

Selective effects on tumor neovasculature

Treatment of Intransit Melanoma with Tumor Necrosis Factor Administered via Isolated Limb Perfusion

The initial clinical results with TNF, IFN-γ, and melphalan administered as a 90-minute hyperthermic ILP for intransit melanoma was confirmed in a subsequent report by Liénard and Lejeune regarding 29 patients with intransit melanoma who underwent 31 ILPs (184). The combination and doses of TNF and IFN-γ initially used in ILP were derived mostly empirically based on the fact that chemotherapeutic doses used in ILP historically have been approximately tenfold higher than the maximally tolerated systemic i.v. dose. A tenfold higher dose of TNF than that tolerated intravenously (200 to 250 µg per m^2) would be approximately 4 mg. Because leak rates greater than 10% occur in less than 2% of patients undergoing ILP, and because treatment can be terminated if unacceptable leak rates (>10%) occur by using a continuous leak monitoring system, that dose of TNF should be considered safe. IFN-γ was included in the regimen because of its ability to upregulate TNF-Rs on tumor and endothelium (185) and its synergistic antitumor activity with TNF in experimental models (84,186). The sequence in which agents were administered was also largely empirical. IFN-γ was administered subcutaneously at a dose of 200 µg for 2 days before ILP and given at the beginning of treatment into the perfusion circuit with TNF. After 30 minutes, melphalan was added slowly to the circuit, and treatment continued for 60 additional minutes. This regimen was modified in subsequent clinical trials.

The overall response rate in 23 assessable patients reported by Liénard and Lejeune was 100% with 21 patients or 90% experiencing a complete response to treatment (Table 8-6). Of

note, this cohort included 18 patients who failed a prior ILP. One-third of patients had more than ten intransit lesions present on extremity. The mean duration of response was 33 weeks, although median follow-up time was short (41 weeks) in this study (184).

Table 8-6 Results of Clinical Trials Using Tumor Necrosis Factor for Isolated Limb Perfusion to Treat Extremity Melanoma

Authors (Reference)	Trial Type (Phase)	Regimens	Assessable (n)	Response Rates CR (%)	PR (%)	Overall (%)

CR, complete remission; IFN, interferon; Melp, melphalan; PR, partial response; TNF, tumor necrosis factor.

Note: Melp/IFN/TNF: 90-minute perfusion described by Liénard et al. (184) with preoperative IFN-γ. Time 0 perfusate: IFN-γ, 0.2 mg; TNF, 4 mg; and melphalan, 10 mg per L (lower extremity), 13 mg per L (upper extremity) at time 30 minutes. Melp: Other regimens with standard melphalan dose as with the triple combination.

Regional (extremity) toxicity was considered acceptable with most patients experiencing reversible grade II erythema, as defined by Wieberdink (187). All patients were treated with prophylactic dopamine during ILP and for 48 hours thereafter to prevent hypotension and tachycardia. With considerably more experience, most investigators would agree that regional toxicity from TNF and melphalan is more severe than that of the original report. The incidence of severe systemic toxicity, however, has been overestimated, and the routine use of perioperative dopamine has been abandoned.

A subsequent multicenter, randomized trial was conducted in Europe in which patients received the original three-agent regimen versus melphalan and TNF while eliminating the preoperative and perfusate doses of IFN-γ. Two interesting results were reported from this trial (188). The complete response rates in either arm of this study were less than the 89% complete response rates in the initial series of patients. In addition, no significant difference existed in the response rates observed with the two arms, with the complete response rates being 78% and 69% with and without IFN, respectively (see Table 8-6).

A phase 3 random assignment trial was initiated at the National Cancer Institute in Bethesda, Maryland, and expanded to a multicenter trial comparing the three-agent regimen with a standard treatment arm consisting of a melphalan (alone) ILP administered in an otherwise identical fashion to the experimental regimen. Although this trial was terminated early because of the loss of TNF for clinical trials in the United States, an interim analysis reported a complete response of 80% for the three-drug regimen and 61% for the melphalan alone group (189). The duration of complete responses were similar in both arms of the trial. In an unplanned subgroup analysis of a small number of patients, it appeared that the complete response rate was greater for patients who had bulky or numerous lesions when TNF was included in the regimen.

The question as to the optimal dose of TNF used in conjunction with melphalan administered via ILP has not been critically evaluated. A study was reported by Vaglini et al. from Milan in which 12 patients with extremity melanoma were treated with the three-agent regimen (190). Of interest, three patients were treated with a dose of 2 mg of TNF. Two of the three patients had a complete response to treatment. Of 11 evaluable patients, seven complete responses occurred with an overall response rate of 64%. One institutional report of ILP in patients with various types of extremity tumors using TNF in a relatively unusual dose-deescalation regimen was reported in 1993 by Hill and coworkers (191). Nine patients were treated with a regimen using a short 45-minute total perfusion time, which included melphalan given at time 0 at a dose of 1.5 mg per kg followed 15 minutes later by TNF at doses of 500, 250, and 125 mg in three patients at each level. Of the patients on this deescalating study, four had melanoma and all had complete responses to therapy. The extremely low doses used in the report by Hill and coworkers are approximately 10% of the usual 4-mg dose. This dose was given for only 30 minutes compared with the usual 90-minute interval. The complete responses observed in the four patients treated using this strategy are remarkable and suggest that further work is necessary to determine the optimal dose of TNF.

A phase 1 study was reported in which the dose of TNF was escalated in the perfusion circuit from 4 to 6 mg (192). The peak perfusate levels of TNF were significantly higher when the higher dose of TNF was administered into the perfusion circuit. The complete response rate, however, was 76% in 26 patients treated in the 4-mg TNF group and only 36% in 12 patients in the 6-mg TNF group. This response rate was explained by differences in disease burden before therapy. Most notably, regional toxicity, including myopathy and neuropathy, was greater with the addition of higher doses of TNF. Taken together, these data suggest that lower, rather than higher, doses of TNF may be optimal in ILP.

Posner et al. have reported the only experience using TNF alone administered via ILP for intransit melanoma of the extremity (193). Six patients were treated with a 60- to 90-minute hyperthermic ILP in which three patients received either 1, 2, or 3 mg of TNF, and three patients received a total of 4 mg of TNF. Of these six patients, only one patient had a complete response of 7 months' duration and then relapsed. Three of the cohort underwent a second perfusion with the three-agent regimen, including melphalan, TNF, and IFN-γ, and all had a response to therapy. These data indicate that TNF alone applied via ILP for melanoma has essentially no meaningful antitumor activity. This raises many important questions with respect to the role of TNF in this setting. A prospective randomized trial is under way in Europe comparing melphalan alone with melphalan and TNF. A second similarly designed trial has been initiated in the United States.

Although the data do not definitively demonstrate any bonafide improvement in response rates when TNF is included in the regimen, some compelling data exist that indicate that TNF may be important in some patients. When TNF is included in the regimen with melphalan, the antitumor effects are rapid, and the mean time to response is 9 days (184), which is considerably different from the character and time course of responses in patients treated with melphalan alone (194). Secondly, a frequently rapid necrosis and eschar formation of cutaneous lesions are present that occurs with TNF reminiscent of the findings in preclinical murine models (195) (Fig. 8-1). Nevertheless, the complete response rate with ILP using melphalan alone for intransit melanoma has been reported to be between 50% and 65% (194). It is possible that the therapeutic benefit from the addition of TNF may be limited in patients with extensive or bulky disease. The duration of complete responses with melphalan alone or with melphalan combined with TNF was 320 and 495 days, respectively (188), illustrating the limitations of ILP with any regimen to provide durable disease control in the limb.
FIGURE 8-1. Sequential photographs of extensive cutaneous and subcutaneous metastases from a primary eccrine gland adenocarcinoma. The patient did not respond to combination systemic chemotherapy and intraarterial doxorubicin hydrochloride (Adriamycin) and platinum. The patient was treated with an isolated limb perfusion using tumor necrosis factor, interferon-γ, and melphalan at the National Cancer Institute in Bethesda, Maryland. Note the rapid eschar formation apparent within days of treatment and the selective effects of treatment on the tumor with sparing of normal skin along the edge and within the tumor bed.

Isolated Limb Perfusion with Tumor Necrosis Factor for Unresectable Extremity Sarcoma

Despite significant improvement in limb-sparing techniques to control high-grade extremity sarcoma, approximately 10% to

15% of patients present with primary or recurrent tumors that are not amenable to local therapy. Despite amputation in this group of patients, systemic metastases occur in more than 50% of patients. Therefore, strategies to preserve limb function translate into markedly improved quality of life for patients afflicted with this disease. Although ILP using various chemotherapeutics has been used in the past for extremity sarcoma, the data represent poorly controlled trials for which the benefit for limb perfusion has not been clearly established (196).

Most of the experience using TNF-based regimens administered via ILP for extremity sarcoma has come from a large multicenter trial. Results have been presented in several reports (197,198). The application of ILP in extremity sarcoma differs in several ways from ILP for intransit melanoma. For patients who have a large but potentially curable, locally unresectable extremity sarcoma as a result of its proximity or involvement with neurovascular or bony structures, ILP is administered as a neoadjuvant therapy with the goal of converting an unresectable lesion to a resectable one. Under these circumstances, after maximal tumor response to perfusion, an interval procedure is performed in which the tumor is excised usually between 4 to 12 weeks later. For patients who have multifocal sarcoma with no local resection option, ILP is administered primarily with curative intent. Lastly, in patients who have unresectable metastatic disease and a symptomatic primary tumor in place, limb perfusion is administered primarily as a palliative measure in which the success of therapy is gauged by its ability to provide sufficient tumor regression for relief of symptoms during the life of the patient. In the initial report from Liénard and Lejeune, four patients with extremity sarcoma were treated, all of whom had an objective response, including two patients who had a complete response at a follow-up of 12 and 23 months(12) (Table 8-7). Eggermont et al. initially reported the results of ILP with TNF, IFN, and melphalan for unresectable extremity soft tissue sarcoma in which 55 patients were treated (197). This cohort represented a relatively heterogeneous population, including 30 patients with primary lesions, 25 with recurrent sarcomas, and seven patients with low-grade tumors. Limb perfusion was administered exactly as described in the setting of intransit melanoma, using IFN administered for 2 days subcutaneously before limb perfusion. Tumor response was graded according to radiographic and pathologic criteria. If the lesion showed more than 50% necrosis on careful histopathologic examination, this was scored as a partial response in patients who underwent tumor resection, although, radiographically or clinically, the lesion may have shown only minimal or no size regression. If no evidence of tumor viability existed on histopathologic evaluation, the final outcome was scored as a complete response, even if a residual lesion was present radiographically or clinically. The clinical complete response rate was 18% and increased to 36% after pathologic evaluation. The clinical partial response rate was 64% and decreased slighly after the pathologic evaluation because some lesions that had partially regressed radiographically or clinically were found to be 100% necrotic. The overall response rate was 87%. Limb salvage was achieved in 84% of patients with follow-up ranging from 20 to 50 months (see Table 8-7). Of note, one-third of the 39 patients who underwent tumor resection after ILP received adjuvant external beam radiation therapy (EBRT). Olieman et al. have reported results in 34 patients with high-grade unresectable extremity sarcoma treated with TNF, IFN-γ, and melphalan ILP (199). In 15 patients with close or positive margins after resection, EBRT was administered with a local control rate of 100%. EBRT has been shown to provide excellent local control, however, even for large high-grade,

deep-seated lesions or in the presence of microscopically positive margins after resection without a prior ILP (200-202). Lastly, it is interesting that in the series reported by Olieman et al., 19 patients did not receive EBRT because of a possible adequate resection margin, or because a complete pathologic response to ILP occurred. In this cohort, the local recurrence rate was high at 26%.

Table 8-7 Summary of Isolated Limb Perfusion Trials Using Tumor Necrosis Factor for Extremity Soft Tissue Sarcoma

Authors (Reference)	n	Agents	Dose	Response Rate CR (%)	PR (%)	Limb Salvage (%)	Comments

CR, complete remission; EBRT, external beam radiation therapy; F/U, follow-up; ILP, isolated limb perfusion; PR, partial response; STS, short-term storage; TNF, tumor necrosis factor.

[a]Two patients received TNF without melphalan.

The last update reported by Eggermont et al. included data on 186 patients with locally advanced soft tissue extremity sarcoma with results that largely confirmed the earlier experience (198) (see Table 8-7). At a median follow-up of almost 2 years with a range of 6 to 58 months, an 82% limb salvage rate occurred in the setting of an overall clinical and pathologic response rate of 82%. Of note, only the first 55 patients received IFN-γ, and the effectiveness of therapy did not appear to be compromised when it was omitted from the treatment regimen. Based on the considerable efforts of the European investigators to establish ILP as a reasonable treatment option for patients with unresectable extremity sarcoma, it has been approved and licensed in Europe for this indication.

The cumulative U.S. experience of ILP with TNF for unresectable extremity sarcoma has been presented in abstract form (203) and includes results of 43 patients treated with TNF and melphalan, 12 of whom received IFN-γ (see Table 8-7). Using standard radiographic size criteria to define outcome, 56% of patients were shown to have an objective response to therapy with 11 patients (26%) having a complete response. Of the 11 patients who had a complete response, eight had multifocal sarcoma, such as angiosarcoma or epithelioid sarcoma. Fourteen patients (32%) eventually underwent amputation, resulting in a limb salvage rate of 68%.

Some of the most compelling clinical data that TNF exerts selective and significant effects on tumor neovasculature comes from results observed after ILP for advanced extremity sarcoma. Gutman et al. reported an overall response rate of 91% and a limb salvage rate of 85% in 34 patients with advanced extremity soft tissue sarcoma (204) (see Table 8-7). Pre- and post-ILP arteriograms showed complete obliteration of tumor-associated neovasculature with sparing of normal vessels. This phenomenon has been reported by others (82,205) (Fig. 8-2). We have observed this effect in a patient with large, high-grade thigh sarcoma treated with TNF alone, however, who had clinical and radiographic evidence of progression 2 months after ILP. Because of the fact that TNF alone has minimal antitumor efficacy in any isolation perfusion setting, the significance, if any, of these vascular effects must be questioned.

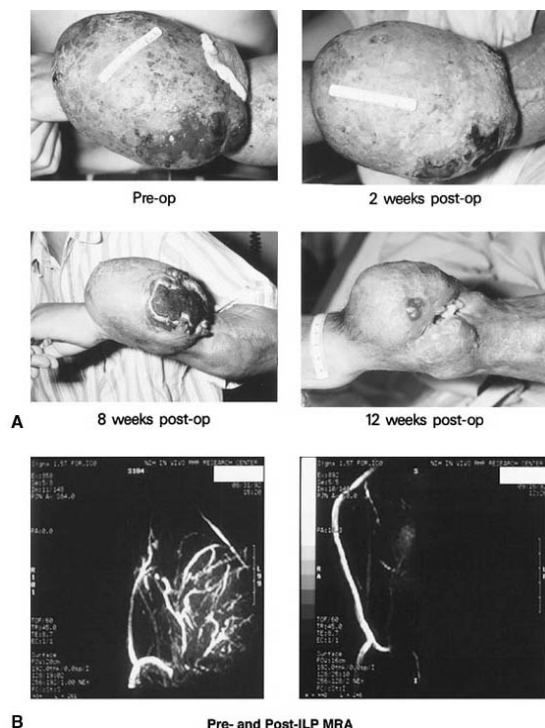
Pre- and Post-ILP MRA


FIGURE 8-2. A large, multiple, recurrent symptomatic Ewing's sarcoma arising from the dorsum of the left forearm in a patient with small-volume metastatic disease. The patient was treated with an isolated limb perfusion (ILP) using tumor necrosis factor, interferon, and melphalan at the National Cancer Institute in Bethesda, Maryland. A: Photographs show a significant antitumor response observed after ILP. The patient had a stable response in the arm but died approximately 2 years later from progressive systemic metastases. B: Magnetic resonance angiogram (MRA) shows a pre- and post-ILP tumor neovasculature before therapy (left) and the complete obliteration of the neovasculature after ILP (right).

Results of Tumor Necrosis Factor Administered via Isolated Hepatic Perfusion for Unresectable Liver Cancers

Regional treatment strategies for primary or metastatic cancers confined to the liver have been under clinical evaluation because of their common ability to apply dose-intensive therapy to a cancer-bearing region of the body with apparently improved efficacy over the best available systemic treatments for many patients with colorectal cancer, neuroendocrine tumors, ocular melanoma, or primary hepatocellular cancers (206). The first application of isolated hepatic perfusion (IHP) for unresectable cancers of the liver was performed in the late 1950s.

IHP has never gained widespread clinical application, however, because of its complexity, the risks associated with the major operative procedure necessary to deliver this therapy, and the overall lack of established efficacy using standard therapeutics. Based on the results using TNF and melphalan administered via ILP for bulky intransit melanoma metastasis or high-grade unresectable extremity sarcoma, a number of institutions evaluated this regime administered via IHP in the early 1990s.

The technique of IHP has been described in detail and conceptually is similar to ILP. During hepatic perfusion, however,

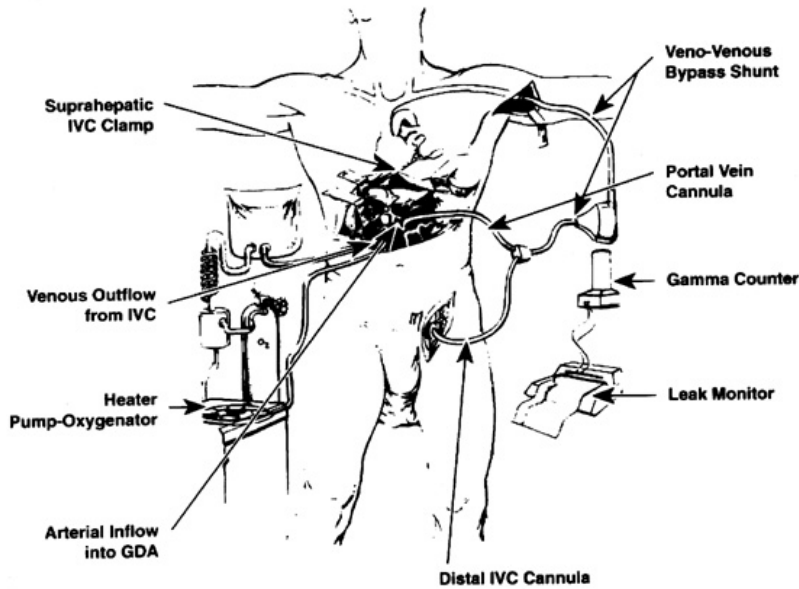
inferior vena caval and portal blood flow must be temporarily interrupted. To maintain hemodynamic stability during IHP, a second veno-veno bypass circuit is used to shunt venous return from these vessels to the heart. A schema of the hepatic perfusion setup is shown in Figure 8-3 .


FIGURE 8-3. Isolated hepatic perfusion procedure shows the extracorporeal bypass circuit on the patient's right with inflow through the gastroduodenal artery (GDA) and outflow obtained from a cannula positioned in an isolated segment of retrohepatic inferior vena cava. Portal venous and inferior vena cava (IVC) flow are shunted externally to the axillary vein to maintain venous return to the heart during treatment. The bypass circuit is shown on the patient's left. Just below the bypass circuit is the gamma detection camera, which is used for continuous intraoperative leak monitoring.

Because little information was available regarding liver tolerance to IHP with TNF alone or TNF and melphalan, a phase 1 trial was initiated by the Surgery Branch of the National Cancer Institute. This trial used a fixed low dose of IFN-γ administered in a schedule identical to the ILP schedule with escalating-dose TNF administered as a 60-minute IHP. A subsequent phase 1 trial of alternating dose escalation of TNF and melphalan was then conducted omitting IFN-γ from the treatment regimen. In the initial 16 patients treated with escalating-dose TNF alone, dose-limiting toxicity was observed at 2 mg of TNF, which was manifested by coagulopathy. In the subsequent phase 1 trial, the maximum safe, tolerated doses of TNF and melphalan when used in combination were 1 mg and 1.5 mg per kg, respectively, with dose-limiting toxicity manifested as veno-occlusive disease for melphalan and coagulopathy again for TNF (207). Using a dosing schedule of 1.5 mg per kg of melphalan, the mean dose administered in a subsequent phase 2 trial of TNF and melphalan was approximately 105 mg, which is similar to the total dose administered in isolated lower extremity perfusion for intransit melanoma or sarcoma. The dose of TNF that the liver can tolerate, however, is substantially

lower than that administered into the extremity, which reflects the highly variable tissue tolerances to this protein.

The results of IHP using TNF and melphalan from several centers around the world are shown in Table 8-8 . de Vries and coworkers reported results in eight patients treated with 1 mg per kg of melphalan and 0.4 mg of TNF administered as a 1-hour hyperthermic perfusion (208). The treatment mortality in this series was significant, with 33% of patients suffering fatal perioperative treatment-related complications. In five of six evaluable patients, however, evidence existed of significant antitumor effects from treatment. Hafström reported results in 11 patients treated with a combination of agents at doses somewhat lower than used in other centers. Treatment-related mortality in this series was 18% (209). The low efficacy of the treatment most likely reflects the fact that doses of melphalan and TNF were lower than those used at other centers. Oldhafer reported a series of 12 patients treated with IHP, of whom six patients received TNF and melphalan (210). In this group of six patients, however, no treatment mortality was evident in the overall cohort of 12 patients. Two patients treated with mitomycin alone succumbed to hepatic veno-occlusive disease after treatment. In the six patients treated with TNF and melphalan, three patients had a response to treatment.

Table 8-8 Summary of Isolated Hepatic Perfusion Trial Using Tumor Necrosis Factor

Authors (Reference)	n	Agent(s)	Dose	Duration	Temp (˚C)	Results
de Vries et al. (208)	8	Melphalan	1 mg/kg	1 hr	>41	Mortality, 33%
		TNF	0.4 mg			5/6 PRs
	1	TNF Alone	0.8 mg			
Hafström and Naredi (209)	11	Melphalan	0.5 mg/kg	1 hr	39	Mortality, 18%
		TNF	30–200 µg			Morbidity, 45%
						3/11 PRs
Oldhafer et al. (210)	6	Melphalan	60–140 mg	1 hr	40–41	Mortality, 0%
		TNF	200–300 µg			1/6 CR, 2/6 PR
Alexander et al. (211)	50	Melphalan	1.5 mg/kg	1 hr	39.5–40	Mortality, 4%
		TNF	1.0 mg			1/48 CR, 36/48 PRs

CR, complete response; PR, partial response; TNF, tumor necrosis factor.

The largest institutional trial with IHP using TNF and melphalan has been reported from the National Cancer Institute and includes more than 50 patients treated with melphalan and TNF at doses derived from initial phase 1 dose-seeking studies (see Table 8-8). In a cohort of 50 patients, a treatment-related mortality of 4% was evident, of which one was secondary to hepatic veno-occlusive disease. The overall response rate in this trial was 75%. Responses were observed across all histologies treated (Table 8-9).

Table 8-9 Response to Tumor Necrosis Factor and Melphalan Isolated Hepatic Perfusion in 50 Patients

Histology	n	Assessable	CR	PR	Overall Response Rate (%)
Overall	50	48	1	35	75
Colorectal	37	35	—	25	71
Ocular melanoma	8	8	1	6	88
Other	5	5	—	4	80

CR, complete radiographic response; PR, partial radiographic response.

Response data in 34 patients who had been evaluated in detail (211) are shown in Table 8-10 . Of note, responses were observed in patients regardless of tumor size, number of lesions, or percent of liver replaced by tumor. The duration of responses

are highly variable, however, and strategies that improve the duration of response are under evaluation. The mean duration of response in the liver after therapy is approximately 9 months and ranges from 6 to 48 months (Fig. 8-4).

Table 8-10 Response to Isolated Hepatic Perfusion Based on Number of Lesions, Diameter of Largest Tumor, or Percent Hepatic Replacement in 33 Evaluable Patients

	n	PR or CR	%
Overall	33	25	25
Number[a]			
1-4	9	7	78
5-19	13	9	69
≥20	11	9	81
Diameter largest lesion (cm)			
<5	4	2	50
5.0-9.9	12	9	75
≥10	17	14	82
% Hepatic replacement			
<20	6	5	83
20-49	15	10	66
≥50	12	10	83

CR, complete response; PR, partial response.

Pre-op MRI

10 Months Post-IHP MRI
FIGURE 8-4. Pre- and post–isolated hepatic perfusion (IHP) magnetic resonance imaging (MRI) in a patient treated with 1-mg tumor necrosis factor and 1.5 mg per kg melphalan at the National Cancer Institute in Bethesda, Maryland. The patient did not respond to systemic and intraarterial chemotherapy. The patient had a stable response in the liver but developed new pulmonary metastases 13 months after treatment.

The liver is subjected to significant physical manipulation, brief periods of eschemia, and the effects of perfusion using high-dose TNF and melphalan. Most patients have significant but transient elevations in hepatic function tests, which typically return towards baseline within 7 to 10 days of treatment (211). The systemic effects of IHP with high-dose TNF and melphalan may occur primarily as a result of the release of proinflammatory cytokines presumably from the liver after hepatic perfusion. IL-6 and IL-8 levels have been routinely detected in patients after hepatic perfusion. The release of vasoactive cytokines from the liver transiently after perfusion may be responsible for some of the hemodynamic alterations that are typically observed after treatment. Leak of perfusate TNF into the systemic circulation is extremely rare when a complete and systematic preparation of the liver is performed before IHP. Systemic TNF concentrations are not measurable in patients after hepatic perfusion and were only detectable in 2 of 34 patients who also had a small (<3%) leak of perfusate during treatment.

IHP with TNF and melphalan may be ideally suited for patients with ocular melanoma metastatic to liver because of the

selective uptake of melphalan by melanocytes (212). The response rate in this subgroup of patients treated with TNF and melphalan is more than 80%, and, in some cases, has been durable, extending beyond 2 to 3 years (Fig. 8-5).
FIGURE 8-5. Pre- and post–isolated hepatic perfusion (IHP) magnetic resonance imaging (MRI) in a patient with metastatic ocular melanoma to the liver. The patient was treated with 1-mg tumor necrosis factor and 1.5 mg per kg melphalan at the National Cancer Institute in Bethesda, Maryland. The patient had a solitary site of extra hepatic intraabdominal recurrence resected 2 years after treatment and has an ongoing response in the liver 2.5 years after IHP.

The initial results with hepatic perfusion in various centers have been encouraging. With additional application, IHP may be a more routinely considered option for people with extensive metastatic or primary unresectable cancers confined to the liver. The exact contribution of TNF in IHP when combined with melphalan has not been established. In the initial phase 1 study of escalating-dose TNF alone, the overall response rates in that cohort of patients was only 20% and occurred in patients treated with the lowest doses of TNF, suggesting transient antitumor effects may have been caused by some other nonspecific effects of the perfusion, such as eschemia or acidosis.

Because TNF has presumed effects of the tumor neovasculature (82,205), the effect of TNF on capillary leak in tumor during IHP was evaluated and reported by Alexander et al. (213). In this study, patients were administered iodine-131–radiolabeled albumin as part of the leak monitoring system. Biopsies of liver and tumor before and after therapy and interstitial concentrations of iodine-131–radiolabeled albumin were determined. A significant increase in capillary leak was observed in tumor at the end of treatment compared with liver. This augmentation and capillary leak were comparable in patients who received TNF and in those who did not, suggesting that the augmentation in capillary leak must occur via other unknown TNF-independent mechanisms. The exact contribution of TNF administered via hepatic perfusion deserves continued and critical clinical evaluation.

Isolated Lung or Liver Perfusion with Tumor Necrosis Factor

A phase 1 trial was reported by Pass and colleagues from the National Cancer Institute of isolated lung perfusion with escalating-dose TNF under conditions of moderate hyperthermia for patients with unresectable pulmonary metastases (214). Twenty patients were treated with doses of up to 6 mg of TNF. A short-term (6 to 9 months) decrease in nodules was noted in only three patients. No long-term sequelae of high-dose TNF perfusion occurred in the pulmonary parenchyma and all patients except one were extubated immediately or within 24 hours of the procedure. Consistent with the findings of TNF alone, perfusion of the limb or liver and minimal antitumor efficacy was observed in this trial. Further application of isolated lung perfusion combining TNF with chemotherapeutics is necessary to determine the use of isolated lung perfusion for pulmonary metastases.

A case report of isolated kidney perfusion using TNF has been reported by Walther and colleagues from the National Cancer Institute (215). The application of TNF via isolated kidney perfusion may be limited to unusual circumstances when renal-sparing surgery is indicated, such as in familial multifocal bilateral renal cell cancer syndrome.

Summary

Part of "8 - Tumor Necrosis Factor: Basic Principles and Clinical Applications in Systemic and Regional Cancer Treatment "

In conclusion, although enthusiasm for the use of TNF administered via isolated perfusion for regionally advanced cancer of the extremity or liver has been considerable, several major issues remain unanswered. With respect to ILP for intransit melanoma, the use of TNF has focused concern on the potential systemic toxicities of TNF and has heightened awareness of the importance of the technical aspects of isolation perfusion; most notably, the need for continuous leak monitoring systems to ensure complete vascular isolation with minimal leak of perfusate. These technical refinements may be responsible in part for the relatively high complete response rate observed in both arms of a single phase 3 random assignment trial comparing melphalan

alone with melphalan, TNF, and IFN. These data suggest that the ability to define a role for TNF in ILP for intransit melanoma may be difficult. For patients with a small or limited number of lesions, melphalan alone may be efficacious as the combination therapy. For high-grade extremity sarcoma, the weight of data from the multiinstitutional European trial has been sufficient to result in the licensing of TNF for this indication in Europe. The experience with TNF-based ILP for high-grade extremity sarcoma in the United States is limited.

IHP for unresectable cancers confined to the liver using TNF-based regimens at a small number of centers around the world is under active evaluation. Many patients with unresectable cancers confined to the liver have conditions based on the size and number of lesions for which IHP may be ideally suited. Data suggest that IHP can be conducted safely. Continued clinical evaluation is warranted to define those patients best suited for TNF-based treatment.

Interferon-α and -ß: Basic Principles and Preclinical Studies

Bryan R. G. Williams

Introduction

Part of "9 - Interferon-α and -ß: Basic Principles and Preclinical Studies "

Interferons (IFNs) are antiviral cytokines originally described by Issacs and Lindenman (1) as factors induced by viral infection that can inhibit the replication of other viruses. In fact, IFNs are synthesized and secreted by vertebrate cells in response to other stimuli in addition to viruses, including chemical compounds, microbial and cellular products, and even other cytokines. Cells exposed to IFNs respond by acquiring resistance to subsequent viral infection. IFNs are also able to inhibit the proliferation of cancer cells. IFNs are used as therapeutic agents for the treatment of viral infections and cancer because of their properties that induce antiviral resistance and regulate cell growth. IFNs are also able to modulate the immune response. This has led to their clinical use in diseases with underlying immunologic etiologies, including forms of multiple sclerosis. Although IFNs were discovered and named for their ability to induce resistance to viral infection, IFNs were the first described members of what is known to be a large family of biologically important regulatory cytokines. IFNs are the only members of this family with potent antiviral activity.

Studies on the mechanism of action of IFN have provided significant insight into the mechanism of action of other cytokines, including the characteristics of receptors, signal transduction pathways, and transcriptional regulation of inducible genes. In a physiologic context, however, it is important to remember that IFNs act in concert with a complex network of other cytokines. They are essential to the development of a normal immune response. IFNs provide a bridge from innate to specific immunity and are potent immunomodulators.

The therapeutic potential of IFNs was apparent from their mode of discovery. The subsequent description of antiproliferative and immunomodulatory activities spurred further interest, but early clinical use was limited to IFN produced from virus-induced buffy-coat leucocytes. These trials, particularly in osteogenic sarcoma, however, encouraged the molecular cloning of IFN, which radically changed its availability and paved the way for subsequent regulatory approval for use in different malignancies and other diseases. More than 40 years of basic and clinical research has produced a vast literature on the mechanisms of action of IFNs. Comprehensive reviews (2,3) are available, and, when consulted along with this chapter, offer a current picture of IFN-α and -ß biology.

Discovery and Description of Interferons

Part of "9 - Interferon-α and -ß: Basic Principles and Preclinical Studies "

IFNs were discovered in 1957 as antiviral agents synthesized in influenza virus–infected chick embryo cells (1). IFNs are produced by cells in response to viral infection and confer an antiviral state on cells exposed to them. In addition to avians, IFNs are also present in fish, reptiles, and mammals. The cloning and characterization of IFNs revealed the existence of two types: type I and type II. The type I IFN family predominately comprises IFN-α and -ß but also includes two other subfamily members: IFN-ω and IFN-τ. Type II is comprised of only IFN-γ.

The Type I Interferon Gene and Proteins

Part of "9 - Interferon-α and -ß: Basic Principles and Preclinical Studies "

IFN-α is induced mainly in leucocytes or in lymphoblastoid cell lines, whereas IFN-ß is a fibroblast cell product. The genes and corresponding proteins of the type I IFN superfamily are structurally related, and the human genes are clustered within 400 kilobase (kb) on the short arm of chromosome 9. Fourteen genes comprise the human IFN-α family. Twelve IFN-α proteins of 165- or 166-amino acid residues are produced from these 14 genes (two of the genes are pseudogenes) (Table 9-1). In primates and rodents, only a single IFN-ß gene exists. In humans, the IFN-ß gene is located at the telomeric end of the α cluster. Six IFN-ω genes exist in humans, but only one is functional. IFN-ω (which has not been described in mice) is characterized by a 6-amino acid extension at the carboxyl terminal compared with IFN-α (4). The functional IFN-ω gene maps to the end of the IFN-α cluster between IFN-α2 and -ß. IFN-τ (trophoblast) is unique to cattle and sheep, where it is essential for the development and maintenance of pregnancy. IFN-ω and -τ have 172 residues. IFN-τ, like IFN-ω, has a 6-amino acid carboxyl terminal extension when aligned with IFN-α. Four conserved cysteines exist in IFN-α proteins, forming two intramolecular disulfide bonds (cysteine 1 to cysteine 98 and cysteine 29 to cysteine 138). Human IFN-α proteins do not contain *N*-glycosylation sites and are not *N*-glycosylated. The solution of the crystal structures of IFN-α2 and IFN-ß has placed them in a class of helical cytokines that is defined by five

short helices, labeled A to E. Two surfaces on opposite sides of the molecule are sensitive to amino acid substitutes, supporting a model for single ligand interaction with two receptor chains analogous to growth hormone-receptor interactions.

Table 9-1 Human Interferon Genes and Proteins

Genes	Proteins
IFNA1	IFN-α_1, IFN-αD
IFNA2	IFN-α_2 (IFN-A$_{2B}$), IFN-αA (IFN-α_{2a}), IFN-α_{2c}
IFNA4	IFN-α_{4a} (IFN-α76), IFN-α_{4b}
IFNA5	IFN-α_5, IFNα-G, IFN-α61
IFNA6	IFN-α_6, IFN-αK, IFN-α54
IFNA7	IFN-α_7, IFN-αJ, IFN-αJ1
IFNA8	IFN-α_8, IFN-αB2, IFN-αB
IFNA10	IFN-αC, ΨIFN-α10, ΨIFN-αL, IFN-α6L
IFNA13	IFN-α13 (sequence identical to that of IFN-α_1)
IFNA14	IFN-α14, IFN-αH, IFN-αH1
IFNA16	IFN-α16, IFN-αWA, IFN-αO
IFNA17	IFN-α17, IFN-αI, IFN-α88
IFNA21	IFN-α21, IFN-αF
IFNA22	ΨIFN-αE
IFNB1	IFN-β
IFNW1	IFN-ω

IFN, interferon.

IFN-ß has 166-amino acid residues, an *N*-glycosylation site at position 80, and is glycosylated as a mature protein. Both unglycosylated, *Escherichia coli*-derived, recombinant IFN-ß and glycosylated products produced from mammalian cell-expression vectors are used in clinical applications.

Induction of Interferon Synthesis

Part of "9 - Interferon-α and -ß: Basic Principles and Preclinical Studies "

Inducers

Type I IFNs can be induced by different infectious agents in most vertebrate cell types, although viral infection is most commonly linked to IFN production. Bacteria, mycoplasma, and protozoa also induce IFNs in different cells. Low-molecular-weight molecules can induce IFNs in animals and remain under clinical investigation as IFN inducers (5). Bacterial lipopolysaccharide is an efficient inducer of type I IFNs in mononuclear phagocytes. The mechanisms of induction have been studied in detail only with viruses. Viral induction of IFN synthesis is mediated by double-stranded RNA (dsRNA), although, in some cases, constituents of viruses, such as hemagglutinin (influenza virus), may act as IFN inducers in animals and humans. Viral dsRNA, which is produced during the replication of DNA and RNA viruses, is an effective inducer of type I IFNs in cell culture. The type I IFN genes are usually transcriptionally silent unless activated through a signal transduction pathway mediated by dsRNA. The synthesis of IFN-ß, however, has been detected in normal epithelial cells (6). The nature of the inducer is not known, but different cytokines and growth factors can induce IFNs in cell culture and may provide physiologic stimuli. In tumors, a downregulation of IFN-ß exists at the tumor-epithelial cell interface, suggesting that maintenance of IFN-ß expression in epithelial cells is important in maintaining homeostasis (7).

Type I IFN synthesis is regulated at the transcriptional and posttranscriptional levels. Transcriptional activation of the type I IFN genes requires the formation of active transcription factor complexes on enhancer elements located 5" of the transcriptional start sites of these genes. This is achieved by a combination of posttranscriptional activation of preexisting transcriptional factors and displacement of repressors, which, in the absence of inducer-mediated signals, silences the type I IFN genes. Type I IFN messenger RNAs (mRNAs) are unstable because they are rapidly degraded as a result of the presence of instability sequences in the 3" untranslated regions of their transcripts. Thus, mRNA synthesis in response to virus or dsRNA induction is transient and returns to basal levels within a few hours. Type I IFN induction can be enhanced by priming cells with small amounts of type I IFN. This results in a maximum response after exposure to inducers, such as dsRNA or viruses. Inhibitors of protein synthesis, such as cycloheximide, can superinduce IFN mRNA by inhibiting the synthesis of negative regulatory factors that act at the levels of transcription and mRNA stability. Overall, the molecular mechanisms regulating the transcriptional induction of type I IFN synthesis involve a complex interplay between *cis*-acting negative and positive regulatory DNA elements and their cognate transcription factors. The steady level of RNA product is dictated by host mRNA stability factors, which are themselves subject to poorly understood regulators factors.

Induction of Interferon-ß Synthesis

IFN-ß gene regulation has been studied in detail as a model for understanding the role of inducible enhancer elements in regulating gene expression. Approximately 200 base pairs of 5" regulatory sequences upstream of the transcriptional start site constitute the virus-responsive promoter of IFN-ß. Overlapping positive regulatory domains (PRDI-IV) and a negative regulatory element (Fig. 9-1) originally identified by deletional and point mutation analyses (8) are key features of this promoter.
FIGURE 9-1. Transcriptional activation of the interferon-ß (IFN-ß) promoter. **A:** Different transcription factors are activated as a result of viral infection and bind cognate DNA elements arranged in a unique pattern in the promoter region of the IFN-ß gene. **B:** The high mobility group protein (HMG1)(Y) is required for assembly of the complex. The transcriptional coactivator Creb-binding protein (CBP) integrates the action of different transcription factors. (ATF, activating transcription factor; IRF, IFN regulatory factor; NF-κB, nuclear factor kappa B; PRD, positive regulatory domain.)

The transcriptional activation of the human IFN-ß gene by viruses is dependent on the assembly of a higher-order transcription-enhancer complex, termed the *enhancersome* (9). The assembly of the enhancersome requires different transcription factors and is coordinated through specific interactions with the high mobility group protein, HMG1(Y). These proteins promote the cooperative binding of the transcription factors and mediate their synergistic action *in vivo*. PRDI, which overlaps with PRDII, binds IFN-regulatory factor 1 (IRF-1) and other IRF family members. PRD-II is recognized by nuclear factor kappa B (NF-κB) and PRDI-V binds a heterodimer consisting of activating transcription factor 2 and c-jun. The transcriptional activator proteins, IRF-3 and IRF-7, as well as the transcriptional coactivators P300 and Creb-binding protein (CBP), are also required for induction of IFN-ß synthesis. The enhancersome complex includes activating transcription factor-2, C-jun, NF-κB, HMG1(Y), and IRFs and can be assembled *in vitro* to stimulate IFN-ß gene transcription (9). Several other DNA-binding proteins have been described that have no transcription activation potential, but can still bind to the enhancer region. These include IRF-2, PRDI-binding factor 1, and

homodimers of the NF-κB component, p50. These proteins may repress the IFN promoter in the uninduced state. In virus induction, HMG1(Y) acts to cooperatively assemble the different transcriptional activators. Once assembled, the activation domains of these factors form a high-affinity binding site for the recruitment of the CBP/p300 coactivator. CBP/p300 interacts with the RNA polymerase II holoenzyme via its carboxyl terminal domain, whereas the activation domains of the other transcriptional activators contact components of the basal transcriptional apparatus. CBP/p300, which contains an intrinsic histone acetyltransferase, subsequently acetylates HMG1(Y), destabilizing the enhancersome, thereby terminating IFN-ß gene transcription (10). Thus, the coordinate activation of a number of transcriptional-activated proteins and their cooperative assembly into a transcriptional-enhancer complex is required to drive transcription of the IFN-ß gene after viral infection or dsRNA treatment of cells (see Fig. 9-1). In the mouse IFN-ß promoter, the binding of histone H1 to an upstream adenosine thymidine-rich region of DNA appears to be responsible for the constitutive repression of the promoter. The displacement of histone H1 by HMGI(Y) protein may convert the IFN-ß promoter from a repressed state to an active state (11).

Interferon Receptors

Part of "9 - Interferon-α and -ß: Basic Principles and Preclinical Studies "

IFNs mediate their effects by binding and activating high-specific-affinity receptors on cell surfaces. This is a necessary first step in initiating a cellular response to IFNs and results in the generation of signals required for transcriptional induction of IFN-responsive genes, which encode the specific effectors for the different activities of IFNs. IFN-α and -ß bind to the same type I receptor, whereas IFN-γ binds to a distinct type II receptor. IFNs exhibit host range restriction in their activities, mediated at the level of receptor binding. In general, human IFNs act on human cells and show only limited activity on cells from other species, although this varies among the several IFN-α subtypes.

The type I IFN receptor is present at only a few thousand binding sites per cell and exhibits an affinity for IFN in the subnanomolar range. Early investigations using radiolabeled recombinant type I IFNs revealed the cell surface expression of low-affinity and high-affinity receptors for type I IFNs (12,13,14,15,16,17 and 18). Studies on binding and cross-linking of radiolabeled IFNs to the cell surface suggested the existence of a multisubunit structure for the type I IFN receptors (19,20). This was subsequently demonstrated using specific monoclonal antibodies to receptor subunits (21). It is known that to elicit a cellular response, the type I IFN-α/ß receptor requires two subunits, ifnar-1 and ifnar-2, which belong to the class II family of helical cytokine receptors (Fig. 9-2). Ifnar-1 was the first molecularly characterized subunit and was identified by an expression-cloning strategy using the species-specific recognition property of type I IFNs. This protein conferred resistance to vesicular somatitis virus replication in mouse cells in the presence of human IFN-α8 (22). The human ifnar-1 complementary DNA (cDNA) encodes a glycoprotein of 557 amino acids with a 436-amino acid extracellular region and a 21-amino acid transmembrane domain, followed by a cytoplasmic tail of 99 amino acids (22). When the human ifnar-1 cDNA was expressed in mouse cells, however, the protein could only bind to IFN-α8 at 37°C, but not to the other type I human IFNs (22). The human IFN-α8 was later found to possess some binding affinity for the mouse receptor. Therefore, ifnar-1 was not sufficient to confer responsiveness to all type I IFNs, indicating that another species-specific ligand-binding receptor subunit was required for signal transduction.
FIGURE 9-2. Essential components of interferon (IFN) signaling. In ifnar, *C* denotes conserved cysteine residues, and *TM* denotes the transmembrane domain. In the Janus kinase, *UR* refers to a unique region and *JH* refers to the Jak homology domain. In the signal transducers and activators of transcription proteins (STATs), *Y* denotes a regulatory tyrosine residue.

A human IFN-α binding protein was purified from urine and sequenced, leading to the identification of a novel subunit of 331 amino acids for the type I IFN receptor (23). This protein, termed *ifnar-2b* (or the ß$_s$ *subunit*), was not a functional receptor subunit. A longer 515-amino acid form of human ifnar-2, termed the *ifnar-2c* (or ß$_L$ *subunit*), was subsequently identified as the universal ligand-binding subunit of the type I IFN receptor (24). Neither ifnar-1 nor ifnar-2 alone binds to IFNs with high affinity, and the functional type I IFN receptor comprises ifnar-1 and ifnar-2c (25,26). Ifnar-1 and ifnar-2 are required to constitute a high-affinity α/ß receptor, but only

ifnar-2c is capable of transducing a signal after ligand binds to the receptor complex. The human ifnar-2 gene, located on chromosome 21, produces four transcripts, encoding the three different polypeptides through alternate splicing and differential usage of alternate polyadenylation sites (27). Ifnar-2a is probably secreted, whereas ifnar-2b and ifnar-2c are expressed as transmembrane proteins with identical extracellular and transmembrane domains but divergent cytoplasmic domains of 67 and 76 amino acids, respectively. When overexpressed, ifnar-2b can dominantly inhibit the IFN response (27).

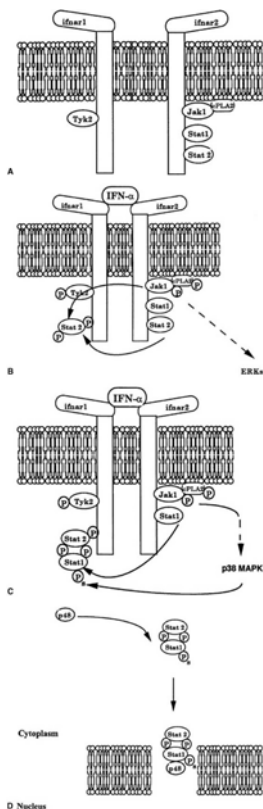
The solution structure of other members of the helical cytokine receptors II family (IFNGR1 and tissue factor) has allowed the three-dimensional structure of the extracellular domains of ifnar-1 and ifnar-2 to be modeled (28). The domains are divided into two subdomains of approximately 100 amino acids (sd100A and 100B from the N-terminal), which each adopt an immunoglobulin-like fold with seven ß strands (S1 to S7) in two ß sheets. The ifnar-1 extracellular domain (317 amino acids) has a duplication of these subdomains. It is important to note that the structural integrity and formation of an active IFN-α/ß binding site not only requires ifnar-1 and ifnar-2, but also requires the association of intracellular Janus kinases (Jaks) with the cytoplasmic domains. A binding site exists for the signal transducing Jak, Tyk2 (Fig. 9-3), on the cytoplasmic tail of the ifnar-1 receptor subunit. The ifnar-2c subunit is 315 amino acids. The first 217 amino acids constitute the ligand-binding domain, followed by a transmembrane-spanning region of 22 amino acids and a cytoplasmic tail of 76 amino acids, which contains a binding site for another member of the Jak family, Jak1. The high-affinity binding and signaling receptor for IFN-α/ß requires ifnar-1 and ifnar-2c and their associated kinases.


FIGURE 9-3. Interferon-α (IFN-α) signal transduction. **A:** Components of the signal transduction pathway are preassociated with the unliganded receptor. **B:** IFN-α binding activates Janus kinases (Jaks), resulting in phosphorylation of different components of the pathway. Signal transducers and activators of transcription proteins (STAT)2 moves to its docking site on ifnar1. **C:** Phosphorylated STAT1 interacts via SH-2 domains with STAT2, p38 mitogen-activated protein kinase (MAPK) phosphorylates serine 727 on STATs, and the heterodimers are released from the receptor and interact with p48 to form IFN-stimulated gene factor-3. **D:** IFN-stimulated gene factor-3 migrates to the nucleus.

IFN-ß shares only 35% identity with the IFN-α subtypes and appears to engage the α/ß receptor differently. This can result in the activation of selective subsets of genes (29,30) by IFN-ß, even though it binds and activates the same receptor. Apparently, distinctive structural differences are transmitted through the membrane to the cytoplasmic domains of the receptors, which then mediate a differential response. Mutant cell lines lacking Tyk2, which are completely defective in their response to natural IFNs, IFN-α1, or IFN-α2, still respond to IFN-ß or IFN-α8, albeit with reduced activity. In fact, by using these and other mutant cell lines reconstituted with different mutant proteins, three distinct modes of type I interaction with receptor subunits have been discerned: IFN-α with ifnar-1 and ifnar-2, IFN-ß with ifnar-1 and ifnar-2, and IFN-ß with ifnar-2 alone (28). Thus, IFN-α and -ß signal differently through their receptors because they interact with the receptor in different ways.

A tight correlation exists between receptor occupancy and the transcriptional response to IFN. The degree of receptor occupancy is a rate-limiting step in determining the transcriptional response to IFN, which is transient and accompanied by the downregulation of receptors on the cell surface (31). Downregulation of type I IFN receptors is also seen *in vivo* on peripheral blood lymphocytes after IFN therapy (32). This is a temporary state. Receptors reappear on the cell surface 24 to 48 hours later.

Signaling Pathways Activated by Interferon-α and -ß

Part of "9 - Interferon-α and -ß: Basic Principles and Preclinical Studies "

Type I IFNs can be induced ubiquitously, and most cells have a common response pathway initiated by the engagement of cellular receptors. The most well-characterized components required for this response are the receptor subunits themselves, Jaks and signal transducers and activators of transcription proteins (STATs) (see Fig. 9-2). IFN-receptor interactions result in the activation of the different components by phosphorylation of specific tyrosine residues. STATs form homodimers or heterodimers through mutual phosphotyrosine src homology region 2 (SH-2) interactions. STAT1 homodimers bind to DNA elements, termed *gamma activated sites* (GAS elements), which drive the expression of target genes. STAT1 and STAT2 heterodimers bind to p48, a member of the IRF family. The resulting complex, termed *IFN-stimulated gene factor* 3 (ISGF3), binds to IFN-stimulated regulatory elements (ISREs) upstream of different IFN-responsive genes. The primary response to IFN-α/ß can be divided into several distinct steps (see Fig. 9-3). These include (a) IFN-driven dimerization of the receptor subunits outside the cell, (b) initiation of a tyrosine phosphorylation cascade inside the cell, (c) dimerization of the phosphorylated STATs, (c) transport of the STATs into the nucleus, and (d) binding to specific DNA sequences and stimulation of transcription. It is important to note that other signaling cascades are also activated by type I IFNs. It is the combined actions of these different pathways, coupled with their downregulation in the continued presence of IFN, that lead to the overall

cellular response. For example, IFN-α/ß treatment of cells causes the transient release of arachidonic acid, resulting from the phosphorylation and activation of cytosolic phospholipase A_2 ($cPLA_2$) (33,34). Inhibition of this enzyme blocks the formation of the transcription factor complex ISGF3. Mobilization of the phosphatidylinositol 3" kinase occurs in response to IFN-α/ß in a Jak-dependent event. The mitogen-activated protein kinase (MAPK) cascade is also triggered by IFN-α/ß (35,36). The latter may be differentially stimulated by the different IFN-α subtypes or by IFN-ß, but this remains to be determined.

The IFN receptor subunits are primed to respond to the dimerization event driven by ligand binding. STAT1 and STAT2 are preassociated in latent form with the ifnar-2c subunit of the IFN-α/ß receptor. STAT1 binds well only when STAT2 is present, however, and functionally redundant phosphotyrosine-dependent and phosphotyrosine-independent binding sites for STAT2 also exist on ifnar-1 and ifnar-2 (37,38 and 39). The Jak kinases are also preassociated with receptor subunits, but in this case, a specificity of association exists. Tyk2 is associated with ifnar-1 and Jak1 with ifnar-2. The binding of IFN-α/ß to ifnar-2c and receptor subunit dimerization brings the Jak kinases together, allowing cross-phosphorylation on tyrosine and kinase activation. Tyk2 is phosphorylated by Jak1, which, in turn, cross-phosphorylates Jak1 to increase its kinase activity. The tyrosine at residue 466 on ifnar-1 is phosphorylated. Latent STAT2 is then transferred to this docking site on ifnar-1 through an interaction requiring its specific SH-2

domain and the phosphotyrosine residue at 466 on ifnar-1. STAT2 then becomes tyrosine phosphorylated and provides a docking site for recruitment of STAT1 to ifnar-1, which is then tyrosine phosphorylated and activated. The arrangement of the IFN-α/ß receptor preferentially results in the formation of heterodimers of STAT2 and STAT1, which are released from the receptor to interact with the IRF-1 family member p48 to form ISGF3, the major transcription factor activated in response to IFN-α/ß. The heterodimers then translocate to the nucleus and form a high-affinity DNA-binding complex for the ISRE with p48. STAT1 and STAT2 heterodimers and STAT1 homodimers also form in response to IFN-α/ß and can drive the transcription of a subset of genes through GAS elements. This action depends on the relative amounts of p48, which can vary among different cell types.

Components of the Interferon Signal Transduction Cascade

Part of "9 - Interferon-α and -ß: Basic Principles and Preclinical Studies "

Janus Kinases

Jaks are a family of cytoplasmic protein tyrosine kinases that are essential for IFN action. As described in the section on Signaling Pathways Activated by Interferon-α and -ß, two members of the Jak kinase family, Jak1, and Tyk2, are involved in IFN-α/ß signaling (40). They each possess a tyrosine kinase activity mediated through a conserved catalytic domain and have seven highly conserved regions of shared homology, designated Jak homology (JH) domains 1 to 7 (see Fig. 9-2). The C-terminal JH-1 domain has conserved residues consistent with protein tyrosine kinase activity. The JH-2 kinase-like domain is the N-terminal to this site. This contains several amino acid substitutions, which render it inert for kinase activity. In the case of the JH-2 domain of Tyk2, however, it is essential for IFN-α signaling. The function of the other conserved domains remains to be established. After interaction of IFN with its receptor, the Jak kinases are phosphorylated on tyrosine and activated. The phosphotyrosine residue on Tyk2, activated as a result of IFN-α/ß binding to ifnar-2c, maps to the JH-1 kinase domain. The specificity of Tyk2 and Jak1 is determined by their association with their particular IFN receptor subunits, not through a high degree of substrate specificity. Subtleties to the involvement of Jaks in the IFN response exist, however, that are still under investigation. For example, catalytic Tyk2 is required for the induction of the ß-R1/I-TAC (IFN-inducible T-cell α-chemoattractant) gene, which is selectively induced by IFN-ß compared with IFN-α, despite robust expression of other ISGFs induced by IFN-ß through a Tyk2-independent pathway (41).

Signal Transducers and Activators of Transcription

IFN-induced receptor aggregation and activation of the Jak kinases results in the phosphorylation and assembly of STAT proteins (3). Phosphorylation of STATs on tyrosine permits the dimerization by reciprocal SH-2 phosphotyrosine interaction and entry into the nucleus to regulate the transcription of the different IFN-responsive genes. The STAT proteins most closely associated with the IFN response include STAT1α/ß and STAT2. STAT3 is also activated to a lesser extent. The STAT1α/ß proteins are encoded by a single gene and are generated by alternative pre-mRNA splicing. They are identical through the first 712 amino acids, but STAT1α has additional 38 C-terminal residues. ISGF3 is composed of STAT1α, STAT2, or STAT1ß/STAT2 heterodimers, along with p48. Single tyrosine residues (701 on STAT1 and 699 and STAT2) are phosphorylated after the activation of the Jak kinases. These tyrosine residues are situated in a phosphotyrosine-binding pocket of the SH-2 domains. They are essential for recruitment of the STAT proteins to the cytoplasmic tail of the activated receptor and for the formation of dimers either between STAT1 and STAT2, in the case of the formation of the complex ISGF3, or STAT1 homodimers that result from engagement of the IFN-γ receptor. In each case, dimerization occurs via association of the corresponding phosphotyrosine residues in the C-terminal of each partner with the SH-2 domain of the other member of the complex. Signal specificity in the IFN system is governed by localization of specific STATs to the cytoplasmic tails of the corresponding receptors. This is mediated by the SH-2 domains of the individual STAT molecules. The C-terminal domains of STATs are involved in transcriptional activation and in their ligand-dependent activation. As described previously in this section, the conserved tyrosine residue (701 on STAT1α) is responsible for the ability of STAT proteins to homodimerize. Phosphorylation of this residue is the hallmark of STAT activation. In STAT1α, the 38 C-terminal amino acids form an essential transcriptional activation domain. STAT1ß lacks these residues and accordingly lacks transcriptional activation function. Serine residue 727 at the C-terminal of STAT 1α is required for full transcriptional activation and is phosphorylated by an unknown serine threonine kinase. STAT2 does not have a C-terminal serine phosphorylation site, but has a highly acidic transactivation domain downstream from the tyrosine phosphorylation site at residue 699. The terminal 181 amino acids of STAT2 are important for binding and association with the basal transcription machinery. The SH-2 of STAT proteins are the determinants of signaling specificity. STAT2 interacts specifically with the cytoplasmic domain of ifnar-2 through an SH-2 phosphotyrosine action. The SH-2 domain of STAT1 mediates an interaction with the phosphotyrosine 699 on STAT2, transmitting the signal through the IFN-α/ß receptor.

Other functional domains on STATs include the amino-terminal domain, which is involved in binding protein tyrosine phosphatases and also in STAT dimer/dimer formation. The N-terminal domain of STAT2 is involved in binding to p48 via lysine residue 161. The N-terminal of STAT1 interacts with CBP-p300. Finally, the interaction of STAT2 and STAT1 is also mediated by the N-terminal domain of STAT2.

STAT1 is signaled through type I and type II IFN receptors. After type I receptor activation, STAT1 forms an essential component of ISGF3, along with STAT2 and p48. STAT1 and STAT2 heterodimers do not bind DNA strongly unless they are complexed with p48. STAT2 homodimers bind DNA weakly. Dimers of STAT1, however, are competent to bind DNA and drive the activation of transcription through GAS sites. In this

case, phosphorylation of serine 727 is important for maximum transcriptional activation.

p48

p48 (earlier known as *ISGF3*-γ) is a member of a family of transcription factors, the IRFs (42). Different family members function as activators or repressors of transcription but share significant homology in their N-terminal DNA-binding domain. The signature feature of this domain is a cluster of five tryptophan residues, three of which are essential for contacting DNA. The C-terminal region of 398–amino acid p48 protein contains an IRF-association domain, which mediates the interaction between p48 and STAT1 and STAT2 heterodimers. As the essential DNA-binding domain subunit of ISGF3, p48 recognizes and binds to ISREs, usually located in the 5" upstream regions of IFN-stimulated genes. The association of p48 with STAT1 and STAT2 increases p48 DNA-binding activity 25-fold. Although the DNA-binding domain of p48 is sufficient for DNA binding, the first N-terminal 9 amino acids of p48 are essential for DNA target specificity.

Other Signaling Molecules in the Type I Interferon Response Pathway

Cytosolic Phospholipase A$_2$

The formation of ISGF3 after type I IFN signaling requires the enzymatic activity of cPLA$_2$ (33,34). Although type I and type II IFNs increase cPLA$_2$ activity, the formation of STAT1 homodimers by either type of IFN is unaffected by the inhibition of this enzyme. Activation of cPLA$_2$ is not seen in Jak1 mutant cells. Jak1 and cPLA$_2$ are physically associated in cells, even in the absence of IFN treatment. After IFN treatment, cPLA$_2$ is tyrosine phosphorylated, although it is not clear whether this affects its activity. In fact, cPLA$_2$ is known to be activated by serine phosphorylation by p38 MAPK. Specific inhibitors of p38 MAPK block IFN-induced ISGF3 formation and antiviral activity of IFN, suggesting that serine phosphorylation of cPLA$_2$ by p38 MAPK is an important event in type I IFN signaling (43). In accord with this, IFN-α induces the rapid activation of p38 MAPK, which can be blocked by dominant negative inhibitors of upstream kinase activators of p38 MAPK. Further analyses of this pathway also shows that IFN-activated p38 MAPK activity is necessary for serine phosphorylation of STAT1, which is required for maximum transcriptional activity of STAT1 homodimers.

Extracellular Signal-Regulated Kinase 2

The 42-kd MAPK or extracellular signal-regulated kinase 2 (ERK2) interacts with ifnar-1 *in vitro* and *in vivo* (36). Treatment of cells with IFN-ß induces tyrosine phosphorylation and activation of ERK2 and causes it to associate with STAT1. The functional importance of ERK2 activation was shown by the inhibition of IFN-ß-induced transcription of a transfected ISRE-dependent reporter by dominant negative MAPK (36). IFN-ß also stimulates Raf-1 enzyme activity in a Ras-independent manner. Raf-1 activity can be coimmunoprecipitated with Jak1 or Tyk2 (44). In mutant cells lacking Jak1, IFN-ß does not activate Raf-1. Transient expression of Jak1, however, reconstitutes the ability of IFN-ß to activate Raf-1, indicating that Jak1 is required for Raf-1 activation by IFN-ß (41).

IFN-γ also induces the activation of the MAPKs ERK1 and ERK2 in a Jak-dependent manner in several different cell types. It appears, however, that the proline-rich tyrosine kinase Pyk2 is required for IFN-γ, but not IFN-α-mediated activation of ERK2 (45).

Interferon-Induced Proteins

Part of "9 - Interferon-α and -ß: Basic Principles and Preclinical Studies "

Treatment of cells with type I IFN induces the synthesis of many cellular RNAs and their corresponding proteins. The numbers of genes regulated by type I IFNs exceed 200 (27), but only a small number of the encoded proteins have been assigned specific IFN-regulated functions. IFN-α and -ß induce the same set of proteins but, in addition, IFN-ß induces unique ß-specific genes. The spectrum of proteins induced by IFNs depends on cell type, but most type I IFN-inducible mRNAs are transcribed as a primary response and do not require protein synthesis regulated through preexisting STAT1. The induction of protein synthesis by IFN is transient, peaking after several hours and then declining to uninduced levels. The element in the promoters of IFN-α/ß-stimulated genes required for the response is the ISREs. GAS elements are also able to mediate a response to IFN-α, but to a lower level.

Interferon-Induced Antiviral Pathways

Part of "9 - Interferon-α and -ß: Basic Principles and Preclinical Studies "

The function of IFN-induced proteins has been most thoroughly studied in the antiviral response. Although IFN induces the synthesis and accumulation of many cellular RNAs and proteins that may differ in type and amount with different cells, only three IFN-regulated pathways have been definitively assigned an antiviral function. Two of these function at the level of protein synthesis inhibition, whereas the third selectively inhibits viral RNA transcription. IFNs are known to inhibit virus replication at different stages of infection, however, including entry into the cell and uncoating of the virus particle (e.g., SV40, retroviruses), DNA and RNA synthesis (e.g., influenza, vesicular stomatitis virus), protein synthesis (e.g., picornaviruses, adenovirus, vaccinia), and virus assembly and release from the cell (e.g., retroviruses, vesicular stomatitis virus). With the exception of protein synthesis and transcription, IFN-induced proteins that act specifically at different stages have not been described.

Three pathways that mediate the antiviral activity of IFNs have been characterized in detail; the Mx, PKR, and the 2-5A pathways (Fig. 9-4). The Mx pathway was discovered during the investigation of genetic resistance to influenza viral infection in mice. The latter two were discovered as a result of an investigation of the inhibitory effects of dsRNA on protein synthesis performed in extracts from IFN-treated cells. The key enzyme intermediates in both pathways require dsRNA for activation.

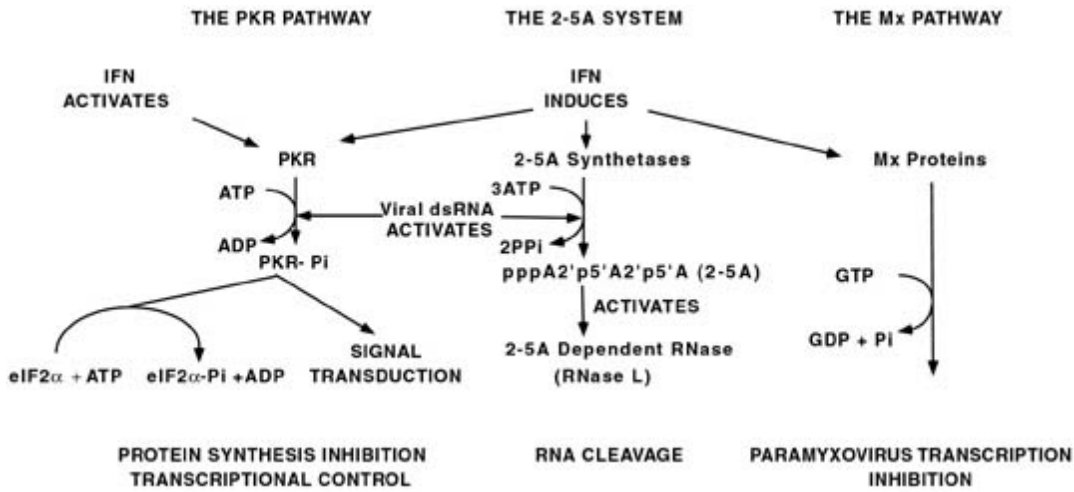
During viral infection, dsRNA can be derived from the incoming viral RNA genome or from viral replication intermediates.


FIGURE 9-4. Three major pathways mediate the antiviral activities of interferons (IFNs). (ADP, adenosine diphosphate; ATP, adenosine triphosphate; GDP, guanosine diphosphate; GTP, guanosine triphosphate.)

Mx Proteins

The Mx proteins are IFN-inducible 70- to 80-kd glutamyl transpeptidases, which belong to the Dynamin superfamily (46). Mx proteins, like other Dynamins, self assemble into horseshoe and ring-shaped helices and other helical structures. The Dynamins play important roles in transport processes, such as endocytosis and intracellular vesicle transport. In plants, Dynamins are important for cell formation. Transfected cells and transgenic mice expressing Mx proteins are resistant to Mx-sensitive viruses, demonstrating that Mx proteins are powerful antiviral agents. In humans, synthesis of MxA is observed during self-limiting viral infections and may thus promote recovery from disease. The human MxA protein is induced by type I IFNs and accumulates in the cytoplasm of cells, where it forms tight oligomeric complexes. MxA interferes with the multiplication and spread of orthomyxoviruses, rhabdoviruses, paramyxoviruses, and bunyaviruses. Synthesis of MxA is induced during acute viral infections and impairs the growth of influenza (a paramyxovirus) and other viruses at the level of transcription. MxA works in the cytoplasm to bind viral nucleocapsids and blocks their normal movement into the nucleus. This has been demonstrated for Thogoto virus, an influenza virus–like orthomyxovirus transmitted by ticks (47). This virus is susceptible to MxA, which blocks the transport of virus nucleocapsids into the nucleus, thereby preventing transcription of the viral genome. These reveal a novel antiviral mechanism, whereby an IFN-induced protein traps the incoming virus and interferes with proper transport of the viral genome to its ultimate target compartment within the infected cell.

Semliki Forest virus (SFV), a togavirus with a single-stranded RNA genome of positive polarity, has been found to be sensitive to MxA (48). Expression of MxA in different cell lines prevented the accumulation of 49S RNA and 26S RNA, indicating that SFV was inhibited early in its replication cycle. Thus, the antiviral spectrum of MxA is not restricted to negative-strand RNA viruses but also includes SFV, which contains an RNA genome of positive polarity. Importantly, the MxA protein can exert its inhibitory activity against SFV in the absence of viral structural proteins, suggesting that viral components other than the structural proteins are the target of MxA action. This could be a limitation in the use of SFV-based, self-replicating vectors in antitumor vaccine strategies. In contrast to the human MxA protein, the murine Mx-1 protein inhibits the primary transcription of viruses in the nucleus (49). Although the mechanisms of their action have not been established, the conservation of Mx proteins in vertebrates, including fish, suggest a broader spectrum of antiviral action (50).

The promoter of the MxA gene contains two functional ISREs near the transcription start site and one homologous ISRE-like element, which is apparently nonfunctional, further upstream (51). The two proximal ISRE sites are essential for IFN-α–induced transcription and bind ISGF3. The transcription factor Spl, which binds with high affinity to a region encompassing nucleotides 25 and 50, is most likely important for interacting with the basal transcriptional machinery (51). The highly responsive Mx promoter has proved useful for the induction of transgene expression by IFN in cell cultures and mice, including inducible gene targeting (52). The standard laboratory mouse strains carry deleted Mx-1 alleles and are susceptible to influenza virus, whereas mouse strains originating from wild mice carry the wild-type allele, which likely serves a protective function against orthomyxoviruses (49).

A novel function for MxA has been suggested in Fanconi anemia, a group of five autosomal recessive disorders that share common phenotypes of birth defects, hematopoietic failure, sensitivity to cross-linking agents, and predisposition to apoptosis. MxA is upregulated in the different complementation groups, but repressed when the Fanconi anemia complementation group C (FAC) gene cDNA (which encodes a 63-kd cytoplasmic protein thought to protect from DNA damage) is overexpressed in group C cells (53). This work suggests that MxA is a downstream target of FAC probably at the posttranscriptional level, although the presence or absence of FAC does not affect the expression of other IFN-regulated genes. Overexpression of MxA can lead to phenotypic abnormalities similar to those observed in Fanconi anemia group C cells, including sensitivity to mitomycin C and increased apoptosis.

Double-Stranded RNA-Dependent Protein Kinase

The IFN-inducible dsRNA-dependent kinase, PKR, is a serine-threonine kinase initially described as a mediator of protein synthesis inhibition by dsRNA. It has become apparent, however, that PKR plays roles in different cellular processes, including growth regulation, antiviral protection, and signal transduction and differentiation. Most cells express constitutive levels of PKR, but type I IFNs, through an ISRE, can induce the transcription of the PKR gene (54,55). PKR is normally inactive but, on binding dsRNA, undergoes a conformational change exposing the catalytic domain for activation. Autophosphorylation activates the kinase function, allowing phosphorylation downstream substrates independent of dsRNA. The binding of dsRNA requires the presence of two dsRNA-binding motifs present in the N-terminal regulatory domain of PKR. The first motif is the most critical for binding dsRNA and is highly conserved within a large family of dsRNA-binding proteins, most of which have no known functions. A single PKR dsRNA-binding motif can recognize as few as 11 base pairs of dsRNA. No sequence specificity exists to this recognition because this is based on interactions between conserved residues and hydroxyl groups of the minor groove of dsRNA (56). Most viruses present an opportunity to activate PKR during the infection cycle through the production of dsRNA. As dsRNA is also a structural feature of cellular RNAs, it is possible that these may activate PKR as part of a cellular regulatory control mechanism. In accord with this, exposure of cells to stress, such as heat shock, activates the transcription of cellular Alu RNAs, which can regulate PKR activity (57). PKR activity is also regulated during the cell cycle, although the nature of the endogenous activator has not been discerned (58).

The antiviral activity of PKR is largely mediated by its phosphorylation of the α-subunit of erythrocyte initiation factor (eIF2) (see Fig. 9-4). Phosphorylation of eIF2 prevents recycling of eIF2:guanosine diphosphate to eIF2:guanosine triphosphate, trapping the recycling factor eIF2α, inhibiting protein synthesis. PKR also mediates programmed cell death (apoptosis) induced by dsRNA (59). Consequently, a combination of protein synthesis inhibition and induction of apoptosis likely act to restrict viral replication and spread.

PKR can act as a signal transducing kinase for the transcription factor, NF-κB (60,61,62 and 63). Activation of PKR by dsRNA leads to the phosphorylation of IκB, the inhibitor of transcription factor NF-κ, causing its release from the inactive NFκB/IκB complex (60). This allows NF-κB to migrate to the nucleus and regulate the expression NF-κB-dependent genes, many of which are important in the development of an inflammatory response (62,63).

PKR is not constitutively active, but IFNs (and other cytokines) can directly activate latent PKR (63,64). Under these circumstances, the activation of PKR is a necessary step in a signal transduction pathway that eventually leads to the induction of expression of different genes involved in the cellular inflammatory response, including the synthesis of chemokines, class I major histocompatibility complex (MHC), and molecules involved in apoptosis. The loss of PKR function not only results in a decreased antiviral activity of IFNs, but also attenuates the cellular response to certain cytokines and growth factors.

To circumvent the antiviral effects of IFN and reduce an inflammatory reaction mediated by PKR, many viruses have elaborated mechanisms to inhibit this enzyme and other components of IFN-regulated pathways (65,66). These include the synthesis of inhibitory dsRNAs (e.g., adenoviruses, Epstein-Barr virus, human immunodeficiency virus) or the synthesis of proteins, which can bind and sequester dsRNA activators of PKR (e.g., reovirus, vaccinia). Other viruses synthesize protein inhibitors of PKR (e.g., hepatitis C virus, herpes simplex virus, vaccinia) or proteases that cleave PKR (e.g., poliovirus, encephalomyocarditis virus). In some cases, the inhibitors are normally sequestered but are activated in response to viral infection (e.g., influenza virus). Despite the fact that different viruses have targeted PKR, viral replication in PKR-null mice is accelerated, even in the absence of IFN, suggesting that PKR is important in restricting infection (62,67). In the context of an inflammatory response, PKR appears to be an important mediator of the synergy between cytokines. For example, synergy between tumor necrosis factor–α (TNF-α) and IFN-γ for induction of NF-κB is dependent on PKR (64). This may be an important role for PKR in a physiologic context.

PKR is a cell growth inhibitor. Transdominant mutants of the enzyme act as dominant oncogenes in NIH 3T3 cell assays (68,69). Some attempts have been made to link PKR dysregulation to cancer. It has been reported that PKR levels correlate inversely with proliferative activity in different human tumors and tumor cell lines (70,71 and 72). Human invasive ductal breast carcinomas, however, have high levels of PKR. In several breast carcinoma cell lines, PKR levels are high compared with those found in the normal breast cell lines (70,73). The activity of PKR from the carcinoma cells, however, is attenuated, although it remains capable of binding dsRNA. Mixing experiments suggest that carcinoma cells contain a transdominant inhibitor of PKR (73). Although this suggests a role for PKR in the pathogenesis of cancer, the underlying mechanism remains to be established. This could occur by disrupting the control of protein synthesis initiation by PKR. In support of this ribosomal protein, L18, a 22-kd protein that is overexpressed in colorectal cancer tissue, has been shown to bind to PKR through the first dsRNA-binding domain (74). L18 inhibits PKR autophosphorylation

and PKR-mediated phosphorylation of eIF2-α *in vitro* and *in vivo.* It is speculated that overexpression of L18 in tumors may promote protein synthesis and cell growth through inhibition of PKR activity. A large number of dsRNA-binding proteins exist, however, that also bind PKR (75). Pinpointing any one of these as the crucial PKR regulator in tumorigenesis without more direct evidence is premature. Murine PKR has been shown to have undergone a rearrangement of one allele in a murine lymphocytic leukemia cell (76). Analyses of human acute lymphatic leukemia for PKR rearrangements could prove informative.

Although the regulation of eIF2 phosphorylation has remained a focus of several studies on the role of PKR in cell growth control, an interesting connection to regulation of the proto-oncogene c-Myc also exists that might prove to be of more fundamental importance in tumor development. IFN has been known for some time to suppress c-Myc expression. In M1, myeloid leukemia cells expressing inactive mutant forms of PKR can abrogate this (77). Transfection of M1 cells with wild-type human PKR inhibited proliferation in the absence of IFNs, but this could be rescued by the ectopic expression of deregulated c-Myc. Thus, a link appears to exist between PKR and c-Myc suppression. In accord with these results, transfection of breast carcinoma MCF-7 cells with a dominant negative mutant of PKR relieved c-Myc downregulation, occurring as a consequence of the synergistic inhibition of growth with all-trans-retinoic acid and IFN-α (78). Experiments show that PKR and STAT1 are required for IFN-mediated downregulation of c-Myc (79). In PKR or STAT1-null cells, c-Myc gene expression is stimulated, not repressed, by IFN. Moreover, in PKR-null cells, the phosphorylation of STAT1 on serine 727 is deficient (79). These results place PKR in pathways required for cell growth control and, potentially, tumor suppression.

2-5A Synthetase/Ribonuclease L System

Type I IFNs induce the 2-5A synthetase/ribonuclease (RNase) L system. This is a multienzyme cellular RNA degradation pathway that is activated by dsRNA (see Fig. 9-3). The 2-5A synthetases are transcribed from ISRE-containing genes in response to IFNs. The enzymes are activated by dsRNAs to polymerize short 2" and 5" oligoadenylates (2-5A). This unique oligomer activates the 2-5A-dependent ribonuclease RNase L. Thus, the enzymes in this pathway are present in all cells as inactive or latent forms and require first dsRNA as a cofactor in the case of the 2-5A synthetase enzymes and 2-5A as the activator for the latent ribonuclease, RNase L. IFNs can also stimulate the synthesis of RNase L by activating transcription. Latent RNase L is a monomer, but binding to 2-5A induces dimerization, activating the enzyme (80). Because 2-5A is rapidly degraded by phosphodiesterases and phosphatases, the activation of RNase L is reversible, resulting in deactivation of the 2-5A pathway. The three genes encoding the 2-5A synthetases map to a single locus (12q21) in humans (81). Although the individual enzymes reside in different subcellular locations, they are found in all cellular compartments. The different isoforms have differing activities. The largest 100-kd isoform is active as a monomer and preferentially synthesizes dimers of 2-5A. The 69-kd enzyme and its alternatively spliced 71-kd isoform are myristylated and glycosylated and exist as membrane-bound homodimers. The small human 2-5A synthetase isoforms result from alternative splicing of the same gene, yielding 40- and 46-kd proteins. Although the amino terminal 346 residues of both proteins are identical, the 54 C-terminal unique residues of the 46-kd isoform are highly hydrophobic and allow the localization of this form to membranes. The 46-kd form, which lacks the hydrophobic C-terminal sequence, is cytoplasmic. The first 346 amino acids of 40- and 46-kd isoforms constitute a domain that is duplicated in the 69- and 71-kd isoforms and occurs three times in the 100-kd isoform. Unique antiviral functions for the different 2-5A synthetases have not been described. The only well-described function of these enzymes is to synthesize 2-5A, the activator of RNase L. Because the 100-kd form of the enzyme synthesizes predominantly dimers, which are not able to activate RNase L, it remains possible that other functions exist. The dsRNA-binding domains of the 2-5A synthetase isoforms bear no structural similarity to the dsRBD of PKR and require a higher concentration of dsRNA for activation than PKR. Thus, under situations when PKR can be inhibited by high concentrations of dsRNA, the 2-5A system becomes activated, providing a second line of defense against viral infection.

RNase L is single isozyme encoded by a unique gene mapping to human chromosome 1p31 (82,83). The human RNase L protein has 741 residues. The N-terminal is comprised of a repeated P-loop motif and 9 ankryin repeats, which are involved in 2-5A binding and function to repress RNase L activity in the absence of 2-5A (84). The C-terminal half of the protein contains a region of protein kinase homology, which consists of a cysteine-rich domain and a ribonuclease domain. The isolated C-terminal half of RNase L cleaves RNA in the absence of 2-5A. RNase L binds 2-5A with high affinity and the active ribonuclease activity is sequence nonspecific, but cleaves U-U and U-A bonds preferentially. Inhibition of RNase L activity by expression of dominant negative derivatives or deletion of the gene from mice result in a defective antiencephalomyocarditis virus effect of IFN-α (85).

RNase L is involved in cell growth control and apoptosis (85,86,87 and 88). Dominant negative inhibitors of RNase L block different apoptosis responses (e.g., staurosporine-induced apoptosis of NIH 3T3 cells and SV40-transformed BALB/c cells) (87,88). K562 cell lines expressing inactive RNase L are more resistant to apoptosis induced by decreased glutathione levels. When human RNase L cDNA is stably overexpressed in murine NIH 3T3 cells, the cell growth inhibitory activity of IFN and the proapoptotic activity of staurosporine are enhanced. The replication of different viruses are also inhibited. Inducible overexpression of human RNase L in NIH 3T3 fibroblasts decreases cell viability and triggers apoptosis (89). Activation of endogenous RNase L, specifically with 2-5A, also induces apoptosis, whereas inhibition of RNase L with a dominant negative mutant suppresses polyrI.rC-induced apoptosis in IFN-primed cells and suppresses apoptosis induced by poliovirus. Overproduced RNase L by recombinant vaccinia virus causes apoptotic death of mammalian cells, which can be prevented by the apoptosis antagonist Bcl-2 (90).

In accord with these results, RNase L–null mice exhibit enlarged thymuses resulting from a suppression of apoptosis (85). Apoptosis is also suppressed in RNase L-null thymocytes and fibroblasts treated with different apoptotic agents. Taken together, these results suggest that IFN action and apoptosis can be controlled at the level of RNA stability by RNase L.

In a study more directly connected to cancer, elevated levels of RNase L mRNA and activity were detected in colorectal tumors compared with corresponding normal mucosa (91). The occurrence of elevated levels of RNase L seems to be an early event in colorectal tumorigenesis, suggesting that control of RNA turnover is an important step in tumor progression (91). Clearly, these levels were insufficient to trigger apoptosis but, rather, suggest that activating RNase L activity, perhaps by delivery of 2-5A, may be a useful strategy in treating colorectal carcinomas.

The regulation of RNase L activity towards specific targets has been achieved by linking the 2-5A moiety to antisense oligonucleotides. Proof of principle for this was shown when the unaided uptake into HeLa cells of 2-5A linked to an antisense oligonucleotide, resulting in the selective ablation of mRNA for PKR (61). Cells depleted of PKR activity were unresponsive to activation of NF-κB by dsRNA (61). This strategy also works against cancer targets. For example, 2-5A antisense directed against the fusion site or against the translation start sequence in bcr/abl mRNA is selective in degrading this mRNA in chronic myelogenous leukemia cell lines and is accompanied by decreases of p210 (bcr/abl) kinase activity levels and suppression of cell growth (92). In primary chronic myelogenous leukemia cells isolated from bone marrow of patients, the 2-5A-antisense treatments suppressed proliferation of the leukemia cells and selectively depleted levels of bcr/abl mRNA. These findings suggest that these compounds may have potential as *ex vivo* purging agents of autologous hematopoietic stem-cell transplants from CML patients.

Telomerase is the RNA protein complex that elongates telomeric DNA and appears to play an important role in cellular immortalization. The almost exclusive expression of telomerase in tumor cells has offered an opportunity to exploit 2-5A antisense. This expression does not involve most normal cells. A 19-MER antisense oligonucleotide against human telomerase RNA linked to a 2-5A effectively suppressed glioma tumor cell growth and survival *in vitro* and inhibited survival of tumors grown in nude mice with the antisense possibly by the induction of apoptosis (93). Targeting telomerase RNA with 2-5A antisense could prove an effective treatment for a broad range of cancers.

The ability of IFNs to confer an antiviral state is a fundamental property that allows for classification and individual activity measurement. Different stages of virus replication may be inhibited by IFNs, including entry, uncoating, or both, and transcription initiation of translation, maturation, assembly, and release. Because the pathways described in this section are primarily directed towards translational control mechanisms, it is obvious that other IFN-regulated antiviral proteins exist to interfere with different stages of virus replication. Despite identification of a large number of IFN-regulated genes and proteins, however, the assignment of specific antiviral activities to these remains to be achieved.

Inhibition of Cell Growth and Immune Regulation by Type I Interferons

Part of "9 - Interferon-α and -β: Basic Principles and Preclinical Studies "

The cell growth inhibitory properties of IFNs are assumed to contribute to their use as anticancer agents. IFNs also regulate cellular responses to inducers of apoptosis, however, and modulate the immune response. These effects underlie antitumor activity. The prolonged activation of STAT1 and the induction of synthesis of several proapoptotic genes by IFNs may sensitize cells to apoptosis inducers, including chemotherapeutic agents. Thus, the modulatory effects of IFNs influences the development of resistance to infection and antitumor activities. Direct inhibition of cell growth by IFN is displayed against a variety of cultured cells *in vitro*. This is partly caused by the promotion of differentiation, which is particularly apparent when used in combination with other agents, such as retinoids. Significant IFN-induced gene products have not been linked directly to antiproliferative activity. IFN-α does regulate properties of different components of the cell cycle, however, including c-Myc, pRB, cyclin D3, and cdc25A. The mechanisms by which the cell cycle is suppressed may differ in different cell types. Thus, the involvement of cyclin-dependent kinase inhibitors, such as p21, p27, and p57 kip, have been invoked in some cells, whereas in others these inhibitors are not involved.

A major problem in attributing the antiproliferative effects of IFNs on specific gene products is that they induce many hundreds of genes. This has been illustrated by determining mRNA profiles from IFN-α, -β, or -γ treatments of the human fibrosarcoma cell line, HT1080, using oligonucleotide arrays with probe sets corresponding to more than 6,800 human genes (30). Many novel IFN-stimulated genes were identified that were diverse in their known biologic functions. Moreover, several IFN-repressed genes also were identified. Until theses genes can be manipulated by overexpression or deletion, delineation of their role in the antiproliferative response of IFNs can only be speculative. It is noticeable that a number of genes induced by type I IFNs are involved in apoptosis, however, including RAP46/Bag-1, phospholipid scramblase, and hypoxia-inducible factor-1α (30). Consequently, it is likely the antitumor effects of IFNs *in vivo* can be augmented by combination with apoptosis-inducing agents. For example, the expression of TNF-related apoptosis-inducing ligand, a proapoptotic member of the TNF family of type II membrane proteins, is rapidly induced on the surface of CD4+ and CD8+ peripheral blood T cells on stimulation with anti-CD3 monoclonal antibody and type I IFNs, but not other cytokines (94). Most renal cell carcinoma cell lines are susceptible to TNF-related apoptosis-inducing ligand apoptosis. Type I IFNs can augment cytotoxic activity of anti–CD3-stimulated PBT cells against renal cell carcinoma cell lines in a TNF-related apoptosis-inducing ligand-dependent manner. This unique ability of type I IFNs to regulate TNF-related apoptosis-inducing ligand–mediated T-cell cytotoxicity may contribute to the antitumor effects of type I IFNs against various tumors. Type I IFNs also interfere with the rapid death of activated T

cells without raising the levels of Bcl-2 or Bcl-XL, which distinguishes them from the interleukin-2 family or CD28 engagement (95). In some cases, for example, in hemopoietic progenitor cells, IFNs directly induce cell death. This requires the expression of PML to mediate Fas and caspase-dependent DNA damage-induced apoptosis.The PML-RAR α fusion protein of acute promyelocytic leukemia renders hemopoietic progenitor cells resistant to Fas-, TNF-, and IFN-induced apoptosis with a lack of caspase-3 activation by dominant negative inhibition of polymorphonuclear leukocytes (96). In most primary cell cultures, IFNs are not apoptotic by themselves but require the addition of dsRNA presumably to activate PKR and 2-5A-mediated apoptotic pathways. In the case of viruses, the dsRNA is generated during the course of infection, and the subsequent virus-induced apoptosis can be inhibited by anti type I IFN antibodies. This is not seen in cells lacking ifnar-1 or STAT1 (97). The selective promotion of apoptosis by IFN in virally infected cells could perhaps be exploited in cancer by combining IFN therapy with dsRNA analogues.

IFNs can have significant effects on all phases of innate and adaptive immune responses. Type I IFNs are largely responsible for increasing the effectiveness of the adaptive immune response to resist viral infection, including the stimulation of CD44 memory T cells (98). This bystander proliferation does not require T-cell receptor ligation but may result from IFN induction of macrophages to synthesize interleukin-15, which causes selective stimulation of CD44hi CD8+ (but not CD4+) cells.

Type I and type II IFNs enhance the expression of MHC class I proteins to promote the development of CD8+ T-cell responses (99). MHC class I expression is dependent on the transcription factor IRF-1. Mutations in genes linked to the IRF-1 signal transduction pathway result in failure to actively upregulate MHC class I proteins on cell surfaces in response to IFN. Both type I and type II IFNs are able to upregulate the expression of the different protein components, which constitute the proteosome-protein processing pathway responsible for generating antigenic peptides expressed by MHC class II (100). Accordingly, IFNs can enhance immunogenicity by increasing the quantity and repertoire of peptides displayed in association with MHC class I proteins, which are dependent on an active proteosome-mediated pathway.

Both type I and type II IFNs effect humoral immunity in complex ways by indirectly regulating the development of specific T-helper subsets or by directly regulating the specialized B-cell functions, including development and proliferation, immunoglobulin secretion, and immunoglobulin heavy chain switching. In immunoglobulin class switching, the type I IFNs can function redundantly to type II IFN (101).

Conclusion

Part of "9 - Interferon-α and -β: Basic Principles and Preclinical Studies "

Type I IFNs have proved to be remarkably pleiotropic cytokines with a broad range of clinical activities as antiviral and antitumor agents. The mechanisms underlying these activities are complex because of the large number of genes regulated by IFNs and also because of likely cell-type differences in responses. Although the introduction of recombinant IFN-α2 and IFN-β has enabled the evaluation and approval of these biologic response modifiers for different indications, natural IFN-α is a mixture of subtypes, some of which may have differing biologic activity. Further clinical evaluation of these different subtypes of IFNs alone or as adjuvant therapy is necessary. For example, early trials provided evidence for differing activity and lower side effects of IFN-α1 versus IFN-α2. This needs to be revisited using new methods for stabilizing IFN to increase its bioavailability and reduce side effects. The rapid protein clearance and systemic toxicities seen with unmodified IFNs can be modulated by conjugation with polyethylene glycol. Polyethylene glycol conjugation of proteins also makes them tolerogenic, inhibiting antibody responses, thus potentially overcoming the problem of developing neutralizing antibody. This has been reported in patients receiving IFN-α therapy. Although IFN therapy at therapeutic doses causes a number of dose-related side effects, these reactions are reversible on termination of therapy. The mechanisms underlying the most common adverse effects, such as flulike syndrome, fatigue, anorexia, and depression, are not well understood. IFNs can change the expression of more than 300 genes, including a number of proinflammatory cytokines. Thus, side effects may be unavoidable. Moreover, the use of antiinflammatory drugs to control side effects may be counterproductive because these drugs may also block IFN signaling. Alternatives, including the combination of systemic low-dose IFN administration with cytotoxic- or differentiation-inducing agents and gene therapeutic approaches, may deliver high concentrations of IFN into the tumor bed. Oral IFN therapies have shown efficacy in animal models and may be appropriate for treatment of diseases in which high-dose systemic administration and its associated toxicity are inappropriate.

Introduction

Part of "10.1 - Leukemias, Lymphoma, and Multiple Myeloma "

The description of the viral inhibitory factor termed *interferon* (IFN) by Isaacs and Lindenman in 1957 (1) can be considered one of the first steps in the development of the field of biotherapy in medicine. Considerable progress in understanding the biology and clinical effects of these agents has led to their increased applications in various fields of medicine, including oncology. Hematologic malignancies in which applications of IFN have been extensively studied include chronic myelogenous leukemia (CML), hairy cell leukemia (HCL), follicular lymphomas, cutaneous T-cell lymphoma, and multiple myeloma (2).

Three types of IFNs have been identified in humans and are designated as IFN-α, IFN-β, and IFN-γ. These are produced by a variety of cells but most specifically by leukocytes, fibroblasts, and T-lymphocytes, respectively. IFN-α and IFN-β, collectively known as *type I IFNs*, are coded by genes located on chromosome 9. They share approximately 40% homology and act on cells through a common receptor (3). IFN-γ has little homology to type I IFNs, is classed as type II IFN, and is coded by a gene on chromosome 12 (4).

Interferons have potent effects on cell proliferation, although the mechanisms responsible for their antiproliferative effects remain unclear. The downregulation of the proto-oncogene c-myc and the induction of the enzyme 2",5"-oligoadenylate synthetase may be involved (5 ,6). Various immunomodulatory effects of IFNs have been described, including enhancement of cytotoxic activity of natural killer (NK) cells, stimulation of release of other cytokines, and increased expression of major histocompatibility antigens on the cell surface (7 ,8 and 9).

Research into cellular effects of IFNs—in particular, IFN-α—has shed light into possible mechanisms of their antitumor activity. Type I IFNs have been shown to induce G_1 arrest in hematopoietic target cells. This arrest is mediated by a number of biochemical events, including inhibition of c-myc expression (10), inhibition of phosphorylation of retinoblastoma protein (11 ,12 ,13 and 14), and downmodulation of E2F activity (15). Cell cycle progression is regulated by proteins known as *cyclins*, which activate cyclin-dependent kinases (CDKs), a process counterbalanced by CDK inhibitors (16). IFN-α has been shown to induce the expression of CDK inhibitors, including p21/WAF1, p15, and p16[INK4] (17 ,18 and 19). The upregulation of these inhibitors is responsible for the downregulation of phosphorylation of retinoblastoma protein and G_1 arrest of cells (17 ,18 and 19).

IFN-α has also been demonstrated to be an inducer of apoptosis in certain cell lines by a mechanism independent of its antiproliferative effects (20 ,21). The exact mechanism of IFN-induced apoptosis remains unclear, but it likely involves effects on various families of proteins involved in controlling programmed cell death, including the Bcl-2/Bax family of proteins, the ICE[4]/Ced-3 proteases, and the tumor necrosis factor/Fas receptor family.

This chapter reviews the clinical applications of IFNs in hematologic malignancies.

Interferon Therapy of Chronic Myelogenous Leukemia

Part of "10.1 - Leukemias, Lymphoma, and Multiple Myeloma "

CML is a chronic myeloproliferative disorder with an initial, chronic course lasting 3 to 5 years (22 ,23 and 24). It eventually transforms into accelerated and blastic phases, which are generally fatal. CML was one of the first diseases in which a specific chromosomal abnormality was identified: (9;22) (q34;q11), or Philadelphia chromosome.

Until the introduction of IFN-α in 1981, CML was traditionally treated with hydroxyurea (25 ,26). After a large body of clinical studies, IFN-α became the mainstay of CML nontransplant-based therapy. In this chapter, clinical studies with IFN-α in CML are summarized, and possible mechanisms of action of IFN leading to this rewarding clinical effect are discussed.

Interferon-α in Chronic Myelogenous Leukemia: Single Agent Studies

The initial demonstration of IFN activity in newly diagnosed CML patients was published by a team from M. D. Anderson Cancer Center (MDACC) (27 ,28 ,29 and 30). This work was subsequently expanded with results that confirmed initial observations. Their update is summarized in Table 10.1-1 (31). In this study, patients were administered an intended 5 MU per m² treatment dose of IFN-α; these patients were monitored frequently (every 3 to 4 months) for hematologic and cytogenetic changes. Additional studies from other institutions confirmed the MDACC studies, but failed in general to demonstrate a similar response rate (Table 10.1-2) (32 ,33 ,34 and 35).

MDACC, M. D. Anderson Cancer Center.

[a]Report states significant dose reduction.

From Talpaz M, Kantarjian HM, O'Brien S, Kurzrock. R The M. D. Anderson Cancer Center experience with interferon-α therapy in chronic myelogenous leukemia. In: Goldman JM, ed. *Clinical haematology.* London: Baillière Tindall, 1997:291–305, with permission.

Although most of these early studies demonstrated lower hematologic and cytogenetic response rates, several centers were able to reproduce in full the MDACC experience by adhering to similarly intensive dose regimes. It appears that doses of IFN-α influence hematologic and cytogenetic response rates; this notion was challenged, however, by Schofield et al., who demonstrated a high response rate with low doses of IFN-α (32). Nevertheless, these studies failed to address disease prognostic features; thus, they may have introduced a patient selection bias that could have had a major impact on IFN-α response outcomes.

In the MDACC study, a high response rate was demonstrated in low-risk patients, shown in Table 10.1-3 (31). It is apparent, therefore, that responses to IFN-α are influenced by characteristics of a study's patient population (and, most likely, by treatment intensity as well). Accordingly, a metaanalysis of a series of phase II studies or a comparison of studies from different centers may be problematic, unless they adhere to strict analysis by disease prognostic features.

Table 10.1-3 Response and Survival by Prognostic Risk Groups

Prognostic Model	Risk Group	No. of Patients (%)[a]	Proportion with Major Cytogenetic Response (%)	*p* Value	Median Survival (mo)	*p* Value

MDACC, M. D. Anderson Cancer Center.

[a]Percentage of evaluable patients.

From Talpaz M, Kantarjian HM, O'Brien S, Kurzrock R. The M. D. Anderson Cancer Center experience with interferon-α therapy in chronic myelogenous leukemia. In: Goldman JM, ed. *Clinical haematology.* London: Baillière Tindall, 1997:291–305, with permission.

This observation applies to newly diagnosed patients, and initial studies indicated poor responses in long-standing disease. Although hematologic responses were frequently seen in patients with long-standing CML—albeit to a lesser extent than in newly diagnosed patients—major cytogenetic responses were uncommon. Thus, resistance to IFN-α is slow to develop, although failure to induce cytogenetic response occurs early in the disease. These findings imply that cytogenetic responses may depend on a pool of "normal" stem cells that are depleted at a rapid pace, whereas true resistance of malignant clones are slow to develop and occur much later in the course of disease.

Survival Outcome: Summary of M. D. Anderson Cancer Center Experience and Randomized Studies

The survival outcome of patients treated at MDACC has been published on several occasions and was updated with patient follow-ups exceeding 10 years (29 ,30 and 31). A median survival of 89 months and a survival rate of 40% were noted in patients at 10 years' follow-up, compared to a rather negligible number of patients alive at 10 years with standard chemotherapy (Fig. 10.1-1) (36).

This impact on survival was a result of excellent survival among complete cytogenetic and partial cytogenetic responders. The impact of these responses on survival was demonstrated in a landmark analysis (Fig. 10.1-2), a study that can be criticized for not being randomized against a control group, thereby allowing possible factors unrelated to therapy, such as change in time of initial diagnosis (earlier diagnosis), to influence survival outcome. This study does provide information on very long patient follow-up, however, and appears to complement survival data from randomized studies by demonstrating long follow-up data not available in randomized trial summaries. The data are, therefore, much less subjected to impact on survival by disease-related prognostic features.
FIGURE 10.1-1. Survival of chronic myelogenous leukemia patients treated with interferon-α (total of patients, 274; number of patients who died, 92) (after censoring those who underwent allogeneic bone marrow transplantation—total number of patients, 274; number of patients who died, 104). (From Talpaz M, Kantarjian HM, O'Brien S, Kurzrock R. The M.D. Anderson Cancer Center experience with interferon-α therapy in chronic myelogenous leukemia. In: JM Goldman, ed. *Clinical haematology*. Survival Outcome in Randomized Studies

Several randomized studies comparing IFN-α therapy with chemotherapy have been published; four are summarized in Table 10.1-4 (37 ,38 ,39 ,40 ,41 and 42). Three of these studies demonstrate survival advantage for patients treated with IFN-α. An average survival benefit of 20 months was demonstrated in Italian and United Kingdom studies. In a German study, IFN-α was found to be significantly superior to busulphan, although it only modestly prolonged survival over hydroxyurea (a difference that was not significant statistically). A difference in patient populations may explain some differences in these studies (such as inclusion of accelerated-disease patients in the German study), but differences in INF-α dosage may account for some of the differences. An update of the German study demonstrates that IFN-α is superior to hydroxyurea in low-risk patients.

Table 10.1-4 Comparison of Survival Outcome of Interferon-α versus Chemotherapy in Randomized Studies

Study (Reference)	No. of Patients	Survival (Mo) Interferon	Chemotherapy	*p* Value
Italian Cooperative Study Group on Chronic Myeloid Leukemia (37)	322	72	52	.002
Hehlmann et al. (38)	513	66	45 (busulphan)	.008
			56 (hydroxyurea)	.44
Allan et al. (39)	587	61	41	<.001
Ohnishi et al. (40)	159	54% at 5 yr	325 at 5 yr for busulphan	.029

From Talpaz M, Kantarjian HM, O'Brien S, Kurzrock R. The M. D. Anderson Cancer Center experience with interferon-α therapy in chronic myelogenous leukemia. In: Goldman JM, ed. *Clinical haematology*. London: Baillière Tindall, 1997:291–305, with permission.

Randomized studies were subjected to rigorous analysis by the CML Trialists' Collaborative Group (42). Using standard methods, these trials were analyzed individually and collectively. This analysis finds an overall improvement in survival among IFN- versus hydroxyurea-treated patients, with 26% reduction in odds of death (2p = .0001) [95%, confidence interval (CI) of 11% to 38%]. Furthermore, differences between different trial outcomes are consistent with chance effects. This analysis also indicates IFN-associated survival advantage for all disease prognostic groups.

Although many factors may contribute to survival prolongation with IFN-α, delay of blast crisis is probably the most significant one, demonstrated in the Italian study (37). Compared to the MDACC study, randomized studies resort to short follow-up, and early analysis focuses on a moderate gain in average survival (whereas a more significant impact on survival may be noted in a subset of patients at a much longer follow-up). Because survival benefits were noted even with low treatment doses, an erroneous conclusion may be reached that treatment intensity has only marginal significance. Its real benefit, however, may lie in complete and partial cytogenetic

responses, whose survival benefits may be observed late in the course of disease and not detected when median survivals are compared in randomized studies [e.g., the duration-of-survival advantage with IFN in the Italian study is similar to that in the Medical Research Council (MRC) trials, which used much lower doses of IFN, although IFN-α dose intensity may actually have a dramatic impact on the incidence of long-term survivors]. Although the single-arm studies at MDACC are subjected to criticism, the analysis of survival outcome among the 274 patients treated with IFN-α as single-agent therapy demonstrates a median survival of 89 months (see Fig. 10.1-1). Perhaps more significant, however, are the unique survival patterns emerging for subsets of patients according to degrees of cytogenetic responses (see Fig. 10.1-2), and the notion that long-term survival of IFN-α–treated CML patients may be strongly influenced by degree of cytogenetic response. A substantial percentage of CML patients may live 10 years or more if the patterns of survival observed in Fig. 10.1-1 and Fig. 10.1-2 are maintained, representing a remarkable quantitative shift in the paradigm established by Sokal et al., who demonstrated only a negligible number of patients alive with CML at 10 years of follow-up when treated with standard chemotherapy (36).

Cytogenetic Responses

Cytogenetic responses have been observed in virtually all IFN-α studies in CML. Their incidences, however, varied greatly, from 22% of patients in the MRC trial to 58% of patients in the MDACC study (31 ,39). Incidences of complete and partial cytogenetic response also vary. Impacts of complete and partial cytogenetic responses on survival were demonstrated in most of the large studies. In the MRC study, the 5-year survival rates of complete, partial, minor, and no cytogenetic responders were 100%, 92%, 59%, and 47%, respectively (p = .004) (39). Similarly, the 3-year survival of the 7% of patients who achieved complete cytogenetic remission was 100%, compared with 72% survival for other patients (p = .2). In the Italian study, those patients who achieved cytogenetic response within 24 months had a 5-year survival of 88%, versus 65% survival for other patients (p <.01) (37). Impact of cytogenetic response is best demonstrated by the MDACC study (31). A landmark analysis demonstrates the respective survival impacts of complete and partial cytogenetic remissions obtained at 12 months of IFN therapy (see Fig. 10.1-2). Furthermore, a multivariate regression analysis demonstrates the independent effect of cytogenetic responses on survival (Table 10.1-5). This impact is maintained in all pretherapy prognostic groups and overrides their impact on survival (Table 10.1-6). As is observed in Table 10.1-6 , incidences of cytogenetic responses decrease with worsening of disease characteristics. Survival of all patients with cytogenetic responses is virtually constant regardless of prognostic groups, however.

Table 10.1-5 Summary of Proportional Hazards Regression Model Relating Fixed and Time-Varying Covariates to Survival Outcomes

Factor	Multiplier (95% Confidence Interval)	p Value
Fixed		
Spleen size[a]	1.62 (1.05-2.49)	.029
Marrow basophils[b]	1.82 (1.18-2.80)	.007
Time-varying		
Complete or partial response[c]	0.21 (0.11-0.39)	.0001

[a]Baseline group: spleen size smaller than 5 cm.

[b]Baseline group: percentage of basophils less than 3%.

[c]Baseline group: other responses.

Studies of Minimal Residual Disease and Interferon-a Therapy

Patients with complete cytogenetic remission were subjected to a series of studies that exploited the characterization of the molecular abnormality in Ph-positive CML.

Southern blot DNA hybridization with BCR probe confirmed that complete cytogenetic responses are also associated with disappearance of rearranged BCR bands (43). Nevertheless, standard cytogenetics and Southern blot have relatively low levels of sensitivity for detecting residual disease at a 3% to 5% level (44).

Western blot, which is conducted at MDACC with an antibody directed against an ABL epitope, provides information on the ratio between BCR-ABL and ABL protein, a ratio that correlates well with cytogenetic tests and perhaps has a higher level of sensitivity (45).

Fluorescent *in situ* hybridization (FISH) has become a useful technique after a modification developed at MDACC. Hypermetaphase FISH (HMF) is theoretically capable of detecting 0.2% of residual disease. Accordingly, we were able to detect residual disease among patients previously defined as complete cytogenetic responders by standard cytogenetics (Table 10.1-7) (45).

Table 10.1-7 Number of Patients in Cytogenetic Response Categories as Determined by Standard Karyotype Analysis and Their Classification as Determined by Hypermetaphase Fluorescence *In Situ* Hybridization

	No.	Cytogenetic Response (Standard Cytogenetics)		Cytogenetic Response (HMF)	
		None	Minor	Partial	Complete
None	16	11	5	—	—
Minor	9	2	7	—	—
Partial	6	—	2	4	—
Complete	19	—	—	3	16

Finally, studies using reverse-transcriptase polymerase chain reaction (RT-PCR) amplification of the BCR-ABL RNA transcript were introduced to MDACC in the late 1980s. These tests possessed a theoretical level of resolution several thousandfold higher than the standard cytogenetic test. In the initial analysis, residual disease was detected in 17 of 18 studied patients (46). In an update, however, a reversal of this situation was observed, with 10 of 18 studied patients not demonstrating residual transcripts (47). The major difference between the current study and the previous one is the much longer follow-up of patients in complete cytogenetic remission [42 months for polymerase chain reaction (PCR)-negative patients; 21 months for PCR-positive patients] (Table 10.1-8). RT-PCR data in CML vary with different laboratories; at least one reason for this variance is a marked difference in sensitivity of assays (48). The achievement of BCR-ABL negativity by RT-PCR is not necessarily consistent with disease elimination. Based on cytogenetic results, treatment with IFN-α was discontinued in 30 patients at MDACC. Disease relapse occurred in ten of these patients; the remaining 20 patients remained in unmaintained and sustained complete cytogenetic response for an average period of 6 years (1+ to 11+ years) (49). Samples from seven of these patients were tested by high-sensitivity PCRs; residual disease was detected in four of them, despite long and uninterrupted

remissions (M Talpaz, *unpublished data*). These results support our observations on detectable residual disease in these patients, and provide findings consistent with establishment of tumor dormancy.

Table 10.1-8 Cytogenetic Remission Duration and Polymerase Chain Reaction Status of 18 Chronic Myelogenous Leukemia Patients with Long-Term Responses

Patient	Bone Marrow (BM) or Blood (Bl)[b]	Positive vs. Negative	Junction Found to Be Positive (b2-a2 or b3-a2)	Continuous Complete Cytogenetic Remission Duration (Mo)
	RT-PCR Results[a]			
1	BM	Positive	b3-2a	34
2	BM-Bl	Negative-negative	NA	85
3	BM-Bl	Negative-negative	NA	48
4	BM	Positive	b3-a2	63
5	Bl	Positive	b3-a2	23

16	BM	Positive	b2-a2	19
17	Bl	Negative	NA	29
18	Bl	Positive	b3-a2	16

NA, not applicable; PCR, polymerase chain reaction; RT, reverse transcriptase.

[a]All samples listed showed positive results for PCR amplification of normal antigen-binding lymphocyte.

[b]Where BM-Bl is listed, both bone marrow and blood from the same date were available and tested.

From Talpaz M, Kantarjian HM, O'Brien S, Kurzrock R. The M. D. Anderson Cancer Center experience with interferon-α therapy in chronic myelogenous leukemia. In: Goldman JM, ed. *Clinical haematology*. London: Baillière Tindall, 1997:291-305, with permission.

Analytic methods used greatly improved understanding of residual disease after IFN-α therapy, especially with active changes in quantity of residual disease occurring post-cytogenetic remission. They suggest an ongoing process of residual disease depletion occurs that requires several additional years of therapy. This information implies there is a need to continue IFN-α therapy for several years beyond complete remission. It is apparent, however, that a quantitative assessment of residual disease (in addition to qualitative assessment by PCR) is required to evaluate the impact of residual disease on disease relapse patterns.

Information that the association between residual disease and sustained remission is not purely quantitative exists, however. Residual disease was demonstrated in patients with ongoing sustained complete remission. Furthermore, residual disease was also demonstrated in PCR-negative remission when myeloid and erythroid colonies from the same patients were analyzed by PCR (50). We postulated, therefore, that mechanisms such as specific immune recognition may operate at that particular disease setting.

Interferon-α Combination Therapy of Chronic Myelogenous Leukemia

The effect of IFN combined with low-dose cytosine arabinoside (ARA-C) was examined at MDACC in two separate studies in which IFN was administered at 5 MU per m², whereas ARA-C

was administered at two different doses and schedules: In study I (1989), ARA-C was administered at 15 mg per m^2 daily × 7 days, every 30 days. In study II (1993), ARA-C was administered at 10 mg daily. Results of the study indicate an improvement in hematologic and cytogenetic responses of IFN-α single therapy and are summarized in Table 10.1-9 (51). These results were also demonstrated in a large randomized French study that noted survival benefit for combination therapy (52 ,53).

Table 10.1-9 Interferon (IFN)-α plus Low-Dose Cytosine Arabinoside in Ph-Positive Early Chronic Phase Chronic Myelogenous Leukemia

Parameter	IFN + LD ARA-C, 7 D/Mo	IFN + LD ARA-C, Daily
CHR (%)	84	95
CG response (%)		
Overall	64	78, p = .08
Major	38	53, p = .10
Complete	20	30
3-yr survival (%)	78	84

ARA-C, cytosine arabinoside; CG, cytogenic; CHR, complete hematologic response; IFN, interferon; LD, low-dose; Ph, Philadelphia chromosome.

The combination does not worsen IFN-α-induced toxicities because it frequently requires dose reduction due to myelosuppression. Although additional studies may be required, the combination is likely to become the standard of care in CML.

The effect of combining IFN-α and intensive chemotherapy was examined in a study at MDACC (Kantarjian et al., *unpublished data*). Seventy-four patients were included in the study; all were administered a standard dose of IFN-α (5 mIU per m^2). For 16 patients who failed to achieve hematologic or cytogenetic responses, however, at lease one course of intensive chemotherapy was added to treatment. This chemotherapy consisted of daunorubicin, vincristine, a standard dose of ARA-C, and prednisone. Although only a minority of patients received this additional therapy, an impact on survival occurred. Fifty-five percent of patients were alive at 10 years and beyond, implying (although it requires confirmation) that the intensive chemotherapy probably delayed transition to blastic crisis among the high-risk patients subjected to this treatment.

Interferon-a: Mechanism of Action

Although several groups of investigators have studied the role of IFN-α in CML, its mechanism of action in CML remains largely unknown. The reasons for these problems may lie with the unique growth features of CML, which behaves more like a premalignant disease. CML Ph-positive cell lines can be established only from the blast crisis phase of the disease, a stage mostly resistant to IFN-α. Other *in vitro* systems, such as short-term clonogenic growth assays or long-term bone marrow culture assays, failed to simulate the disease pattern of benign-phase CML; therefore, their usefulness may be limited. Animal models, either BCR-ABL transgenic mice or severe combined immunodeficiency mice xenotransplanted with human CML, develop hematopoietic abnormalities that follow only in part the typical phenotype of CML in humans.

A number of mechanisms of IFN-α action have been proposed to play a role in CML, including induction of FAS and its ligand on CML progenitors, thereby facilitating cell death of early stem-cell populations (54 ,55). Adhesion defects of CML progenitors that disrupt their ability to adhere to bone marrow stromal layers were proposed as major pathophysiologic defects in CML. These defects were attributed to an abnormal function of integrin α4α5/β1 receptors that affects their binding to fibronectin, a defect shown to be partially corrected with IFN-α (56). Suppression of CML cells by a cellular immune system has also been proposed to be a possible mode of action of IFN-α, and may explain long-term complete cytogenetic remission in spite of the presence of residual disease (50). IFN-α may possess all of these activities, which may operate at different times during the course of therapy. Understanding this mechanism of action is critical to the rational development of the next therapeutic modality for CML because it allows exploitation of the unique activities demonstrated by IFN-α.

Interferon Therapy in Hairy Cell Leukemia

Part of "10.1 - Leukemias, Lymphoma, and Multiple Myeloma "

HCL, a malignant proliferation of cells of lymphoid lineage associated with splenomegaly, pancytopenia, and recurrent infections, was the initial U.S. Food and Drug Administration-approved indication for IFN therapy. HCL was first described by Bouroncle et al., who referred to it as *leukemic reticuloendotheliosis* (57). The name *hairy cell leukemia* was coined by Schreck and Donelly to describe its characteristic morphology (58). Approximately 90% of patients with HCL require treatment during the course of their disease. Quesada et al. first reported on achievement of remission in seven patients with HCL using partially purified IFN-α, with three patients obtaining complete remissions and four obtaining partial remissions (59). Similar results were later obtained with recombinant IFN-α preparations (60 ,61). In these reports, nine and 22 patients, respectively, were treated with IFN-α-2b, 2 MIU per m^2, subcutaneously, three times per week, and frequent partial responses were observed. Other studies using IFN-α-2a reported major response rates together with significant complete responses (62 ,63 ,64 and 65). These studies demonstrated an overall response rate of 89%, including 9% complete response, 71% partial response, and 10% minor response (66) (Table 10.1-10).

Table 10.1-10 Selected Trials of Recombinant Interferon-α Therapy in Hairy Cell Leukemia

Study (Reference)	Patient (No.)	Response (%)			
		Complete	Partial	Minor	None
Quesada et al. (62)	30	30	60	10	0
Foon et al. (75)	14	7	86	0	7
Rai et al. (65)	25	28	24	48	0
Golomb (64)	195	4	78	5	13
Total	264	9	71	10	10

IFN-α is effective as initial therapy and as therapy in patients with disease progression after splenectomy. Although the majority of these responses are partial responses, most patients with remissions have normal blood counts, with only a few residual hairy cells in the bone marrow and without predisposition to infections, the factors responsible for disease morbidity and mortality. Normalization of platelet count usually occurs after 2 months; normalization of hemoglobin and neutrophil counts usually takes longer, 4 to 5 months. Recovery of immune status accompanies the increases in blood counts with restoration of NK-cell and T-lymphocyte activity; these are associated with a decrease in incidence of infections.

In a small number of patients (5% to 10%) developments of neutralizing antibodies to recombinant preparations results in

IFN-resistance (67 ,68). This resistance can be overcome using the partially pure IFN-α preparations (69).

Necessary duration of IFN-α therapy was examined by several studies (64 ,70); 12 months of IFN-α therapy was recommended as optimal. Most investigators have suggested that discontinuation of IFN-α results in relapse in most patients, however, with relapses responding to a reinstitution of IFN-α (2).

Because IFN-α therapy is associated with significant toxic side effects, low-dose IFN-α (0.2 MIU per m^2) was administered and examined for 6 to 12 months to minimize toxicity (71). Although toxicity was minimal, only 54% of patients had responses. Also, low-dose IFN-α was shown to be an ineffective regimen in treatment of relapse after previous IFN therapy (72). Therefore, low-dose regimens cannot be recommended in therapy of patients with HCL. At least 23 different IFN-α alleles have been identified, coding for 15 different proteins. Two approved IFN-α preparations are IFN-α-2a (Roferon-A) (Hoffman-La Roche, Nutley, NJ) and IFN-α-2b (Intron A) (Schering, Kenilworth, NJ). These differ only in amino acid residue at position 23, with IFN-α-2a having a cysteine residue and IFN-α-2b having an arginine residue at this position. The current suggested regimen for treatment of HCL is IFN-α, 2 MIU per m^2, three times per week for 12 to 18 months. Few studies of IFN-β and IFN-γ in the therapy of HCL exist, and they do not appear to have any advantage over IFN-α in response or toxicity (73 ,74).

The exact mechanisms of action of IFNs in HCL are not clear. NK cells are known to be deficient in HCL, and efficacy of IFNs in inducing NK cell activity may be important (75 ,76 and 77). HCL cells have been shown to be resistant to NK cell lysis; therefore, recovery of NK cell function cannot be the only mechanism of IFN effects (75 ,76). The antiproliferative and differentiating effects of IFNs demonstrated in other cell lines are also likely to be important (78 ,79). Interferons stimulate HLA-deoxyribose (DR) antigen expression in HCL cells. Increased expression of class II major histocompatibility antigens facilitates T-cell–mediated cytotoxic activity, which may be important in the antitumor effects of IFNs. Several different mechanisms of action, therefore, may account for the therapeutic effect of IFN-α.

The use of nucleoside analogues pentostatin (2-deoxycoformycin [DCF]) and cladarabine (2-chlorodeoxyadenosine [2CDA]) has changed the management of HCL. Pentostatin, an adenine deaminase inhibitor, administered at a dose of 4 mg per m^2 every 2 weeks, produced complete responses and partial responses in 50% and 25% of patients, respectively (80 ,81). Toxicity associated with this therapy is generally mild and remissions are durable. Patients who have not experienced success with previous IFN therapy do respond to pentostatin (81). Cladarabine, an adenine-deaminase–resistant purine analogue, has been administered at a dose of 0.1 mg per kg per day by continuous infusion for 7 days, achieving an 80% complete response rate, with most of the remaining 20% of patients experiencing good partial responses (66 ,82). Again, toxicity of the drug is mild and limited to transient fevers and neutropenia. The responses, including partial responses, are durable, and the few patients who relapse respond to a second course of cladarabine. These drugs have been approved by the U.S. Food and Drug Administration for the treatment of HCL. At present, therefore, IFNs, although effective agents in therapy of HCL, should be considered as second-line agents used for the few patients who do not respond to one or two courses of cladarabine and pentostatin.

With the use of these effective treatments, relevance of long-term outcome in patients with HCL has become more significant. Kurzrock et al. compared survival of patients referred to a single institution before and after the availability of IFN-α and 2CDA therapy and noted significantly different 5- and 10-year rates (67% versus 89% and 64% versus 84%, respectively, p = .0009) (Fig. 10.1-3) (83). Overall mortality, however, still exceeded that in the general population, due to neutropenia-related infections (83).
FIGURE 10.1-3. Kaplan-Meier analysis of actuarial survival of 265 hairy cell leukemia patients referred after January 1, 1984, compared with 85 patients referred before that date. (From Kurgrock R, Strom SS, Estey E, et al. Second cancer risk in hairy cell leukemia: analysis of 350 patients. *J Clin Oncol* 1997;15:1803–1810, with permission.)

Previous epidemiologic studies suggested that HCL patients were twice as likely as other cancer patients to have second malignancies (84). It has been postulated that their impaired immune functions, including impaired NK cell activity, may predispose these patients to a second cancer. It has been suggested also that the immune impairments associated with treatment

with IFN-α, 2CDA, and DCF could contribute to this tendency (83 ,85). Kurzrock et al. studied 350 HCL patients treated in a 27-year period and found 26 patients (7.4%) with a second cancer developing at least 6 months after the HCL diagnosis (83). This increase, however, did not reach statistical significance and was not associated with therapy with IFN-α, 2CDA, or DCF (83). Other smaller studies have been conflicting in their results (86 ,87 and 88).

Interferon Therapy in Multiple Myeloma

Part of "10.1 - Leukemias, Lymphoma, and Multiple Myeloma "

Multiple myeloma is a malignant proliferation of plasma cells that has remained incurable despite considerable progress in understanding its biology. Several numeric and structural chromosomal abnormalities (particularly involving chromosomes 13 and 14) have been identified (89); it is believed that these abnormalities prevent the normal processes of differentiation and apoptosis of the myeloma cells, thus resulting in their accumulation in the bone marrow. In this process, deregulation of the c-myc oncogene is believed to be important (90). The role of interleukin-6 (IL-6) and bone marrow microenvironment have been extensively studied, and it has been shown that IL-6, produced by the stromal cells of marrow, promotes tumor growth and prevents dexamethasone-induced apoptosis (91 ,92 and 93).

After demonstrations in preclinical trials of the antitumor activity of IFNs in myeloma cell lines, considerable interest in examining this activity in patients was generated. Mellstedt et al. first reported the antitumor activity of IFN in myeloma (94). *In vitro* studies have demonstrated a direct and dose-dependent inhibitory effect on the proliferation of myeloma cells by IFNs (95 ,96). This growth inhibition is seen in IL-6-dependent and IL-6-independent cell lines (97). Interferons have also been reported to downregulate expression of c-myc and N-ras oncogenes (98 ,99).

Initial pilot studies in patients with relapsing or refractory myeloma found evidence of activity; IFN-α as a single agent was not shown to be superior to conventional chemotherapy in previously untreated patients (94 ,100 ,101). It was concluded that the activity of IFN in multiple myeloma is comparable to that of several other agents, but is inferior to that of melphalan.

Because of the reported synergistic activities of IFNs and several cytostatic drugs (102 ,103), combinations of IFN-α with chemotherapy were examined, and initial phase 1/2 studies showed promising results. In a study combining IFN-α with melphalan and prednisone, a response rate of 75% was observed (104); in an alternating regimen—IFN-α combined with vincristine, bischloroethyl-nitrosourea, melphalan, cyclophosphamide, and prednisone—a response rate of 80% (including 30% complete responses) was reported (105). Subsequent prospective randomized trials, however, have not confirmed unequivocally that regimens combining chemotherapy with IFN are superior to chemotherapy alone (106 ,107 ,108 ,109 ,110 ,111 ,112 ,113 ,114 ,115 ,116 ,117 ,118 ,119 and 120) (Table 10.1-11). The IFN arms in these trials have produced outcomes ranging from substantially higher response rates or disease-free and overall survival to no difference from standard chemotherapy protocols (106).

BepiVDex, BCNU, epirubicin, vincristine, dexamethasone; CR, complete response; CP, cyclophosphamide; IFN, interferon; PCAB, prednisone, cyclophosphamide, actinomycin D, bleomycin; PR, partial response; VABP, vincristine, actinomycin D, bleomycin, and prednisone; VMCP, vincristine, melphalan, cyclophosphamide, and prednisone; V-MTZ-CP, vincristine, mitoxantrone, cyclophosphamide, and prednisone.

The rationale for use of IFN-α as maintenance therapy in patients responding to conventional induction regimens was the finding that at the end of induction, myeloma cells in responding patients enter a plateau phase similar to the G phase of the cell cycle (121). Therefore, the antiproliferative activity of IFNs can be used to maintain responses obtained with chemotherapy. The first randomized trial using IFN-α for remission maintenance was reported by Mandelli et al. (122). During a period of 3 years, 101 patients with multiple myeloma who had responded to induction chemotherapy were

randomized to receive IFN-α-2a three times weekly (n = 50) or observation (n = 51) (122). Median duration of response from time of randomization was 26 months in the IFN-treated group versus 14 months in controls (*p* = .0002). Median survival was 52 months in the IFN arm and 39 months in controls (*p* = .035) (122). Other randomized trials have produced differing results; although relapse-free survival was usually prolonged in the IFN-treated patients, prolongation of disease-free and overall survival was substantial in some trials but minimal in others (106). In the Swedish study reported by Westin et al., induction therapy with melphalan and prednisone was followed by randomization to IFN-α therapy or observation in 120 patients achieving a plateau phase (123). Interferon-α-2b, 5 MIU, three times per week was administered subcutaneously to 59 patients until relapse. A prolongation of the plateau phase for the IFN-treated patients occurred (60 versus 25 weeks, *p* <.0001), but no improvement was observed in overall survival (123). In the study by the Southwest Oncology Group, however, no differences in response or overall survival duration were seen in patients treated with IFN-α-2b, 3 MIU, three times weekly, after achieving a response with conventional induction regimens (124).

Combination of IFN and dexamethasone has also been investigated because dexamethasone has been reported to reduce the toxicity of IFN without affecting its efficacy. A considerable response (57%) was noted in newly diagnosed patients (125), but a reported 68% response rate with this combination in refractory patients (126) could not be confirmed (127). This combination has resulted in the improvement of quality of partial responses (128 ,129).

IFN therapy has also been examined after high-dose chemotherapy and autologous bone marrow or stem-cell transplantation on the assumption that it may be more effective in patients with minimal residual disease (130 ,131 and 132). In one study, disease-free survival was found to be significantly prolonged in the IFN-treated patients (130).

IFN-α therapy cannot be considered as the standard in induction therapy or a way to maintain remission produced by conventional chemotherapy. Because no standard treatment for myeloma exists, however, the decision to incorporate IFN-α into a patient's regimen should be individualized, with the most consideration being given to younger patients with minimal residual disease who are able to tolerate the therapy.

Interferon Therapy in Lymphomas

Part of "10.1 - Leukemias, Lymphoma, and Multiple Myeloma "

IFNs have little significant activity in aggressive-histology lymphomas, but their roles in therapy of follicular lymphomas and cutaneous T-cell lymphoma has been extensively investigated. Foon et al. reported four complete responses and nine partial responses among 24 patients with advanced non-Hodgkin's lymphoma treated with IFN-α-2a, 50 MIU per m^2, three times weekly (133). These responses were short-lived and were only maintained by continuing the toxic regimen. Using a lower dose of IFN-α-2a, 6 MIU per m^2, three times per week, Mantovani et al. reported a 52% response rate (134). VanderMolen et al. were unable to demonstrate a clear dose-response relationship in a trial of low-dose (3 MIU daily) versus high-dose (50 MIU per m^2, twice weekly) IFN-α-2a (135). Responses were generally of greater magnitude and longer duration using the higher dose (135). Several groups have clearly demonstrated the activity of IFNs in relapsed and refractory low-grade lymphomas, with responses of 30% to 40% (135 ,136 ,137 ,138 and 139).

IFN has been demonstrated to exhibit synergistic activity against follicular lymphomas when administered concomitantly with chemotherapy and has been investigated with conventional regimens in the hope of maintaining remission and prolonging disease-free survival. Several prospective randomized trials have been reported that assessed benefits of the addition of IFN to induction chemotherapy (Table 10.1-12) (140 ,141 ,142 ,143 ,144 ,145 ,146 ,147 and 148). In trials combining IFN with a single alkylating agent (chlorambucil or cyclophosphamide), no beneficial effect was demonstrated (140 ,141 and 142). Price et al. randomized patients with previously untreated stage III or IV follicular lymphoma to chlorambucil, with or without IFN-α-2b, for an 18-week induction period. Responding patients were next randomized to maintenance therapy with IFN-α-2b or observation (141). No improvements in response rate or overall survival were noted, but significantly lower recurrence rates were noted in a follow-up report (146). In the trial by Peterson et al., 581 previously untreated patients with stage III or IV follicular lymphoma were randomized to receive cyclophosphamide alone or with low-dose IFN-α-2b, followed by further randomization of responders to IFN maintenance or observation (142). No differences in response rate, estimated time to treatment failure, or overall survival for the two induction regimens occurred. Patients who received IFN maintenance showed a trend toward prolongation of time to treatment failure (*p* = .06) but no difference in survival.

Cb, chlorambucil; CHVP, cyclophosphamide, doxorubicin, teniposide, prednisone; COPA, cyclophosphamide, Oncovin (vincristine), prednisone, Adriamycin (doxorubicin); CP, cyclophosphamide; CR, complete remission; CVP, cyclophosphamide, vincristine, prednisone; DFS, disease-free survival; IFN-α, interferon-α; OS, overall survival; PR, partial remission.

[a]Six-year data.

In contrast, significant improvements in response rate and duration were observed by adding IFN to anthracycline-containing combination chemotherapy (143 ,144). In these studies, significant prolongation of overall survival was also noted for combination therapy. In the trial by the Groupe d'Etude des Lymphomes Folliculaires, reported by Solal-Celigny et al., patients received either cyclophosphamide, doxorubicin, teniposide, and prednisone alone or with IFN-α-2b, 5 MIU three times per week for 18 months. A higher response rate (85% versus 69%), event-free survival (34 months versus 19 months), and overall survival at 3 years (86% versus 69%) was observed in the IFN-treated group (143 ,147). An increase in incidence of some adverse events in the IFN-treated group occurred; a quality-adjusted time without symptoms of disease or toxicity of treatment analysis, however, suggested that the IFN-treated patients had more time without symptoms of disease or toxicity of therapy. The Eastern Cooperative Oncology Group investigated the effect of adding IFN-α-2a to cyclophosphamide, vincristine, prednisone, and doxorubicin (COPA) for patients with stage III or IV low-grade non-Hodgkin's lymphoma (144). Overall response rates were comparable in both groups (86%), as were complete remission rates (COPA, 29%; IFN-COPA, 32%). Time to treatment failure was significantly longer for the IFN-treated group, however, with 34% disease-free survival at a median of 5 years versus 19% (p = .0013). At 5-year follow-up, median survivals of the two groups were not significantly different (148).

The role of IFNs in maintaining remissions achieved by conventional cytoreductive chemotherapy has been investigated in six prospective randomized trials using IFN maintenance without further chemotherapy (Table 10.1-13) (149 ,150 ,151 ,152 ,153 and 154). In four of these studies, the benefit of IFN therapy in prolonging disease-free survival was not statistically significant or could be seen only in patients in complete remission after initial chemotherapy. It has been argued that the low dose and short duration of IFN therapy in these trials may be the reason for suboptimal results (155). In a study by the German Low Grade Lymphoma Study Group using a relatively high dose of IFN-α (5 MIU, three times weekly) with no restriction on duration of therapy, a significant prolongation of median disease-free survival was observed (152). Using IFN maintenance, 49% of patients remained relapse-free at 4 years, versus 27% in the control arm (152). IFN therapy was well tolerated, an important consideration in a disease with a long natural history. A metaanalysis of these studies, including a total of 1,756 patients, showed a survival difference favoring IFN therapy (156). When dividing the trials into those with more intensive anthracycline-containing regimens versus those that used less intensive initial chemotherapy with alkylating agents, a large survival advantage for IFN-treated patients was observed in the more intensive trials (5-year survival, 74%, versus 60%, 2p = 0.00001). In the less intensive trials, no survival differences occurred between the two groups (2p = 0.89). The advantage for IFN was limited to patients achieving a response (2p = 0.00004) (156). Use of IFN in maintaining remission after minimal residual disease is achieved as a result of myeloablative therapy is currently under investigation. The European Organization for Research and Treatment of Cancer has initiated a randomized, controlled, multicenter, phase III trial to evaluate the role of IFN-α as maintenance treatment after autologous bone marrow or stem-cell transplant for previously untreated patients with stage III or IV follicular lymphoma.

Table 10.1-13 Trials of Interferon (IFN)-α Maintenance Therapy in Follicular Lymphomas

| Study (Reference) | Patients without Progression of Disease | | | Follow-Up Time | p Value |
	IFN-α	Observation	Total		
Peterson (150)	53	441	94	4 yr	.06
Hagenbeck (151)	44	38	82	3 yr	.12
Unterhalt (152)	49	27	76	4 yr	.003
Aviles (149)	62	25	87	8 yr	<.001
Dana (154)	?	?	279	4 yr	.18
Rohatiner (153)	68	28	96	4 yr	.05

It appears that IFN-α is a useful addition to the treatment of follicular lymphomas in combination with anthracycline-containing regimens for induction and for the maintenance of remissions after initial cytoreductive therapy.

IFN has been used effectively in the treatment of cutaneous T-cell lymphoma. IFN-α-2a at a dose of 50 MIU per m^2, three times weekly, achieved two complete responses and seven partial responses among 20 previously treated patients (157). Other investigators have reported even higher response rates in previously untreated patients (158). Combination of IFN-α with extracorporeal photopheresis (ECP) was investigated by Dipple and colleagues (159). Nine patients with advanced cutaneous T-cell lymphoma were treated with the combination,

and ten patients received ECP alone. Of the patients treated with ECP alone, one achieved a complete remission, one showed a minor response, and eight patients had stable disease. When using the combination, four patients had complete remissions, two had partial responses, two patients had stable disease, and one patient had progressive disease (159). Combination of IFN-α with retinoids has also been investigated in several studies (160 ,161 ,162 and 163). These studies combined relatively low doses of IFN-α with etretinate or 13-*cis*-retinoic acid, reporting significant improvements in patient outcomes.

The role of IFN-α in Hodgkin's lymphoma has also been investigated. Although the use of current regimens of combination chemotherapy cures a high proportion of patients with untreated Hodgkin's disease (HD), 30% to 35% of these patients relapse. Despite the use of aggressive regimens, including bone marrow or stem-cell transplant, the prognosis of patients with relapsed or refractory disease is generally poor. IFN-α has been used with benefit in some cases of refractory HD (164 ,165 ,166 ,167 and 168). Mazza et al. randomized patients with high-risk HD who were treated with combination chemotherapy to receive maintenance therapy with IFN-α-2b or no further treatment (169). IFN was administered at a dose of 3 MIU per day for 3 months, followed by 3 MIU, three times per week for 9 months (169). They observed that IFN maintenance could improve duration of complete remission, but follow-up was too short to arrive at definitive conclusions. Aviles and colleagues reported 135 patients with stage IIIB-IVB HD who were initially treated with epirubicin, bleomycin, vinblastine, and dacarbazine (170). After the achievement of complete remission, the patients were randomized to either maintenance therapy with IFN-α, 5 MIU, three times per week for 1 year, or no further therapy. After a median follow-up of 74.3 months (range, 49 to 108 months), 91% of IFN-treated patients remained in remission (as compared to 58% of controls). Overall survival was also better in IFN-treated patients (92% at 7 years, compared to 67% in controls, *p* <.01) (170). Therefore, IFN-α appears to have activity in HD and may be beneficial in prolonging duration of remission—and possibly survival—in patients treated with combination chemotherapy.

Interferon Therapy in Other Hematologic Malignancies

Part of "10.1 - Leukemias, Lymphoma, and Multiple Myeloma "

Interferon therapy has been investigated in other hematologic malignancies, albeit infrequently. Montserrat and colleagues reviewed the experience in chronic lymphocytic leukemia (CLL) (171), reporting that responses to IFN in CLL appeared to be transient, rarely complete, and more significant in early-stage disease. They concluded that IFN-α is not effective in previously treated patients or patients with more advanced disease. With the advent of more effective regimens in CLL, the role of IFNs in CLL may be limited to maintaining minimal residual disease.

The role of IFN therapy has also been examined in Waldenstrom's macroglobulinemia (WM), a differentiated B-cell malignancy that is usually less responsive to standard chemotherapeutic agents because of slow proliferating cells. Rotoli et al. examined the efficacy of IFN-α in 88 patients with an immunoglobulin M monoclonal protein greater than 10 g per L (172). Thirty-eight patients were classified as WM. Response to therapy was based on a reduction in monoclonal protein in two consecutive measurements. They concluded that IFN-α produced a significant improvement in 50% of patients with immunoglobulin-M monoclonal protein greater than 30 g per L, including occasional complete remissions. In patients with a low protein (immunoglobulin M-monoclonal gammopathies of undetermined significance), therapy was, however, ineffective (172). Legouffe and colleagues used IFN-α in 14 patients with progressive WM manifested by a high level of monoclonal component (>10 g per L), severe anemia (hemoglobin <8.5 g per L), and a high tumor mass (lymphadenopathy or hepatosplenomegaly, or both) (173). Interferon-2α, 1 MIU, three times a week, was administered for a mean duration of 10.3 months (range, 2 to 44 months). An increase in hemoglobin level was observed in 42% of patients, and a significant reduction in monoclonal protein was observed in 28% of patients (173).

Direct Effects: Interferons Binding Receptors of Type I: Interferon-α, -ß, -τ, and -Ω

Part of "10.2 - Melanoma "

Human interferon-α (IFN-α) is comprised of a complex array of subspecies of approximately 165 to 166 amino acids, each encoded by a superfamily of closely related genes located with the IFN-α and IFN-ß genes on the short arm of human chromosome 9 that are variably modified by posttranslational glycosylation (1,2 and 3). In humans, 14 nonallelic IFN-α genes and four pseudogenes are clustered together with genes for IFN-α. A

variable mixture of IFN-α species is induced in leukocytes and other host cells by stimuli classically including viruses or nucleic acids. A remarkable number of biologic effects of these separate subspecies are held in common, despite variable relative antiviral, antiproliferative, antigen-modulating, and immunomodulating effects (4,5).

IFNs α and β bind with high affinity (dissociation constant of 10^{-10} to 10^{-12} M per L) to single receptors of 110 kd that are specified on chromosome 21 and range in density from 100 to 10,000 receptors per cell (6,7). A range of cellular processes induced by IFNs follow the production of a new set of proteins after binding and internalization. Knowledge of events that occur after the binding of IFN to its receptors has advanced significantly in the 1990s (8,9 and 10). A multimeric transcription activator, interferon-stimulated growth factor 3 (ISGF3), is stimulated to translocate to the nucleus, where it binds *cis* to the IFN-response element of DNA, inducing genes that comprise the array of IFN-stimulated genes (10,11,12,13 and 14). When the cytoplasmic and nuclear components of ISGF3 associated with IFN-α are activated, ISGF3-γ, the component of the complex specifically recognizing the interferon-stimulated response element (ISRE), and ISGF3, which contains three polypeptides activated specifically on phosphorylation, interact and translocate to the nucleus without the requirement of protein synthesis to activate the IFN response element.

Interferon Binding Receptor of Type II: Interferon-Gamma

Part of "10.2 - Melanoma "

IFN-γ binds a receptor that is discrete from that which is reactive with type I IFNs. Evidence for two classes of receptors, one with low affinity (10^{-9} M) and one with high affinity (10^{-11} M), have been reported (15). Most melanomas have been found to express high-affinity receptors (16). The *in vitro* and preclinical *in vivo* immunomodulatory activity of IFN-γ has been one of the most potent of all interferons, leading to expectations that IFN-γ may also be the most therapeutically active interferon against cancer. Trials of IFN-γ in patients with advanced melanoma, as well as in patients with a high risk of relapse, have been conducted systematically as for interferon-α-2 (IFN-α-2), as detailed below.

Preclinical Effects of the Interferons Relevant to Melanoma

The pleiotropism of IFNs has posed a significant problem in their quantification. The specific activity of various IFN preparations may be expressed in terms of differing functions (e.g., antiviral, antiproliferative, differentiative, effector cell activating, antigen augmenting, and enzyme inducing). Antiviral activity has been accepted as the basis of IFN standardization, although it is not clear that this function is related to the effects of IFN-γ in cancer therapy. Units of antiviral activity determined against reference standards of the Center for Biologics in Washington, DC, are commonly used to quantify IFNs α and β; recombinant IFN-γ and newly developed polyethylene glycol (PEG)–bound forms of IFN-α-2 are generally reported in terms of mass. The various species, subspecies, and molecular variants (muteins) of IFNs argue for the adoption of functional standardization in terms of alternative mechanisms relevant to antitumor activity for clinical trials.

Pleiotropic actions of IFNs may be separated into several categories that are useful in analyzing preclinical and clinical data, as summarized in Table 10.2-1 . Direct effects of IFNs include antiproliferative and differentiative effects that may be demonstrated against fresh melanoma tissues or cultured cell lines *in vitro*. Effects that result in alterations in tumor cell surface antigen expression without direct impact on tumor cell growth, invasion, or metastasis, or all three, have been designated as *composite.* These effects may permit host recognition and response *in vivo.* Three major categories of IFN effects that are potentially relevant to melanoma have been studied in some detail and may provide a basis for understanding the outcome of therapeutic trials. Indirect effects of IFNs are those mediated by the host immune system, including cellular elements such as large granular lymphocyte, natural killer (NK) or lymphokine-activated killer (LAK) cells, macrophage or dendritic cells, neutrophils, and T and B cells (17,18,19 and 20).

Table 10.2-1 Pleiotropy of Interferons: Direct, Composite, and Indirect Effects

Direct (Tumor Cell)	Composite (Tumor Cell Antigens)	Indirect (Immune)	Indirect (Vascular)
Antiproliferative	MHC class I and MHC class II cell surface antigens	Nonantigen-specific effector activation	Antiangiogenic
Differentiative	Tumor-restricted cell surface antigens	Macrophage-monocyte/dendritic cell	
Antiviral	Adhesion molecules	Large granular lymphocyte	
	ICAM-1	FcR expression	
		MHC class I/II expression	
		Antigen-specific effector modulation	
		T cell	
		B cell	

FcR, Fc receptor; ICAM-1, intercellular adhesion molecule-1; MHC, major histocompatibility complex.

Direct Effects

Actual mechanisms of antitumor action of IFNs in human cancer remain uncertain. Nonrecombinant IFNs α and β and recombinant subspecies of IFN-α-2, -β, and -γ have been evaluated *in vitro* for antiproliferative activity against cultured

and fresh melanoma. These IFNs demonstrate comparable growth-inhibitory activity, and one may draw from them three general observations: (a) a direct dose-response tumor-inhibiting relationship exists for each, (b) heterogeneity among different tumors regarding sensitivity to inhibition occurs, and (c) a sensitivity of a majority of melanomas to high levels (greater than 500 U per mL) of IFN *in vitro* exists. Molecular probes for the dissection of pathways of IFN signaling are available, allowing their analysis beyond measurement of IFN-induced enzymes such as oligoadenylate synthetase (see below), and more distal effects on target-cell major histocompatibility complex antigen expression. Some of these studies conducted with tumor cells suggest that acquired defects in the signal transducers and activators of transcription (STAT) pathway exist that may lend to combined IFN-α-2 therapy. Clinical trials to test these possibilities are underway. Analysis of signal transduction intermediates of IFNs in cells of the melanocytic series (such as atypical and dysplastic nevi) is feasible as a surrogate for effects on tumor cells remaining in patients after surgery for high-risk melanoma. These studies have revealed unexpected evidence of constitutive activation of some elements of the STAT pathway in precursor atypical nevi, arguing for the prospective evaluation and correlation of these intermediates and the markers of progression in prospective trials (21).

Enzyme Induction

A number of enzyme pathways are activated after induction of the IFN response element, including some that have been evaluated in clinical trials. These include 2"5" oligo adenylate synthetase (2"5" oligo-As), and protein kinase (p67) (22). Two molecular forms of 2"5" oligo-As of 33 kd and 110 kd have been identified, differing in subcellular localization and activation requirements (23,24). Roles of different forms of 2"5" oligo-As in relation to antitumor effects of IFN have not been established. Indoleamine 2,3,-dioxygenase is induced by IFNs in a dose- and time-dependent fashion; this enzyme alters tryptophan metabolism (25) and, with xanthine oxidase, generates superoxides that may relate to therapeutic and toxic effects of IFN, as well as to depression of cytochrome P-450 enzyme levels (26,27). IFN-γ–induced neopterin production may provide an additional biochemic tool for analyzing intermediate effects of IFN-γ *in vivo.*

Direct Effects: Antiproliferative Effects of Interferons in Combination with Chemotherapy and Other Biologic Agents In Vitro

The presence of additive or synergistic effects of chemotherapeutic agents have been examined with IFNs *in vitro*, using isobologram plots to assess comparing agents in combination with one another for synergistic, additive, or subadditive effects against melanoma lines (28). Synergistic effects between IFN-α-2a, doxorubicin, and bleomycin against SKMel-28 have been identified; additive effects between IFN-γ and doxorubicin have also been reported (29). Synergism between IFN-ß and vinblastine, using melanoma line CRL 1424 (30), have been reported, as have negative interactions between vinblastine and IFN-α (29).

Synergistic antiproliferative interactions of IFNs α, ß, and γ have been noted against murine B16 melanoma (31) and a human melanoma line (32), as well as fresh and cryopreserved human melanomas (33). At low levels of 1 to 10 U per mL, IFN-γ has been shown to increase the induction of enzyme 2"5" oligo by IFN-α and -ß (34). IFN-γ has been shown to potentiate apoptotic cell death and DNA fragmentation induced by tumor necrosis factor (TNF) (35), whereas IFNs α and γ potentiate the tumor-cytotoxic activity of TNF in clonogenic stem cell assays (36).

Direct Effects: Differentiation In Vitro and In Vivo

Differentiative and growth regulatory, or apoptotic, effects of IFNs became focal points of interest in the 1990s. A number of adhesion molecules, growth factors, and receptors have been identified in malignant melanoma but not in normal nevi. Receptor-ligand pairs may serve as paracrine or autocrine growth-stimulating circuits in melanoma. A progression cascade has been proposed (37) in which precursor atypical (and histologically dysplastic) nevi evolve through discrete stages that culminate with invasive melanoma. Growth factor receptors, ligands, adhesion molecules, and other progression factors that distinguish the later phases in this melanocytic progression sequence may serve as ideal targets for interventions to prevent melanoma (38). Epidermal growth-factor receptor (EGFR) expression plays an uncertain role in melanoma. TNF, IFN-γ (or a combination of these cytokines) enhance expression of EGFR in melanoma line DX3 *in vitro.* In contrast, IFN-α and retinoic acid inhibit EGFR expression in other systems. Retinoids, as well as IFNs, are studied as potential inhibitors of melanoma induction in which the molecular impact of these agents on discrete mediators of progression provides the strongest preclinical rationale for their use in long-term melanoma prevention efforts.

All three species of IFN modulate melanocyte-stimulating hormone (MSH) receptor expression and have been reported to influence the response to MSH *in vitro*, with production of tyrosinase and melanization (39). In the absence of MSH, no prodifferentiative effect, augmented tyrosinase, or melanin production was demonstrable for any IFN. The differentiative effects of MSH *in vivo* provide one rationale for consideration of IFNs in treatment of melanoma precursors. Paradoxically, the induction of differentiation (melanization) by IFN-γ in experimental melanoma has been reported to be associated with increased metastatic potential of murine B16 melanoma (40).

Human IFN-α (N1) and IFN-γ have been tested against human DX3 melanoma, which metastasizes in the nude athymic mouse. Metastatic lung disease is reduced, and survival of mice is significantly prolonged without apparent effects on differentiation (pigmentation), NK activity, or macrophage activity in this model, in which therapeutic benefit has been attributed to direct antimetastatic effects of IFN-γ (41). Intercellular adhesion molecule-1 (ICAM-1) expressed in metastatic melanoma and associated with invasion in primary melanoma is

induced by exposure of melanoma cells to IFN-γ (42,43). Effects on ICAM-1 and other molecules associated with progression may explain the untoward results obtained in some clinical trials.

Composite (Antigenic) Antitumor Mechanisms: Modulation of Melanoma-Associated Cell Surface Antigens

The effects of IFNs have been related to their impacts on cell surface antigens of melanoma in several systems. The histocompatibility complex is among the most consistent and sensitive targets of IFNs (see Composite Effects: Modulation of Major Histocompatibility Complex Antigens). The effects of IFNs on expression of melanoma-associated gangliosides or receptors for growth factors, or both, have been studied, in the hope that these effects may result in enhanced tumor cell susceptibility to host immune recognition and rejection by effector cells or antibodies.

IFNs modulate the expression of many cell surface molecules, not all of which have been assigned physiologic functions in the melanocyte, although some may play a role in the progression from premalignant process to metastasis-competent invasive disease, as noted in Table 10.2-1 (44,45,46,47 and 48). Markers found to be expressed in melanoma but not—or significantly less—in normal nevic melanocytes include antigens of class II major histocompatibility complex, ICAM-1, nerve cell adhesion molecule (N-CAM)-like molecule Muc-18, and growth factors like basic fibroblast growth factor (bFGF) and transforming growth factor-alpha (TGF-α), as well as gangliosides such as GD_2(49,50,51,52,53,54,55,56 and 57). The molecular events of tumor progression may potentially be targeted immunologically or modulated by agents such as IFNs, retinoids, or antisense RNA, or all of these, to prevent evolution of melanoma. The ability of IFNs to modulate markers that distinguish melanoma from other tissues also lends to their use in combined-modality therapy.

Combined Use of Interferons and Antibodies

The expression of the melanoma-associated antigen p96 has been shown to be augmented by IFN-γ, but not by IFNs α or β. IFN-α and IFN-β have been reported to enhance the expression of the transferrin receptor-like glycoprotein p97, although neither affects the high-molecular-weight melanoma proteoglycan-associated glycoprotein antigen p240. Diagnostic and therapeutic results obtained with the corresponding antibody (96.5 anti-p97) were reported to be improved when combined with IFN and associated with a significantly prolonged plasma half-life and increased volume of distribution of radiolabeled 96.5 antibody administered 24 hours after IFN. Improved localization of antibody to tumor with threefold increased tumor: blood distribution was suggested, although direct evidence from tumor and normal tissue biopsies is lacking.

The monosialoganglioside G_{M2} and the disialoganglioside G_{D3} are recognized cell surface antigens of melanoma. G_{D3} is reported to be modulated in some cell lines by IFN-α and -β without apparent synergy or additive effects between IFN types. These effects of IFN have served as a rationale for trials of IFN in conjunction with antibodies to melanoma. In early series, the anti-G_{D3} antibody R_{24} is reported to induce objective remissions in 10% to 20% of patients with metastatic melanoma (59,60 and 61), but these results have not been confirmed in larger subsequent studies studied to identify immunologic dose-response correlates and maximal tolerable dosage (62,63). IFN-α administered concomitantly with R_{24} has been reported to decrease circulating T-suppressor cell and NK cell numbers in patients (64).

Composite Effects: Modulation of Major Histocompatibility Complex Antigens

The modulation of major histocompatibility complex (MHC) class I HLA-A, -B, or -C antigens has been described for all classes of IFN. IFN-γ, and to a lesser extent, IFN-β, regulate MHC class II [HLA deoxyribose (DR), DP, and DQ], as well as class I antigens (45,65,66,67,68 and 69).

Human melanoma cells express class I and class II MHC antigens; class II MHC antigens are expressed hierarchically (with HLA-DR > DQ > DP) in melanoma (70). Expression of HLA-DR antigens is demonstrable in the majority of primary melanomas, whereas HLA-DQ antigens are detected in only 38% (71). Variable loss or alteration in expression or membrane transport of HLA-A, -B, or -C has been reported in dysplastic and congenital melanocytic lesions, as well as melanoma (72,73). The prognosis of primary melanoma has been correlated with the expression of MHC class I and II antigens. Melanomas expressing HLA-A, -B, or -C antigens in greater than 50% of tumor cells concomitantly, with HLA-DR expressed in less than 50% of cells, are noted to have a better prognosis.

Clinical implications of altered MHC antigen expression relate to their pivotal functions in intercellular immunologic recognition and communication at multiple levels. Antigen presentation to T cells by macrophages, Langerhans' or dendritic cells, and B cells are associated with the expression of MHC class I and II antigens, adhesion molecules, and costimulating molecules (e.g., B7) as recognition structures for helper and cytotoxic T cells. The expression of HLA-DR was recognized to be necessary but insufficient for recognition and response to melanoma by autologous T lymphocytes (71,74). Antitumor effects of IFNs α and β may thus occur through their augmentation of melanoma MHC class I antigen expression, whereas differing therapeutic effects of IFN-γ may relate to its broader impact on MHC class I and II antigens in melanoma and other tumors (75,76). Although induction of class II MHC antigens in primary melanoma cells may increase their immunologic reactivity, the treatment of metastatic melanoma cells *in vitro* with IFN-γ does not enhance autologous T-cell recognition, mitotic burst, or cytotoxic function. Decreased susceptibility to NK cells is associated with induction of increased class I major histocompatibility antigen expression (77,78). IFN-γ protects human melanoma cells from lysis by LAK or activated NK cells; exposure of melanoma cells to as little as 1 to 10 U per mL of IFN-γ decreases tumor cell sensitivity to LAK cell lysis within hours (79,80).

The induction of MHC class I and II antigens by IFN-γ may increase the immunogenicity of melanoma cells used for vaccination, outweighing effects on susceptibility to NK or LAK effector cells in a murine model (81). IFN-γ-treated B16 melanoma cells elicit improved host immune resistance to subsequent tumor

challenge through effects attributed to an enhanced T-cell response (82). Thus, induction of increased MHC class I and II tumor-cell surface-antigen expression may account for the enhanced efficacy of host T-cell-mediated immunity or tumor cell elimination by means of a composite mechanism, irrespective of the modulation of effector cell functions.

Indirect Immunomodulatory Effects

Part of "10.2 - Melanoma "

Macrophage, Natural Killer, T, and B Cells

The macrophage is a key target of IFN-γ, which is described as a macrophage-activating factor (83,84 and 85). The large granular lymphocyte known as the *NK cell* is a well-recognized target of IFNs *in vitro* (86,87). Clinical relevance of the effects of IFNs on NK activity has been sought *in vitro* and *in vivo* with IFNs α, β, and γ. NK activity measurements in multiple trials has depended on assay conditions, effector cell manipulation, and delay from blood-drawing to assay (rest period). No convincing evidence of a relationship between NK cell activity *in vivo* and therapeutic activity of IFNs in patients with melanoma or other solid tumors has been documented (88,89,90 and 91). Antibody-dependent cellular cytotoxicity (ADCC) function of peripheral blood lymphocytes is mediated in part by NK cells, and has been augmented *in vitro* and *in vivo* by IFN-α, as well as interleukin-2 (IL-2) (92). As trials of antitumor antibodies are further developed, the optimization of NK activity and ADCC with IFNs, IL-2, IL-12, and other biologics continues to be important.

T Cell

Specific T-cell-mediated immunity has been implicated as the basis of antitumor effects of IFNs in human melanoma. Durable complete responses have been reported in multiple clinical trials of IFN-α (Table 10.2-2). Population shifts in T-cell subsets has been noted during therapy with IFNs α and γ, and clinical antitumor response to IFN-α and IFN-γ have been correlated with reproducible shifts in T-cell subset distribution, but not with other mechanisms examined to date (93,94,95,96,97,98 and 99). IFN-α modulates mixed leukocyte reactions *in vitro*(100), and the presence of T-cell infiltrates *in situ* has been correlated with favorable prognosis (101). The modulation of specific cytotoxic T-cell immune responses to melanoma by IFN-α-2 remains a leading hypothetical basis of durable antitumor effects observed with IFN-α-2 in multiple trials; prospectively, this observation is being evaluated in cooperative group trials that have sufficient numbers to permit correlation with treatment and outcome (18,19,102,103,104,105,106 and 107). The definition of MHC class I-restricted and MHC class II (DR)-restricted epitopes recognized by CD4[+] T cells adds a new dimension to the expanse of CD8[+] T-cell-defined MHC class I-restricted epitopes for analyzing IFN-modulated effector functions (108).

Table 10.2-2 Recombinant Interferon (IFN)-α in Metastatic Melanoma

Study (Reference)	Dose (MU)	Route/Schedule	Entered/Evaluable	Response			Median Duration (Mo)

CR, complete response; PR, partial response.

In preclinical systems, Belardelli, Gresser, and colleagues (109,110 and 111) have shown that IFN prevents the outgrowth of experimental murine tumors treated shortly after tumor challenge. Antitumor activity of murine type I IFN in this system critically depends on the presence of an intact immune system in the host and the participation of the CD4[+] subset of T cells. Tumor response does not correlate with the tumor cell susceptibility to direct tumor growth inhibition by IFN in this model; rather, tumor regression induced by IFN in this system appears to be associated with immunologic effects of IFN on the tumor and host.

B Cell

In relation to the B cell response to tumor, IFN-γ increases production of immunoglobulin G (IgG)-2a and decreases that of IgG-3, IgG-1, IgG-2b, and IgE by human B cells (112). The last several years have seen the initiation of trials of several whole-cell tumor vaccines administered in conjunction

with IFN-α-2. The Eastern Cooperative Oncology Group (ECOG) trial E2696 analyzed immunomodulatory effects of IFN-α-2b administered together with or after the (GM2) vaccine [GM2-KLH plus QS 21 (GMK)] (Progenics, Tarrytown, NY), establishing the feasibility of this combination without loss of serologic response to GM2 (as detected by enzyme-linked immunoadsorbent assays for IgM and IgG) and paving the way for a GM2 plus IFN combination (see Adjuvant Combinations). A further phase 3 trial of Melacine (Ribi Immuno Chem, Inc.) is also in progress, testing vaccine plus IFN versus IFN at lower dosages.

Specific effects of IFNs α, ß, and γ on specific immune function against autologous melanoma have not been examined, however. Difficulty measuring immune response to autologous tumor cell-surface antigens has impeded this analysis in clinical trials of IFNs, and it may be no less important than in the interpretation of therapeutic response to vaccine trials.

Multiparameter Analysis of Immunomodulation *In Vivo* during Phase 1B Trials for Melanoma

Part of "10.2 - Melanoma "

Effects of IFN-α on elements of the immune system have been summarized. The activity of IFN-α and IFN-γ on several effector cell populations (potentially related to clinical antitumor effects of IFN-α) has been reported by many authors (19,88,92,104,113,114).

Two single-institution dose-response studies of IFN-γ focusing on melanoma have been reported (Table 10.2-3). One phase 1-2 trial (105,115) of 30 patients with measurable metastatic melanoma conducted at the Pittsburgh Cancer Institute Melanoma Center evaluated the immunomodulatory effects of five different dosages of IFN-γ (Biogen, Inc., Cambridge, MA), ranging from 3 to 30 to 300 to 1,000 to 3,000 μg per m^2 per day intravenously, in groups of six patients each. Phenotypic markers of host effector-cell activation, NK cell activity, and IFN-induced enzyme activation reveal no major differences in the effects of 2-hour daily and 24-hour continuous intravenous infusions (115,116). The most potent and consistent augmentation of host mononuclear cell 2"5" oligo-As enzyme and NK cell activity, as well as relative T helper: suppressor cell shifts at 2 weeks of treatment has been reported between dosages of 300 and 1,000 μg per m^2 per day.

Table 10.2-3 Systemically Administered Interferon (IFN)-γ Alone and in Combination with Other Biologics and Chemotherapeutic Agents

CR, complete response; PR, partial response; rIFN, recombinant interferon.

[a]Genentech, San Francisco, CA.

[b]Biogen, Inc., Cambridge, MA.

The Biological Response Modifier Program of the National Cancer Institute has carried out a phase 1B trial (117) of IFN-γ in patients without measurable known metastatic disease. Twenty-five patients with resected stage I to III melanoma were treated for 15 days with one of five dosages ranging from 0.1 to 1 to 10 to 100 to 250 μg per m^2 per day intramuscular (i.m.) IFN-γ (Genentech, Inc., San Francisco, CA). NK activity, monocyte H$_2$O$_2$ release, Fc receptor expression, and HLA-DR expression were evaluated serially during the 15-day treatment cycles (118). A daily dosage of 100 μg per m^2 was found to induce maximally

monocyte Fc receptor density, hydrogen peroxide production, and MHC class II DR antigen expression. These investigators recommended pursuing a three-times-weekly regimen of 0.2 mg IFN-γ, administered subcutaneously (see Adjuvant Applications of Interferon in High-Risk Melanoma). Kleinerman et al. have studied IFN-γ administered by 6-hour intravenous (i.v.) infusion in terms of monocyte tumoricidal activity; i.m. inoculations of 0.25 to 0.5 mg per m^2 per day were effective, but higher doses of 1.0 mg per m^2 per day did not activate monocytes (118).

Together, the data of the Melanoma Center of the Pittsburgh Cancer Institute and the Biologic Response Modifier Program of the National Cancer Institute suggest that intermediate dosages of IFN-γ, ranging from 100 to 1,000 mg, induce optimal activation of NK activity, CD4/CD8 ratio, DR expression, and 2″5′ A synthetase on one hand, and NK activity, monocyte H_2O_2 release, and Fc receptor/DR antigen expression on the other (105,115,118,119). These studies have been limited in numbers, however; they included a total of only 25 to 30 patients each, with only three to seven patients per dose tier. Furthermore, IFN produced by two different pharmaceutical sources—Biogen and Genentech, respectively—were evaluated. In neither study were the immunologic effects of dose evaluated over intervals generally considered adequate for determining clinical antitumor effects (i.e., 1 to 3 months).

The ECOG reported a dose-seeking phase 2 study of seven dosages of IFN-γ (E4687) ranging from 0.01 to 0.90 mg (0.01, 0.03, 0.10, 0.30, 0.50, 0.70, and 0.90 mg per m^2, i.v., three times weekly). The dosages tested in this trial bracketed the suggested optimal immunomodulatory dosages of previous studies and extended to lower and higher dosages than previously evaluated. The clinical trial was complemented by a laboratory study of immunomodulatory effects measured in serial blood samples drawn over a 29-day interval from a majority of participants in the clinical study (118,120,121). Ninety-eight patients entered this therapeutic trial, with 11 to 16 per dose tier, several times the number studied in previous dose-response analyses. One-half of the patients treated during the clinical study E4687 entered the laboratory immunologic corollary study E4987, nested within the clinical trial.

The immunomodulatory impact of IFN-γ was found to be significant and durable at 29 days of treatment. Immune effects of IFN-γ were most pronounced in the T-cell compartment at the lowest dosages tested, whereas effects on the NK/monocyte compartment were maximal at the mid-to-higher dosages tested. This multiparameter analysis of immune response to IFN-γ produced results more complex than originally envisioned: rises in CD4/CD8 ratio and suppression of CD8 T-cell subset numbers occurred early in treatment and were durable through day 29 in only the lowest-dose (0.01 mg per m^2 per day) tier. NK and monocyte activation, determined either by functional assays or by phenotypic markers, were most notable earlier and correlated significantly with IFN-γ dosage for all dose groups over the lowest dosage (0.03→0.9 mg per m^2 per day). The results of this study differ according to time of assessment and dosage regarding phenotypic shifts (at low dosages) and NK cell/monocyte activation (at high dosages), suggesting that results of previously reported clinical trials must be interpreted with caution.

Role of Interferon-γ as a Mediator of Clinical Effects of Other Cytokines

Part of "10.2 - Melanoma "

IFN-γ induction by IL-2 has been documented in several trials (122) in which ambient levels of 1 to 7 U per mL were shown to be induced after continuous i.v. infusion of IL-2 at dosages of 1.5 to 20 MIU per m^2. IFN-γ induced during therapy with IL-2 may play a role in therapeutic, as well as toxic effects of IL-2. Other cytokines that are T-cell activators and modulators, including IL-4, IL-7, and IL-12, may also achieve their effects in part through IFN-γ or its modulation. The effects of IL-12 are closely related to the induction of IFN-α, in which the toxicity of induced IFN-α has proven to be problematic (123).

Antiangiogenic Actions of IFN-α

Part of "10.2 - Melanoma "

IFN-α was one of the earliest available antiangiogenic agents for clinical exploration. Based on seminal observations in B16 murine melanoma, angiogenesis is recognized as a factor in tumor progression (124). Despite the large clinical trial experience with IFNs α, ß, and γ, no direct evidence of a role for antiangiogenic effects in clinical benefits exists for IFN-α or IFN-ß in human melanoma and other solid tumors. The observation that IFN-α is able to cause regression of hemangiomas of childhood stands as a clinical basis for exploration of this mechanism in relation to the clinical antitumor activity of IFN in malignant neoplasms (125). Signaling through bFGF and its receptor, FGFR-1, is demonstrated to be relevant to human melanoma growth *in vitro* and in explant tumors of nude mice. The application of antisense ligand- and receptor-specific oligonucleotides is required for significant inhibition of tumor growth (126,127). Delivery of antisense nucleotides is an issue for extrapolation of this observation to clinical trials; the relevance of bFGF and VEGF to vascularization of human melanoma has not been documented directly, although studies now in progress may resolve this question. A balance between proangiogenic (bFGF) and antiangiogenic (IFN-2) effects have been proposed, based on preclinical studies that require evaluation.

Toxicity and Pharmacokinetics of the Interferons: Results of Phase 1 Trials

Part of "10.2 - Melanoma "

The clinical toxicity of different IFN species involves a similar range of target organs, although relative components of toxicity differ from species to species (128,129). Acutely, a flulike constitutional syndrome with fever, chills, headache, malaise, myalgias, arthralgias, and fatigue occurs in the majority of patients and is diminished over time with continued daily or alternate-daily administration (best at bedtime). Long-term toxicity of IFN consists of constitutional flulike symptoms compounded by anorexia, weight loss, and fatigue. These late toxicities are complex results of dysgeusia, low-grade fever, and nutritional compromise and may be difficult to differentiate from the appearance of thyroid dysfunction or other endocrine pathology on the basis of the autoimmune processes recognized for IFN-α as for IL-2. Neuropsychiatric toxicity ranges from

mild cognitive deficits to frank depression and psychosis. Low back pain and headache with severe rigors have been associated with IFN-α in particular. Metabolic alterations in the blood-lipid profile and elevated low-density lipoproteins (LDLs), owing to inhibition of lipoprotein lipase, have been noted with hypertriglyceridemia (130). IFN-α may depress plasma cholesterol by 15% to 40%, with a parallel decrement in high- and low-density cholesterol (although very low-density lipoproteins are not altered) (131,132 and 133).

Leukopenia is a hematologic toxicity of the IFNs; less frequently, thrombocytopenia and anemia result. Infections are a recognized complication of leukopenia, but bleeding complications have been rare. Diminished colony-forming capacity and hypocellularity have been noted in the bone marrow, which are rapidly reversible on withdrawal of IFN (134,135).

Hepatotoxicity observed at high doses frequently includes elevated circulating transaminase enzyme levels that are dose-related and reversible on withdrawal of the agent without evidence of cholestasis. Rarely, subacute hepatic necrosis and cholestatic liver failure resulting in death have been observed when IFN is administered in the face of hepatotoxicity with hyperbilirubinemia or history of antecedent viral or alcoholic liver disease. Careful observation of hepatic function generally permits the avoidance of such problems, with treatment modified according to signs and symptoms of toxicity (18,136). After the initial report of two cases of fatal hepatotoxicity of high-dose IFN in the pivotal E1684 adjuvant trial for high-risk melanoma (137), the confirmatory intergroup trial E1690 was completed without any instance of life-threatening hepatotoxicity; the only two toxic fatalities noted were cardiovascular and cerebrovascular, occurring on low-dose IFN.

Cardiovascular, renal, and central nervous system (CNS) toxicity is less common. Supraventricular tachyarrhythmias noted with IFNs may be direct effects or related to fever, nutritional, and fluid imbalances. Complex conduction disturbances have been observed with IFN-γ, including bradycardia with high-grade heart block (105). Cardiotoxicity is increased among elderly patients and patients with underlying heart disease or previous exposure to cardiotoxic agents, but the mechanism has not been defined (138,139). Hypotension occurs through at least two separate mechanisms: acute hypotension 1 to 2 hours after IFN administration may be related to peripheral vasodilatation and responds to a fluid repletion (or, rarely, may require pressors); hypotension during chronic administration of IFNs is related to subclinical low-grade fever with insidious fluid losses, anorexia, dysgeusia, and diminished fluid intake. Proteinuria is the most common renal manifestation of IFN and is generally reversible on its withdrawal (140,141,142 and 143). Rarely, interstitial nephritis and nephrotic syndrome have been reported with IFNs α and γ (138,144).

CNS toxicity associated with global changes in mentation is often subtle. Although cognitive dysfunction induced by IFN may be documented in formal testing, it is often more apparent to families and friends of patients. Stupor and coma with diffuse slowing of electroencephalogram pattern has been reported infrequently and is reversible on discontinuation of IFN (139,145). Mild peripheral neuropathy has also been noted, with paraesthesia and slowing of nerve conduction velocity. Reversible retinal microvascular toxicity has been noted during studies of IFN-α administered for macular degeneration that may indicate the need for ophthalmologic evaluation of IFN-α therapy in other settings (146).

Rhabdomyolysis has rarely been reported in association with IFN-α-2 at high dosages (147). The significance and attribution of such occurrences is difficult to resolve, however, because it has been reported to occur less than a week into IFN-α-2 therapy in patients who are postoperative. Although monitoring for elevations in creatine phosphokinase enzymes has been suggested, it is not an adopted practice because the event is rare and occurs early, precluding use of laboratory values to monitor treatment and supportive care. The maximum tolerated dose for IFN-α lies between 10 and 20 MU per m² daily and 50 MU per m² alternate-daily for periods of weeks to months, regardless of subspecies. The half-life of IFN is 6 hours in the blood and allows alternate-daily schedules of outpatient administration by i.m. and subcutaneous (s.c.) routes. The maximum tolerated dose for IFN-α varies according to industrial preparation used, schedule, and route; acceptable absorption and activity have been reported with IFN-γ administered intravenously or intramuscularly (148,149). Early pharmacokinetic studies of IFN-α-2 have demonstrated that peak levels at 5 MU per m² obtained by the intravenous (i.v.) route do not reach 100 U per mL, whereas by the i.m. and s.c. routes generally adopted for therapy, they remain less than 50 U per mL. By contrast, the administration of doses of 20 MU per m² (or 36 MU per dose in early pharmacodynamic studies) achieves serum levels approaching 10,000 U per mL. This difference in the pharmacodynamics and peak levels has been the focus of considerable interest as the positive results of trials using the i.v. administration of 20 MU per m² have shown the first survival benefits in melanoma, whereas lower dosages administered by alternative routes have yielded less clinically meaningful results. The maximum tolerated dose of IFN-γ ranges between 1,000 to 5,000 μg per m² for daily and alternate-daily (three times weekly) schedules and differs for the several preparations of IFN-γ (Biogen, Inc., Cambridge, MA; Genentech, San Francisco, CA; Schering Plough, Kenilworth, NJ) (105,143).

Interferon-γ as a Single Agent for Metastatic Disease: Phase 1–2 Trials of Interferon-α-2

Part of "10.2 - Melanoma"

The reference agent for treatment of melanoma, and the only chemotherapeutic agent approved by the U.S. Food and Drug Administration since 1976, is dacarbazine (dimethyl triazine imidazole carboximide). Dacarbazine therapy is associated with response rates of 15% to 25% (20%, mean) in collected series and median duration of response is 5 to 6 months (151,152 and 153). Few patients with metastatic melanoma treated with dacarbazine achieve a complete response. Temozolomide is an orally well absorbed and widely distributed prodrug that has wider tissue distribution than dacarbazine and spontaneously converts rather than requiring hepatic anabolism to mitozolomide, the active agent in dacarbazine. Temozolomide has received accelerated approval from the U.S. Food and Drug Administration

Oncologic Drug Advisory Committee for use in anaplastic astrocytoma, and has shown equivalence to dacarbazine in large international phase 3 trials against melanoma with greater ease of administration of the potential for CNS antitumor activity (154). The nitrosoureas, vinca alkaloids, taxanes, and platinum coordination compound have exhibited activity against metastatic melanoma, although the response rate for each of these classes has generally been less than 15%.

Against this background, IFN-α was initially brought to clinical trial against melanoma in 1978, when the American Cancer Society began a series of trials of buffy-coat leukocyte IFN produced by K. Cantell from the Finnish Red Cross. These trials were limited by the extremely short supply of the agent, and trials that therefore endured for only 6 weeks; therefore, no firm conclusions can be drawn. The trials served as an important impetus for the pharmaceutical industry to begin commercial production of IFNs α, β, γ, and other biologics, using recombinant DNA (rDNA) technology. The large-scale production of IFNs by rDNA technology enabled the first systematic evaluation of appropriate dose, route, and schedule of IFN-α-2, as well as the other major subspecies of IFNs α, β, and γ.

Phase 2 trials that document the antitumor activity of recombinant IFN-α-2 in melanoma are summarized in Table 10.2-2 (93,128,155,156,157,158,159,160,161,162 and 163). The overall response rate with IFN-α-2 is 15.4% in these collected series, with one-third of those responses complete in the longest-followed series (5% overall), irrespective of IFN-α-2 subtype. No cross-resistance to IFN after unsuccessful previous chemotherapy, radiation therapy, hormonal therapy, IL-2, bacille Calmette-Guérin, or other non-IFN biologics has been reported. The comparable antitumor activity of IFN-α-2 in metastatic disease, whether administered early (as initial therapy) or late (after other modalities were unsuccessful), has led to its early exploration for advanced disease. It has been argued, however, that the best opportunity for additive or synergistic curative immunologic effects is available in initial treatment with the smallest tumor burden. The median duration of partial responses with recombinant IFN-α-2 is 4 months, whereas the duration of complete responses sustained off all therapy for as long as 7 years in results from several centers. A summary of long-term responders has shown in these patients no distinguishing features of disease that might allow prediction of response or any role of maintenance therapy with IFN after induction of complete response. The median interval to complete response in melanoma and other solid tumors may be as long as 3 months, with some responses noted as late as 6 months on therapy.

Predictors of Favorable Response

The best therapeutic results with IFN-α-2 have been reported with uninterrupted schedules of therapy, regardless of the route (s.c., i.m., or i.v.), and no clear advantage of lower or higher dosages exists in the range between 10 MU per m^2 daily and 50 MU per m^2, administered daily or alternate-daily (97,129,163). Intermittent cyclic treatment with IFN-α-2a administered 5 out of every 14 days, or IFN-α-2b, administered 5 of every 21 (163,165) days, are inactive (157,163,165). IFN-α-2 administered alone at dosage ranges below 10 MU per m^2 three times weekly have not been studied adequately to date in metastatic measurable disease to allow firm conclusions.

Response to IFN-α-2 has been associated with cutaneous and soft tissue, pulmonary sites of disease, and low tumor bulk. Responses in visceral disease have been reported with IFNs in multiple series, however (128,129,163,164). In contrast to chemotherapy with dacarbazine, in which women appear to have a significant advantage, no influence of gender on response to IFN-α has been observed (129).

Predictors of Unfavorable Outcome

Creagan et al. (129,156,166) have prospectively stratified patient accrual for potential prognostic factors in several different trials. A logistic regression analysis of the effect of performance status (0 to 1), previous chemotherapy, site of dominant tumor involvement (visceral), age (older than 55 years), male gender, and treatment dosage, has demonstrated that response was not correlated with performance status, previous chemotherapy exposure, age, or gender. Only the site of dominant metastatic disease (and, in particular, the presence of visceral involvement) was associated with reduced response rate (129). The presence of visceral disease in this series may have served as a surrogate for increased tumor burden, which has also been correlated with diminished likelihood of objective response.

Visceral disease in the CNS has been a major problem with biologic modalities in general, and IFNs in particular. The occurrence of metastatic disease in the CNS (167) after remission of peripheral disease has been attributed to the presence of an immunologic sanctuary in the CNS (167), and anecdotal studies have demonstrated poor penetration of IFNs into the CNS. Observed activities of IFN-β in chronic relapsing multiple sclerosis suggest that IFN may mediate effects on disease sites in the brain, even if the IFN molecule has not been demonstrated to penetrate the CNS in significant levels during therapy.

The development of anti-IFN neutralizing serum antibodies has been correlated with loss of antitumor effects in other diseases (e.g., chronic myelogenous leukemia) and appears to vary with disease state and species of IFN used. In representative series, antibodies have been detected in up to 5% of subjects after 2 to 6 months of therapy (157,168) without demonstrable adverse consequences for therapeutic effects in patients with melanoma. Strategies to reduce immunogenicity and increase the likelihood of tolerance to recombinant IFN-α have included the initial use of i.v. (as opposed to s.c. or i.m.) routes and continuous (as opposed to interrupted) schedules.

Regional Therapy with Interferon-α or Interferon-γ

Part of "10.2 - Melanoma "

Intralesional administration of IFN-α (169) at 6 to 10 MU twice or three times weekly is reported to improve tumor response in treated lesions. Three complete responses and six partial responses were noted in 51 patients, with some responses in lung lesions remote from the sites of intralesional IFN

administration (170). However, the overall response rate for uninjected lesions among patients treated intralesionally in this series (18%) does not differ from that observed with systemic parenteral, i.m., or s.c. administration.

Regional therapy with IFN-γ has focused on two disease settings: malignant ascites and *in transit* involvement of extremities. In the former setting, Edington et al. (171) have demonstrated the feasibility of infusing large numbers of IFN-γ–activated autologous blood monocytes intraperitoneally and have shown the stable localization of radiolabeled monocytes in the peritoneum for 5 days. In the setting of regional *in transit* disease of extremities, Liénard and LeJeune (172,173) have reported striking efficacy of hyperthermic isolated limb perfusion with combinations of melphalan, TNF, and IFN-γ. IFN-γ was administered for the purpose of modulating TNF receptor expression during the subsequent isolated limb perfusion in this trial, but the role of IFN-γ has not been formally established in this setting. Response rates approaching 90% have been reported from Switzerland using this multimodal approach. These results have been confirmed by investigators in the United States (174,175) and the Netherlands (176,177). A more limited exploration of hyperthermic isolated limb perfusion with TNF alone at comparable doses has shown only brief and limited antitumor activity (178), arguing that melphalan, or melphalan and IFN-γ, may be critical to this therapeutic effect. Fraker and colleagues have undertaken a controlled study of isolated limb perfusion with and without IFN-γ that may allow more definitive conclusions (174,179).

Phase 1 and 2 Trials with Systemic Interferon-γ

Part of "10.2 - Melanoma "

Phase 1 and 2 studies of IFN-γ have been more limited in number than those of IFN-α but have systematically developed the agent based on preclinical evidence of immunomodulatory activity for IFN-γ (105,180,181,182 and 183). IFN-γ has exhibited the greatest immunomodulatory activity of any IFN studied; in view of this potent immunologic activity (90,115,120), it has been studied intensively in a number of single-institution and cooperative group trials, as therapy for melanoma. Published trials of IFN-γ administered alone or in combination with other biologics are summarized in Table 10.2-3 . Phase 1 and 2 experience with IFN-γ has shown minimal antitumor activity against melanoma. Phase 1 and 2 studies by the i.v., i.m., and s.c. routes (105,148) have yielded one complete and three partial responses among 75 patients in phase 1-2 trials. A major dose-seeking phase 2 randomized trial of ECOG (E4697) has tested the antitumor activity of seven different dosages of therapy in a total of 98 patients with soft tissue or nodal-dominant disease. Even in this select group of patients with relatively favorable stage i.v. disease, only four responses were obtained (out of 81 evaluable subjects) (2 out of 16 at 0.01 mg per m^2, 1 out of 12 at 0.5 mg per m^2, and 1 out of 13 at 0.9 mg per m^2), for an overall response rate of 4.2%. Antitumor responses occurred at low and high dosages tested, not supporting the hypothetical bell-shaped dose-response relationship for anticancer effects of IFN-γ in humans. The immunomodulatory effects of IFN-γ in the dose-response evaluation by ECOG (E4987) (120,121) establish a potent direct dose-response relationship for NK and monocyte activation; modulation of T-cell subset distribution followed a different dose-response pattern that was greatest at the lowest tested doses of IFN-γ 0.01 mg per m^2 per day and durable for the 1-month interval studied in this trial. Neither the impact of IFN-γ on NK cells and monocytes nor its impact on T cells have followed patterns observed in earlier murine models (184), and no correlation has occurred between immunomodulatory and clinical antitumor effects of IFN in this large clinical-laboratory evaluation. Given the evidence for immunomodulation by IFN-γ in this trial, these effects may have little relationship to clinical antitumor outcomes or the pleiotropy of IFN-γ may include counterbalancing regulatory effects that outflank primary postulated effector systems. The impact of IFN-γ on specific host T-cell responses to tumors was not evaluated in this or any other trial of the IFNs; therefore, the correlation between the tumor-specific immunomodulatory effects of IFN and responses of metastatic disease have not been evaluated.

Phase 2 Trials of Combinations of Biologics—Types I and II: Interferon-α-2 plus Interferon-γ

Part of "10.2 - Melanoma "

Combinations of IFNs of types I and II (IFN-α-2, IFN-β, and IFN-γ, respectively) have been of theoretical interest, given the potential synergism of IFNs interacting through the two separate classes of IFN receptors. The modulation of receptors for IFN-α-2 by IFN-γ and elucidation of signal transduction modulated by IFN-α and IFN-γ (11) provide a further impetus for the exploration of combined-IFN therapy. Cytoplasmic and nuclear gene-regulatory mechanisms induced by these different IFNs may achieve molecular synergism through transcriptional activators of the IFN response elements summarized by Darnell (8,10,11,12,13 and 14).

Clinical studies of combinations of IFNs α and γ have followed two strategies, concurrent and sequenced administration. Concurrent programs of treatment have revealed increased toxicity without apparent therapeutic benefit in several trials (see Table 10.2-3) (185,186,187 and 188). Studies using sequenced delivery of IFNs α and γ suggest improved therapeutic and immunomodulatory activity in renal cell carcinoma (98,113) and deserve examination in melanoma (98,189).

Modulation of Antitumor and Immunologic Effects of Interferons by Biologics, Cytotoxic Drugs, and Nonsteroidal Antiinflammatory Drugs

Part of "10.2 - Melanoma "

The pleiotropic effects of IFN-α-2 include the induction of a variety of feedback mechanisms, including immunosuppressive mechanisms that may be associated with histamines and prostaglandins, for which cimetidine and nonsteroidal antiinflammatory drugs might be effective. In addition, it is hoped that these agents might alleviate the significant constitutional toxicity and flulike syndrome of IFN therapy. A large number of

studies of IFN-α, administered with a variety of dosages and schedules of cimetidine, have not yielded convincing evidence of improved outcome (Table 10.2-4).

Table 10.2-4 Clinical Trials of Interferon (IFN)-α-2 in Combination with Cimetidine

Study (Reference)	Dose (MU)	Route/Schedule	Entered/Evaluable	Response CR	PR	Percent	Duration (Mo)
Flodgren (272)

CR, complete response; PR, partial response.

[a]All patients treated after failure of IFN-α-2 alone.

Clinical trials have explored difluoromethylornithine to modify polyamine-mediated pathways of immunosuppression, as well as low-dose cyclophosphamide, administered to inhibit suppression mediated by suppressor T cells. Neither of these approaches has altered clinical antitumor outcome significantly in small phase 2 trials (160,164,165 and 166,190,191 and 192). Analyses of intermediate end points relevant to postulated mechanisms being exploited have generally been omitted, so it is difficult to draw firm conclusions from these trials.

Miller (193) has conducted a more extensive study of the potential impact of indomethacin, demonstrating neither significant immunologic interactions, nor any durable amelioration of chronic toxicity of IFN-α-2 therapy, in this randomized controlled trial. Dexamethasone has been assiduously avoided in trials of IFN-α, IFN-ß, and IFN-γ as a consequence of its potent immunosuppressive effects. Corticosteroids have been demonstrated to abrogate the benefit of other biologic interventions in experimental animals, and until clearer evidence of the mechanism of antitumor benefit has been obtained, are to be avoided on this basis (193,194).

Modulation of Antitumor and Immunologic Effects of Interferon-α by Retinoids

Part of "10.2 - Melanoma "

Broad interest has developed regarding the potential applications of retinoids for therapy and prevention of a range of cancers. Unexpected and dramatic clinical responses of acute promyelocytic leukemia with retinoids (and the discovery that this disorder is associated with a lesion in the chromosomal region coding for the retinoic acid receptor) have led to studies in a number of epithelial neoplasms. Retinoic acid receptors exhibit sequence homology with the steroid hormone receptor superfamily, suggesting that both may function in the regulation of gene transcription through specific response elements and promoters. The affinities of retinoic acid receptors α, ß, and γ differ for the various retinoids currently under exploration in cancer therapy (e.g., all-*trans*-retinoic acid binds retinoic acid receptor-α, with fivefold higher affinity than 13-*cis*-retinoic acid) (195).

Clinical trials of 13-*cis*-retinoic acid (13cRA) as a single agent have not generally shown activity in solid tumors and have been unrewarding in melanoma in particular. The effects of fenretinoin or topical tretinoin (Retin-A), or both, on dysplastic nevi are of interest and currently under exploration in patients with multiple large atypical or dysplastic nevi and personal or a familial histories of melanoma (ECOG trial E2695). Based on the different antitumor mechanisms and nonoverlapping toxicities of these agents, retinoids and IFNs have been explored for therapy of a number of other solid tumors. Combined modality therapy of squamous cell carcinoma with 13cRA and IFN-α-2 has provided responses in 19 of 28 patients (68%; seven complete responses). On this basis, IFN-α-2 has been combined with either 13cRA or all-*trans*-retinoic acid in a larger series of trials against other solid tumors, including melanoma. The combinaion of IFN-α-2 and 13cRA, however, has shown no benefit in a limited series of patients with melanoma (196).

Modulation of Interferon-α-2 by Prostaglandin Synthetase Inhibition with Piroxicam

Part of "10.2 - Melanoma "

Piroxicam, an inhibitor of prostaglandin synthetase, has been evaluated as a means to inhibit suppression of peripheral blood mitogen responses after IFN therapy, thereby potentially improving the antitumor activity of IFN-α against melanoma. In patients with renal cell carcinoma, *in vitro* immunologic responses were improved with enhanced antitumor activity (197,198 and 199). In a clinical trial against melanoma, neither antitumor effects nor immunosuppressive effects of IFN-α were benefited by the use of piroxicam combined with IFN-α (Table 10.2-5) (199).

Table 10.2-5 Clinical Trials of Interferon (IFN)-α in Combination with DFMO, Cyclophosphamide, Retinoids, and Nonsteroidal Antiinflammatory Agents

Study (Reference)	Dose (MU)	Route/Schedule	Entered/Evaluable	Response CR	PR	Percent	Duration (Mo)
Difluoromethylornithine (DFMO)							
Talpaz (274)

IFN-α-2b + indomethacin	25 mg	p.o. t.i.d.	27/27	1	2	11.1	NS

CR, complete response; NA, not applicable; NS, not significant; PR, partial response.

The occurrence of a vitiligolike hypopigmentary process among patients responding to this combination is notable. A favorable prognostic significance has been associated with "spontaneously" occurring hypopigmentation reported in 1983 (200). The occurrence of vitiligolike depigmentation among patients responsive to IFN-α as a single agent or in more complex regimens of other biologics, suggests that antitumor response and induction of this vitiligolike syndrome may be interconnected and potentially autoimmune (201).

Combined Modality Therapy with Interferons: Concurrent Systemic Chemotherapy with Interferon

Part of "10.2 - Melanoma "

Given the differing presumed mechanisms and nonoverlapping toxicities of cytotoxic chemotherapy and interferon regimens available for melanoma, as well as the lack of a survival impact of previous combination chemotherapy in metastatic melanoma (153), dacarbazine has been empirically evaluated with IFN-2. Single-institution and multiinstitution studies in Australia, Europe, and the United States demonstrate a range of response rates. In Australia, McLeod et al. (202) reported a 30% response rate, with IFN-α-2a combined at low-modest dosage concurrently with dacarbazine at conventional doses. Kirkwood et al. (203,204) reported a randomized multicenter trial of ten centers in Europe and the United States, noting the absence of any apparent benefit of the concurrent combination of dacarbazine and IFN-α-2 over either single agent. A series of larger clinical trials suggested a lack of benefit from IFN-α-2 at a range of dosages administered concurrently with dacarbazine (205,206,207 and 208). Thompson et al. have evaluated IFN-α-2a at moderately high dosages, administered s.c., daily, concurrently with dacarbazine (versus dacarbazine alone), finding the complete response rate to be nearly doubled (6 out of 18, or 33%, versus 2 out of 14, or 14%) but without an advantage in overall response rate or median duration of responses. Sertoli et al. and Bajetta et al. (209,210) reported a multicenter Italian Cooperative Group trial of the Melanoma Biologic Response Modifier Group. This multicenter study demonstrated no improvement in response rate by combination of dacarbazine with either high or low dosages of IFN-α-2b, administered concurrently with chemotherapy. The median duration of response was longest among recipients of the highest doses of IFN-α-2a in the series (9 months with high-dose IFN-α-2a, versus 2.6 to 3.0 months with no or low-dose IFN-α-2a). Uncontrolled studies from Gunderson (207) and Mulder (208) show response rates of 20% to 35%, without qualitatively improved complete response rates or durability of responses.

Combined Modality Therapy with Interferons: Interferon Followed by Dacarbazine

Part of "10.2 - Melanoma "

In contrast to results with concurrent dacarbazine and IFN-α-2, the sequenced delivery of IFN-α-2 before chemotherapy suggested augmented antitumor activity in terms of response rate, quality of response, and survival (211). A phase 2 and 3 study of 64 patients reported objective response rates of 53% versus 20%, with median survival of 16.2 months among IFN-α-2b plus dacarbazine-treated subjects (versus 8.8 months among recipients of dacarbazine alone). Tamoxifen has also been suggested to modulate antitumor effects of dacarbazine (212,213 and 214), and one small randomized study of the Italian Cooperative Group demonstrated a significant benefit of the combination of tamoxifen and dacarbazine over dacarbazine alone in terms of response and overall survival (OS) of metastatic melanoma.

The suggestion of survival advantages in these two randomized controlled trials of dacarbazine combined with tamoxifen or IFN-α-2b led ECOG to test these two binary combinations in a factorial 2 × 2 study. The E3690 trial accrued 272 patients and evaluated end points of survival and progression-free intervals (215). The results demonstrate a lack of any advantage of either interferon (high-dose i.v. IFN-α-2b at 15 MU per m^2 and s.c. IFN-α-2b at 10 MU per m^2 three times weekly) or hormonal (oral tamoxifen as administered by the Italian Cooperative Group multicenter trial) over dacarbazine alone. The median survival of the four trial subgroups receiving dacarbazine or dacarbazine with IFN-α-2b or tamoxifen, or both, was remarkably consistent at 9.1 months and the median progression-free survival was 3.7 months in all four groups. This large multicenter controlled trial has put to rest the question of synergism of dacarbazine with either tamoxifen or IFN-α at the doses and schedules evaluated.

Interferon-α Combined with Temozolomide

Part of "10.2 - Melanoma "

The oral agent temozolomide (Temodal) (Schering Plough Corp., Kenilworth, NJ) is an anabolite of mitozolomide, the active agent in dacarbazine (Dome Laboratories, New Haven, CT). Complete absorption of this agent, distribution to third-space compartments (including the CNS), and spontaneous conversion to mitozolomide have led to the exploration of temozolomide with IFN-α (as has been undertaken with dacarbazine). The results of one phase 1 study that have been reported by Kirkwood et al. (107) show the feasibility of temozolomide at dosages of 750 to 1,000 mg over 5 days with IFN-α-2b at dosages of 7.5 MU per m^2 s.c., three times weekly; further phase 2 and 3 studies of this combination, in conjunction with evaluations of mechanisms of drug resistance—alkyl guanine alkyl transferase—that may themselves be modulated by IFN and temozolomide, are of interest.

Non-Dacarbazine-Based Combinations with Interferon-α-2

Part of "10.2 - Melanoma"

A number of regimens have evaluated the role of IFN-α-2 in combination with cisplatin or more complex polychemotherapy regimens with or without IL-2. These regimens have generally exacted greater toxicity than binary regimens, requiring hospitalization for administration of IL-2 when administered by continuous i.v. infusion or high-dose bolus schedules. One regimen evaluated in France used cisplatin at 100 mg per m^2 on the initial day of therapy, followed by IL-2 at 18 MU per m^2 per day, administered as a continuous i.v. infusion from days 3 to 6 and 17 to 21 of each cycle; IFN-α-2b, 9 MU s.c., three times weekly, is administered over a 28-day cycle (216). A response rate of 54% was reported for this regimen, and response was associated with the number of the sites of metastasis. The occurrence of vitiligo during treatment recalls earlier experiences in untreated melanoma and IFN-α-treated melanoma (199,200). A randomized trial of this regimen, with and without the addition of IFN-α-2, reported by the European Organization for Research and Treatment of Cancer (217,218,219 and 220), has shown increased response rate without survival prolongation using cisplatin. Walsh (221), Schuchter (222), and Richner (223) conducted studies with IFN-α and cisplatin, achieving less striking results. The combinaton of dacarbazine and platinum with IL-2 in bolus (224) or continuous infusion schedules (225) resulted in an increased response rate of greater than 50%, although toxicity was substantially increased.

A more complex regimen at the University of Chicago (201) using multiple cytotoxic agents, IFN-α-2, and IL-2, was one of the earliest to achieve elevated overall and complete response rates. This polychemotherapy regimen (Table 10.2-6) has recorded high overall response rates of 24/42 (55%), and complete response rates of 10/42 (24%). Vitiligolike depigmentation has been correlated with antitumor response to this combination. Response rates of greater than or equal to 50% have also been obtained with a four-drug chemotherapy regimen of dacarbazine, vincristine, bleomycin, and lomustine in Finland (226) in a series including patients with ocular melanoma metastatic to the liver, a setting for which other researchers have found few effective treatments (Table 10.2-7). A series of trials at the M. D. Anderson Cancer Center have evaluated the more complex and toxic regimen of IFN-α-2b with IL-2, either concurrent or preceded by polychemotherapy incorporating cisplatin, dacarbazine, and vinblastine. Response rates for the concurrent regimen known as biochemotherapy have exceeded 50%, with complete response greater than or equal to 10%, although toxicity requiring hospitalization occurs in a significant fraction of patients (see Table 10.2-7). ECOG and the Southwest Oncology Group have begun an intergroup study (E3695) to evaluate whether use of IL-2 as a continuous infusion at high dosage for 4 days and IFN-α-2b at the modest daily dosage of 5 MU per m^2 s.c. adds significantly to the survival and complete response rates associated with cisplatin, vinblastine, and dacarbazine polychemotherapy. This study provides the first multicenter head-to-head evaluation of the IL-2/IFN-α biologic combination with an established polychemotherapy regimen.The high overall and complete response rates associated with this regimen have also

prompted its consideration for adjuvant therapy of high-risk, multiple lymph node-positive patients.

In overview, survival and progression-free intervals reported with more complex regimens of polychemotherapy combined with IFN-α and IL-2 have not been demonstrated to exceed results obtained with dacarbazine alone. Whether a significant advantage can be demonstrated for polychemotherapy with high-dose infusion IL-2 and IFN-α is being determined in an intergroup trial (E3695) (201,202,204,206,207,208 and 209,211,216,221,223,224,225,226 and 227).

Adjuvant Applications of Interferon in High-Risk Melanoma

Part of "10.2 - Melanoma "

Prognostic Assessment of Melanoma

Prognosis of melanoma is defined by a patient's TNM stage and has been grouped by the American Joint Council on Cancer (AJCC) staging into localized stages I and II, nodal stage III, and distant stage IV. The cardinal prognostic variable for patients with localized cutaneous melanoma has been recognized as the microstage, or Breslow depth (168), in those patients without metastases (stages I and II). In addition, the presence or absence of ulceration of the primary tumor is an important factor not currently included in the AJCC system (228,229). The presence or absence of lymph node involvement or in transit disease (AJCC stage III) and distant (AJCC stage IV) metastases are the dominant adverse prognostic features once metastasis has occurred beyond the primary. The determination of regional lymph node status has been made on clinical grounds or by elective lymph node dissection for pathologic evaluation of regional nodal status, a morbid and costly method that often has missed regional nodal disease in areas not suspected of involvement. In the 1990s, the advent of isotopic scintigraphic and hand-held gamma probe or dye localization for sentinel lymph node mapping from primary sites of skin has advanced the precision of such assessment significantly (230,231). Using combined isotopic or dye localization procedures (or both) for sentinel node identification, up to one-third of melanoma patients evaluated by elective proximal regional node dissections may have experienced drainage to different nodal basins as identified by sentinel node mapping techniques. These procedures, which are potentially useful in patients with primary tumors over 1 mm Breslow depth or with other adverse primary features, have supplanted elective regional lymph node dissection without mapping; OS, therefore, has not improved in multiple large, randomized, controlled trials. Sentinel lymph node mapping and selective lymphadenectomy directed by isotopic lymphoscintigraphy or blue dye lymphography has been shown to identify lymph node metastases more precisely and with less surgical morbidity, hospitalization time, and cost than elective dissection (232,233). The increasing adoption of sentinel node mapping procedures throughout the United States and Europe has substantially altered the selection of node-positive and node-negative patients for trials in the late 1990s. This approach improves the prognosis of node-negative (stage II) patients by culling out higher-risk patients with subclinical nodal disease from this heterogeneous group, whereas at the same time improving the prognosis of node-positive (stage III) patients by adding this group with minimal tumor burden to it (i.e., the "Will Rogers" phenomenon). Discussion of sentinel node mapping technology and the therapeutic role of this technique lie beyond the scope of this chapter but must be considered in the design and evaluation of the results of all randomized trials.

The benefit of systemic adjuvant therapies is divided according to risk category of patients studied, with nodal metastasis as a defining characteristic of high risk. Sentinel node evaluation defines groups of node-positive patients with a substantially better prognosis than that of node-positive patients discovered or proven at elective or therapeutic dissection (234). Populations defined as node-negative in AJCC stage II categories may potentially be contaminated with increasing fractions of occult node-positive patients, according to primary Breslow depth and presence of ulceration. Clinically node-negative stage II populations may contain substantial fractions of patients who could be defined as node-positive by sentinel node staging techniques, excluding node-negative patients who are more reliably node negative than when judged clinically or by older elective regional lymph node dissection.

The therapeutic regimens tested in these major randomized trials may be divided according to the dosage, route, and duration of therapy, as well as the subspecies of IFN-α-2 used.

Trial of High Dose IFN-α-2b versus Observation in High-Risk Resected

Part of "10.2 - Melanoma "

Two-hundred eighty-seven patients were accrued in a trial conducted between 1984 and 1990 (E1684) that was unblinded and reported to the American Society of Clinical Oncology in 1993 at 5 years of median follow-up (237); the trial was published in 1996 at 6.9 years median follow-up (Table 10.2-9). This trial used a year-long aggressive therapy of IFN-α-2b, 20 MU per m² i.v., daily for 5 days per week for 1 month, then 10 MU per m² s.c., three times weekly for the balance of the year. Of the 287 patients enrolled, 252 were evaluable. Patients were observed as reference standards of care or received IFN-α-2b at maximally tolerable dosages intravenously and subcutaneously for 1 year. Risk groups were defined at lymph node pathology (reviewed in all cases) and stratified to allow analysis of therapeutic impact in homogeneous groups of patients whose susceptibility to this therapy was postulated potentially to be related to tumor burden and disease extent (101,238).

Table 10.2-9 Randomized Controlled Trials of Postoperative Adjuvant Therapy in High-Risk Interferon (IFN) Melanoma

Cooperative Group (PI)	Agent	Eligible Subjects	No. of Subjects	Investigational Treatment	Study Status
ECOG 1684 (Kirkwood)	IFN-α-2b	T_4^a, N_1^b	287	High-dose (20 MU/m²/d) i.v. × 1 mo, followed by high-dose s.c. t.i.w. regimen × 11 mo	Disease-free and survival benefit 6.9-yr follow-up
NCCTG 83-7052 (Creagan)	IFN-α-2a	T_4, N_1	273	High-dose 20 MU/m², limited-duration i.m. regimen × 3 mo	RFS trend stage III
SWOG (Meyskins)	IFN-ß	T_3, T_4, N_1	134	Low-dose (0.2 mg/d), s.c. t.i.w. × 1 yr	Closed, negative
EORTC 18871 (Kleeberg)	IFN-ß vs. IFN-α	T_{3-4}^c, N_1	900	Low-dose IFN-α (1 MU/d) vs. low-dose IFN-γ immunology action (0.2 mg/d) IFN-γ × 1 yr	Closed, negative
WHO 16 (Cascinelli)	IFN-α-2a	N_1^d	426	Low-dose (3 MU/d) s.c. t.i.w. regimen × 3 yr	Closed, negative
EORTC 18952 (Eggermont)	IFN-α-2b	T_4, N_1	1,000	Intermediate dose for 1 or 2 yr	Open
ECOG 1690 (Kirkwood)	IFN-α-2b	T_4, N_1	42	High-dose (20 MU/m²/d) i.v. × 1 mo plus s.c. × 11 mo (total, 1 yr) vs. low-dose prolonged s.c. t.i.w. (2+ yr) regimen	Closed, RFS benefit but non-OS benefit
ECOG 1694 (Kirkwood)	IFN-α-2b	T_4, N_1	880	High-dose IFN-α-2b vs. GM2 ganglioside	Closed, analysis pending
ECOG 3697 (Rosenstein)	IFN-α-2b + RT vs. IFN-α-2b	N + ECE	200	High-dose IFN-α-2b + RT vs. high-dose IFN	Open

[b]Regional node involvement without extracapsular soft tissue extension.

[c]Regional nodal involvement, including extracapsular extension.

[d]Deep primary >3 m.

The dosage of IFN-α-2b selected for this study was based on phase 1 and 2 studies reported by Kirkwood et al. (95,161,239) that demonstrated that 20 MU per m² i.v., daily, and 10 MU per m² s.c., three times weekly, approach the maximum tolerated dosages for these two routes. Initial i.v. therapy was chosen to provide peak dosage intensity approaching 10,000 U per mL and to minimize potential anti-IFN antibody responses (based on a lack of antibody formation against IFN-α-2b observed in patients studied in several phase 1 and 2 trials) (95,161).

A group sequential design was used for the analysis of this trial with one-sided log rank tests. Distribution of patients entered onto the two arms of this trial was well balanced for all prognostic factors evaluated. Toxicity observed in this trial was considerable, with dosage reductions required in one-half of subjects during the first month of i.v. dosing; reductions in dosage were required during the s.c. maintenance treatment in more than one-half of patients, especially during the first month of s.c. treatment.

The analysis of treatment impact for high-dose IFN-α-2b (HDI) on relapse for the overall trial revealed a highly significant reduction of relapse rate at each of the interim analyses (p = <.005) and on final intention-to-treat analysis (p = .002). A significant benefit on survival was demonstrated in the intention-to-treat analysis, as well (p = .046). A Cox multivariate analysis demonstrated significant improvement in disease-free and OS (p = .001 to .010) and estimated the relative improvement in continuous relapse-free survival (RFS) to be 50%.

Subgroup Analyses

The impact of therapy was analyzed in four stratification subgroups according to estimated risk: (a) patients with clinical stage I with deep primary tumors (> 4 mm; Breslow depth, ˜T4) and pathologically proven absence of nodal disease (11% of accrual, clinical stage 1[CS1], pathalogical stage 1 [PS1]); (b) patients with clinically inapparent but pathologically proven regional lymph nodal disease (10% of accrual, CS1 PS2); (c) patients with clinically apparent regional lymph node disease, post lymphadenectomy (14% of accrual, CS2 PS2); and (d) patients with clinical and pathologic evidence of regional lymph node recurrence at some time after adequate surgery for primary melanoma (64% of accrual, CS2 PS2R). Given a significant overall betterment of relapse and death rates, subset analyses were performed to identify whether treatment benefit was general or restricted to particular subsets of disease. The greatest impact of therapy was noted in patients who presented with overt nodal metastatic disease; in this small subset of only 41 patients, RFS was improved for the treated patients, who achieved nominal statistical significance (p <.01). Curiously, the small subset of patients with T4 primary lesions who were without nodal disease at elective dissection did not appear to benefit from HDI (n = 31). This group was unbalanced for the presence of ulceration in treated and observed populations and was too small to permit further analysis. Analysis of node-positive patients demonstrated highly significant relapse-free and OS benefits for IFN-α-2, driving the pursuit of nodal evaluation by sentinel node mapping to select patients that would benefit most from administration of HDI. The original trial did not gather information regarding the numbers of nodes involved in the 89% of node-positive patients; Smith et al. subsequently performed a retrospective analysis of this data in more than 90% of patients, however, demonstrating excellent balance between treated and observed populations for numbers of nodes involved at original pathology and demonstrating the most remarkable benefits of IFN in patients with single positive lymph nodes (107).

The median interval to relapse with IFN-α-2b adjuvant therapy was prolonged from 0.9 to 1.6 years, whereas the median survival of treated patients was prolonged from 2.62 to 3.78 years. Relapse-free survival in E1684 was 37% at 5 years for treated patients and 26% for observed patients. The continuous RFS advantage of 11% (a relative improvement of 40% over observation) has been durable, suggesting a curative potential for IFN-α-2 in patients with high-risk melanoma.

Quality of Life and Cost Efficacy

The impact of high-dose IFN-α-2b on quality of life (QOL) was evaluated in a retrospective quality-adjusted analysis of time spent without symptoms or toxicity (i.e., Q-TWiST study) (240). This study was developed by Goldhirsch et al. (241) in 1989 to allow a balanced evaluation of side effects and benefits of therapy. Time spent during and after treatment with treatment-related toxicity, relapse, and quality-adjusted analysis of time spent without symptoms or toxicity were analyzed for patients, weighted according to accepted indices that have been validated in a time–utility analysis (242). After 84 months of follow-up, the group of patients receiving IFN-α-2b gained a mean of 8.9 months without relapse (p = .03) and 7 months of OS time (p = .02) compared to the observation group. The treated group experienced at least one episode of severe treatment-related toxicity over a period averaging less than 5.8 months. As an overall result, the IFN-α-2b–treated group had more QOL–adjusted survival time than the observation group, regardless of relative valuations placed on time with toxicity and time with relapse.

The cost of IFN-α-2b in E1684 has raised serious societal questions about patient and insurer costs of the regimen. An economic analysis of the E1684 regimen was published by Hillner et al. (243), performed with coinvestigators of the E1684 trial; a separate analysis also has been published in Europe by Messori (244,245) with remarkably consistent results. The projected incremental cost gained in the IFN cohort of patients (in 1996 U.S. dollars per life-year) ranged from $13,700 (after 35 years) to $32,600 (at 7 years, the median follow-up of E1684). The benefits of IFN, projected over a lifetime, yield incremental costs per life-year or quality-adjusted life-years that are both less than $16,000. This figure is less than the rigorous Canadian benchmark of $20,000 per QOL-year gained and is comparable to other accepted adjuvant therapies of breast and colorectal cancer. Given the significant and durable benefit of this therapy, it has been approved for resected high-risk melanomas rapidly by regulatory authorities across North and South America, Europe, and Australia.

United States Intergroup Trial of High-Dose and Low-Dose Interferon versus Observation for Resected High-Risk Melanoma

To confirm and extend the preliminary results of the E1684 trial, the E1690 intergroup trial was initiated in 1990, just as the first striking relapse-free interval benefits of HDI in E1684 became available (but before any survival advantage had become apparent). This randomized three-arm study compared the same high-dose regimen of IFN-α-2b as was administered in E1684 to a low-dose, 3 MU s.c., three-times-weekly regimen of IFN-α-2b, chosen in conjunction with the WHO Trial 16 in Europe. Because this trial was initiated before maturity of E1684, the control arm remained observation. Targeted accrual of 642 patients was completed in June 1995. Entry criteria for this study were the same as for E1684, except the requirement for elective lymphadenectomy for patients with pT4cN0, clinically node-negative disease, was eliminated. Primary end points were relapse-free and OS, using a two-sided log-rank statistic comparing high-dose and low-dose arms versus observation. The statistic design used a mixed cure-rate model, seeking to establish a 10% cure rate and 50% improvement in time to relapse or death among those patients not cured with a power greater than 80% at maturity.

Six hundred forty-two patients entered the study between 1990 and 1995, with 608 evaluable patients at 52 months median follow-up when the study was unblinded in 1998. The study was unblinded at 91% of the projected number of events stipulated in the original protocol due to a reduction in event rate and a projected time of more than 2 years (which is the period that would have been required to reach the numbers of events originally specified in the protocol). The study population, comprised by stage groupings, included 25% deep primary, clinically node-negative patients (versus 11% in E1684); only 51% had recurrent nodal involvement (162 T4cN0, 68 T14pN1cN0, 83 T14cN1, and 326 recurrent node-positive). An improvement in RFS for the high-dose arm over observation (hazard ratio, 1.28; p = .05) was noted; the benefit for node-negative and node-positive populations was consistent overall. Improvement in RFS was significant by Cox multivariate analysis for the high-dose arm (p = .03) but not for the low-dose arm (p = .16). Neither the high-dose arm nor the low-dose arm showed an improvement in OS compared with observation. OS was not prolonged in the face of results, corroborating a benefit on continuous RFS that has been attributed to post-relapse salvage with IFN, which became widely available during the trial interval. IFN was used extensively in patients whose observations were unsuccessful, more than after treatment with adjuvant IFN (p = .004) and among these patients the use of IFN was associated with significantly improved OS.

Other Trials of High-Dose Interferon-α-2a and Low-Dose Interferon-α-2a in High-Risk Resected Melanoma: North Central Cancer Treatment Group 83-7052 and World Health Organization Trial 16

Part of "10.2 - Melanoma "

The NCCTG adjuvant trial 83-7052 used IFN-α-2a, a short, 3-month treatment period, and a lowered dose of 10 MU per m^2 i.m., three times weekly, throughout. The NCCTG study randomized 273 patients to receive 3 months of treatment with IFN-α-2a at moderately high dosages by i.m. route or observation; the trial, conducted between 1984 and 1990, was reported at a follow-up interval of more than 5 years. The trial included 162 patients with nodal involvement and 111 patients with T3/T4 primary disease (>3.69 mm). No advantage in terms of RFS or OS was observed in the overall study, but a trend to improvement in the RFS was reported for the node-positive population (p = .03, by Cox analysis).

WHO's Melanoma Programmed Trial 16 evaluated 3 years of treatment with IFN-α-2a at the same dosage that the intergroup-ECOG E1690 trial tested for the U.S. intergroup trial (versus standard observation). WHO accrued patients with regional lymph node involvement (largely at recurrence), excluding deep primary (T4) node-negative or electively dissected, clinically node-negative populations. An early report of the findings of WHO Trial 16 suggested a lack of any durable impact of IFN-α-2a at low dosage on RFS intervals or OS (246). If these findings are borne out in a more formal complete analysis of the trial, they have important implications for the optimal integration of IFN-α-2b therapy in melanoma treatment.

High-Dose IFN-α-2b for Abbreviated Interval Induction Therapy: E1697

Part of "10.2 - Melanoma "

On the basis of previous considerations, and the strong evidence of early impact for high-dose IFN-α regimens in E1684 and E1690, ECOG and the National Cancer Institute of Canada have designed a trial to test the benefit of 1 month of high-dose i.v. IFN-α-2b administered 5 out of 7 days per week for 4 weeks in T3N0M0 stage IIA patients with resected cutaneous melanoma. This study requires 1,444 patients to detect a cure rate benefit of 7.5% with a power of greater than 85% in a mixed-cure-rate model. This study was opened to accrual in December 1998 and is anticipated to accrue patients through 2001. This

trial provides the first test of the hypothesis that peak-dose exposure is important to the therapeutic benefit of the E1684 regimen. Given the importance of preservation of QOL for such patients, a module evaluating QOL is incorporated into this study.

High-Dose Interferon-α-2b in Conjunction with Radiotherapy for Patients with Gross Extracapsular Extension

Part of "10.2 - Melanoma "

Neither the completed E1684 and E1690/S9111/C9190 studies, nor the current E1694/S9512 intergroup trials have allowed entry of any patient with gross extracapsular extension of disease at the regional lymph node basin. The local-regional relapse rate is substantially elevated for this group, as was first noted in relation to melanoma of the head and neck by the group at the M. D. Anderson Cancer Center (247). It is uncertain whether a benefit of IFN-α-2 is manifest in this population; uncontrolled pilot data from the M. D. Anderson Cancer Center has suggested a potential role of hypofractionated radiotherapy for these patients (247). ECOG has therefore undertaken a test of the role of IFN-α-2b at high dosage administered with hypofractionated radiotherapy, versus IFN-α-2b at high dosage for 1 year alone in this group of patients (D. Wazer, principal investigator). This study began in October 1998, seeking accrual of 167 subjects to the evaluation of this combination, hoping for an improvement in local-regional relapse and the first evaluation of IFN-α-2b at high dosage with radiotherapy in this population.

Low-Dose Interferon in Intermediate-Risk Melanoma: Austrian and French Multicenter Trials

Part of "10.2 - Melanoma "

Pehamberger (248) reported a study of IFN-α-2a administered 3 MU s.c., three times weekly, for 1 year after a period of 3 weeks of daily administration in 310 patients with intermediate-risk clinically node-negative patients. Excellent tolerance of this regimen has been noted, and an early outcome reported a significant reduction in frequency of relapse, although median follow-up was short (3 years). No survival data have been reported as initially published; therefore, the results of this experience must hear further follow-up. Grob et al. (249) have reported the significant prolongation of RFS interval but not OS for intermediate-risk (clinically node-negative AJCC stage II AB) melanoma patients treated with low-dose IFN-α-2a administered subcutaneously for 18 months at a median follow-up of 5 years (117). This trial entered 499 subjects and is relatively early in follow-up, given the intermediate-risk profiles of its subjects. The observed prolongation of RFS interval with these two low-dose regimens suggests a qualitatively different effect than that obtained with high-dose IFN, as tested by ECOG in E1684 and intergroup trials E1690 and NCCTG 83-77052. The low-dose effects reported in these two trials for immediate-risk patients (and in WHO Trial 16 for high-risk patients) appear to develop more gradually over time on therapy and wane over months after cessation of therapy. The curves plotting the treatment and observation differential described by Grob suggest a transient relapse-free benefit rather than a durable curative advantage for the low-dose regimen.

The benefit of low-dose IFN-α in intermediate-risk patients is significant in terms of relapse-free interval at 3 to 5 years follow-up, although not in terms of survival. Pressing questions relate to the mechanism by which these results were induced and how they might be improved. One option is to protract the treatment interval, either to a fixed interval (e.g., 5 years) or indefinitely. The intermediate-risk population has a limit (risk of relapse is less than 50%); it poses difficulties with consideration of indefinite therapy, therefore, because therapy would be given needlessly to one-half of this population for an indefinite interval. Trials that would use IFN-α-2 at low dosages for more protracted intervals are being designed or discussed in several cooperative groups.

Intergroup Evaluation of Vaccine GM2-KLH plus QS 21 versus High-Dose Interferon in High-Risk Melanoma

Part of "10.2 - Melanoma "

ECOG and Southwest Oncology Group Melanoma committees have undertaken a trial to build on the results of E1684 and E1690, evaluating effects of the chemically defined vaccine composed of the immunogenic ganglioside GM2 coupled with the carrier molecule KLH (i.e., GMK), administered with the potent adjuvant agent QS 21 (in comparison to IFN-α-2b at high dosage). The rationale for the use of the GMK vaccine is drawn from a study conducted at the University of California, Los Angeles, by Jones et al. (250), who demonstrated that patients with native anti-GM2 antibody relapse less frequently than those without the antibody; the studies of Livingston et al. (251 ,252 and 253) corroborated this observation, demonstrating a trend to improved relapse-free OS in high-risk, node-positive stage III patients vaccinated with GM2 and bacille Calmette-Guérin (as opposed to bacille Calmette-Guérin alone) after resection of melanoma. The E1694/S9512 trial seeks to define the superiority of GMK over HDI in terms of RFS and OS of high-risk melanoma, and has completed accrual of 880 patients in 1999. The E1694 intergroup study tests the first of a potential series of vaccines that may induce either humoral or cellular immune response to defined antigens of melanoma, in which the opportunity to evaluate intermediate end points of antibody or cellular response to the immunogen exists.

With the recognition that combinations of GMK and IFN-α-2b are desirable for administration—provided the combination does not abrogate antibody response to GM2—ECOG trial E2696 (conducted with Memorial Sloan-Kettering) tested the induction of the anti-GM2 antibodies IgG and IgM by vaccine alone (as opposed to vaccine combined with or followed by IFN-α-2b at high dosage, as in E1684 and E1690). Completion and analysis of this trial demonstrated no significant inhibition of immunogenicity of the GMK vaccine in terms of IgG and IgM (254). Thus, it is reasonable to consider the combined use of this vaccine and HDI in adjuvant trials, once efficacy of the vaccine has been demonstrated.

Rationale for Study of Interferon Mechanism

Part of "10.2 - Melanoma "

The lack of a fundamental understanding of key mechanisms of therapeutic benefit with IFN in patients with melanoma has served as the impetus for developing laboratory corollary analyses of immune mechanisms modulated by IFN, tumor and MHC antigen expression, and direct antiproliferative effects that might explain antitumor activity of IFN against melanoma in humans (e.g., U.S. Intergroup Cooperative Trial E1690, WHO Trial 16, and Austrian/French Multicenter Studies).

In the context of the intergroup-ECOG E1690 trial, as well as WHO Trial 16, the opportunity has been taken to examine the potential mechanisms of specific T-cell–mediated antitumor actions of this therapy. The underlying goals of laboratory corollary studies are to identify the mechanisms of IFN-α-2 in melanoma therapy that correlate with therapeutic benefit. Successful trials allow future investigations to refine and heighten impacts on appropriate mechanisms, ideally permitting selection of candidates most likely to benefit from treatment. This has obvious relevance to high-risk populations (and compelling significance for the larger population of intermediate-risk patients); more long-term treatment is considered.

The therapeutic impact against melanoma is being evaluated in terms of direct tumor inhibition or antigen modulation, MHC-restricted cytotoxic T-cell function, and non-MHC restricted effector cell activation. The Melanoma Cancer Center of the Pittsburgh Cancer Institute (for the intergroup-ECOG E1690 trial) and Istituto Nazionale dei Tumori Experimental Oncology D Laboratories (for WHO Trial 16) have evaluated autologous tumors obtained at regional lymph node dissection and HLA-matched, cultured tumor cell lines of participating patients in treatment and control arms of these large ongoing studies. These laboratory corollaries are being analyzed; their respective clinical trials have now just been unblinded.

Although potent immunomodulatory activity of IFN-γ provided ample initial justification to prevent melanoma relapse in adjuvant settings, where immunologic activity may be optimally assessed, the observation of minimal antitumor activity in large phase 2 dose-seeking trials (ECOG E4687/E4987) makes it unlikely that further trials of IFN-γ will be undertaken in high-risk melanoma.

Adjunctive Use of Interferons with Vaccines

Part of "10.2 - Melanoma "

Peptide antigens recognized by the host T-cell response will be more relevant antigenic targets for specific vaccine immunization against melanoma in years to come. The assessment of host-response end points relevant for peptide and for ganglioside immunologic therapies differ: response to peptide and protein immunizations are defined by T-cell responses, either proliferative, cytokine-inductive, or cytotoxic; in contrast, serologic outcomes are critical covariates of ganglioside immunization strategies, and some data suggest that the production of antibodies against gangliosides is associated with favorable outcome of melanoma (251,255). The analysis of mechanisms of synergism with the interferons will likely also differ but will depend on the outcome of current and future trials of vaccine strategies as single interventions.

Epidemiology, Etiologic, and Biologic Heterogeneity: Future Potential for Earlier Biologic Intervention

Part of "10.2 - Melanoma "

The rising incidence of melanoma and the lack of effective treatment for distant metastatic and high-risk resectable disease has raised issues regarding the preventive role of available modalities. In the United States alone, incidence of cutaneous melanoma has tripled since 1950 and nearly doubled in the 1990s. More than 41,000 new melanoma cases were identified in 1998, with 7,500 deaths attributable to melanoma. One in every 75 whites will contract melanoma by the end of the 1990s, based on current incidence projections.

Nonfamilial (Sporadic) and Familial Melanoma and their Precursors

Part of "10.2 - Melanoma "

Approximately 10% of cutaneous melanomas are famrlied, linked with a syndrome of clinically atypical and histologically dysplastic nevi described by Clark et al. (257). A larger fraction of up to 40% of melanoma occurring outside the familial setting (258,259) is also associated with the presence of clinically atypical and histologically dysplastic nevi that closely resemble precursor lesions of the familial syndrome. Atypical (dysplastic) nevi may therefore serve as intermediate markers of nevi or patients at high risk for melanoma. The syndrome of atypical dysplastic nevi has been described in terms of increased numbers of larger-than-normal (i.e., >5 mm) nevi of irregular or indistinct margins, variegated pigmentation, and macular surfaces. Histopathologically, these lesions may be hyperplastic, with bridging or fusion of rete ridges manifesting cytologic or nuclear atypia, or both, and elicit a host lymphocytic response. IFNs have been shown to regulate a number of cellular genes in normal and neoplastic cells of the melanocytic lineage and have demonstrated activity in the advanced metastatic and adjuvant settings. Therefore, the evaluation of IFNs and retinoids as modulators of tumor progression is a reasonable goal and one that is in progress in clinical laboratory protocols of ECOG and University of Pittsburgh Cancer Institue.

IFNs are the best-studied biologic antineoplastic agents in melanoma. There are no compelling bases for choosing one over another species for investigation of melanoma-preventive activity. rDNA-produced IFNs of all three subspecies have shown activity against melanoma *in vitro;* antiproliferative activity has been related to their abilities to inhibit protein synthesis after binding to specific membrane receptors. IFN modulation of effector cell function, MHC class I and II antigens, and tumor-associated antigens, as well as receptors for growth factors, such as melanocyte-stimulating hormone, suggests a variety of potential mechanisms of action for clinical antitumor activity. Enhanced immunogenicity and altered susceptibility to T-cell-mediated

cytotoxicity or differentiate effects are of major interest. Immunomodulatory effects on NK-cell activation appear to be related to antitumor activity in experimental animals, but no clear evidence for a role of similar mechanisms in human cancer exists.

Summary of Adjuvant Experience in High- and Intermediate-Risk Melanoma

Part of "10.2 - Melanoma "

The only current evidence for a therapeutic benefit in patients with high-risk operable melanoma has been observed with maximally tolerable dosages of IFN-α-2b. Regarding high-risk melanoma, the E1684 regimen remains state-of-the-art, and its impact on continuous RFS has been corroborated by the E1690/S9111/C9190 intergroup trial, unblinded at 52 months' follow-up. Low-dosage IFN-α in high-risk disease (as pursued by WHO) has no durable relapse interval or survival impact of significance. In E1690, the only head-to-head comparison of high and low dosage regimens, the benefit of high-dose IFN differed quantitatively and quantitatively from that of low-dose IFN.

In patients with node-negative melanoma at higher risks as consequences of primary depth (Breslow depth, > 4 mm), the E1684 and NCCTG 83-7052 trials contained populations too small to derive meaningful conclusions regarding efficacy of high-dose IFN therapy. The Austrian and French Multicenter Trials have reported relapse interval prolongation with low-dose IFN-α-2a therapy administered for 1 to 1.5 years at median follow-ups of 3 and 5 years. Effects in these trials were only significant regarding RFS intervals. The larger and more mature French multicenter trial suggests a benefit that is not durable after withdrawal of treatment. This therapy did not significantly impact OS, and the basis of this difference has not been determined. In intermediate-risk disease, the French and Austrian trials have achieved transient relapse delays but not the stable durable impacts of high-dose regimens. Alternative trials of longer duration, either with previously administered low dosage or using newer formulations of polyethylene-glycol conjugated IFN-α-2, are of great interest. Is the impact of this therapy manifest only in certain limited (i.e., node-negative) spheres of disease? Neither Austrian nor French trials evaluated nodal involvement more precisely than by more precise sentinel or elective nodal staging techniques than clinical examination, however. RFS interval prolongation is achieved with low-dose IFN therapy administered for 12 to 18 months, occurring gradually on treatment, and lost gradually after discontinuation of therapy. Further studies of IFN at low doses for longer periods or with high doses for shorter intervals are reasonable and in progress. As surrogate markers of risk for the stage II population and the population susceptible to benefits for stage II and III patients, the therapeutic index for IFN-α-2 and its yield may improve. In conjunction with radiotherapy and vaccines, and as an earlier prevention strategy, much more remains to be explored using tools available for dissection of the molecular pathways of IFN-α-2 action, as well as specific host-immune response to potentially relevant tumor antigens.

- Summary

Introduction

Part of "10.3 - Renal Cell Cancer "

Epithelial kidney tumors, comprised of seven morphologic types arising from the proximal tubule or collecting duct, are collectively known as *renal cell carcinoma* (1). An estimated 30,000 new cases of renal cell cancer (RCC) resulting in 11,900 deaths will occur in the United States in 1999 (2). Common risk factors for RCC do not distinguish patient populations that may benefit from screening, except in cases of rare inherited disorders, such as von Hippel–Lindau disease. Although many patients present with local symptoms, such as hematuria, flank pain, a palpable mass, or signs and symptoms of metastasis, an increasing number of patients have asymptomatic renal tumors identified serendipitously when undergoing radiologic evaluation of the abdomen (e.g., computed tomography scan, ultrasound) for unrelated reasons. Approximately 50% to 60% of patients have surgically resectable disease at the time of diagnosis. Five-year survival rates are approximately 61% for all stages and 62% to 89% for local regional disease (2). Metastatic disease carries a bleak prognosis with a 74% mortality rate at 1 year and a 96% mortality rate at 3 years (3). Even those patients with resectable disease have a risk of recurrence of at least 10% over a 10-year period (4,5). When metastases develop, they are most commonly seen in the lungs (approximately 65% of patients), followed by bone (40%), liver (14%), adrenals (8%), peritoneum (8%), and brain (5%) (3).

RCCs can secrete a variety of biologically active substances, which accounts for RCC-associated paraneoplastic syndromes. Common paraneoplastic syndromes include cachexia, anemia, fever, and hypercalcemia. Polycythemia and hepatitis are less frequently observed (6). These paraneoplastic syndromes have not been found to have a significant impact on prognosis except when overall performance status is compromised.

Spontaneous or unexplained regression of RCC metastases have been observed in a variety of patients. Initially thought to occur after nephrectomy, spontaneous regression was commonly used as a rationale for removal of the primary neoplasm in the setting of metastatic disease. Spontaneous regressions are infrequent, occurring in less than 1% of patients, and are not necessarily associated with resection of the primary (7,8 and 9) neoplasm. Thus, nephrectomy in patients with metastatic disease should be reserved for those with symptoms directly caused by their renal mass. These patients may benefit from palliative resection. A randomized study of interferon-γ (IFN-γ) versus placebo in metastatic RCC patients reported a response rate of 6.6% in the placebo group, suggesting that unexplained regressions may be more common than once thought (10). The documented cases of spontaneous regression most often occurred in pulmonary metastases and were usually short-lived (a few months), although a small percentage of patients have remained disease-free for years (7,9).

In general, the failure of established endocrine therapy and chemotherapy to significantly impact clinical response or overall survival has led to the abandonment of these approaches as first-line therapy. Although the benefit of single-agent immunotherapies, including IFN-α and interleukin-2 (IL-2), is modest, clinical response rates of 10% to 20% in RCC patients have been seen and long-term survivors have been reported. Thus, cytokine therapies have become the foundation of modern treatment strategies for RCC patients.

It is well established that prognostic groups of patients with metastatic RCC can be defined by clinical criteria. Performance status, time from nephrectomy at initial diagnosis, the number of metastatic sites, prior cytotoxic chemotherapy, and recent weight loss can be used as important indicators of survival, predicting as much as a sixfold difference in survival between good and poor prognostic groups (2.1 to 12.8 months) (11). Furthermore, these factors can be used to predict the likelihood of response to biologic therapies. Performance status, recurrence at the renal bed, weight loss, history of nephrectomy, sarcomatoid

histology, and bone metastasis correlated with response to biologic treatment on univariate analysis with only bone metastasis, sarcomatoid histology, and performance status significant predictors in a multivariate analysis (12). This may explain the variation in responses reported in many series. It is therefore critical that carefully controlled randomized studies be conducted before adopting new strategies for treatment of this disease.

Endocrine Therapy and Chemotherapy

Part of "10.3 - Renal Cell Cancer "

Initial reports by Bloom described a response rate of 16% with little toxicity for medroxyprogesterone (13). When evaluated in randomized studies, medroxyprogesterone has had little to no activity (14). Although other endocrine therapies have been used, true complete and partial response rates using objective response criteria are less than 5% (15). Progestins have also been used as adjuvant therapy for patients with high-risk, resectable primary lesions but have not been effective (16). A trial of high-dose tamoxifen demonstrated a 10% response rate in hormone refractory patients, but patient numbers were small (17). Combination hormonal therapy has not increased the efficacy of this modality (17). The lack of significant clinical benefit from hormonal therapy in RCC and the lack of evidence that human RCC is under hormonal regulation does not support the use of this approach in the treatment of RCC today.

Chemotherapy for RCC has also been unsatisfactory. Reviews of chemotherapy and endocrine therapy for advanced disease confirm the poor response to systemic treatment (15,18,19,20,21 and 22). Almost all single-agent trials have been associated with response rates less than 10%. Part of this difficulty arises from the high prevalence of expression of multidrug resistance (MDR) mechanisms present in *de novo* RCC at diagnosis (23). Overexpression of p-glycoprotein (MDR1) with associated drug resistance has been described in more than 80% of primary RCCs (24). Traditionally, vinblastine has been used for therapy of metastatic disease, but phase 2 studies failed to confirm significant single-agent activity. One explanation of vinblastine's poor response rates is the expression of MDR1 in RCC. The addition of MDR1 inhibitors, such as tamoxifen, quinidine, and cyclosporin, have also failed to enhance vinblastine activity in RCC patients (25,26). Given as a chronobiologically defined continuous infusion, floxuridine (FUdR) has been associated with response rates of 28% (27), although it is not clear that this route offers any advantage over constant infusion FUdR (28). This issue continues to be evaluated in an ongoing randomized trial of circadian versus flat infusion of FUdR. Combining vinblastine with other chemotherapeutic or endocrine agents has not resulted in superior response rates and has been associated with greater toxicity. Although vinblastine is still used as a single-agent therapy, the response rates and overall survival are poor. This poor response rate to chemotherapy and endocrine therapy has led many physicians, including some urologists and surgical and medical oncologists, to offer only supportive care to patients with metastatic RCC. The lack of an effective treatment for metastatic RCC has led to clinical trials with numerous agents, including IFNs. A review of the basic principles and preclinical studies of IFN therapy is presented in Chapter 9 .

Interferon Therapy

Part of "10.3 - Renal Cell Cancer "

Overview of Interferon-α and -β Clinical Trials

Of the three types of IFNs (α, β, and γ) commercially available, only IFN-α has shown significant single-agent clinical response rates in RCC to warrant consideration for use. Table 10.3-1 represents the list of clinical investigations involving single-agent IFN-α or IFN-β (29,30,31,32,33,34,35,36,37,38,39,40,41,42,43,44,45,46,47,48,49,50,51,52,53,54,55,56,57,58,59,60,61,62,63,64,65,66 and 67). Results are presented according to IFN type and include six trials using leucocyte preparations, nine trials using lymphoblastoid (partially purified) IFNs, 19 trials using recombinant IFN-α (rIFN-α), and three trials using IFN-β. When possible, response criteria following World Health Organization guidelines and calculated 95% confidence intervals (CIs) are reported for these trials to explore the effect of selected covariables on response, duration of response, and survival. We attempt to formulate meaningful recommendations from interpretation of this data, although small numbers of patients, dose and schedule variations, and nonrandomized study designs make it difficult to draw firm conclusions (68). Doses of IFN are presented as MU (1 MU = 1×10^6 IU).

CI, confidence interval; CR, complete remission; IFN, interferon; PR, partial response; rIFN, recombinant IFN.

Note: Dose in MU/m² unless specified.

[a]Total dose.

[b]Randomized study; results of each arm(s) given, when possible.

[c]Given 4 to 8 weeks only; responders given maintenance.

[d]Nonrandomized (usually sequential studies): results of each arm(s) given, when possible.

[e]No response in ten patients with prior IFN.

[f]Initial 15 patients randomized.

Initial IFN trials used crude preparations of leukocyte IFN produced by methods described by Cantell et al. at the Finnish Red Cross Blood Center (69). These preparations likely contained other cytokines capable of augmenting response, and dose was limited by volume of subcutaneous (s.c.) injections. Response rates of 18% (95% CI of 13% to 25%) were observed. Nine trials reported the use of partially purified lymphoblastoid IFN; in at least seven of these trials, the IFN studied was obtained from the Namalwa strain of lymphoblasts originally derived from a young female with Burkitt's lymphoma. This partially purified IFN developed by Burroughs-Wellcome contains eight different IFN-αs. An overall response rate of 16% (95% CI of 13% to 20%) were noted in these nine trials.

The development of recombinant DNA techniques made it possible to produce highly purified preparations of IFN with high specific activity, as measured by antiviral U per mg of protein (70). This allowed for the expansion of clinical trials, which began in 1981. At least 19 trials have involved rIFN-αs. rIFNα-2a (Roferon, Hoffman LaRoche Laboratories) has been used in nine trials with an overall response rate of 15% (95% CI of 12% to 19%). rIFNα-2b (Intron, Schering Plough Laboratories), a second rIFNα-2, has displayed an overall response rate of 16% (95% CI of 12% to 22%). Porzsolt and colleagues noted only a 6% response rate in 47 patients using rIFNα-2c (52). rIFN-ß has been studied by three groups, each with small numbers of patients; the overall response rate of 7% has a 95% CI of 1% to 24%.

These data do not suggest the superiority of one IFN-α preparation over another. Cantell-derived IFN preparations and lymphoblastoid IFN have been associated with higher response rates than their recombinant counterparts. Without randomized studies, however, these minor differences do not provide support of one preparation over another. The most commonly used preparations of IFN-α include rIFNα-2a and rIFNα-2b, which currently represent the "standard" of comparison for future clinical trials.

Response by Dose and Type of Interferon

The dose, route, and schedule of IFN administration are presented in Table 10.3-1 . In an attempt to determine the relationship of response versus dose, available data for phase 2 studies were converted into an average daily dose when possible; no attempt was made to calculate cumulative doses of therapy (Table 10.3-2). These data must be interpreted cautiously because of major scheduling differences (many of the trials used an escalating induction sequence), variable dose modification procedures, and different IFN preparations.

Table 10.3-2 Phase 2 Studies: Average Daily Dose Interferon-α

	<5 MU	>5 MU
No. in series	15	6

CR	14	4
PR	60	28
CR/PR (%)	16	17
95% CI	13–19	12–22

CI, confidence interval; CR, complete remission; PR, partial response.

Three randomized studies have evaluated dosage (32 ,45 ,50). Kirkwood and colleagues performed a randomized trial of 1 MU versus 10 MU of leukocyte IFN. The trial allowed for a cross-over from low-dose to high-dose arms. None of 14 patients responded to low-dose therapy, whereas 3 of 16 patients responded to high-dose therapy. As responses to IFN may take several months, many of these patients may not have had an adequate trial at a low dose. Of four patients initially treated with low-dose therapy who subsequently received 10 MU daily, one partial response occurred.

Quesada and colleagues performed a randomized trial of rIFNα-2a comparing 2 MU per m^2 with 20 MU per m^2 given daily for a minimum of 8 weeks; none of 15 patients randomized to the low-dose arm responded, whereas 22 of 41 patients receiving high-dose therapy responded (39). These results differed from a previous study by Quesada and colleagues (29 ,30) using Cantell-type IFN in which a response rate of 26% was noted at the daily 3-MU dose. It was speculated that the differences in response rates may have been the result of other IFNs and lymphokines with potential antitumor activity present in the Cantell-type preparation. Like Kirkwood (32), however, it is also possible that their initial induction phase using the low-dose treatment was too short.

Of the five trials using rIFNα-2b, Muss and colleagues randomized patients to receive rIFNα-2 at 2 MU per m^2 subcutaneously three times weekly or 30 to 50 MU per m^2 given intravenously for 5 consecutive days every 3 weeks (50). A 10% response rate occurred in the low-dose regimen (5 of 51 patients). A 7% response rate occurred in the high-dose regimen (3 of 46 patients). Differences in the two groups may be related to schedule, route of administration, or both. Intermittent dosing, as used in the high-dose group, may be inferior to continuous dosing schedules. The pharmacokinetic profile of IFNs differs significantly between the s.c. and intramuscular (i.m.) route and the i.v. (intravenous) route. The s.c. and i.m. route provides more prolonged systemic exposure.

In general, no clear dose-response relationship is supported by published data. Randomized data are incomplete but suggest that doses greater than 3 MU per m^2 given in a continuous dosing schedule are therapeutic. As IFN toxicity is directly related to dose, a dose of 5 to 10 MU given at least three times per week appears to have the best therapeutic index. Route does not seem to be a major factor in determining response, as i.m. and s.c. administration appear equivalent (an observation supported by pharmacologic data). i.v. regimens are more difficult to administer and are not superior to i.m. or s.c. treatment.

Time to Response and Response Durability

Time to response, duration of response, and the number of patients responding for longer than 12 months are presented in Table 10.3-3 . The time to achieve a partial response was generally 1 to 3 months; however, on occasion, responses were seen after 6 months or longer (62). Once response was obtained, the median duration of response ranged from 2.5 to 35 months with an average duration of approximately 6 months. Of the 159 responders, 77 had long-term follow-up data concerning response duration. Twenty-eight of these 77 patients (36%) had response durations longer than 1 year, representing about 3% of all patients treated with IFN; Minasian et al., however, reported that 3% of their patients had survival durations that exceeded 5 years (60).

Characteristics of Interferon Responders

Pretreatment characteristics, including age, gender, disease-free interval, performance status, prior treatment, sites of metastasis, and nephrectomy, as well as toxicity secondary to treatment, were analyzed to determine their effect on response. No obvious relationship existed between age and gender to response. In most trials, males predominated and responded more frequently, reflecting the increased incidence of RCC in males. Disease-free interval was not associated with response. Responses were more frequent in patients with good performance status; however, most protocols restricted eligibility to patients who had favorable or normal performance-activity levels. Several investigators noted higher response rates in patients without prior chemotherapy or radiation (32 ,42), whereas others reported no major differences. Again, many trials restricted entry to patients without prior chemotherapy, and most studies were too small and had too few responders for major analyses. Leukopenia secondary to IFN treatment significantly correlated with response in two series (29 ,42), but not in four other studies (32 ,41 ,46 ,50). In a univariate and multivariate analysis of response to biologic therapy in metastatic RCC, Mani et al. (14) confirmed that performance status was the most important predictor of responses. The univariate analysis revealed that nephrectomy, histology, weight loss, and local recurrence were predictors of response as well. Indeed, the best responses were seen in patients with pulmonary or lymph node metastases only. Bone metastases, performance status, and sarcomatoid histology remained predictive in the multivariate model. In review of RCC patient characteristics, performance status, minimal disease in the soft tissue or lung only, and survival greater than 1 year postnephrectomy were associated with a better likelihood of response to treatment. Bone metastases and sarcomatoid histology predicted a poor outcome.

The relationship of response to sites of metastases may help the clinician identify patients more likely to respond to IFN-α therapy. Approximately 80% of patients in published trials have had nephrectomy. It is unlikely to observe response in primary RCC, even when distant metastases have responded to treatment. Although trials of patients with nephrectomy report response rates of 17% and an 11% response rate has been observed in patients without nephrectomy, it is erroneous to conclude that a potential advantage may exist in patients who had nephrectomy. The data should be interpreted cautiously, as other patient characteristics are likely to confound this type of analysis. Approximately 20% of patients with lung metastases displayed a complete or partial response, a rate almost double that of patients with other metastatic sites. Of 143 patients who had metastases confined only to the lung, 51 (36%) displayed response. Few authors presented detailed data on sites of metastases; nevertheless, only a small percentage of patients with liver or bone metastases displayed objective responses. Responses were described in at least ten patients with primary lesions in the kidney and in others with soft tissue lesions, including the skin and retroperitoneal lymph node metastases. Caution is advised, however, when interpreting these results. Pulmonary lesions were usually easily measured, and, in most trials, chest x-rays were obtained more frequently than liver scans, bone scans, or computed tomography scans. For these reasons, brief responses were more likely to be seen in the lung. In addition, measurement of bone metastases is frequently indirect (i.e., bone scan), whereas skeletal x-rays may require long periods to show improvement. Also, patients with bone and liver metastases are more likely to have poor performance status, making them less likely to be eligible for study or tolerate the side effects of IFN therapy.

Toxicity

Patients receiving IFN therapy for RCC display similar toxicity profiles to those receiving IFN for other malignant diseases. Even at lower doses, almost all patients display fever, taste change, lassitude, myalgia, loss of appetite, and other flulike symptoms. For most patients, this represents the most distressing aspect of treatment. As the dosage is increased, depression, anorexia, leukopenia, transient elevation of liver function tests, and increasing lassitude become more common and more pronounced. Nausea, vomiting, diarrhea, and atrial tachyarrhythmias are uncommon side effects, even at higher doses. Moderate to severe symptoms are especially frequent at

doses greater than 10 MU per day. For patients receiving IFN for long periods, fatigue frequently becomes the most distressing symptom, resulting in marked reduction of physical activity. Neuropsychiatric manifestations of IFN may result in moderate to severe changes in behavior, possibly a result of direct effects of IFN on the brain (71 ,72). Discontinuation of IFN generally results in the resolution of toxicity after several days to several weeks. Frequently, IFN-induced tachyphylaxis for fever and chills develop, making treatment better tolerated. In addition, the use of acetaminophen may help ameliorate mild symptoms. Although corticosteroids can control the flulike symptoms related to IFN and do not appear to adversely affect response, we generally do not use them (73 ,74 and 75). Aspirin, however, does not control the flulike symptoms (76). Newer approaches to ameliorate toxicity have focused on different preparations of IFN (see the section on Response and Antiinterferon Antibodies). Once recognized, depression can be treated with antidepressant agents with good response.

Response and Antiinterferon Antibodies

Several investigators have monitored patients for the development of anti-IFN antibodies during the course of therapy. An overview of these data are presented in Table 10.3-4 . An analysis of six phase 2 trials using human lymphoblastoid IFN (Wellferon, Burroughs Wellcome Company) failed to show antibody development in 267 patients (77). This is likely due to the fact that the preparation of IFNs are genetically identical to natural forms. Antibodies have frequently been demonstrated in patients receiving rIFNα-2a, however, and less frequently in patients receiving rIFNα-2b. The most frequently detected antibodies are IFN-binding antibodies, which are detected by enzyme-linked immunoassay; neutralizing antibodies, demonstrable by decreased inhibition of virally induced cytopathic changes in cell cultures, are also frequently found. Thirty-eight percent of patients treated by Quesada et al. (45) and 32% of patients treated by Figlin et al. (47) developed neutralizing antibodies. In Quesada's series, the development of such antibodies was associated with relapse in all seven patients who developed them. The median duration of response in antibody-positive patients was 2 months versus 10 months in those who were antibody negative (p = .009). Median survival was also shorter (12 months) in antibody-positive than in antibody-negative (19 months) patients. Of note, antibody development was associated with a decrease in fatigue, anorexia, and IFN levels; an increase in white blood cell counts; and normalization of liver function tests. The authors concluded that such antibody production neutralized the biologic effects of IFN, abrogating response and toxicity. In contrast, Figlin et al., using an identical rIFNα-2a preparation at a similar dosage, noted the appearance of antibody before response in two patients and found no relationship between antibody formation and response duration. Buzaid et al. noted neutralizing antibodies in one partial responder who continues in remission for 17+ months (46). Fossa and colleagues were unable to demonstrate any difference in clinical outcome between antibody-positive and antibody-negative patients, although patient numbers were small; a reduction in serum levels of IFN correlated with the presence of neutralizing antibodies (73). An adjuvant study reported by Prommer for the Delta P Study Group did not demonstrate any difference in disease-free interval nor relapse rate based on anti-IFN antibody status (78). The reasons for these discrepancies are not clear. Using rIFNα-2a, Muss et al. detected antibodies in three of seven responders (50). Anti-IFN antibody production in this series was low and had no effect on response. A summary of neutralizing antibodies in a combined series of trials using rIFNα-2b revealed a neutralizing antibody rate of 2.4% (10 out of 423 patients) (79). The development of such antibodies was not associated with amelioration of IFN toxicity when compared with antibody-negative patients and had no discernible effect on response (80). In summary, the role of neutralizing antibodies in the development of clinical IFN resistance occurs rarely. Patients receiving IFN with chemotherapy have not been studied for antibody information to determine whether chemotherapy can prevent antibody development; prednisone may be capable of blunting formation

of anti-IFN antibodies (81), although a randomized trial has not been performed.

Table 10.3-4 Antiinterferon Antibodies

Author	Reference	IFN Type	Patients Positive	Patients Tested	Patients Positive (%)	Assay	Comments

EIA, enzyme-linked immunoassay; IFN, interferon; Ly, lymphoblastoid IFN; NS, method not stated; PR, partial response.

[a]Bioassay is viral challenge in cell culture to detect neutralizing antibody.

[b]Bioassay only performed on EIA-positive patient.

The data strongly suggest that successful treatment of metastatic RCC with single-agent IFN-α is related to clinical characteristics, IFN dose, and schedule. In this regard, convenience of administration and flulike symptoms are major barriers to therapy. To reduce toxicity and provide prolonged serum levels of IFN-α, IFNα-2b has been coupled to polyethylene glycol (polyethylene glycol-IFNα-2b, Schering) and has been tested in a phase 1 setting (82). A maximum tolerated dose of 6 µg per kg is well tolerated with significantly less toxicity than antiviral equivalents of IFNα-2b. Responses have been noted in a variety of tumors, including RCC. A phase 2 trial has been initiated and is currently under way.

Interferon Combined with Other (Non Interleukin-2) Biotherapies

rIFN-γ has been extensively studied in patients with metastatic RCC and has demonstrated a low response rate of 6% to 10% (95% CI of 6% to 14%) in 236 patients. The observation that IFN-α and IFN-γ can exhibit synergy *in vitro* has prompted several clinical trials of rIFN-α and rIFN-γ used together (83). IFN-α and IFN-γ bind to different cell surface receptors and enhance expression of different classes of histocompatibility antigens. Although initial studies of combined IFN-γ and IFN-α were limited by toxicity, a sequential trial design allowed for higher combined doses to be administered (81). A hint of greater activity was seen in a single institution study of sequential IFN-γ followed by IFN-α, which was not confirmed in a later multiinstitutional trial (46,56,57,81,84).

Two small trials of IFN-α in combination with tumor necrosis factor or mismatched double-stranded RNA are listed in Table 10.3-5 . Although *in vitro* data have suggested a synergistic effect for combinations of IFNs (85) and tumor necrosis factor (86), the pilot clinical trials have not supported this approach. Another approach for enhancing response is to use recombinant hybrid IFNs, but this has not shown promise in clinical trials (87).

Table 10.3-5 Combinations of Interferon or Interferons and Other Biologics[a]

Interferon Combined with Chemotherapy

The combination of vinblastine and IFN have been the most extensively studied combination of IFN and chemotherapy. In addition to demonstrable synergism *in vitro* (88), vinblastine represents the most used single agent for metastatic RCC. The results of published trials of this combination are presented in Table 10.3-6 . Response rates for this combination have ranged from 7% to 43%. In general, vinblastine was given in a dose of 0.1 mg per kg every 3 weeks combined with i.m. IFN given three times weekly. Also, time to response and response duration of the vinblastine/IFN combination are similar to that of IFN alone. In a randomized trial of 178 patients comparing rIFNα-2a (18 MU t.i.w.) plus vinblastine (0.1 mg per kg every 3 weeks) with IFN alone, an improvement in the overall response rate (11% vs. 24%) occurred, but no difference in survival between the treatment arms (89) was detected. Another phase 3 trial reported by Pyrhonen et al. also compared vinblastine with IFNα-2a plus vinblastine (90). The combination therapy improved overall response rates (16% vs. 25%), as well as overall survival (15.8 months vs. 8.8 months). Although direct comparison between vinblastine and IFN-α has not been performed,

the data suggest that single-agent IFN-α has significant clinical activity in patients with metastatic RCC. In the opinion of these investigators, the addition of vinblastine to IFN has not improved response and has resulted in substantially higher hematologic toxicity; its use outside the setting of a clinical trial is not justified.

Combinations of IFN-α and pyrimidine antimetabolites have been explored in metastatic RCC based on preliminary clinical data in other diseases and *in vitro* studies. *In vitro* data suggests that IFN-α enhances 5-FU thymidylate synthetase inhibition (91,92). In addition, 5-FU may enhance host cell-mediated immunity (93). Table 10.3-7 summarizes some key studies that evaluated the effects of the combination of 5-FU and IFN-α in metastatic RCC.

IL-2, interleukin-2; ORR, objective response rate; 5-FU, 5-fluorouracil; +, present; -, not present.

[a]Number of patients evaluable/number of patients enrolled.

[b]In mg/m^2/d.

Of these 11 studies, only two did not include IL-2 in the treatment regimen. Elias et al. (92) combined IFN-α (3 × weekly) with 5-day continuous infusion of 5-FU every 3 weeks and reported 5 out of 34 partial responses. Gebroskey et al. (94), using lower doses of daily 5-FU and daily IFN-α, reported a response rate of 43% after 6 months of therapy. Again, large controlled studies have yet to be completed, and the optimal dose and schedule of this regimen has not been identified.

Other regimens have used IL-2 in combination with 5-FU and IFN-α. Hanninen et al. reported a trial comparing the three-drug regimen (IL-2, IFN-α, 5-FU) with low-dose IL-2 (95). Triple therapy resulted in an improved overall response rate (39% vs. 28% for combined cytokine therapy) and a better complete response rate (13 complete responses vs. 2 complete responses). Patients with good prognostic characteristics had a survival benefit to three-drug therapy. Subsequent phase 2 trials confirmed the response rates of the three-drug regimen (96). A limited randomized phase 3 trial comparing the three-drug combination with tamoxifen (97) confirmed a 39% response rate and an improved overall median survival of at least 28 months. The M. D. Anderson group further attempted to optimize this regimen by using continuous infusion 5-FU, continuous infusion IL-2, and IFNα-2a. This therapy demonstrated a 31% response rate, but more than 50% of patients needed blood pressure support and 25% of patients developed gram-positive bacteremia.

Two reports raise questions about response rates and toxicity. Using bolus 5-FU combined with s.c. IL-2 and IFN-α, Subcutaneous Administration Propeukin Program Cooperative Group investigators reported only a 19% response rate in 62 patients; 43% of patients required dose reduction, delay, or termination

of therapy because of toxicity (98). Furthermore, Ravaud et al. (99) reported only a 1.8% response rate when continuous 5-FU was combined with s.c. IFN-α and IL-2. Forty-nine percent of patients experienced greater than a grade 3 toxicity and five deaths occurred. Thus, the role of three-drug therapy in metastatic RCC remains unclear. Dose, schedule, and route have not been optimized for clinical benefit and limited toxicity. Further evaluation of the "Atzpodien regimen" in larger multiinstitutional trials are needed.

Several small trials of IFN and other agents in RCC are presented in Table 10.3-8 . Most of the trials of IFN and chemotherapeutic agents included small numbers of patients. The addition of IFN to 5-FU and mitomycin (100) and to ifosfamide and vindesine appears somewhat higher than for IFN alone, but not convincingly so; further trials are necessary to confirm these data. Dexeus et al. noted that of 12 patients who received prior IFN therapy, seven subsequently responded to combination chemotherapy with 5-FU, doxorubicin, mitomycin, and cisplatin (101). To determine if IFN exposure increased the likelihood of response to chemotherapy, they conducted a randomized trial comparing chemotherapy alone with chemotherapy alternating with IFN (101). Four responses occurred in 32 patients, two in each arm. This small trial failed to show that alternating IFN with chemotherapy improved response. To the limited extent one can compare trials, it would appear that the addition of the fluorinated pyrimidines may only be useful when infused for longer durations (102,103,104 and 105). Further, it is not clear whether circadian-modified infusions of FUdR are essential (103,106). Clearly, randomized trials are needed to resolve these issues.

[e]Given 1 to 2 hours before hyperthermia.

[f]Nonrandomized (sequential studies); results of each study given.

Combinations of IFN and substances intended to ameliorate the flulike symptoms of IFN (i.e., steroids, aspirin) have not affected response rates, although only corticosteroids have been useful against the flulike side effects of IFN (73,74,75 and 76). Neither agent prevents hepatic or other toxicities associated with IFN. Nevertheless, we recommend nonsteroidal antiinflammatory drugs and acetaminophen as palliative approaches. In addition, we consider antidepressant agents to treat the depression associated with IFN therapy.

Kotake and colleagues studied the combination of IFN and cimetidine and noted responses in 6 of 20 patients (107). Previous data suggested that cimetidine might inactivate suppressor T cells by binding to the histamine receptor present on such cells. One study comparing IFN and medroxyprogesterone acetate with IFN alone showed no benefit for this combination (52). Another trial combining IFN with the antiandrogen flutamide demonstrated a response rate of 27% in 52 patients, warranting further investigations of this combination.

The continued development of trials using combinations of biologics, as well as biologics and chemotherapy based on encouraging laboratory data, is justified. Also, several *in vitro* systems have been extensively studied and provide a major

resource for studying IFNs in combination with other agents (108,109,110,111,112 and 113).

Interest in combining IFNs with *cis*-retinoic acid is derived from data that demonstrated synergistic interaction against tumor cell lines *in vitro* (114). An initial trial performed in 1997 by Motzer and colleagues achieved a 29% response rate with combined therapy in a series of 24 patients with metastatic RCC (115). Duration of response in some of these patients lasted as long as 9 months. Another series was able to demonstrate increased time to progression and increased 1-year survival in patients who responded to a combination regimen of *cis*-retinoic acid and IFN-α (116). Other small studies have been conducted with response rates ranging from 18% to 29% (116,117), including one study that examined IL-2 (118). These results are promising and await larger trials to properly test these preliminary findings.

Summary

Part of "10.3 - Renal Cell Cancer "

Newer therapies are needed for the treatment of metastatic RCC. IFN represents a small but significant advance in this area, and numerous trials have confirmed an objective response rate of approximately 15%. The side effects of IFN may be considerable, but may be limited by supportive care, including hydration, antipyretics, and antidepressants. Newer preparation of IFN-α may allow higher doses with less toxicity.

The lack of major long-term toxicity of IFN led to a clinical trial comparing rIFN with observation in the adjuvant setting by the Eastern Cooperative Oncology Group (protocol, 2,886), which is closed to accrual. Outcomes are awaiting data analysis. Another study of adjuvant therapy compares 6 months of combination rIFNα-2b with 5-FU versus observation for patients with resected stage III or IV RCC. Lack of significant myelosuppression with lower doses of IFN also makes it ideal for trial in combination regimens with myelosuppressive agents. In addition, the discovery and cloning of new cytokines and the potential for combined cytokine therapy are promising.

The ideal candidate for IFN therapy is a patient with good performance status and pulmonary lesions, as one-third of such patients may respond to IFN; liver, bone, and other visceral metastases are more resistant, although responses in all metastatic sites have been reported. Age, gender, disease-free interval, and prior therapy do not clearly affect response. Patients with favorable or normal performance appear to respond more frequently.

The effect of IFN therapy on the survival of patients with RCC is unclear. Trump et al. reported a median survival of 7.1 months for their IFN-treated patients with metastases, a similar survival duration to their prior phase 2 studies of chemotherapeutic agents (38). Buzaid et al. (46) noted a median survival in excess of 18.6 months in his trial; his patients, however, may have been more highly selected for favorable prognostic factors. Porzsolt and colleagues noted a median survival of 7 months in their series (52). Our review of the literature indicates that approximately 3% of patients treated with IFN have a sustained clinical response lasting longer than a year; this number may be an underestimate given the data from Minasian and colleagues of a 5-year survival rate of 3% (60). Two reports have evaluated prognostic factors. In a data-based study of 610 patients with metastatic RCC, multivariate analysis identified five variables related to survival: (a) performance status, (b) disease-free interval, (c) prior cytotoxic chemotherapy, (d) number of metastatic sites, and (e) recent weight loss (11). Five risk groups were defined by these variables. The most favorable group had a median survival of 12.8 months. The least favorable group had a median survival of 2.1 months. It is not possible to draw firm conclusions on possible improvement in survival related to IFN, but it is likely that the influence of IFN on survival for most patients with RCC is small. Nevertheless, a subset of patients (3%) may have prolonged survival secondary to such therapy, which is comparable with the long-term survival rates reported for the more toxic IL-2. Manni et al. reported histology, performance status, and base disease as prognostic factors for response to biologic therapy (12).

Finding new biologic parameters that may help select patients most likely to respond to IFN in the adjuvant or advanced setting would be of major clinical importance. In one trial, flow cytometry analysis of renal cell tumor specimens suggested that patients with aneuploid tumors had a higher risk of recurrence after potentially curative resection than patients with diploid tumors (119). In another study, the risk of distant metastases was similar for patients with aneuploid and diploid tumors, but multiple metastases and lung metastases were more common with aneuploid lesions (120). Cytogenetic and molecular abnormalities involving 3p, 17p, and other regions are recognized in hereditary renal carcinoma (121) and sporadic RCC (122), but no correlation to clinical outcome, response to IFN, or other treatment is known (123,124). Further investigations are needed.

The selection of patients for IFN therapy frequently poses a dilemma for the oncologist. The best candidates are usually those who may be candidates for more toxic or investigational therapies, yet it is these same patients who may remain asymptomatic for long periods. The benefit of a response in such patients must be carefully weighed against treatment toxicity. Quality of life issues obviously are of paramount importance in making such decisions, and the risks and benefits of therapy should be discussed carefully with the patient. Improved therapy, however, can only result from the continued development of clinical trials. The increased availability of such trials in the community makes it possible to accrue patients and complete important studies in shorter periods. Computerized databases of active protocols are available through the Protocol Data Query System (125) and other sources. This information is readily available to physicians who manage such patients. IFN therapy represents an appropriate standard of care for the treatment of patients with metastatic RCC. Fundamental research related to the biology of RCC, as well as exploration of new therapies, will undoubtedly improve the outlook for patients in the future.

Kaposi's Sarcoma

Susan E. Krown

- Introduction
- Kaposi's Sarcoma: Pathogenesis and the Rationale for Using Interferon
- Interferon-α Therapy
- Interferon-ß
- Potential Future Applications of Interferon in Kaposi's Sarcoma Therapy

Introduction

Part of "10.4 - Kaposi's Sarcoma "

Kaposi's sarcoma (KS), the most common malignancy associated with human immunodeficiency virus type-1 (HIV-1) infection, was one of the first recognized clinical manifestations of the acquired immune deficiency syndrome (AIDS) (1,2 and 3). Although interferon-α (IFN-α) has been used to treat KS since 1981, only recently have advances in understanding KS pathogenesis and relevant IFN actions provided a strong rationale for IFN use and supported its use in conjunction with modern antiretroviral drug regimens. In addition, IFN dosages have been modified in recent years as treatment of coexisting HIV-1 infection has evolved. This chapter reviews pertinent information on KS pathogenesis and IFN actions, use of type I IFNs to treat AIDS-associated KS, and potential applications of IFN therapy.

Kaposi's Sarcoma: Pathogenesis and the Rationale for Using Interferon

Part of "10.4 - Kaposi's Sarcoma "

When IFN was first used to treat KS, its antiproliferative activity was thought to play a major role in mediating tumor regression, although poorly characterized immunomodulatory and antiviral activities were also considered to have potential roles. In the earliest studies of IFN-α in KS, it appeared that very high IFN-α doses were required to induce tumor regression, whereas low doses rarely induced responses (4,5). This was usually interpreted to mean that direct inhibitory effects on cell proliferation were essential for tumor regression to occur, although an alternative explanation may be that other antitumor effector mechanisms were optimally activated at high IFN doses. Because KS had been shown to occur with increased frequency in immunosuppressed individuals, including recipients of solid organ transplants, and to occasionally regress when immunosuppressive drugs were withdrawn (6,7,8,9 and 10), a link between tumor and immune function had been established. Although changes in immune function were observed in some IFN-α-treated patients with KS, consistent effects were not documented, even in patients whose lesions regressed. In addition, although neither HIV nor human herpesvirus 8 (HHV-8) had yet been discovered when IFN-α's activity against KS was first described, earlier studies implicated a link between cytomegalovirus

(CMV) infection and KS (11). It was suggested, therefore, that antiviral effects of IFN-α might be important in mediating tumor regression.

In recent years, a multistep model for KS pathogenesis in HIV-infected individuals emerged that is depicted in simplified form in Fig. 10.4-1 . An essential element of the model is exposure to an infectious agent, HHV-8, that infects B cells and vascular endothelial cells (the latter being the likely cell of origin of KS). The model also includes altered expression and response to cytokines and stimulation of KS growth by an HIV-1 gene product, often in the setting of at least moderate immunosuppression. These factors contribute to the development of a lesion comprised of elongated spindle cells organized into slitlike vascular spaces containing extravasated erythrocytes and surrounded by a variable cellular infiltrate. This model does not completely explain the interplay of factors that leads to the development of KS in some, but not all, HHV-8-infected individuals. It does, however, not only help to explain the frequent occurrence and unusually aggressive behavior of KS in HIV-infected individuals but also provides a stronger rationale for the therapeutic use of IFNs than the one proposed in the early 1980s.
FIGURE 10.4-1. Factors in the development of acquired immunodeficiency syndrome–associated Kaposi's sarcoma. (bFGF, basic fibroblast growth factor; HHV-8, human herpesvirus 8; HIV, human immunodeficiency virus; VEGF, vascular endothelial growth factor.)

Major advances in understanding factors involved in the development and growth of KS lesions were made possible in the late 1980s when techniques to establish KS-derived spindle cell cultures were first developed (12,13). Cultured KS-derived spindle cells were subsequently shown to secrete a variety of cytokines and growth factors that included, among

others, interleukin-6 (IL-6), interleukin-1 (IL-1), basic fibroblast growth factor (bFGF), and vascular endothelial growth factor/vascular permeability factor (VEGF/VPF) (14,15 and 16), and to express receptors for these factors. In addition to secreting factors with potential autocrine and paracrine activities, KS-derived spindle cells were also shown to proliferate in response to exogenous cytokines and growth factors. These KS growth factors include tumor necrosis factor (TNF), IL-1, IL-6, IFN-α, platelet-derived growth factor, bFGF, VEGF/VPF, oncostatin M, and granulocyte-macrophage colony-stimulating factor (GM-CSF) (15,17,18,19,20,21 and 22). Many of these factors were present in the retrovirus-infected T-cell–conditioned media that were found to support KS spindle cell growth *in vitro* (17,18 and 19). Many of these cytokines, in particular TNF, IFN-α, IL-1, and IL-6, are also produced in excess in patients with advanced HIV infection (23,24 and 25), can stimulate HIV expression *in vitro* in infected cells (17,26), and can induce normal vascular endothelial cells to acquire a spindle morphology, secrete bFGF, and express $α_vβ_3$, a cell surface adhesion protein of the integrin family required for angiogenesis (17,21,22).

Although HIV has not been found within KS spindle cells and is not required for the development of KS, several observations suggest that the virus may contribute indirectly to the development of KS and its unusually aggressive course in HIV-infected individuals. A role for HIV was originally suggested by the observation that transgenic mice bearing the HIV transactivation gene, *tat*, transiently developed KS-like angiogenic lesions (28). In addition to being associated with the excess production of KS-stimulatory cytokines, active HIV infection results in the secretion by infected CD4 cells and monocytes of a biologically active form of the *tat* gene product, Tat (29). Extracellular Tat binds to $α_vβ_3$ and $α_5β_1$, which are strongly expressed on KS-derived spindle cells (30). IFN-γ, which is increased in KS lesions (20), has been shown to upregulate the expression and activation of Tat-binding integrins and to induce endothelial cells to proliferate and invade the extracellular matrix in response to Tat (21). Tat has also been shown to stimulate proliferation of KS-associated spindle cells *in vitro* (31) and to synergistically stimulate KS cell proliferation when combined with bFGF or inflammatory cytokines (32). In addition, in the presence of bFGF and cytokines, normal vascular endothelial cells become responsive to the stimulatory effects of Tat on proliferation, cell migration, and angiogenic differentiation (15,27). Tat also induces the expression *in vitro* of the adhesion molecules VCAM-1 and ICAM-1, the monocyte chemoattractant protein MCP-1, and IL-6 in KS-derived cells (33), which could help recruit leukocytes to a developing KS lesion.

Epidemiologic studies have long suggested that exposure to a transmissible or environmental cofactor distinct from HIV might be required for the development of AIDS-associated KS (34,35). A sexually related factor was implicated by the high incidence of KS in HIV-infected homosexual men (compared to men from other risk groups), a higher incidence in women who acquired their HIV infection through sex with bisexual men (compared to women from other transmission groups) (34), and anecdotal reports of a higher than expected frequency of KS in homosexual HIV-seronegative men (35). Although many of the factors previously investigated for their possible etiologic role in KS (e.g., CMV, human papillomavirus, HHV-6, inhaled nitrites) have been eliminated from serious consideration, studies performed over the past 5 years have conclusively demonstrated a central role for a newly described HHV in the development of KS. Sequences of the virus, called HHV-8 or Kaposi's sarcoma-associated herpesvirus (KSHV), have been shown to be present in virtually all KS tissue, whether from HIV-infected individuals or those with the classic, endemic African or organ transplant–associated forms of the disease (36,37,38 and 39). HHV-8 sequences have also been identified in a limited number of other pathologic conditions, in some normal cells of patients with KS, and in the cells of some HIV-infected patients without KS who subsequently developed KS (40,41,42 and 43).

The precise mechanisms by which HHV-8 leads to KS development are incompletely understood. It has been shown, however, that HHV-8 can infect and transform human primary endothelial cells *in vitro* (44) and that in KS tissue, the virus can be found in the flat endothelial cells lining vascular spaces of KS lesions as well as in KS spindle cells (45). HHV-8 has also been found to encode an array of functional homologues of cellular proteins, including bcl-2, IL-6, the IL-8 receptor, interferon regulatory factor, chemokine-like macrophage inflammatory proteins (MIP-I and MIP-II), and a D-type viral cyclin that can direct phosphorylation of the retinoblastoma tumor suppressor protein (pRB) (46,47,48,49 and 50). In addition, viral MIP-I and MIP-II were highly angiogenic in the chorioallantoic membrane assay, suggesting a possible role in KS pathogenesis (49).

With this model for KS pathogenesis in mind, a more robust and multifaceted rationale for the use of IFN and possible explanations for its activity can be proposed (Table 10.4-1). Current knowledge of the multiplicity of IFN actions suggest that several steps in KS pathogenesis can be considered potential targets for IFN, although many of these activities have not been specifically studied in patients with KS or KS cell cultures. In addition to their direct inhibitory effects on cell proliferation, IFNs have been shown *in vitro* to increase natural killer cell and monocyte-mediated cytotoxicity against KS targets (51,52 and 53). IFNs α and β have also been shown to downregulate steady-state bFGF messenger ribonucleic acid (mRNA) expression and protein production in certain tumor cell lines by proliferation-independent mechanisms (54,55). Additionally, IFN treatment has been shown to increase circulating levels of the soluble TNF receptor and the IL-1 receptor antagonist (56,57), which are endogenous downregulators of the KS-stimulatory cytokines TNF and IL-1. IFNs have also been shown to have direct inhibitory effects against HIV (58) and to synergistically inhibit HIV when used in combination with other antiretroviral agents (59,60 and 61). HIV inhibition could directly affect KS growth by decreasing release of the HIV Tat protein and could act indirectly by decreasing the production of inflammatory and angiogenic cytokines associated with poorly controlled HIV infection. The relatively recent observation that KS sometimes regresses when effective, multiagent antiretroviral therapy is introduced (62,63)

suggests that these actions may be important, although enhanced immune function may also result in more effective control of HHV-8 infection. A direct inhibitory effect of IFN on HHV-8 is also possible and has been demonstrated in a preliminary *in vitro* study (64). In one patient with classic KS, however, IFN-α treatment reportedly led to complete tumor regression, but HHV-8 sequences remained detectable in the lesional skin (65).

Table 10.4-1 Targets for Interferon Treatment of Acquired Immunodeficiency Syndrome-Associated Kaposi's Sarcoma

Target	Relevant Interferon Action
Angiogenic growth factors	Inhibits basic fibroblast growth factor production
Inflammatory cytokines	Increases levels of endogenous downregulators of tumor necrosis factor (sTNF-R) and interleukin-1 (IL-1RA)
Endothelial cell proliferation	Inhibits proliferation
Human immunodeficiency virus	Inhibits replication
Human herpesvirus-8	Inhibits replication
Immune effector cells	Stimulates natural killer and monocyte cytotoxicity versus Kaposi's sarcoma targets

IL-1RA, interleukin-1RA; sTNF-R, soluble tumor necrosis factor receptor.

Interferon-α Therapy

Part of "10.4 - Kaposi's Sarcoma "

Monotherapy

Monotherapy refers to IFN treatment in the absence of other antitumor or antiretroviral drugs. IFN-α's single-agent activity against AIDS-associated KS was initially demonstrated in the early 1980s, long before the availability of specific antiretroviral therapy directed against HIV. Tumor regression was documented in various studies in which either recombinant IFN-α-2a or -α-2b or lymphoblastoid IFN (IFN-α-n1) was administered daily or three times a week (4,5,66,67,68,69,70,71,72,73,74 and 75). A common feature of these studies was the superiority of very high IFN-α doses (≥20 MU per m^2 body surface area) over lower doses. Objective tumor response rates averaging 30% were observed in patients treated with high IFN-α doses (4,5,66,67,69,71,72,73,74 and 75), whereas an average response rate of less than 10% was observed among patients treated at doses ranging from 1.0 MU to 7.5 MU per m^2 (4,5,67).

These studies also documented superior response rates among patients with CD4-positive T-lymphocyte counts of 200 per μL or more and no previous AIDS-defining opportunistic infections (OIs) or lymphoma-like "B" symptoms than among patients with lower CD4 counts or histories of OIs or B symptoms, or both. For example, a cross-study analysis of patients without previous OIs or B symptoms who were treated with high-dose IFN-α-2a revealed response rates of 7.2%, 27.5%, and 45.4% among patients with <200, 200-400, and >400 CD4-positive T lymphocytes per μL, respectively (66). Only one of 28 patients (3.6%) with previous OIs or B symptoms responded (66). Other factors reported to be associated with a higher likelihood of response to IFN-α include the absence of cutaneous anergy, relatively high proliferative responses of PBMC to mitogens and microbial antigens, the absence of endogenous, acid-labile IFN-α in the serum, and relatively low serum levels of β$_2$-microglobulin and neopterin (76,77,78 and 79). Although various markers of immune function or activation, or both, have been shown to correlate with the response of KS to IFN-α, neither tumor stage nor gastrointestinal KS were associated with response (4,66,67 and 68,76,77).

Although evidence for tumor regression often occurs within the first 4 to 8 weeks of treatment, maximum responses often require continued treatment for 6 months or more. The relatively slow response of KS to IFN-α makes this treatment inappropriate for highly symptomatic patients in whom rapid cytoreduction is required—for example, patients with lung lesions, symptomatic gastrointestinal KS, or severe tumor-associated edema. The optimal duration of treatment in responding patients is not known. Before the availability of effective antiretroviral treatment, discontinuation of IFN-α therapy was usually followed within 6 to 8 months by tumor progression. Although it has not been systematically studied, some indications suggest that successful systemic therapy for KS may be discontinued in some patients in whom HIV replication is well controlled. Response duration with IFN-α monotherapy has not been well studied. The few published data indicate that partial responses last, on average, from 6 to 12 months, and complete responses persist for an average duration of 2 years (4). In some cases, responses persist for over a decade.

Interferon with Chemotherapy

In the 1980s, several trials were conducted in which IFN-α was combined with chemotherapeutic agents in an attempt to increase KS response rates (66,73,80,81,82 and 83). IFN-α was combined with vinblastine, etoposide, or a combination of actinomycin-D, vinblastine, and bleomycin. Little or no evidence for increased efficacy was found, and the combination regimens led almost uniformly to greater toxicity. In a randomized trial that compared IFN-α alone to IFN-α with vinblastine, objective response rates in the two groups were almost identical, but dose-limiting hematologic and constitutional toxicity was twice as frequent in the combination therapy arm than with IFN-α alone (66,83). In a nonrandomized trial of the IFN-α and vinblastine combination in patients with advanced KS, 12 of 27 patients (44%) required dose attenuation or discontinuation of therapy because of severe toxicity (73). Sequential administration of IFN-α followed by etoposide induced a response rate of only 8% (80), whereas concurrent administration of these drugs was toxic and ineffective; only one of 14 patients (7%) showed an objective response (80). Maintenance of chemotherapy-induced response with IFN-α was also unsuccessful in a small group of patients (84).

All of the studies cited were conducted well before the widespread availability of effective antiretroviral therapy, and all used IFN-α doses associated with significant constitutional, hematologic,

and hepatic toxicities. It is not known whether IFN-α would be an effective and less toxic adjunct to chemotherapy if it were used at lower, better tolerated doses in patients whose HIV infection was well-controlled and for whom supportive therapies (e.g., hematopoietic colony-stimulating factors or appetite stimulants) were available.

Interferon with Antiretroviral Therapy

High-dose monotherapy with IFN-α-2a and IFN-α-2b received U.S. Food and Drug Administration approval in 1989 for treatment of patients with AIDS-associated KS. At that time, zidovudine (ZDV) was the only antiretroviral agent approved for treatment of a subset of HIV-infected individuals. Several studies were already underway in 1989 to evaluate the IFN-α and ZDV combination in KS, and subsequent trials to evaluate IFN-α with ZDV and other antiretroviral agents have been completed or are in progress. Current standards for antiviral treatment do not support the use of IFN monotherapy for HIV-infected individuals with KS. Nonetheless, despite safety and efficacy data indicating that lower doses of IFN-α than those originally recommended for monotherapy should be used in conjunction with other antiretroviral agents, the approved doses of IFN-α were not modified in the 1990s.

The rationale for combined IFN-α and antiretroviral therapy was originally based on *in vitro* studies showing synergistic suppression of HIV replication when IFN-α was combined with ZDV (59). These observations were later extended to the combinations of IFN-α with didanosine and zalcitabine (60,61). In addition, the combination of IFN-α and ZDV induced synergistic suppression of retrovirus-induced splenomegaly and viremia in mice (85,86). Single-agent nucleoside reverse transcriptase inhibitor therapy is no longer the standard of care for HIV-infected individuals and has shown no significant activity against KS (87,88). These drugs sometimes induced improvements in the levels of markers associated with responsiveness of KS to IFN-α, however, including enhanced CD4 T-lymphocyte counts and skin test reactivity, and decreased serum levels of β_2-microglobulin and neopterin (89,90). Furthermore, it was suggested that IFN-α, which inhibits HIV at a step in virus replication distinct from that of other antiretroviral agents (91), might overcome or inhibit the development of nucleoside resistance. Indeed, combinations of IFN-α with ZDV or didanosine induced synergistic inhibition *in vitro* of ZDV-resistant clinical isolates of HIV-1 (61).

The results of ten published clinical trials of the IFN-α and ZDV combination are summarized in Table 10.4-2 (92-101). Although it is difficult to compare the results of one study with another because of nonuniform trial design, drug dosages, and patient prognostic features (including the duration of previous ZDV treatment), the majority documented response rates of 40% or more. In some, but not all, of these studies, objective tumor regression was attained at IFN-α doses significantly lower than those shown to be effective without concurrent antiretroviral therapy. Also, some of these studies documented response rates of up to 30% in patients with pretreatment CD4 T-lymphocyte counts below 200 per μL (92,95,100,101), a group with a low probability of response to high-dose IFN-α monotherapy. Patients with higher CD4 counts also showed higher response rates with combination therapy than previously reported for high-dose IFN monotherapy (92,93,94,95,96 and 97,99,100 and 101).

Table 10.4-2 Results of Combined Interferon-α (IFN-α) and Zidovudine (ZDV) Therapy for Kaposi's Sarcoma

IFN-α Dose (MU) and Schedule	Total Daily ZDV Dose (mg)[a]	Evaluable Patients (n)	Response Rate (CR + PR) (%)	Reference
4.5–18 q.d.	600–1,200	37	46	92
9–27 q.d.	600–1,200	43	47	93
<5 to >25 q.d.	300–1,200	26	42	94
18 q.d.	600	62	40	95
10 q.d.	500	15	27	96
1 q.d.	500	53	8	97
8 q.d.	500	54	31	97
9–18 q.d.	600	20	5	98
3 t.i.w.	500	17	65	99
10–20 q.d.	500–800	40	45	100
18 q.o.d.	800–1,200	15	46	101

CR, complete response; PR, partial response.

[a]Administered as divided doses, two to six times daily.

The combination of IFN-α with ZDV often induces neutropenia and anemia, along with other side effects typically associated with single agents. These hematologic side effects were anticipated by the known toxicities of the two drugs and by *in vitro* studies showing synergistic suppression of granulocyte-monocyte (colony-forming unit, granulocyte-monocyte) and erythroid (burst-forming unit, erythroid) precursors when the two drugs were combined (102). Two strategies have been used to reduce the hematologic toxicity associated with combination therapy. In two clinical studies in patients with KS, low doses of GM-CSF were shown to prevent or ameliorate neutropenia induced by the IFN-α and ZDV combination (103,104). The improved hematologic tolerance was offset in some cases by the toxicities of GM-CSF (104), and there was

no indication that nonhematologic toxicities were affected or that maximally tolerated IFN-α doses or response rates were substantially increased. The use of less myelosuppressive nucleoside analog reverse transcriptase inhibitors has also been investigated. In one randomized trial, the AIDS Clinical Trials Group has evaluated didanosine in combination with either 1 MU or 10 MU of IFN-α daily. These doses are approximately three- to 30-fold less than the IFN-α doses considered effective as monotherapy. Although the final trial results are still under analysis, KS regression has been observed at both IFN-α doses and in patients with low CD4 T-lymphocyte counts (S. Krown, *unpublished results*). In a phase 1 trial, the AIDS Malignancy Consortium is investigating the clinical and pharmacologic interactions between IFN-α and protease inhibitor-based combination antiretroviral regimens.

Interferon Effects on Human Immunodeficiency Virus

No question exists that type I IFNs inhibit HIV replication *in vitro* (58,59,60 and 61,105). The data in patients are conflicting, however, and their relevance to KS regression is unclear. Many studies of high-dose IFN-α monotherapy were conducted before the discovery of HIV and before standardized, sensitive methods were available to evaluate viral burden. By the late 1980s, two studies had documented a decrease in serum levels of the HIV p24 antigen in KS patients whose tumors regressed during high-dose IFN-α monotherapy (74,75), whereas patients whose KS did not regress showed no virus suppression. Those patients whose KS regressed and whose p24 antigen levels decreased were more likely than nonresponders to have high CD4 T-lymphocyte counts. These concordant effects suggested that common mechanisms were involved in IFN's antitumor and antiviral activities, and that intact immunologic effector mechanisms might be required for both. Of the 21 patients in one of these studies, three with CD4 T-lymphocyte counts above 500 cells per μL showed clearance of HIV from cultured peripheral blood mononuclear cells (74). These observations led to a randomized clinical trial of high-dose IFN-α versus placebo in asymptomatic HIV-seropositive patients with CD4 counts of 400 per μL or more and positive PBMC cultures for HIV (106). Sixty-four percent of the patients who received IFN-α for 12 or more weeks had consistently negative HIV cultures during treatment, whereas negative cultures were documented in only 13% of placebo recipients (106). The combination of IFN-α and ZDV was also reported to synergistically suppress p24 antigen levels in HIV-infected patients who had CD4 counts above 200 per μL and measurable p24 antigen levels before treatment (107), but clinical end points were not monitored in this study. Suppression of serum p24 antigen levels and inhibition of HIV recovery from peripheral blood cells was also reported in several trials of the IFN-α and ZDV combination in patients with KS (92,94,95,96 and 97,100), but the effect was not limited to patients whose KS regressed. In one study, however, an undetectable p24 antigen level at baseline was associated with a greater likelihood of KS regression (101). Finally, a randomized study compared the efficacy of combination therapy with IFN-α (5 MU, three times a week) with ZDV (500 mg daily) to ZDV alone in 250 evaluable HIV-seropositive patients who were asymptomatic or minimally symptomatic and who had a baseline CD4 count of 200 to 500 cells per μL (108). The concomitant administration of IFN-α with ZDV had no effect on the development of AIDS-defining clinical events, viral burden (measured by serum p24 antigen and quantitative PBMC microcultures), or the development of phenotypic resistance to ZDV (108).

In the late 1990s, sensitive polymerase chain reaction-based assays have been developed to quantitate HIV viral load and have proved more useful than p24 antigen or quantitative microculture for monitoring patients receiving antiviral therapy. These methods are currently being applied to patients with KS in a variety of clinical studies, including those involving IFN-α treatment. It should eventually be possible to determine whether baseline viral load or changes associated with the administration of IFN-α-containing regimens predict the response of KS to therapy.

Intralesional Interferon

IFN-α has been reported to induce local regression of directly injected KS lesions in patients with HIV-associated and classic KS (109,110,111 and 112). Neither the dose nor the administration schedule of IFN have been optimized; individual doses ranging from 50,000 U to 1 MU were injected into or around each lesion two to three times a week for up to 8 weeks. In one study, intralesional IFN and a sterile water placebo were found equally effective (109).

Interferon Toxicity

The side effects induced by IFN-α in patients with AIDS-associated KS are not unique. They may, however, be exacerbated by the many other drugs used to treat HIV-infected patients and by the presence of coexisting conditions (e.g., chronic hepatitis, neutropenia, distal sensory peripheral neuropathy, and cognitive defects) commonly observed in such patients. When IFN treatment is initiated at relatively high doses, high fever, chills, and labile blood pressure are common. These side effects can be ameliorated, although not always eliminated, by gradual dosage escalation and pretreatment with either acetaminophen or nonsteroidal antiinflammatory agents. The severity of these side effects diminishes over time and is less in patients who receive low IFN-α doses (≤5 MU). The more chronic side effects of IFN-α include a flulike syndrome characterized by low-grade fever, myalgias, arthralgias, general malaise, and anorexia. Neutropenia is common and may be dose limiting but responds to administration of low intermittent doses of granulocyte- or GM-CSF. Hepatic enzyme elevations are common, particularly early in the course of treatment. Although in many cases hepatic enzyme abnormalities have resolved without interruption of treatment or a decrease in IFN dose, they were found to be dose-limiting in one phase 1 study in which IFN-α and ZDV were combined (93). A reversible congestive cardiomyopathy was reported in three patients with KS after prolonged high-dose IFN-α treatment (113). Additional side effects may

include rash, thrombocytopenia, headache, depression, minor cognitive impairment, thyroid abnormalities, autoimmune diseases, decreased libido, and distal paraesthesias. Because many IFN side effects mimic the signs and symptoms of other HIV-associated complications, particular care must be taken in evaluating new symptoms and laboratory abnormalities so that intercurrent illnesses are not overlooked. In addition, because IFNs have the potential to influence hepatic microsomal enzymes involved in the metabolism of a variety of drugs (114), including HIV protease inhibitors, the possibility of drug interactions is a concern.

Interferon-β

Part of "10.4 - Kaposi's Sarcoma "

A role for IFN-β in the treatment of KS has not been defined. Despite *in vitro* studies that demonstrate inhibition of HIV replication (105) and inhibition of HIV Tat-induced angiogenesis by IFN-β (115), scant clinical data are published. Furthermore, all published studies were conducted well before the availability of highly effective combination antiretroviral regimens. In one study, recombinant IFN-β$_{ser}$ induced a major response rate of 16% without inducing significant hematologic toxicity (116). Dose-limiting toxicity included injection-site necrosis. In another trial, the combination of IFN-β$_{ser}$ with ZDV was studied at IFN doses of 22.5, 45.0, and 90.0 MU administered by daily subcutaneous injection (117). Although the combination was described as "generally well-tolerated," constitutional symptoms and local skin necrosis were dose-limiting; the maximum tolerated dose was 45 MU daily. Despite the presence of limited KS, only two of 15 patients (13%) showed objective tumor responses (117). Rapid progression of KS was observed in three of four patients treated with a combination of recombinant IFN-β and IL-2 (118).

Potential Future Applications of Interferon in Kaposi's Sarcoma Therapy

Part of "10.4 - Kaposi's Sarcoma "

IFN-α was the first drug to receive U.S. Food and Drug Administration approval for treatment of KS and is currently the only biologic approved for this indication. Although IFN-α activity against KS has been demonstrated in many clinical trials, several factors have limited its use. The requirement for frequent, long-term self-injection of IFN-α has been a disincentive for many patients. Occasional patients have developed painful reactions or infections at injection sites, and most patients are also receiving complex drug regimens for which adherence is often a problem. Chronic side effects, especially malaise and flulike syndrome, have also been troublesome, especially for patients treated at moderate to high doses. These side effects have generally not presented major obstacles for patients treated at lower IFN-α doses, particularly those patients who show objective tumor regression. Many patients and their physicians are aware of the significant toxicities associated with high-dose monotherapy, however, and are reluctant to use even low-dose IFN-α when alternative treatments are available.

Despite these obstacles, reasons to believe that IFN-α can still be a valuable therapeutic agent for KS exist, especially when it is used at better tolerated doses and schedules, probably in conjunction with other agents that inhibit angiogenesis by different mechanisms. Fidler and colleagues found that optimal tumor growth inhibition and down-regulation of bFGF mRNA and protein were achieved when low IFN-α doses were administered twice daily to mice bearing orthotopic implants of human bladder cancer (119,120). When the same total weekly dose of IFN-α was administered less often (i.e., once, twice, or three times per week, or once a day), or if the daily doses of IFN-α were increased, tumor growth inhibition was decreased (119,120). These findings suggest that IFN-α's effectiveness as an angiogenesis inhibitor may depend not only on its administration at an optimal dose (which may be well below the maximum tolerated dose) but also on its administration at an optimal schedule (120). Admittedly, the idea of twice-daily injection of IFN is unlikely to be met with great enthusiasm by patients, even if a very low and nontoxic dose is proved optimal. The use of pegylated IFN preparations may, however, eventually allow less frequent parenteral dosing while maintaining optimal angiogenesis inhibitory effects.

Angiogenesis is a multistep process stimulated by a variety of regulatory factors released by tumor and host cells (many of which may be involved in the development and progression of KS). Although IFNs have the potential to influence many of these factors, other agents may prove more powerful than IFN against some of these factors, or may act synergistically with IFN to suppress angiogenesis. A number of such agents are now under study in KS. These include thalidomide (which may affect KS growth through inhibition of TNF and through TNF-independent mechanisms) (121,122 and 123), inhibitors of endothelial cell proliferation (124,125,126 and 127), and inhibitors of matrix metalloproteinases, enzymes that facilitate capillary budding and invasion by disrupting the extracellular matrix. Other potential approaches include agents that abrogate tyrosine kinase-mediated transmembrane receptor signals for VEGF/VPF (128), antisense oligonucleotides directed against angiogenic growth factors (129), and agents directed against endothelial cell surface molecules expressed on proliferating vasculature, such as α$_v$β$_3$ (130). Once clinically active agents of this type are identified, a reasonable approach would be to design studies to investigate them in combination with IFN-α and effective antiretroviral therapy.

Finally, a better understanding of the expression of HHV-8–encoded genes in KS lesions may make it possible to further optimize the antitumor effects of IFN. Although many HHV-8 gene products have been implicated in the promotion of KS by a variety of mechanisms, it is not clear that the respective genes are expressed in the tumor cells of all KS lesions (131). Perhaps pertinently, however, HHV-8 encodes an IFN regulatory factor homologue capable of repressing transcriptional activation induced by all classes of IFNs (132,133 and 134). If expression of the viral interferon regulatory factor gene in KS cells was found to be associated with a poor response to IFN, this might provide a method for selecting appropriate patients for treatment and a target for therapy.

Introduction

Part of "10.5 - Epithelial Cancers "

Interferon-α (IFN-α) has not been effective as single-agent therapy for most epithelial tumors, with no responses observed in phase 2 trials for cancers of the gastrointestinal tract and non-small-cell lung cancer (1,2,3 and 4). Efforts at exploiting the unique antineoplastic effects of IFN-α are based on the concept of biomodulation and preclinical data of synergy between it and other chemotherapeutic agents.

Biomodulation is the enhancement of the antitumor activity of a cytostatic agent by a drug (the biomodulator) that per se has no direct antiproliferative effect against the tumor of interest. Biomodulators act by manipulating the intracellular metabolic pathways of antineoplastic agents, with subsequent enhancement of antitumor activity or protection of the normal tissues of the host, or both. The interaction between 5-fluorouracil (5-FU) and IFN-α is an example of biomodulation. This chapter discusses the role of IFN as a biomodulator in various epithelial cancers, with emphasis on gastrointestinal cancers and squamous cell carcinoma of the lungs, head, and neck.

Colorectal Cancer

Part of "10.5 - Epithelial Cancers "

Rationale for Use of Interferon in Colorectal Cancer

Interferons as single agents have not shown activity in colorectal cancer. Investigations with IFN in this disease have concentrated on exploiting the biologic synergy between IFN and 5-FU. In concert with 5-FU, IFN-α acts as a biomodulator by inhibiting thymidylate synthetase, a key enzyme in the metabolic pathway of 5-FU. IFN-α also decreases the clearance of 5-FU, thereby increasing plasma levels and the area under the curve (5).

Biomodulation of 5-Fluorouracil by Interferon (Phase 2 Studies)

Wadler et al. were the first to report the encouraging results of a phase 2 trial of IFN-α and 5-FU in 30 patients with metastatic colorectal cancer (6). Of the 17 previously untreated patients,

13 responded; no patient who had received previous chemotherapy had a response. Toxicity was manageable with one toxic death. Median survival was in excess of 16 months.

Subsequent phase 2 trials showed less encouraging results and are summarized in Table 10.5-1 . Response rates (RRs) varied from 10% to 64% and median survival ranged from 8 to 18 months. Most patients in these trials had not received previous chemotherapy for metastatic disease. Clinical toxicities typical of IFN (fever, myalgia, and fatigue) were universally seen. Neurotoxicity in the form of memory disturbance, sensory neuropathy, confusion, and tardive dyskinesia was noted in one study, affecting 13 of 38 patients (34%), 9 of whom were 60 years of age or older (7). All studies used recombinant IFN; lymphoblastoid interferon was used in one trial with a low (10%) RR (8).

NR, not reported.

Biomodulation of 5-FU has also been investigated as second-line therapy in patients with advanced or metastatic colorectal cancer, or both. To assess the ability of IFN to modulate 5-FU in patients refractory to protracted venous infusion 5-FU, Findlay and coworkers added IFN-α, 5 MU subcutaneous (s.c.), three times weekly, to a regimen of protracted venous infusion 5-FU, 200 to 300 mg per m^2 per day, in patients determined to become refractory to the latter. An 8% RR was observed in 60 patients (9). Perez et al. reported the results of FU and IFN in 34 patients refractory to previous therapy with FU with methotrexate or leucovorin, or both (10). Only two responses were observed, with a median survival of 5 months. Hepatic arterial infusion of 5-FU and IFN was tested in 48 patients with unresectable liver metastases from colorectal carcinoma refractory to systemic FU and leucovorin. Fifteen responses [three complete responses, 12 partial responses (PRs)] were seen in 45 evaluable patients; median survival was 15 months. Notable was the lack of hepatobiliary toxicity (11).

Double and Triple Modulation of 5-Fluorouracil (Phase 2 Studies)

Leucovorin and IFN modulate the activity of 5-FU, using different mechanisms of action. Several trials designed to test this potential synergy have been completed. *In vitro* data suggest a minimum dose of 5 MU per m^2 of IFN is necessary for adequate modulation (12,13), but various doses and schedules have been used. Phase 2 clinical trials of so-called double modulation of FU are summarized in Table 10.5-2 . Response rates vary between 10% and 58%, with median survival between 7.8 and 17.0 months. Toxicity was mainly in the form of mucositis and diarrhea and tended to be more severe than with single modulation.

Randomized Phase 3 Trials

Several large, randomized phase 3 trials have matured and helped better define the role of biomodulation of 5-FU in advanced and metastatic colorectal cancer. Results of five randomized trials comparing a combination of 5-FU and IFN to 5-FU alone are available and summarized in Table 10.5-3 . Patients entered into these trials had not received previous chemotherapy for metastatic disease. The regimen used in three of these studies used the initial regimen described by Wadler et al. (Table 10.5-4). One used lower doses of both drugs (14); one used a slightly higher dose of IFN (10 MU) (15); and another used protracted venous infusion of 5-FU (16).

  i.v. bolus starting d 15, q weekly

Interferon-α, 9 MU

  s.c., t.i.w., continuously

Greco and colleagues reported the results of a protocol (N-3411) designed to evaluate the RR, time to progression, survival, and toxicity of a combination of 5-FU and IFN-α-2a versus 5-FU alone in patients with chemotherapy-naïve, advanced colorectal cancer (17). Two hundred forty-five patients were randomized to either 5-FU, 750 mg per m^2 per day continuous intravenous infusion, days 1 through 5, followed by a weekly bolus of the same dose 9 days later or the same regimen concurrent with IFN-α-2a, 9 MU s.c., three times weekly throughout treatment. The overall RR was 24% for the IFN/FU arm and 17% for the FU arm (p = not significant). Neither time to progression nor survival were different in the two arms of the trial. Toxicity was greater on the combination arm. Dufour et al. tested an identical regimen in a randomized trial of 105 patients. Although a higher RR was observed for the IFN- treated group (19.6% versus 6.1%), no significant difference in overall survival (OS) occurred (18). The trial reported by Palmieri and colleagues randomized 235 patients in a similar fashion. No significant difference in the RR (25% versus 21%) or survival (48.5 weeks versus 43.7 weeks) was observed for the IFN-treated patients. A prospective, randomized phase 2 trial was conducted by Piga et al. of a lower dose of FU (500 mg per m^2) and IFN (6 MU per day, later lowered further to 3 MU per

day due to toxicity) in 142 patients. No difference in response or survival occurred and the trial was stopped early (14).

The Royal Marsden Group in the United Kingdom tested a similar combination of 5-FU and IFN-α (10 MU s.c. three times weekly) to 5-FU alone in 106 eligible patients who had not previously received chemotherapy. No improvement in RR, duration of response, or survival was observed for the combination (15). A significantly greater number of patients on the IFN arm had to discontinue therapy due to toxicity (leukopenia, lymphopenia, depression, and alopecia). In another trial conducted by the same group, protracted venous infusion 5-FU, 300 mg per m^2 per day for 10 weeks, was substituted for the 5-day regimen and the IFN-α dose was reduced to 5 MU s.c. three times weekly. Once again, RR did not differ significantly between the two arms of the study. Although the treatment was in general well-tolerated, mucositis, alopecia, and leukopenia were significantly worse for the IFN-treated group. At a median follow-up at 1 year, no difference in time to progression or survival occurred (16).

The Eastern Cooperative Oncology Group and the Cancer and Leukemia Group B conducted a large phase 3 randomized, five-arm trial involving 1,118 patients with previously untreated metastatic colorectal carcinoma. The design of this trial is depicted in Table 10.5-5 . Preliminary results from this large study were available in 1996 for 1,021 patients (20). The addition of IFN-α to 5-FU was not superior to the reference arm of single-agent 5-FU (2,600 mg/m^2/week) and was more toxic.

Table 10.5-5 Intergroup Trial of Biomodulation of 5-Fluorouracil (5-FU)

  IFN-α-2a, 9 MU t.i.w., s.c.

c.i.v., continuous intravenous infusion; IFN, interferon; PALA, *N*-phosphonacetyl-L-aspartic acid.

Randomized trials of double modulation of 5-FU with IFN and leucovorin have also been conducted (Table 10.5-6). The results of a large, multicenter, randomized trial designed to identify the most effective biomodulating agent of 5-FU have been reported (21). 5-FU was administered as a weekly 24-hour infusion of 2,600 mg per m^2 per week in combination with either leucovorin or IFN, or both. After a preliminary toxicity assessment, the double modulation arm was halted. Response rates for patients who received 5-FU and leucovorin were significantly higher than for those who received 5-FU and IFN (44% versus 18%; *p* <.05), as was median survival (16.2 months versus 12.7 months; *p* = .02). Toxicity was worse for the IFN-treated patients.

FA, folinic acid; FU, fluorouracil; HU, hydroxyurea; IFN, interferon; NR, not reported; NS, not significant.

The Hellenic Cooperative Oncology Group trial randomized 106 previously untreated patients with metastatic colorectal cancer to either bolus 5-FU, 450 mg per m^2, and leucovorin, 200 mg per m^2 or the same regimen with IFN-α-2b, 5 MU s.c. three times weekly (22). Objective responses were 7.8% and 9.8%, respectively. Not only was median survival significantly better for the single modulation arm (10.1 months versus 7.2 months), but toxicity was also worse for the patients treated with IFN. The authors concluded that double modulation of 5-FU with IFN and leucovorin is worse than single modulation with leucovorin. The Colorectal Working Party of the United Kingdom Medical Council conducted a randomized, multicenter trial of 5-FU and leucovorin on a 2-week cycle with or without IFN-α-2a administered every other day throughout the treatment period. In 205 assessable patients, the overall RRs and survival were virtually identical (23). A quality-of-life analysis showed a worse quality-of-life for IFN-treated patients. Another trial using IFN-α-2c also showed no significant difference in RRs or survival in an interim analysis.

5-FU and IFN was compared to 5-FU and leucovorin in a randomized trial of 142 patients. A trend to improved survival was noted for the leucovorin-treated patients (25). A larger trial of 496 patients with a similar design showed similar RRs for the two regimens and similar OS (26). Of note, more patients treated with IFN withdrew from treatment due to side effects.

As expected, second-line therapy for metastatic colorectal cancer with 5-FU and IFN combinations with or without leucovorin have been uniformly unsuccessful (Table 10.5-7) (10,29). Hepatic arterial infusion of IFN-α-2b and 5-FU was tested in 48 patients with liver metastases from colorectal cancer refractory to systemic 5-FU and leucovorin. A response was obtained in 33% of patients (median response duration, 7 months) (28).

Table 10.5-7 Salvage Therapy for Advanced Colorectal Cancer

Author (Reference)	No. of Patients	Response (%)	Duration (Mo)
John (36)	9	11	4
Ridolfi et al. (27)	21	1	8
Findlay (9)	64	8	2.5
Bracarda (50)	31	23	4.8
Loffler (51)	55	34	5.2
Patt et al. (28)	48	33	7
Perez et al. (10)	34	6	3

Based on the results of these mature, randomized trials, it is evident that the initial promise of combination therapy 5-FU and IFN has not been confirmed, and this regimen can no longer be recommended for metastatic colorectal cancer. It also appears that regimens of 5-FU modulation using leucovorin are either superior to (or no better than) regimens of double modulation with IFN and leucovorin. Most trials have shown worse toxicity or quality-of-life for IFN-treated patients.

Few data regarding other IFN-containing biologic regimens for colorectal cancer exist. IFN-based therapy has been combined with IL-2 in two small phase 2 trials with disappointing results (Table 10.5-8). Other chemotherapy regimens with IFN also have been unsuccessful (29).

Adjuvant Therapy of Colorectal Cancer

Based on the initial promising phase 2 results of 5-FU biomodulation with IFN and the benefit from leucovorin-modulated 5-FU adjuvant therapy shown in National Surgical Adjuvant Breast and Bowel Project protocol C-03, the NSABP initiated a randomized trial of 5-FU and leucovorin with or without IFN in 1991 (NSABP Trial C0-5). Data are available for 2,176 patients with Dukes' B or C colon carcinoma who were entered through February 1994. The study design is shown in Table 10.5-4 . At 4 years of follow-up, disease-free survival is virtually identical for the two arms (70% for the experimental arm versus 69% for the controls), as is OS (81% versus 80%). Apart from toxicity, which was worse for patients treated with IFN, no other significant differences between the two treatment groups occurred (30). The only other randomized trial of biomodulation in the adjuvant setting was conducted by the Italian Cooperative Oncology Group in 1995. The aim of this study was to evaluate the impact of the addition of levamisole or IFN-α-2b to the combination of 5-FU and leucovorin on the OS and disease-free survival of Dukes' B and C colon cancer. The 5-FU/leucovorin arm was dropped halfway through the trial secondary to poor patient accrual. Only toxicologic data have to date been reported and are worse for the patients who received IFN (31).

Esophagus Cancer

Part of "10.5 - Epithelial Cancers "

Two groups of patients have been the focus of IFN-based modulation of chemotherapy for carcinoma of the esophagus. In addition to the more traditional group with metastatic or unresectable disease, there are those patients in whom a neoadjuvant chemotherapy approach before to planned surgery has been attempted. The goal in this latter group is ostensibly to improve pathologic cure rates and OS by eradicating micrometastatic disease.

IFN combined with 5-FU in a regimen identical to that originally described for colorectal cancer has been tested in two phase 2 studies (56,57). Responses were noted 26% of the time on the average and lasted approximately 6 months. The demonstrated single-agent activity of cisplatin has led to its incorporation in combination regimens with IFN-α. Results from at least four phase 2 trials are available (Table 10.5-9) (58,59,60 and 61). Although RRs as high as 73% have been reported, small numbers of patients have been treated, and follow-up is short. Toxicity has been considerable. No difference appears to exist between adenocarcinomas and squamous cell carcinomas with regard to response or survival. The activity of *cis*-retinoic acid in squamous cell carcinoma of the skin and cervix was the impetus behind its combination with IFN-α. No responses were observed in 23 patients, many of whom had previously received chemotherapy (60,62).

Table 10.5-9 Cisplatin - and Interferon-Based Chemotherapy for Esophagus Cancer

C, cisplatin; FA, folinic acid; FU, fluorouracil; IFN, interferon; NR, not reported.

An aggressive phase 1–2 trial of neoadjuvant cisplatin, 5-FU, IFN-α-2b, and radiation therapy was tested in 45 patients with potentially resectable adeno- or squamous-cell carcinoma (63). Forty-one patients completed chemoradiotherapy; all but four went on to attempted curative resection. Thirty-six of these 37 patients underwent curative esophagectomy, 80% of whom were pathologically free of tumors. Median survival for the group as a whole was 27 months with a 2-year survival of 52%. The authors concluded that although this was an effective regimen, the contribution of IFN was unclear.

In summary, it is not known if IFN has an impact on the treatment of resectable or metastatic esophageal cancer.

Gastric Cancer

Part of "10.5 - Epithelial Cancers "

As with other malignancies of the gastrointestinal tract, IFN has no single-agent activity in gastric cancer. A phase 1 trial of FU and IFN-α in this disease established a lower dose of IFN (3 MU s.c., three times weekly) in combination with FU as compared with the original regimen for colorectal cancer (64). Experience with IFN-chemotherapy combinations in gastric cancer is limited to small phase 2 trials reported mainly in abstract form (Table 10.5-10). An Eastern Cooperative Oncology Group trial of FU, folinic acid, and IFN in 27 patients with metastatic gastric carcinoma produced three PRs of 16, 23, and 33 weeks' duration (25). Grade III and IV toxicities occurred in up to 36% of patients. Median progression-free survival and OS were 2.5 and 7.8 months, respectively. The addition of etoposide to FU, IFN, and folinic acid produced a 73% RR in one trial (65) and 22% in another (66). Other regimens have included cisplatin, epidoxorubicin, and *N*-phosphonacetyl-L-aspartic acid (67,68 and 69). Once again, no conclusions regarding the efficacy of IFN-α in gastric cancer can be drawn.

Cancer of the Pancreas and Neuroendocrine Tumors

Part of "10.5 - Epithelial Cancers "

The outlook for advanced or metastatic pancreatic cancer remains dismal. Several investigators have attempted FU-based regimens in this disease without major success. FU has been combined with IFN in two studies (73,74). In 52 previously untreated patients, three PRs (5%) were observed. Toxicity was substantial, with 19 of 49 patients in one study experiencing grade III or IV mucositis, diarrhea, granulocytopenia, and fatigue. Both studies concluded that this regimen had no efficacy in advanced pancreatic cancer. Experience with FU, IFN, and leucovorin in pancreatic cancer is summarized in Table 10.5-11 . One hundred and forty-seven patients were treated on these trials, with RRs of 0% to 23%. In the largest of these trials (57 patients), eight partial responses lasting 2 to 10 months were reported; median survival for all patients was 10 months (75). Lung metastases appeared to be the most responsive to therapy. Although side effects of IFN (fever and fatigue) occurred in up to 56% of patients, 22 out of 36 patients (60%) with preexisting tumor-related pain experienced significant symptom palliation, regardless of response. Oral *cis*-retinoic acid was combined with IFN-α in a phase 2 trial of 26 patients with unresectable adenocarcinoma of the pancreas; one PR was observed (76).

Table 10.5-11 Fluorouracil, Interferon, and Leucovorin in Pancreatic Cancer

Author (Reference)	No. of Patients	Response (%)
Pazdur et al. (73)	13	23
Knuth et al. (81)	32	12
Scheithauer et al. (82)	24	8
Schneider et al. (83)	21	0
Bernhard et al. (75)	57	14

Interferon has been used singly or in combination with FU or octreotide for the treatment of advanced neuroendocrine carcinoma (77,78,79 and 80). It is difficult to judge efficacy in these trials because several have used biochemical parameters (50% reduction in hormone secretion) as surrogate markers for response. Data are preliminary and no conclusions regarding survival can be drawn.

Hepatocellular Carcinoma and Cancer of the Biliary Tract

Part of "10.5 - Epithelial Cancers "

Initial enthusiasm for the use of IFN-α in hepatocellular carcinoma was kindled by a randomized controlled trial of IFN-α versus best supportive care in 71 patients with inoperable hepatocellular carcinoma (84). A doubling of survival (14 weeks versus 7 weeks) was reported for the treated group, with 31% objective responses. Phase 2 data for IFN-based therapy for hepatocellular carcinoma has, however, been less than favorable. Two trials reported results of FU with IFN. One used a continuous infusion of FU (750 mg per m^2 per day for 5 days) with IFN-α, 5 MU (days 1, 3, and 5) once every 14 days (85). The other tested a 500 mg per m^2 weekly bolus and the same dose of IFN-α (87). PRs were observed in four of 35 patients. Combining doxorubicin with IFN has also not been rewarding, with three PRs in 46 patients (87,88).

Experience with cancers of the biliary tract (gallbladder and bile duct) is even more limited. Thirty-five patients were treated with a 5-day continuous infusion of 5-FU and IFN-α-2b, 5 MU per m^2 every other day (89). One PR was observed in 11 patients and median survival time was 12 months.

Head and Neck Cancer

Part of "10.5 - Epithelial Cancers "

The combination of cisplatin and 5-FU is still the most widely used chemotherapeutic regimen for recurrent and metastatic head and neck cancer (HNC). In addition to its ability to modulate FU, IFN-α has also potentiated the effects of cisplatin in a xenograft mouse model, leading to several phase 2 trials evaluating the combination of IFN-α, cisplatin, and 5-FU for HNC, with initially encouraging results. A 47% RR was reported in a phase 1-2 pilot study with acceptable toxicity. Cisplatin, 20 mg per m^2 per day; 5-FU 200 mg per m^2 per day; and IFN, 3 MU per day for 5 days, were administered to 14 patients with recurrent or metastatic HNC. Two complete responses and two PRs were observed (90). A slight variation of the same regimen was tested in 29 patients with an overall RR of 30% (91). A more prolonged infusion of FU (1,000 mg per m^2 per day for 96 hours) with cisplatin, 100 mg per m^2 on day 1, and IFN-α-2a, 5 MU s.c. days 1 through 4, repeated every 21 days, was reported for 52 patients with advanced HNC. Nine responses were reported, with an estimated median survival of 5 months. The authors concluded that this regimen did not appear to be superior to chemotherapy alone (92). Other phase 2 regimens have included PALA, FU, IFN (93), and the cisplatin, fluorouracil, and leucovorin-induction regimen followed by hydroxyurea, fluorouracil, and concurrent radiation therapy (94). The latter trial included 65 patients with previously untreated disease and reported an overall RR of 86% (complete response, 51%; PR, 35%). As expected, toxicity was considerable and led to treatment-related death in five patients.

A randomized trial of cisplatin, 100 mg per m^2 on day 1, 5-FU, 1,000 mg per m^2 per day for 96 hours, without (arm A) or with (arm B) IFN-α, 3 MU per day s.c. days 1 through 5, was conducted in 244 patients with recurrent or metastatic HNC (95). No significant difference in RRs (47% versus 38%) or survival (6.3 months versus 6.0 months, arm A versus arm B, respectively) was reported. Based on the results of this large phase 3 trial and the added toxicity of IFN in this patient population, the enthusiasm for IFN-containing regimens for this disease has waned.

Lung Cancer

Part of "10.5 - Epithelial Cancers "

Phase 2 data in non-small-cell lung cancer is summarized in Table 10.5-12 . Combinations have in general included variations of cisplatin, ifosfamide, and mitomycin with IFN. Most are small phase 2 studies with immature data. The largest experience is from a European multicenter trial of cisplatin with IFN in which a 27% RR and a median survival of 6.4 months was observed in 55 patients with non-small-cell lung cancer (96). IFN also has been combined with retinoids (cis-retinoic acid and all trans-retinoic acid). Data are available for 111 patients and only a few responses were noted (Table 10.5-13). Results of two randomized trials have not indicated a benefit for IFN-containing regimens over chemotherapy alone. A phase 3 trial of 60 patients treated with cyclophosphamide, epirubicin, and cisplatin, with or without IFN-α, showed an inferior survival for the IFN-treated patients (5.5 versus 6.0 months, $p = .045$) (97), despite an increased RR (19% versus 8%, $p = .042$). A three-arm randomized phase 2 trial of chemotherapy with cisplatin (60 mg per m^2 on day 1) and etoposide (100 mg per m^2 on days 1, 3, and 5) once every 28 days or the same chemotherapy with IFN-γ (0.2 mg per m^2 three times weekly) or IFN-α-2c (6 MU s.c. three times weekly) did not show a difference in responses (6/22, 5/21, and 6/18, respectively) or survival (7, 6, and 7 months, respectively) between the different treatments (98).

Table 10.5-12 Interferon (IFN) in Hepatocellular Carcinoma

Author (Reference)	Regimen	No. of Patients	Response
Patt et al. (85)	FU/IFN	18	3/18
Mughal et al. (86)	FU/IFN	17	1/17
Kardinal et al. (87)	FU/A	31	1/31
Sangro et al. (88)	FU/D	15	2/15

A, adriamycin; D, doxorubicin; FU, fluorouracil.

Table 10.5-13 Interferon-α in Non-Small-Cell Lung Cancer

Author (Reference)	Regimen	No. of Patients	Response (%)
Bowman (99)	C/IFN-α	60	30
Adizzoni (100)	MIP	23	8.8
	MIP/IFN-α-2b	27	7.4
	C/carboplatin	43	14
Garaci et al. (101)	C/E/thymosin-α/IFN-α-2a	60	40
Hasturk et al. (102)	C/E/IFN-α	38	34

C, cisplatin; E, etoposide; IFN, interferon; MIP, mitomycin, ifosfamide, cisplatin.

Efforts in small-cell lung cancer have looked mainly at maintenance IFN in patients who respond to induction chemotherapy. Results of four large, randomized trials are available; only one showed a benefit for IFN treatment (Table 10.5-14).

Table 10.5-14 Randomized Trials of Interferon (IFN) in Small-Cell Lung Cancer

Author (Reference)	Regimen	No. of Patients	Survival (Mo)	Comment

Bladder Cancer

Part of "10.5 - Epithelial Cancers "

Research with the use of IFN in bladder cancer has addressed two areas: prevention of recurrence of superficial bladder cancer after resection and the combination of IFN with chemotherapy for advanced disease. The presence of IFN-α receptors has been demonstrated in normal bladder urothelium and with increased frequency in malignant tissue (107), providing a rationale for its use in intravesical therapy for bladder cancer. Bacillus Calmette-Guérin (BCG) has been widely adopted as the standard prophylactic treatment for superficial bladder cancer to prevent recurrence. IFN-α has been shown to synergize with BCG in bladder cancer cell lines, which has led to efforts to combine the two agents in phase 2 trials. Several randomized trials comparing IFN to BCG and other agents have been completed and analyzed (Table 10.5-15). In general, results have not been encouraging and seem to indicate that intravesical BCG and other chemotherapeutic agents are superior to IFN in the prevention of superficial bladder cancer. Doses and schedules of intravesical IFN have ranged from 50 MU to 100 MU, usually administered once a week and retained in the bladder for 2 hours. Intravesical IFN-α-2b, 50 MU per week, was compared to mitomycin, 40 mg per week, in 287 patients with superficial bladder cancer after transurethral resection (109). Mitomycin was superior with regard to recurrence rate and median time to recurrence (36 months versus 21 months). Local toxicity was higher for patients treated with mitomycin. BCG (150 mg in 50 mL saline) was compared to IFN-α-2a (54 MU) in a prospective, randomized multicenter trial of 122 patients with recurrent superficial transitional cell cancer of the bladder (110). A statistically significant advantage in terms of recurrence and time to progression was found for the BCG group (p = .001).

Table 10.5-15 Randomized Intravesical Interferon (IFN) Trials for Superficial Bladder Cancer

Author (Reference)	Regimen	No. of Patients	Result
Boccardo (111)	IFN	287	TTP: 21 mo
	Mitomycin		TTP: 36 mo
Jimenez-Cruz (110)	BCG	122	RFS: 61%
	IFN		RFS: 44% (p = .001)
Kalble (112)	BCG	78	Recurrence: 15.6%
	IFN		Recurrence: 60% (p = .03)
Raitanen (113)	Observation	81	
	Epirubicin		RFS: 44%
	Epirubicin + IFN		RFS: 63%
Portillo (72)	IFN	90	Recurrence: 53.8%
	Placebo		Recurrence: 51.3% (p = NS)
Tizzani (114)	Mitomycin	210	More recurrences in sequential group (p <.05)
	Mitomycin + IFN (sequential)		
Rajala (115)	Observation	283	Recurrence: 54%
	IFN (single-dose)		Recurrence: 54.5%
	Epirubicin (single-dose)		Recurrence: 29% (p <.01)

BCG, bacillus Calmette-Guerin; NS, not significant; RFS, relapse-free survival; TTP, time to peak.

Conclusions

Part of "10.5 - Epithelial Cancers "

Despite provocative initial results in phase 2 trials, the promise of IFN-α-mediated biomodulation has not been substantiated by randomized phase 3 studies. It appears that in epithelial tumors in general, the added toxicity of this agent does not justify its use outside the context of clinical trials. Further research into the mechanism of action of the IFNs and elucidation of the molecular and immunologic basis behind biomodulation may help provide a rationale for a more tailored approach to therapy with this drug in epithelial cancers.

Interferon-γ: Basic Principles and Clinical Applications

Vijay Shankaran

Robert D. Schreiber

Introduction

Part of "11 - Interferon-γ: Basic Principles and Clinical Applications "

Our understanding of interferon-γ (IFN-γ) has increased greatly since its initial description in 1965 as an antiviral activity produced by phytohemagglutinin-activated human leukocytes. Progress has been especially rapid in the 1980s and 1990s, during which time the genes encoding IFN-γ and its receptor chains have been cloned and expressed. The production of large amounts of recombinant IFN-γ and soluble IFN-γ receptors and the generation of specific monoclonal antibodies to these proteins have facilitated their molecular definition and yielded insights into their *in vivo* function. Structure-function studies of these proteins have identified the key regions required for their biologic activity; these insights have been supported by the solving of the crystal structures of IFN-γ and the IFN-γ–IFN-γ receptor complex. Mice lacking expression of IFN-γ, the IFN-γ receptor chains, or IFN-γ signaling components have been generated and have confirmed and extended the results from previous studies using anti-IFN-γ-neutralizing antibodies concerning the physiologic roles of these proteins. In addition, our understanding of the role of IFN-γ in preventing human disease has been advanced by the identification of human patients with IFN-γ production or signaling deficiencies and the demonstration that IFN-γ plays a critical role in promoting tumor surveillance in immunocompetent hosts. Therefore, we now have a relatively clear view of the biochemistry and biology of the IFN-γ system in mice and humans. This chapter reviews key aspects of the IFN-γ system and discusses data supporting its central role in modulating immune system activity and its ability to coordinate host defense to microbial pathogens and tumors.

Structure of Interferon-γ Genes and Proteins

Part of "11 - Interferon-γ: Basic Principles and Clinical Applications "

IFN-γ is a member of a family of proteins that were originally described as antiviral activities produced by virally infected cells or mitogen-stimulated leukocytes (1,2). These proteins have been divided into two classes on the basis of structural and functional criteria, as well as the stimuli that induce their expression. The first class, termed type I IFNs, is primarily induced in response to viral infection of cells and has been further subdivided into two groups, IFN-α and IFN-β, based on cellular origin (3). The IFN-α family consists of more than 22 structurally related polypeptides that are encoded by distinct genes and produced largely by leukocytes (4,5). IFN-β is the product of a single distinct gene and is produced by fibroblasts (3). The second class of IFNs, termed *type II IFN, immune IFN*, or *IFN-γ*, is the product of a single gene and is produced by T lymphocytes and natural killer (NK) cells after activation with immune and inflammatory stimuli rather than viral infection (6,7).

IFN-γ is unrelated to IFN-α or IFN-β at genetic and protein levels and is encoded by a single 6-kb gene that resides on human chromosome 12 and murine chromosome 10 (8,9). The gene is organized in an identical manner in humans and mice and contains four exons and three introns. The human IFN-γ gene encodes a 1.2-kb messenger ribonucleic acid (mRNA) that is translated into a 166-amino acid polypeptide. After removal of its 23-amino acid signal sequence, the mature human IFN-γ polypeptide consists of 143 amino acids. Differential glycosylation at two *N*-linked glycosylation sites gives rise to mature human IFN-γ polypeptides of molecular mass (Mr) of 17, 20, and 25 kd (10). The murine IFN-γ gene encodes a 1.2-kb mRNA that gives rise to a 134-amino acid mature polypeptide, which, depending on its glycosylation state, displays Mr of 15.4, 20, or 25 kd. In both species, the fully glycosylated IFN-γ polypeptide predominates. Human and murine IFN-γ coding sequences display 60% identity, whereas the polypeptides share only 40% identity. This primary amino acid sequence diversity is the basis for the strict species specificity that human and murine IFN-γ display in binding to and inducing responses in human and murine cells, respectively (6). Under physiologic conditions, two IFN-γ polypeptides self-associate to form a noncovalent homodimer with a molecular mass of 50 kd (11,12). The IFN-γ homodimer is a labile molecule that can be denatured by extremes of temperature (>65°C) or pH (pH <4 or >9). Only the homodimeric form of IFN-γ is fully capable of binding to the IFN-γ receptor on cells and inducing biologic responses. The crystal structure of the IFN-γ dimer has been solved and indicates that two IFN-γ monomers associate in an antiparallel fashion to form a symmetric dimer (13). Subsequent

crystallographic studies of the complex of IFN-γ bound to the ligand-binding chain of the IFN-γ receptor indicate that the IFN-γ homodimer contains two identical receptor binding sites and interacts with two receptor molecules (14).

Interferon-γ Biosynthesis

Part of "11 - Interferon-γ: Basic Principles and Clinical Applications "

In hosts with normal function, IFN-γ production is restricted to appropriately stimulated T lymphocytes and NK cells (6,7). CD8⁺ T cells and the CD4⁺ T-helper (Th)-0 and -1 subsets secrete IFN-γ and other T-cell-derived cytokines in response to antigens presented in the context of the proper major histocompatibility (MHC) protein and costimulation. Agents that mimic T-cell activation, such as antibodies that cross-link the T-cell receptor (TCR), mitogens, or pharmacologic agents (such as the combination of phorbol myristate acetate and calcium ionophore), can also stimulate IFN-γ production in these cells. Neither IFN-γ message nor protein can be detected in resting T cells. IFN-γ transcripts can be detected within 6 to 8 hours of T-cell activation, however, reaching maximum levels by 12 to 24 hours and then subsequently declining to baseline values. The IFN-γ protein is secreted immediately after synthesis and reaches maximal extracellular levels 18 to 24 hours after T-cell stimulation (6). A second, TCR-independent pathway has been shown to induce robust IFN-γ production by T cells. This pathway involves the cytokines interleukin-12 (IL-12) and interleukin-18 (IL-18), which synergize to induce IFN-γ production through mechanisms involving transcription factors STAT4 and nuclear factor kappa B (15,16,17,18,19,20 and 21). Activation of these transcription factors is not sufficient to induce IFN-γ transcription in T cells, however, and additional protein synthesis is required (21). Further work is needed to define these other proteins that regulate IFN-γ production.

Activated NK cells comprise the other cellular source of IFN-γ. Unlike T cells, NK cells produce IFN-γ solely in an MHC-unrestricted manner. Analysis of lymphocyte-deficient severe combined immunodeficiency disease (SCID) mice infected with the gram-positive bacteria *Listeria monocytogenes* identified a cytokine amplification loop that leads to the production of large amounts of IFN-γ by NK cells (22,23). On interaction with bacterial products, tissue macrophages produce small amounts of tumor necrosis factor-α (TNF-α) and IL-12, which together stimulate NK cells to secrete low levels of IFN-γ. This NK-cell-derived IFN-γ in turn stimulates the macrophages to increase their production of TNF-α and IL-12, which subsequently leads to enhanced production of IFN-γ by NK cells. This reciprocal stimulation forms a positive amplification loop that results in the rapid production of substantial quantities of IFN-γ early in the course of infection and facilitates the generation of large numbers of activated macrophages with antimicrobial activity. Therefore, the interdependent synergistic effects of IFN-γ, IL-12, and TNF-α on macrophages and NK cells provides the host with an innate mechanism for IFN-γ production and macrophage activation that facilitates early control of infection (24).

Interleukin-10 (IL-10) is a cytokine produced late in the course of infection that, through indirect mechanisms, downregulates the production of IFN-γ by NK and T cells (20,23,25). IL-10 functions by preventing macrophage secretion of TNF-α and IL-12, although its mechanism of action is undefined.

Interferon-γ Receptor

Part of "11 - Interferon-γ: Basic Principles and Clinical Applications "

IFN-γ interacts with a distinct high affinity (Ka = 10^{10}-$10^{11}M^{-1}$) receptor that is expressed on nearly all cell surfaces (14,26). IFN-γ receptors consist of two species-matched polypeptides. The first is a 90-kd protein known as the *IFN-γ receptor-a chain, IFNGR1, IFN-γ-R1,* or *CDw119* and is encoded by a gene on human chromosome 6 and murine chromosome 10. The IFNGR1 subunit is responsible for ligand binding and ligand trafficking through the cell and is required (but not sufficient) for signal transduction. The second is a 62-kd protein termed the *IFN-γ receptor-β chain, IFNGR2, IFN-γ-R2,* or *accessory factor-1* and is encoded by a gene on human chromosome 21 and murine chromosome 16. The IFNGR2 subunit plays only a minor role in ligand binding but is required for IFN-γ signaling.

The two IFN-γ receptor subunits differ significantly in terms of their cell-surface expression. IFNGR1 is expressed constitutively at moderate levels on the surface of nearly all cells (200 to 25,000 sites per cell), and its expression does not appear to be modulated by external stimuli. In contrast, IFNGR2 is expressed on cells at very low levels, and its expression is regulated in certain cell types (such as T lymphocytes) by external stimuli (27,28). In some cells, expression of the IFNGR2 gene is a critical factor in determining IFN-γ responsiveness.

The human IFNGR1 gene encodes a 489-amino acid precursor that contains a 17-amino acid signal sequence (29), whereas the murine IFNGR1 gene encodes a 477-amino acid polypeptide containing a 26-amino acid signal peptide (30,31,32,33 and 34). The human and murine proteins are organized in a similar manner; both contain a 228-amino acid extracellular and a 23-amino acid transmembrane domain and relatively large, serine- and threonine-rich intracellular domains that also contain several tyrosine residues. Despite this organizational similarity, however, the two polypeptides exhibit only 52.5% overall sequence identity, which applies to extracellular and intracellular domains. The Mr of mature human IFNGR1 proteins from different cells range from 80 to 95 kd due to cell-specific differences in glycosylation (35,36 and 37).

Human and murine IFNGR2 subunits are also structurally similar to one another. Human IFNGR2 is a 337-amino acid type I transmembrane polypeptide that contains a 21-amino acid signal sequence, an extracellular domain of 226 amino acids, a single 24-amino acid transmembrane domain, and a relatively short intracellular domain of only 66 amino acids (38). Murine IFNGR2 consists of an 18-amino acid signal sequence, a 224-amino acid extracellular domain, a 24-amino acid transmembrane domain, and a 64-amino acid intracellular domain (39). Although human and murine IFNGR2 exhibit only 58% overall identity, their cytoplasmic domains display 73% identity. The human and murine complementary DNAs (cDNAs) encode polypeptides of 38 kd. Mature forms of human and murine IFNGR2 display an Mr of 62 kd, however (28). This difference is most likely explained

by the postsynthetic glycosylation of polypeptides, although the composition and location of IFNGR2-associated carbohydrates has not been established.

Signal Transduction Through the Interferon-γ Receptor

Part of "11 - Interferon-γ: Basic Principles and Clinical Applications "

Janus Protein Tyrosine Kinases and Signal Transducers and Activators of Transcription Proteins

Work performed in many laboratories during the 1990s has demonstrated that the IFN-γ receptor, as well as many other cytokine and growth factor receptors, functions as a result of the ligand-induced coupling of the cognate cell surface receptor to a signal transduction pathway termed the *Jak-STAT pathway* (14,40,41,42,43 and 44). The Jak-STAT pathway rapidly transfers signals directly from the cell surface to the nucleus. To do so, the pathway uses two families of molecules. The first is a family of related protein tyrosine kinases known as *Janus kinases*, or *Jaks* (Table 11-1). The second is a family of latent cytosolic transcription factors termed *signal transducers and activators of transcription*, or *STATs* (see Table 11-1).

Table 11-1 Phenotypes of Mice Lacking Jak-STAT Pathway Proteins

Gene Deleted	Knockout Mouse Phenotype	Cytokine Receptors Affected	Reference
Jak1	Perinatal lethality, T- and B-cell deficits, innate immunity defect, neuronal survival deficit	IFN-α and -β, IFN-γ, IL-10, γ_c family, gp130 family	46
Jak2	Early embryonic lethality, no blood formation, lack of IFN-γ signaling	IFN-γ, Epo	47, 48
Jak3	T- and B-cell deficits	γ_c family	142, 142 and 144
Tyk2	ND	ND	—
STAT1	Innate immunity defect, poor Th1 response	IFN-α and -β, and IFN-γ	50, 51
STAT2	Enhanced viral susceptibility	IFN-α and -β	C Schindler, *personal communication*, 1999
STAT3	Early embryonic lethality, dysregulated macrophage production of inflammatory cytokines	IL-10, gp130 family	145, 146 and 147
STAT4	Th1 defect	IL-12	148, 149
STAT5A	Lactation defect	Prolactin	150, 151
STAT5B	Dwarfism	GH	151, 152
STAT5A × STAT5B	T-cell defect	IL-2	151
STAT6	Th2 defect	IL-4	153, 154

Epo, erythropoietin; GH, growth hormone; IFN, interferon; IL, interleukin; Jak, Janus protein tyrosine kinase; ND, no data; STAT, signal transducers and activators of transcription proteins; Th, T-helper cell.

The Janus kinase family currently consists of four molecules: Jak1, -2, and -3 and Tyk2 (40,43,45). The Jak family members are structurally distinguished from other protein tyrosine kinases in that they contain dual kinase domains at their carboxy-terminus, although only the most extreme C-terminal kinase domain has documented kinase activity. The Jaks associate with cytokine receptor subunits in a specific and constitutive manner, and, on ligand addition, are able to phosphorylate activated cytokine receptors and STAT proteins (46,47,48 and 49).

The STAT protein family currently consists of seven distinct polypeptides: STAT1, -2, -3, -4, -5A, -5B, and -6 (41,43). This family of transcription factors is unusual in that its members possess src homology-2 (SH2) domains capable of binding to phosphotyrosine-containing sequences. Studies using cells and mice engineered to lack particular STAT proteins have demonstrated that the STATs play a major role in determining cytokine receptor signaling specificity (40,50,51). This property derives from sequence differences within the SH2 domains of the STAT proteins, enabling the selective recruitment of distinct STATs to different activated, tyrosine-phosphorylated cytokine receptor subunits, and allows for the subsequent specific pairing that occurs between two tyrosine-phosphorylated STAT proteins that form the functionally active transcription factor complex.

Interferon-γ Receptor Signaling

Detailed structure/function analyses performed on the IFN-γ receptor and its signaling proteins has defined proximal IFN-γ signal transduction events and facilitated the construction of a model of IFN-γ signal transduction that currently serves as a paradigm for cytokine receptor signaling (Fig. 11-1). In unstimulated cells, the IFN-γ receptor subunits are not preassociated with one another (52) but rather associate constitutively via their intracellular domains with inactive forms of specific Janus kinases (52,53,54 and 55). Jak1 binds to a $_{266}$LPKS$_{269}$ sequence in the membrane proximal portion of the intracellular domain of the human IFNGR1 chain, and Jak2 associates with a 12-amino acid sequence ($_{263}$PPSIPLQIEEYL$_{274}$) in the intracellular domain of the human IFNGR2 chain. Signal transduction is initiated when a homodimeric IFN-γ molecule binds to two IFNGR1 subunits, leading to the formation of a complex to which two IFNGR2 proteins subsequently bind. Within the ligand-assembled receptor complex, the inactive subunit-associated kinases are brought into close juxtaposition with one another and are activated by mechanisms involving auto- and transphosphorylation. The activated kinases then phosphorylate a key tyrosine residue within a $_{440}$YDKPH$_{444}$ sequence near the carboxy-terminus of the human IFNGR1 chain, thereby forming the phosphorylated sequence that is specifically recognized by the SH2 domain of STAT1 (56,57). Two STAT1 molecules then bind to the paired docking sites on the activated receptor complex, are brought into close proximity with the receptor-associated, activated tyrosine kinases, and are themselves phosphorylated at a specific tyrosine residue (Y701) near their C-terminus (58,59). The two phosphorylated STAT1 proteins then dissociate from the

IFNGR1 subunits, form reciprocal homodimers which have also been serine-phosphorylated during the activation process, and then translocate to the nucleus. In the nucleus, the STAT1 homodimers bind to specific promoter elements (known as *gamma-interferon-activated sites*, or *GAS elements*) and thereby effect transcription of IFN-γ–induced genes (14,40). Studies using cells and mice with induced genetic deficiencies of different Jaks and STATs have demonstrated that most IFN-γ–induced biologic responses require Jak1, Jak2, and STAT1 (see Table 11-1) (46,47 and 48,50,51). These studies therefore establish the physiologic relevance of this IFN-γ signaling model.
FIGURE 11-1. Model of IFN-γ signaling. (IFN, interferon; IFNGR2, interferon gamma-receptor 2; Jak, Janus tyrosine kinase; PIAS, proteins that inhibit activated signal transducers and activators of transcription proteins; SHP, SH2 domain containing protein tyrosine phosphatase; SOCS, suppressor of cytokine signaling; STAT, signal transducers and activators of transcription proteins.)

Regulation of Interferon-γ-Dependent Janus Protein Tyrosine Kinase Signal Transducers and Activators of Transcription Proteins Signaling

Role of Phosphatases

Several different mechanisms have been proposed to regulate IFN-γ signaling. Experiments demonstrating the transient nature of IFN-γ receptor and STAT protein tyrosine phosphorylation inspired the straightforward hypothesis that IFN-γ signaling is regulated directly by specific protein tyrosine phosphatases. Several groups have studied this issue, and some initial data have emerged. The SH2-domain–containing protein tyrosine phosphatase, SHP-2, was reported to interact constitutively with the IFN-γ receptor (60). Embryonic fibroblasts from SHP-2–deficient mice displayed hyperactive STAT activation after IFN-γ stimulation, indicating that SHP-2 plays a negative role in regulating IFN-γ signaling (60). Another group proposed an opposite, positive role for SHP-1 (a different protein tyrosine phosphatase) in regulating IFN-γ signaling, based on the observation that overexpression of a catalytically inactive SHP-1 protein in HeLa cells led to a 30% to 50% increase in STAT1 activation in response to IFN-γ (61). Detailed analyses of the magnitude of IFN-γ–dependent biologic responses in the phosphatase-deficient cells should be performed to establish the importance of tyrosine phosphatases in regulating IFN-γ signaling.

Role of Janus Protein Tyrosine Kinase Inhibitors

Three groups independently cloned a family of proteins, termed *suppressors of cytokine signaling* (SOCS), *Jak-binding proteins* (JABs), or *STAT-induced STAT inhibitors* (SSIs), whose production is induced by many different cytokines; these proteins appear to function by binding via their SH2 domains to activated Jaks and inhibiting their catalytic activity (62,63 and 64). One member of this family, cytokine-inducible SH2 protein (CIS), appears to function in a different manner because it binds directly to activated receptors that contain phosphorylated STAT5 recruitment sequences [such as erythropoietin and interleukin-3 (IL-3) receptors] and thereby blocks STAT5 recruitment and activation at the receptor (65). The SOCS proteins contain an N-terminal region that is variable in length and sequence, a central SH2 domain, and a 40-amino acid region at the C-terminus termed the SOCS box. The formal SOCS family includes eight proteins, SOCS-1 through SOCS-7, and CIS. However, 12 other proteins have also been identified that contain the SOCS box (66). The function of these related proteins remains unknown. The induction of SOCS gene transcription by cytokines appears to be mediated by STAT transcription factors. The time course of induction of many of the SOCS family genes is rapid and transient (transcript appears within 20 minutes of cytokine stimulation and disappears 2 to 4 hours later); for some (such as SOCS-5 and CIS), however, the time course of induction is delayed or prolonged (67). Because many of the functional analyses of the SOCS proteins have relied on overexpression approaches in intact cells and cell-free systems, and because many of the SOCS family members are promiscuously induced by many different cytokines, the *in vivo* role of the SOCS proteins remains unclear. However, an initial view of the physiologic role of these proteins has come from the work of two different groups that generated mice devoid of SOCS-1/SSI-1 (68,69). SOCS-1/SSI-1 gene-targeted mice display retarded growth and die within 3 weeks of age. These mice exhibit fatty liver degeneration and accelerated apoptosis of lymphocytes with aging, which correlates with an upregulation of Bax in the thymus and spleen. Further work, including the generation of mice lacking expression of other SOCS family members, should be done to place the role of these proteins in proper perspective. Key questions that should be addressed are whether the different SOCS proteins specifically regulate distinct cytokine-signaling responses and if they function as a generalized mechanism to affect the return of activated cytokine signaling pathways to their homeostatic baselines.

Role of Signal Transducers and Activators of Transcription Protein Inhibitors

Another family of novel inhibitory proteins termed *proteins that inhibit activated STATs* (PIAS) have been identified and appear to function downstream of the activated receptor complex. The first of these proteins to be described (PIAS-1) was cloned using a yeast two-hybrid screen for STAT1 interacting proteins; another four PIAS family members were subsequently cloned on the basis of homology to PIAS-1 (70,71). The PIAS proteins, which contain a putative zinc-binding motif, are expressed constitutively and are thought to specifically associate with activated STAT molecules upon cytokine stimulation of cells. The PIAS proteins show a high degree of specificity for a particular activated STAT complex. Of the two family members that have been characterized, PIAS-1 binds selectively to activated STAT1 molecules, whereas PIAS-3 binds selectively to activated STAT3 molecules. Whether other PIAS proteins display specificity for other activated STAT molecules should be determined.

Role of the Ubiquitin-Proteasome Pathway

A fourth mechanism proposed to control the amount of activated STAT after IFN-γ stimulation is degradation via the ubiquitin-proteasome pathway. One group showed that an inhibitor of the proteasome MG132 stabilized STAT1 phosphorylation after IFN-γ treatment of HeLa cells. Phosphorylated STAT1 was ubiquitinated *in vivo*, implying that at some time after activation, STAT1 is targeted for degradation by the proteasome (72). However, these data do not exclude the possibility that signaling intermediates upstream of the STATs are also targeted for proteasome degradation. In fact, another group, using ^{35}S-labeling to study the distribution of total STAT1 and activated STAT1 after IFN-γ treatment of cells showed that STAT1 molecules translocate into the nucleus as tyrosine-phosphorylated molecules, later returning quantitatively to the cytoplasm as nonphosphorylated molecules (73). This result indicates that phosphorylated STAT1 molecules are not the main targets of proteasome degradation. Interestingly, a third group reported that the SOCS box of SOCS family proteins mediates interactions with elongins B and C, which may target SOCS-bound proteins (i.e., Jaks or cytokine receptor chains) to the proteosomal degradation pathway (74).

Role of Receptor Downregulation

Finally, IFN-γ signaling can be regulated by a mechanism involving inhibition of expression of particular receptor subunits. IFNGR2 has been shown to be downregulated (probably at the transcriptional level) in T cells as they differentiate to the Th1 CD4[+] subset (27,28). In newly developing T-cell clones, exposure of the cells to IFN-γ leads to a loss of IFNGR2 message and protein. In long-term Th1 clones, IFNGR2 expression is permanently suppressed. The generality and molecular basis of the mechanism underlying this unusual type of homologous desensitization remains poorly understood.

Interferon-γ-Inducible Genes

Part of "11 - Interferon-γ: Basic Principles and Clinical Applications"

The rapid signaling of the Jak-STAT pathway makes it an ideal system to regulate the activation of immediate early genes that provide the host with a rapid mechanism to respond to an infectious agent. In fact, it has been possible to identify a large number of IFN-γ-stimulated genes that are induced rapidly (i.e., within 15 to 30 minutes) after IFN-γ treatment of cells and whose transcription does not depend on new protein synthesis (75,76). The promoter regions of these IFN-γ-stimulated genes contain the GAS element that functions to promote transcription. The GAS site is a nine-nucleotide sequence with

a consensus motif of TTNCNNNAA and is specifically bound by STAT1 homodimers.

Examples of IFN-γ-induced immediate early genes include interferon regulatory factor-1 (IRF-1), guanylate binding protein-1 (GBP-1), and the type I Fcγ receptor (FcγR-I), which encode proteins that participate in inflammatory and immune responses. Several IFN-γ-regulated intermediate genes have also been identified. These genes are induced within 6 to 8 hours of stimulation and require additional protein synthesis for transcriptional activation to occur. Examples of these genes include those that encode class I and class II MHC proteins, which play a central role in determining adaptive immune responses. Studies using STAT1-, Jak1-, or Jak2-deficient mice have shown that these proteins play an obligate role in activating most IFN-γ-inducible genes (47,48,50,51). More than 100 IFN-γ-regulated genes have been identified. This subject has been reviewed elsewhere and the reader is referred to several excellent reviews on the subject (7,75,77).

Interferon-γ Biologic Activities

Part of "11 - Interferon-γ: Basic Principles and Clinical Applications "

Antiviral and Antiproliferative Activities

The molecular basis of the antiviral effects of IFNs has been extensively studied since the mid 1980s. IFN-γ promotes antiviral responses that are either intrinsic to the infected cell itself or extrinsic (in that they effect recognition and destruction of infected cells by components of either the innate or specific limbs of the host immune response).

IFN-γ induces several proteins in cells that promote intrinsic mechanisms of resistance to viral infection, thus functioning in a manner similar to IFN-α and -β (78). Two distinct mechanisms have been identified. The first relies on the actions of a family of enzymes known as 2"5" oligoadenylate synthetases, which are induced by IFN-γ and activated by double-stranded RNA (intermediates or byproducts of viral RNA replication) (79). The activated enzymes polymerize adenosine triphosphate into 2"5"-linked oligomers that in turn activate ribonuclease-L, a latent constitutively expressed endoribonuclease. Activated ribonuclease-L degrades single-stranded RNA, thereby inhibiting protein synthesis in cells. The second antiviral mechanism depends on the protein PKR (also known as *double-stranded RNA-dependent kinase, P1 kinase, p68 kinase*, or *eukaryotic protein synthesis initiation factor-2 kinase*), a serine/threonine kinase also induced by IFN-γ and activated by double-stranded RNA (80,81). PKR phosphorylates and inactivates the eukaryotic protein synthesis initiation factor-2, thereby blocking protein synthesis in cells. Thus, these two mechanisms produce their antiviral effects by inhibiting cellular protein synthesis (82).

Extrinsic antiviral mechanisms induced by IFN-γ are largely those that direct the development of innate and specific immune responses. IFN-γ promotes antigen processing and presentation and plays a key role in the induction of antiviral cellular and humoral immune responses. These actions are discussed in more detail in the section Antigen Processing and Presentation .

IFN-γ has been shown also to manifest antiproliferative effects on cells. Although these biologic effects are well documented, their molecular bases are not yet well defined. Several studies have revealed that at least some of the antiproliferative actions of IFN-γ are due to the induction of proteins that inhibit enzymes involved in cell cycle progression. IFN-γ, for example, has been shown to induce expression of the protein p21[WAF1/CIP1/CAP1], an inhibitor of CDK2, via the Jak-STAT pathway (83,84). This process occurs in a relatively cell-specific manner, however, and it is unclear whether other cell cycle inhibitors may also be involved in this process. Nevertheless, this negative biologic response can still be attributed to a positive induction of a particular gene product.

Macrophage Activation and Innate Immunity

IFN-γ is the major physiologic macrophage activating factor (MAF); thus, it plays a critical role in promoting nonspecific host-defense mechanisms against a number of pathogens (85,86 and 87). Data supporting this concept comes from *in vitro* and *in vivo* studies that have demonstrated that IFN-γ can induce in macrophages the capacity to nonspecifically kill a variety of intracellular and extracellular parasites, as well as neoplastic cells (6,88). In addition, IFN-γ reduces the susceptibility of macrophages to microbial infection and enhances recognition of targets during the early innate phase of immunity through regulation of undefined macrophage cell-surface proteins (89). The physiologic significance of IFN-γ's role in macrophage activation and host defense against microbial pathogens has been established by several *in vivo* murine infection models. Mice pretreated with neutralizing antibodies to IFN-γ lose the ability to resist a sublethal challenge of a variety of microbial pathogens such as *L. monocytogenes* (22,86), *Toxoplasma gondii* (90), or *Leishmania major* (91). In addition, mice with disrupted genes for IFN-γ, the IFNGR1 chain, or the IFN-γ signaling protein STAT1, die when challenged with sublethal doses of microbial pathogens such as *Mycobacterium bovis, L. monocytogenes,* or *L. major* (50,92,93).

Activated macrophages kill microbial targets using a variety of toxic substances, such as reactive oxygen and nitrogen intermediates induced by IFN-γ. Much of the antimicrobial function of IFN-γ-activated macrophages can be attributed to the actions of nitric oxide (NO) or reactive oxygen intermediates, or both (94,95). NO is produced in activated macrophages by the inducible form of NO synthase (iNOS or NOS2). The gene encoding iNOS is transcriptionally activated after treatment of cells with IFN-γ plus a variety of second signals that activate transcription factor nuclear factor kappa B [such as TNF-α, interleukin-1 (IL-1), or bacterial endotoxin]. The enzyme catalyzes the conversion of L-arginine to L-citrulline, giving rise to large amounts of NO. NO is thought to kill target cells by one of two mechanisms. First, it can form an iron-nitrosyl complex with Fe-S groups of aconitase and complex I and complex II, thereby causing the inactivation of the mitochondrial electron transport chain. Alternatively, NO may react with superoxide anion [a reactive oxygen intermediate formed by the IFN-γ-induced enzyme nicotinamide adenine dinucleotide phosphate (NADPH) oxidase] to form peroxynitrite, which decays rapidly once protonated, to form the highly toxic compound hydroxyl radical. Evidence that NO is responsible

for macrophage killing of intracellular parasites comes from a number of studies with *Listeria* and *Leishmania*. Mice pretreated with the L-arginine analogue *N*-monomethyl-L-arginine, an iNOS inhibitor, were unable to resolve footpad infection with *Leishmania* parasites. Similarly, mice treated with another iNOS inhibitor (aminoguanidine) died due to sublethal *Listeria* infection (96). Furthermore, mice lacking the iNOS gene are highly susceptible to infection with microbial pathogens (94,95,97).

Antigen Processing and Presentation

One of the major immunoregulatory roles of IFN-γ is its ability to promote the inductive phase of immune responses. This cytokine significantly influences the generation and presentation of antigenic peptides on cell surfaces (6,7). IFN-γ can regulate the expression of MHC class II proteins on cells, thereby regulating CD4⁺ T-cell responses (7,98). IFN-γ induces MHC class II protein expression on many cells, such as mononuclear phagocytes, endothelial cells, and epithelial cells. IFN-γ can also inhibit IL-4–dependent class II expression on B cells (99), although the molecular basis for this apparently discordant effect is unknown. It is known that type I IFN, TNF, bacterial endotoxin, and immune complexes can either inhibit or enhance IFN-γ's ability to induce MHC class II. In the case of mononuclear phagocytes, for example, preexposure of cells to type I IFNs induces a state of unresponsiveness to IFN-γ. In contrast, treatment of cells with IFN-α and -ß either together with or after IFN-γ treatment leads to enhanced class II expression. Thus, a cell's ability to express MHC class II in response to IFN-γ is influenced by the composition of the microenvironment (6).

IFN-γ also regulates the expression of molecules involved in the MHC class I antigen processing and presentation pathway (7). Some of these effects are at the level of regulating cell surface molecules. IFN-γ enhances the expression of MHC class I proteins and beta₂-microglobulin in a wide variety of cell types. This cytokine also enhances the expression of several cell surface proteins, such as ICAM-1 and B7, which are responsible for increasing target-cell–T-cell contact and T-cell costimulation, respectively (100,101).

IFN-γ also promotes antigen processing by regulating expression of many intracellular proteins required for antigenic peptide generation (7,101). IFN-γ has been shown to play a key role in modifying the activity of the proteasome, a multisubunit enzyme complex responsible for generating the peptides that bind to MHC class I proteins. It does so in part by modulating the expression of the enzymatic proteasome subunits. IFN-γ increases expression of the inducible subunits LMP2, LMP7, and MECL1 while decreasing expression of constitutive subunits x, y, and z, thereby altering proteasome composition and specificity (101,102 and 103). In addition, IFN-γ enhances the production of nonenzymatic proteasome components, such as the α and ß subunits of PA28 (i.e., the 11S regulator of the proteasome), which function to regulate proteasome enzymatic activity (104). Purified 20S and 26S proteosomes from IFN-γ-treated cells show an increased capacity to cleave peptides after hydrophobic and basic residues, revealing that IFN-γ alters the proteasome in a way that changes the types of antigenic peptides that it produces (102).

IFN-γ additionally increases expression of the peptide transporters associated with antigen processing-1 and -2 (TAP-1 and TAP-2), which transfer peptides that have been generated in the cytoplasm by the proteasome into the endoplasmic reticulum where they can bind to nascently produced MHC class I proteins (100,101). Moreover, IFN-γ increases expression of the heat shock protein gp96, which may play a role in transferring peptide within the cell from the TAPs to MHC class I and between cells from nonprofessional antigen-presenting cells to a subset of macrophages (105). Taken together, these data strongly suggest that IFN-γ plays an important role in enhancing immunogenicity by increasing the quantity and the repertoire of peptides displayed on MHC class I.

Helper T-Cell Phenotype Development

Human and murine CD4⁺ T cells can be divided into two subsets based on their pattern of cytokine secretion after stimulation (20,106). Th1 cells promote cell-mediated immunity and delayed-type hypersensitivity responses through their production of IFN-γ, lymphotoxin, and IL-2. In contrast, Th2 cells predominantly produce interleukin-4 (IL-4), interleukin-5 (IL-5), and IL-10, thereby providing help for humoral immune responses. IFN-γ plays an important role in Th1 development. *In vitro*, antibody neutralization of IFN-γ greatly reduces the development of Th1 cells and augments the development of Th2 cells. Importantly, administration of exogenous IFN-γ either *in vitro* or *in vivo* does not drive a Th1 response. Thus, IFN-γ is necessary but is not sufficient for Th1 development.

In vitro and *in vivo* studies have demonstrated that IL-12 is the single most important cytokine that drives T cells to the Th1 pole (107,108). Bacterial products promote Th1 cell development by inducing IL-12 production from antigen-presenting cells such as macrophages. In addition, mice deficient in either the gene for IL-12 or the IL-12-signaling protein STAT4 are unable to generate Th1 cells and display reduced delayed-type hypersensitivity responses.

The role of IFN-γ in Th development has been shown to be due to its effects at the level of the macrophage and the CD4⁺ T cell. The effects of IFN-γ on macrophages were elucidated in studies that used transgenic mice lacking IFN-γ sensitivity specifically in the macrophage compartment. IFN-γ-insensitive macrophages were unable to support efficient Th1 development due to a severely reduced capacity to produce IL-12 (109). IFN-γ has been shown to have direct effects on the developing Th cells themselves. IFN-γ maintains expression of the ß2 subunit of the IL-12 receptor on developing T cells thereby preserving sensitivity of these cells to IL-12 and promoting their development into a Th1 phenotype (110). IFN-γ also blocks development of Th2 phenotype through two mechanisms. First, it inhibits synthesis of IL-4 from undifferentiated, antigen-stimulated T cells, thereby inhibiting production of the cytokine required for Th2 development (111). Second, it inhibits Th2 cell expansion by directly inhibiting proliferation of Th2 cells (112). The antiproliferative effects of IFN-γ are not observed on

Th1 cells because these cells do not express the IFNGR2 subunit (27,28). Thus, IFN-γ simultaneously promotes cell-mediated immunity (through facilitating Th1 cell formation) and inhibits development of humoral immunity (through blockade of Th2 cell expansion).

Humoral Immunity

IFN-γ plays a complex role in regulating humoral immunity, exerting its effects either indirectly by regulating the development of specific T-helper cell subsets (as described above) or directly at the level of the B cell. In the latter case IFN-γ is predominantly responsible for regulating three specialized B-cell functions: B-cell development and proliferation, immunoglobulin (Ig) secretion, and Ig-heavy chain switching.

IFN-γ has been shown to negatively regulate B-cell differentiation by inhibiting IL-4-dependent induction of MHC class II protein expression and proliferation of murine B cells stimulated with anti-Ig and IL-4. In contrast, IFN-γ enhances proliferative responses in human B cells activated with anti-Ig. IFN-γ can also enhance or inhibit Ig secretion by either murine or human B cells. In this process, however, IFN-γ's effects depend on the differentiation state of the B cell, the timing of IFN-γ stimulation, and the nature of the activating stimulus.

The best characterized B-cell-directed effect of IFN-γ is its ability to influence Ig heavy chain switching. Ig class switching is significant because the different Ig isotypes promote distinct effector functions in the host. Immunoglobulin E (IgE) is the only isotype that can bind to Fc-ε receptors on mast cells and basophils and thereby promotes immediate type hypersensitivity and allergic reactions. IgG2a fixes complement and can bind (in monomeric form) to FcγR-I on murine macrophages, a high-affinity Fc receptor upregulated during IFN-γ-induced macrophage activation. Activated macrophages can efficiently use antibodies of the IgG2a isotype to mediate antibody-dependent cellular cytotoxicity. IgG3 is an isotype that can self-aggregate, a process that may enhance its opsonic activity. Along with IgG2a, IgG3 can also bind to the NK-cell-IgG receptor CD16 and effect NK-mediated antibody-dependent cellular cytotoxicity. IFNs, by favoring the production of IgG2a and IgG3 and inhibiting the production of IgE isotypes, can facilitate the interaction between the humoral and cellular effector limbs of the immune response and enhance host defense against certain bacteria and viruses.

In vitro IFN-γ is able to direct immunoglobulin class switching from IgM to the IgG2a subtype in lipopolysaccharide (LPS)-stimulated murine B cells and to IgG2a and IgG3 in murine B cells which have been stimulated with activated T cells (113,114). Moreover, IFN-γ blocks IL-4 induced Ig class switching in murine B cells to IgG1 or IgE (115). The validity of these observations has been stringently tested in experiments in which Ig subclass production was monitored in mice that were injected with immunoglobulin-D (IgD)-specific antiserum to achieve polyclonal activation of B cells. Mice treated in this manner produced large quantities of IgG1 and IgE. When IFN-γ was administered to the mice before anti-IgD treatment, however, they produced high levels of IgG2a and decreased levels of IgG1. Thus IFN-γ is clearly an important regulator of Ig class switching in vivo (116).

Tumor Immunity

An accumulating body of evidence suggests that IFN-γ plays an important role in promoting host defense to tumors. IFN-γ has been proposed to inhibit tumor generation by directly increasing expression of several tumor suppressor genes such as IRF-1 and PKR. IFN-γ also possesses properties that may inhibit the growth of already-transformed cells. In vitro, IFN-γ can exert direct antiproliferative and antimetabolic effects on a wide variety of tumor cells. IFN-γ is also able to activate macrophages to nonspecifically lyse certain tumor cells through mechanisms involving the generation of reactive oxygen and nitrogen intermediates and the production of cytotoxic ligands of the tumor necrosis family, such as TNF, Fas ligand (FasL), and TNF-related apoptosis-inducing ligand (88,117,118). In addition, IFN-γ is required for robust IL-12 secretion by macrophages. IL-12 has been shown in several studies to possess potent antitumor activities, even in mice with preestablished tumors (108). Injection of recombinant IL-12 into tumor-bearing mice reduces the rate of metastasis, slows tumor growth, and, in some cases, effects complete tumor regression. IFN-γ is required for IL-12-mediated antitumor effects. This conclusion is based on the observation that neutralizing IFN-γ-specific monoclonal antibodies ablate the effects of IL-12 on tumors in vivo (119,120).

Many experiments indicate that the major mechanism of IFN-γ's antitumor effects involve its ability to promote the generation of specific immune responses to tumors. IFN-γ upregulates MHC class I and class II molecules on a wide variety of cells and increases the magnitude and changes the nature of MHC class I antigen processing. IFN-γ treatment of a wide variety of nonantigenic tumors made them highly antigenic and correlated with an increase in expression levels of IFN-γ-inducible genes that regulate MHC class I processing and presentation including LMP2, LMP7, Tap1, and Tap2 (121,122). Another study showed that the ability of lymphocytes harvested from draining lymph nodes of mice harboring the fibrosarcoma MCA-105 adoptively transfer immunity to MCA-105 was abrogated by in vivo administration of neutralizing IFN-γ antibodies to the recipient mice (123). Together, these studies suggest that a major effect of IFN-γ is to increase the antigenicity of tumors and augment tumor immunity.

A clear demonstration of a role for IFN-γ in immune-mediated tumor rejection comes from a series of studies using chemically induced fibrosarcomas, such as the Meth-A tumor cell line (124). Meth-A is an MCA-induced fibrosarcoma of BALB/c mice that grows progressively when transplanted intradermally in syngeneic mice. Although the tumor is highly aggressive and eventually kills the host, a tumor-bearing mouse can be induced to reject the tumor by administration of LPS. Using neutralizing mAb specific for murine IFN-γ, it was determined that IFN-γ is obligatorily required for LPS-induced tumor rejection. In addition, Meth-A tumors grew significantly more rapidly in anti-IFN-γ treated syngeneic mice. Although these results established the importance of IFN-γ in Meth-A growth regulation, they did not identify the cellular target of IFN-γ's actions. By introducing a mutant nonfunctional IFNGR1 protein into Meth-A tumor cells, it was possible to specifically ablate tumor cell responsiveness to the cytokine and demonstrate that the tumor itself was a major target of IFN-γ's actions. IFN-γ-insensitive Meth-A grew more rapidly in naive syngeneic mice than did control tumors and were not rejected when the tumor-bearing mice were treated with LPS (Fig. 11-2). In addition, the IFN-γ-insensitive tumors neither primed naive mice for induction of Meth-A immunity nor were rejected in mice with preestablished immunity to the wild-type tumor cell (Fig. 11-3 and Fig. 11-4). This effect was not due to the antiproliferative actions of IFN-γ. Similar studies using different murine fibrosarcomas have yielded similar results. Thus, the ability of the immune system to recognize and reject certain tumors is critically dependent on the tumor's ability to respond to IFN-γ (124).

Although these results established the importance of IFN-γ in Meth-A growth regulation, they did not identify the cellular target of IFN-γ's actions. By introducing a mutant nonfunctional IFNGR1 protein into Meth-A tumor cells, it was possible to specifically ablate tumor cell responsiveness to the cytokine and demonstrate that the tumor itself was a major target of IFN-γ's actions. IFN-γ-insensitive Meth-A grew more rapidly in naive syngeneic mice than did control tumors and were not rejected when the tumor-bearing mice were treated with LPS (Fig. 11-2). In addition, the IFN-γ-insensitive tumors neither primed naive mice for induction of Meth-A immunity nor were rejected in mice with preestablished immunity to the wild-type tumor cell (Fig. 11-3 and Fig. 11-4). This effect was not due to the antiproliferative actions of IFN-γ. Similar studies using different murine fibrosarcomas have yielded similar results. Thus, the ability of the immune system to recognize and reject certain tumors is critically dependent on the tumor's ability to respond to IFN-γ (124).

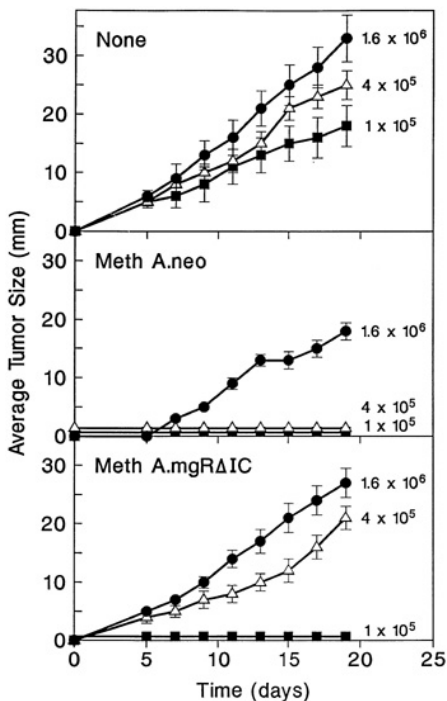
FIGURE 11-2. Effects of lipopolysaccharide (LPS) injection on BALB/c mice bearing IFN-γ-sensitive or –insensitive Meth-A tumor cells. Mice were injected on day 0 with 5 × 10^5 Meth-A, mock-transfected Meth-A (Meth A.neo), or dominant-negative IFNGR1-transfected Meth-A (Meth-A.mgRΔIC) cells. In top panels, day 7 tumors are shown. Intraperitoneal treatment with LPS (3 mg/kg) was administered on day 7 and the middle panels show mice 48 hours post-LPS treatment (day 9). The bottom panels show the mice on day 19, 12 days after LPS treatment. (IFN-γ, interferon-γ.)
FIGURE 11-3. Growth of IFN-γ-sensitive and –insensitive Meth-A tumors in Meth-A-immune mice. A: BALB/c mice were inoculated twice with 1 × 10^7 irradiated (8,000 rads) Meth-A cells. Immunized mice were rested for 2 weeks and then injected subcutaneously on day 0 with either Meth-A, Meth A.neo or Meth A.mgRΔIC cells at the inocula shown. B: BALB/c mice were injected with 2 × 10^5 live wild-type Meth-A tumor cells and cured of Meth-A tumors by lipopolysaccharide administration 7 days later. Immunized mice were rested for 2 weeks and then injected subcutaneously on day 0 with either Meth-A neoadjuvant or Meth A.mgRΔIC at the inocula shown. Data are represented as mean tumor size ± SE of six mice per group.


FIGURE 11-4. Immunogenicity of IFN-γ-sensitive and –insensitive Meth-A tumors. BALB/c mice were left untreated (top panel) or were intradermally inoculated with either Meth A.neo (middle panel) or Meth A.mgRΔIC (lower panel) at a dose of 5 × 10^5 cells. After 7 days of in vivo growth, the tumors were surgically resected. Immunized mice were rested for 10 days, then challenged on day 0 by subcutaneous inoculation of wild-type Meth-A at the inocula shown. Data are represented as mean tumor size ± SE of six mice per group.

A subsequent study suggests that IFN-γ may also exert its antitumor effects in tumor transplant models through a mechanism involving the inhibition of blood vessel recruitment by tumors (125). Overexpression of a mutant nonfunctional IFNGR1 chain in tumor cells rendered them relatively insensitive to IFN-γ, highly tumorigenic, and relatively unresponsive to IL-12 therapy *in vivo*. IL-12 was found to induce ischemic damage only in IFN-γ-responsive tumors. *In vivo* Matrigel assays showed that whereas IFN-γ-sensitive and –insensitive tumors recruited blood vessels equally well, IL-12 therapy only inhibited angiogenesis in the IFN-γ-responsive tumors. IFN-γ induces the expression of a number of angiostatic molecules in target cells, including the chemokines IP-10 and Mig, which may mediate its antiangiogenic activity.

Although the tumor transplantation studies described above identified a critical role for IFN-γ in promoting rejection of transplantable tumors, they did not address the question of whether IFN-γ participates in the elimination of primary developing tumor cells (126). To examine this question, IFN-γ-R[-/-] mice, STAT1[-/-] mice and wild-type mice, all of which were derived on a pure inbred 129/Sv/Ev background, were treated with different doses of the chemical carcinogen methylcholanthrene (MCA) and tumor development followed through 165 days. At every MCA dose examined, IFN-γ-insensitive mice developed tumors significantly more rapidly and with greater frequency compared to wild-type mice (Fig. 11-5). IFN-γ-insensitive mice also displayed enhanced tumor development in a model of spontaneous tumor formation. Mice lacking the p53 tumor suppressor gene were bred onto either a wild-type 129/Sv/Ev background or onto either IFN-γ-R[-/-] or STAT1[-/-] backgrounds, and tumor development in the single or double knockout offspring was assessed (Fig. 11-6). IFN-γ-insensitive p53[-/-] mice developed spontaneous tumors significantly earlier than did their IFN-γ-sensitive counterparts. Furthermore, the two groups of mice displayed differences in the types of tumors that formed. Whereas all of the IFN-γ-sensitive p53[-/-] mice developed lymphoid tumors, 35% of the IFN-γ-R[-/-] × p53[-/-] mice and 38% of the STAT1[-/-] × p53[-/-] formed nonlymphoid tumors without concomitant lymphoid tumors.
FIGURE 11-5. IFN-γ-insensitive mice demonstrate an increased susceptibility to development of chemically induced tumors. Groups of wild-type, IFN-γ-R[-/-], and STAT1[-/-] mice were injected with one of a range of doses of methylcholanthrene; tumor development was monitored for 165 days. Values represent the composite of four independent experiments. (IFN-γ-R, interferon-γ receptor; STAT, signal transducers and activators of transcription proteins.)
FIGURE 11-6. IFN-γ-insensitive mice demonstrate an increased susceptibility to development of spontaneous tumors. **A:** Spontaneous tumor development in IFN-γ-R[-/-] × p53[-/-] and 129/Sv/Ev × p53[-/-] mice. The difference in average tumor development times between 129/Sv/Ev × p53[-/-] (18.5 weeks) and IFN-γ-R[-/-] × p53[-/-] (13.7 weeks) is statistically significant by the Wilcoxon rank sum test (*p* = .001). **B:** Percent 129/Sv/Ev × p53[-/-], IFN-γ-R[-/-] × p53[-/-] and STAT1[-/-] × p53[-/-] mice developing nonlymphoid tumors without concomitant lymphoid tumors. (IFN-γ-R, interferon-γ receptor; STAT, signal transducers and activators of transcription proteins.)

Two series of studies indicate that the increased tumor incidence in IFN-γ unresponsive hosts is due to IFN-γ unresponsiveness at the level of the transformed cell itself. First, tumor cells derived from MCA-treated IFN-γ-insensitive mice grew progressively with identical kinetics when transplanted into either wild-type mice or the corresponding IFN-γ-insensitive mouse strain. Second, introduction of the missing IFN-γ signaling protein into these cells by gene transfer reconstituted their capacity to respond to IFN-γ and converted them into immunogenic tumors that were rejected in wild-type 129/Sv/Ev mice but not Rag2[-/-] mice devoid of lymphocytes. Together, these results thus demonstrate that the interplay between IFN-γ and the specific immune system forms the basis of an effective tumor surveillance system in the host. In addition, these observations indicate that a major target of IFN-γ's antitumor functions is the tumor cell itself. A critical role for lymphocytes in this process has been confirmed by studies showing that lymphocyte-deficient Rag2[-/-] mice are highly susceptible to tumor induction by MCA and that tumors that develop in the absence of lymphocytes are strongly immunogenic.

The existence of an IFN-γ-dependent antitumor system is further supported by the identification of tumor cells that have developed spontaneous and specific insensitivity to IFN-γ (126). A screen of human tumor cell banks revealed that lung adenocarcinomas show a tendency to spontaneously develop permanent IFN-γ unresponsiveness. Four out of seventeen lines tested failed to initiate IFN-γ-dependent signaling (as measured using an electrophoretic mobility shift assay) and failed to develop biologic responses to human IFN-γ as determined by monitoring-enhanced MHC class I expression. Using immunochemical and molecular genetic approaches, the IFN-γ unresponsiveness in each cell line was determined to be the result of a discrete lesion in a proximal IFN-γ signaling component. One tumor cell line lacked the IFNGR1 chain, two others produced abnormal forms of Jak2, and the fourth lacked Jak1. A subset of primary MCA-induced murine tumors have also been identified that develop quantitative insensitivity to IFN-γ. These IFN-γ-insensitive

tumors grow in a highly aggressive manner when transplanted into syngeneic immunocompetent mice.

In Vivo Dysfunction of IFN-γ Signaling

Part of "11 - Interferon-γ: Basic Principles and Clinical Applications "

Mice with Targeted Disruption of Genes Involved in Interferon-γ Signaling

The physiologic consequences of global *in vivo* inactivation of the IFN-γ signaling pathway in mice were originally uncovered using neutralizing monoclonal antibodies specific for IFN-γ. However, the physiologic role of IFN-γ has been more fully elucidated using mice with engineered disruptions in either the IFN-γ structural gene (92), the genes encoding the two IFN-γ receptor subunits (IFNGR1 and IFNGR2) (93,127,128), or the genes encoding either of the three signaling proteins required by IFN-γ for biologic response induction—that is, STAT1 (50,51), Jak1 (46), and Jak2 (47,48). As a group, these mice display a greatly impaired ability to resist infection by a variety of microbial pathogens including *Leishmania monocytogenes, L. major*, and several mycobacterial species, including *M. bovis* and *Mycobacterium avium*. Importantly, mice lacking either IFNGR1 or IFNGR2 are able to mount a curative response to many viruses, whereas mice lacking the IFN-α and -β receptor or STAT1 and cells of mice deficient in Jak1 are not. These results thus demonstrate that under physiologic conditions, the majority of the antiviral effects of the IFN system are largely mediated via type I IFNs (129).

Identification of Human Patients with Defects in Interferon-γ Signaling or Production

Results obtained from IFNGR1–deficient mice suggest that individuals with inactivating mutations in the human IFN-γ receptor genes might suffer from recurrent microbial but not viral infections. Three years ago, two research groups identified children from three unrelated families with such mutations who manifest a severe susceptibility to weakly pathogenic mycobacterial species (130,131). Genetic analysis of these patients' families revealed that susceptibility to atypical mycobacterial infection was inherited in an autosomal recessive manner. Sequence analysis of the patients' IFNGR1 alleles identified missense mutations in genetic regions coding for the extracellular domain of the IFNGR1 polypeptide, leading to the production of truncated receptor proteins that are not able to be retained at the cell surface. The clinical syndromes of these patients were similar. In one study, a group of related Maltese children were identified that showed extreme susceptibility to infection with *Mycobacterium fortuitum, M. avium*, and *Mycobacterium chelonei* (130). In another study, a Tunisian child was identified with disseminated *M. bovis* infection after bacille Calmette-Guérin (BCG) vaccination (131). A third study identified a child of distinct ancestry who had a similar immunocompromised phenotype (132). Biopsies from these patients revealed the presence of multibacillary, poorly defined granulomas, which contained scattered macrophages but lacked epithelioid and giant cells and surrounding lymphocytes. Importantly, these patients showed enhanced susceptibility to mycobacteria and occasionally to *Salmonella*

but not to other typical bacteria or other common microbial pathogens or fungi. Moreover, in all three kindred, the patients were able to mount antibody or curative responses, or both, to several different viruses.

Subsequently, a number of patients were identified who develop less severe mycobacterial disease than the children described above. These patients were successfully treated with IFN-γ and antibiotics. On analysis of their IFN-γ-R genes, some of the patients were found to display distinct mutations in the IFNGR1 gene, leading to reduced but not ablated receptor function (133). A Portuguese family was identified in which one child developed disseminated BCG infection and a sibling who had not been vaccinated with BCG developed clinical tuberculosis. Both patients were homozygous for a point mutation in the extracellular domain-encoding region of the IFNGR1 subunit gene that produced an isoleucine-to-threonine amino acid substitution. The mutant receptors were found to require 100- to 1,000-fold higher concentrations of IFN-γ than normal receptors to activate STAT1 (133).

Another set of 19 patients from 12 unrelated families were found to inherit partial IFN-γ insensitivity in an autosomal dominant manner (134). All of these patients were found to be heterozygous for a wild-type IFNGR1 allele and an IFNGR1 allele with a frameshift mutation that produced an IFNGR1 protein that lacked most of the intracellular domain, including the Jak1 and STAT1 binding sites. Interestingly, in this group of patients, 12 independent mutation events occurred at a single site, defining a small deletion hotspot in the IFNGR1 gene. The truncated receptor chain accumulated on cell surfaces and was shown to act in a dominant negative manner to inhibit IFN-γ responses in cells. The definition of the molecular basis for this defect was facilitated by the observation that these patients phenotypically resembled IFN-γ–insensitive cells and transgenic mice generated earlier that overexpressed a genetically engineered truncated IFNGR1 subunit (124,135). In all of these patients, defects in IFN-γ responsiveness were partial, and cells from the patients retained some degree of sensitivity to IFN-γ. This correlates with the milder infections in these patients, and their positive responses to exogenous IFN-γ therapy.

A case of a child with severe, disseminated infections due to *M. fortuitum* and *M. avium* who lacked mutations in the IFNGR1 gene was described (136). This child was found to be homozygous for mutations in the IFNGR2 gene. The mutation resulted in a premature stop codon in the extracellular domain-encoding region and led to the production of IFNGR2 proteins that could not be expressed at the cell surface. The clinical and histopathologic phenotype of this patient closely resembled that of patients lacking expression of the IFNGR1 chain.

An additional group of patients were identified whose clinical syndromes resembled partial IFN-γ-R deficiency but on analysis were found to express normal IFN-γ-R polypeptides. Seven of these patients lacked functional IL-12 receptor complexes due to null mutations in the IL-12R-ß1 gene (137,138). Lymphocytes from these patients were deficient in producing IFN-γ. This defect could not be corrected by addition of recombinant IL-12. One case of an individual with a homozygous frameshift deletion encompassing two exons of the IL-12 p40 gene was also reported (139). This patient's lymphocytes had a reduced capacity to secrete IFN-γ, which could be complemented by exogenous IL-12. All of these patients with functional defects in IFN-γ production developed atypical mycobacterial infections that could be cured by exogenous IFN-γ therapy. As a group, the patients with defects in either IFN-γ signaling or IL-12–induced IFN-γ production have taught us that IFN-γ plays a critical role in host defense to mycobacterial infections in humans. We must determine why IFN-γ receptor defects in humans lead almost exclusively to enhanced susceptibility to mycobacterial infection.

Clinical Uses of Interferon-γ

Part of "11 - Interferon-γ: Basic Principles and Clinical Applications "

Despite expectations that IFN-γ would be used in the therapy of a wide variety of infectious diseases and malignancies, this cytokine has been shown to be effective in treating only a limited number of human diseases. Clinical trials of IFN-γ for treatment of many different solid and hematologic tumors have been disappointing. One of the few cancers that have been shown to regress in response to IFN-γ therapy is chronic myelogenous leukemia, a hematologic malignancy (140).

IFN-γ has been shown to be somewhat more effective as an adjuvant to antibiotic therapy in decreasing the severity and frequency of infections in patients with chronic granulomatous disease (141). Chronic granulomatous disease patients suffer from chronic bacterial infections as a result of defects in the phagocyte-specific NADPH oxidase system that generates superoxide radicals during the respiratory burst. IFN-γ was selected as a candidate therapeutic for chronic granulomatous disease because it is known to increase superoxide production and the microbicidal activity of phagocytes. IFN-γ's mechanism of therapeutic action appears to be independent of these direct effects on the NADPH oxidase system, however, because cells from patients who responded to IFN-γ therapy did not display enhanced superoxide production or *in vitro* bacterial killing (141).

Type I IFNs have been found to have more clinical efficacy in general than IFN-γ. This is somewhat surprising because of the more potent immunomodulatory activity of IFN-γ versus IFN-α and -ß. These results thus suggest that more research should be conducted before these cytokines can be used most effectively in a clinical setting.

Introduction

Part of "12 - Cell Transfer Therapy: Basic Principles and Preclinical Studies "

The cellular arm of the immune system plays a central role in the destruction of tumor cells, regression of established tumor deposits, and maintenance of antitumor immunity. Adoptive transfer therapy aims to promote these cellular immune functions in cancer patients by the administration of cells that have been cultured *ex vivo.* In adoptive transfer approaches, immune effector cells are collected and cultured, circumventing normal immune regulatory constraints and potential tumor suppression. Desirable cellular characteristics can be enhanced in cell culture, even by agents that are toxic or would otherwise compromise the patient's health *in vivo.* Finally, the activated and expanded effector-cell population is used to treat the autologous patient. Adoptive transfer therapy can be simply a passive treatment aimed at direct lysis of tumor targets *in vivo.* Many approaches, however, aim to use adoptive transfer as an active immunization strategy in which the administered immune cells undergo amplification *in vivo*, elaborate cytokines that regulate host immune responses, and recruit endogenous immune effector cells to eliminate tumor cells.

Preclinical models have helped define the critical parameters of adoptive transfer therapy and have laid the groundwork for designing clinical trials. Early studies relied on immunization of tumor-free donor mice for the generation of potent effector cells that were subsequently transferred into syngeneic, tumor-bearing recipients. These studies proved effective for determining the attributes of transferred lymphocytes that contributed to therapeutic efficacy, as well as for evaluating adjuvant treatments to the recipient animals that could impact disease outcome. The approach of using cells from immunized donor animals to treat tumor-bearing recipients, however, is not easily translated to human tumor therapy. In most clinical settings, each patient must be the donor, as well as the recipient of transferred cells. With technical advances in cell culture methodology and *ex vivo* activation of human cells, studies were undertaken to directly model the clinical application of the new technique. Mouse models helped to evaluate multiple parameters of transfer that could not easily be resolved in clinical trials and defined the *in vitro* characteristics of the transferred cell relevant to therapeutic benefit *in vivo.* The influence of tumor immunogenicity, methods of cell expansion, and other parameters of treatment have been investigated in these preclinical models and have impacted clinical trial design and interpretation.

Adoptive Transfer in Mice Using Syngeneic Immune Splenocytes

Part of "12 - Cell Transfer Therapy: Basic Principles and Preclinical Studies "

Established Tumors Suppress Adoptive Immunotherapy

Many virally or chemically induced tumors of mice have been used to immunize syngeneic mice against challenge by the same tumor. Methods of antitumor immunization have included injection of irradiated tumors (often mixed with *Corynebacterium parvum*) or surgical removal of a transplanted tumor mass. Mice who have undergone a primary immunization *in vivo* ("primed" mice) could subsequently reject a lethal challenge of the immunizing tumor. Furthermore, splenocytes derived from immunized animals could be secondarily stimulated *in vitro* to specifically lyse tumor cells. The same methods of immunization that readily generated protective immunity, however, were generally ineffective for treatment of established tumors. Similarly, although adoptively transferred immune splenocytes conferred protective immunity when transferred before tumor challenge, they did not eradicate established tumors (1 ,2 and 3).

The result that adoptive transfer of immune splenocytes was less effective in treatment of established tumors than in protection against tumor challenge suggested that established tumors could suppress an antitumor immune response. This hypothesis fueled a search for mechanisms of tumor-generated immune suppression. Multiple factors have been proposed to account for tumor suppression of adoptively transferred cells. One proposed mechanism involves systemically active, soluble factors that nonspecifically interfere with immune function in tumor-bearing mice. North et al. (4) reported that a low-molecular-weight factor in the circulation of tumor-bearing mice severely impaired the capacity of the host to resist experimental bacterial infection. Ting et al. (5) similarly reported a humoral factor in the ascitic fluid of tumor-bearing mice that could suppress primary *in vivo* immunization against tumors, as well as the induction of cell-mediated cytotoxic responses *in vitro.* Subsequently, several tumor-produced suppressors of immune function have

been identified at the molecular level, including soluble tumor necrosis factor receptor (6), transforming growth factor–β (7), and prostaglandins (8), as well as additional unidentified factors (9 ,10). Soluble suppressive molecules produced by the tumor could directly inhibit T-cell function or interfere with macrophage or other immune cell functions.

In addition to systemic, nonspecific suppression of immunity, a T-cell-mediated mechanism of immune suppression was described by Berendt and North (11). These authors investigated treatment of the highly immunogenic Meth A fibrosarcoma by adoptive transfer of T cells from immunized donors. They showed that it was possible to invoke the regression of large, established Meth A tumors by intravenous infusion of immune T cells, but only if the tumors were growing in T-cell-deficient mice. Furthermore, tumor treatment in T-cell–deficient mice was prevented by prior infusion of splenic T cells from T-cell-intact, tumor-bearing donors (Fig. 12-1). These studies support a role for suppressor T cells in the resistance of established tumors to adoptive transfer therapy. North and his collaborators extended these results to other immunogenic murine tumors, including the SA-1 sarcoma and the L5178Y lymphoma, and defined a CD4+ subset of T cells as the effector-cell population (12 ,13 and 14). Similarly, Greenberg et al. demonstrated that a suppressive population of T cells was generated when FBL-3-immune splenocytes were cultured *in vitro* for 5 days without antigen stimulation (15). The mechanism of T-cell-mediated suppression in these murine models and the relevance of these findings to poorly immunogenic tumors (including most human tumors) remains to be determined. Whatever the mechanisms involved, an established growing tumor interacts differently with the host immune system than a newly transplanted tumor.
FIGURE 12-1. Evidence that transplantable suppressor T cells prevent tumor elimination by immune spleen cells. A: Normal mice treated by infusion of *in vitro* sensitized or normal splenocytes 6 days after challenge with an intradermal Meth A tumor demonstrate progressive tumor growth. B: Infusion of immune cells into T-cell–depleted (THXB) mice 6 days after challenge with an intradermal Meth A tumor caused complete tumor rejection. THXB mice treated with normal splenocytes showed progressive growth. C: Prior infusion of suppressor splenocytes from a mouse with progressively growing Meth A tumor abrogated the effect of immune cell transfer. Normal splenocytes had no effect on immune cell-mediated tumor regression. [Adapted from Berendt MJ and North RJ. T-cell-mediated suppression of antitumor immunity. An explanation for progressive growth of an immunogenic tumor. *J Exp Med* 1980;151(1):69.]

Systemic Immunosuppression and Interleukin-2 Administration Augment Adoptive Therapy

Although tumor suppression of adoptive immunotherapy has been proposed to occur by many mechanisms, some immunogenic tumors proved to be susceptible to treatment with transferred cells. In 1975, Berenson et al. (16) showed that the immunogenic Friend virus-induced lymphoma, FBL-3, could be successfully treated by adoptive transfer therapy. An intraperitoneal challenge of 1 × 10^4 FBL-3 cells was treated with immune splenocytes administered intravenously within 1 day of tumor challenge. Although treatment using 1 × 10^7 immune cells alone was successful only with a relatively unimpressive tumor burden, manipulation of the tumor-bearing host greatly improved the efficacy of adoptive transfer. Mice inoculated intraperitoneally with as many as 1 × 10^7 FBL-3 cells and treated as late as 5 days after inoculation with cyclophosphamide plus 1 × 10^6 immune spleen cells survived tumor free (Fig. 12-2). The effectiveness of adoptive transfer treatments for many different murine tumors has been greatly improved by immunosuppressive regimens, such as cyclophosphamide administration or radiation treatment. The mechanisms by which cyclophosphamide enhanced adoptive transfer therapy were unclear. For the FBL-3 tumor, cyclophosphamide had a significant tumoricidal effect, but cyclophosphamide alone in this model was not curative. North and his coworkers (12 ,17) indirectly demonstrated that elimination of CD4+ cells from an L5178 lymphoma-bearing

host augmented adoptive therapy by CD8+ immune cells. The researchers championed a hypothesis of suppressor cell abrogation of immune cell function.
FIGURE 12-2. Adoptive immunotherapy cures mice of large tumor burden after pretreatment with cyclophosphamide. Mice received intraperitoneal inoculation with 1 × 10^7 FBL-3 leukemia cells. Five days later, cyclophosphamide mice received cyclophosphamide followed 6 hours later by the indicated number of immune splenocytes. Each dot represents survival of one mouse. (From Berenson JR, Einstein AB, Fefer A. Syngeneic adoptive immunotherapy and chemotherapy of a Friend leukemia: requirement for T cells. *J Immunol* 1975;115:234, with permission.)

In contrast, Cameron et al. (18) concluded that suppressor T cells could not account for the results of experiments with MCA-38 tumors. They investigated the synergistic effects of local irradiation with adoptive therapy of hepatic metastasis of the weakly immunogenic murine adenocarcinoma, MC-38. Mice underwent radiation treatment that included only the right side of the liver, followed by adoptive immunotherapy. When the number of right- and left-sided metastases were individually counted, tumor reduction compared with controls was seen only on the right (irradiated) side. The presence of left-sided tumor did not affect the reduction in the number of right-sided metastases. The authors concluded that these data failed to support a role for suppressor T cells in the abrogation of adoptive immunotherapy. Other possible mechanisms by which cyclophosphamide and radiation augment adoptive transfer therapy include activation of macrophages in the tumor bed or reduction of the tumor burden before immune cell transfer. Additional studies are required to resolve the mechanisms involved. In any case, the use of an immunosuppressive agent before adoptive therapy is a highly effective strategy. This strategy has been used to augment adoptive cell treatment in many of the mouse tumor models described below.

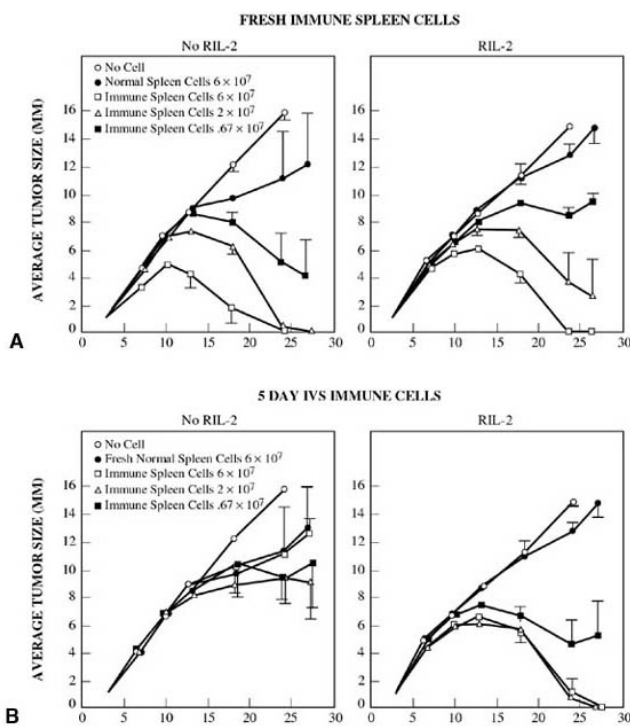
In addition to immune suppression, other manipulations of the tumor-bearing recipient can augment adoptive therapy with immune cells. Interleukin-2 (IL-2) support of transferred T cells *in vivo* can be critical to T-cell efficacy. Cheever et al. (19) investigated the role of IL-2 in the adoptive immunotherapy of the FBL-3 leukemia. When immune splenocytes were specifically activated by *in vitro* culture with FBL-3 and then expanded in culture with IL-2, the resulting T lymphocytes specifically lysed FBL-3. They also mediated specific adoptive therapy of disseminated FBL-3 *in vivo* when used with cyclophosphamide. In this model, IL-2 was highly effective in augmenting the *in vivo* efficacy of these IL-2-dependent, cultured T lymphocytes in adoptive therapy. IL-2 did not augment the *in vivo* efficacy of noncultured immune splenocytes in the FBL-3 model. Shu and Rosenberg (20) reported similar results with a weakly immunogenic transplantable sarcoma, MCA-105. In this study, fresh immune spleen cells were not cytotoxic to MCA-105 tumor targets in a 4-hour chromium-release assay. Adoptive transfer of fresh immune splenocytes, however, mediated the regression of established MCA-105 tumors. The therapeutic efficacy of these cells was not augmented by IL-2 administration *in vivo*. In contrast to fresh cells, secondary *in vitro* sensitization (IVS) by culture of immune cells with irradiated MCA-105 tumors generated cytotoxic cultures that lysed MCA-105 tumors. Effective adoptive immunotherapy with these secondarily sensitized immune cells required the *in vivo* administration of IL-2 (Fig. 12-3).


FIGURE 12-3. Adoptive immunotherapy of MCA-105 tumors with *in vitro* sensitized (IVS) immune cells (B), but not with fresh immune splenocytes (A), is augmented by recombinant interleukin-2 (rIL-2). Preirradiated mice received intradermal inoculation of MCA-105 tumor. Three days later, immune effectors were transferred intravenously and rIL-2 was given intraperitoneally twice a day for 6 days. (From Shu S and Rosenberg SA. Adoptive immunotherapy of a newly induced sarcoma: immunologic characteristics of effector cells. *J Immunol* 1985; 135:2895, with permission.)

One mechanism by which IL-2 treatment may augment adoptive transfer therapy *in vivo* is by promoting the survival and proliferation of transferred cells. Evidence for this proposal was collected using immune effector cells and Thy-1 congenic mice (21). Fluorescence activated cell sorting with an antibody specific for the Thy-1 marker of donor origin was used to identify and enumerate the transferred T cells in the host after adoptive transfer. When cultured T-cell lines immune to the FBL-3 leukemia were transferred into FBL-3-bearing hosts in a manner that was effective in tumor therapy, the T cells proliferated *in vivo* even in the absence of IL-2. The growth rate of donor T cells, however, was augmented by administration of exogenous IL-2. Further work showed that IL-2 and the availability of antigen *in vivo* affected the persistence of T cells after transfer (22). Again, T cells and mice congenic for the Thy-1 marker were used to examine immune cells after transfer. Cultured T cells specific for FBL-3 tumors were adoptively transferred into normal mice and then induced to proliferate *in vivo* by specific stimulation with irradiated FBL-3 and IL-2. The growth of antigen-activated donor T cells, rather than host lymphocytes, was preferentially stimulated (Fig. 12-4). Additionally, IL-2 administration increased the long-term (day 35) survival of transferred lymphocytes.
FIGURE 12-4. Adoptively transferred donor T cells rather than host lymphocytes preferentially expand after administration of interleukin-2 (IL-2) and antigen *in vivo.* Mice were left untreated or injected with irradiated FBL-3 leukemia cells. Concurrently, mice received no additional treatment or administration of cultured FBL-3-specific, Thy-1-congenic T cells. IL-2 was administered by intraperitoneal injection for 7 days. On day 7, the total number of host lymphocytes and donor-derived T cells within the ascites and spleen of each group of mice were identified and enumerated. Mean of donor T cells *(closed bars)* and host lymphocytes *(open bars)* with standard deviations are shown. (From Chen W and Cheever MA. Donor T cells can be induced to grow and survive long term *in vivo* without previous host immunosuppression. *J Immunol* 1994;152:4767, with permission.)

A poorly understood variable in studies of adoptive transfer therapy is the inflammatory context of antigen *in vivo.* In a nontumor model, Jenkins et al. demonstrated that the fate of adoptively transferred naïve T cells is critically dependent on encountering their cognate antigen (23). When naïve CD4+ T cells from T-cell receptor transgenic mice were transferred to syngeneic recipients, the donor cells could be followed by a clonotype-specific, anti-T-cell receptor monoclonal antibody. Without administration of cognate antigen, the transferred T cells disappeared within weeks. If cognate antigen was administered by an "inflammatory route" (i.e., by subcutaneous injection in adjuvant), transferred T cells in the draining lymph node underwent activation, rapid proliferation, and large

numerical expansion within 3 days. If the antigen was administered by a "tolerogenic route" (i.e., by intravenous injection), then the transferred T cells underwent a brief period of activation, followed by apoptosis and anergy. Other studies using T-cell receptor transgenic mice and transplantable tumors have shown that tumor-specific cells in a tumor-bearing animal were also sensitive to the inflammatory environment of the antigen (24 ,25 and 26). In each of these reports, tumor cells survived and tumors grew, despite the presence in the host of many tumor-specific T cells. The persistence and function of lymphocytes *in vivo*, and ultimately their ability to eradicate tumors, were affected by the availability and the inflammatory context of their specific antigen.

These studies demonstrated that the tumor-bearing host can affect the outcome of adoptive transfer therapy. Several systemic treatments of tumor-bearing mice were effective in augmenting adoptive therapy. Host immune suppression by using cyclophosphamide or radiation before immune cell transfer was critical to the treatment of some tumors. Large, well-established, weakly immunogenic tumor deposits (analogous to human tumors) were most dependent on immunosuppressive treatment. Similarly, IL-2 administration after lymphocyte transfer was shown to augment antitumor therapy and increase transferred

cell persistence. IL-2–dependent effector cells derived the most benefit from *in vivo* IL-2 support. Although the use of systemic treatments could increase the morbidity and expense of adoptive transfer protocols, these preclinical studies strongly support a role for systemic treatment with chemotherapy, IL-2, or both, for patients receiving adoptive cell transfer therapy.

In Vitro Sensitization Generates Potent Effector Cells

From the first successful reports of adoptive therapy, attempts to characterize the origin and function of immune cells mediating tumor rejection were undertaken. Early work in the FBL-3 lymphoma model demonstrated that T cells constituted the immune population in transferred splenocytes (16). Cheever et al. (27) demonstrated that transferred splenocytes mediated tumor treatment by an antigen-specific mechanism. Cytolytic assays *in vitro* demonstrated that FBL-3 and EL-4, a chemically induced virus-negative tumor, were antigenically distinct. *In vitro* immune spleen cells lysed the tumor to which they were immunized, but did not lyse the unrelated tumor. Immune cells demonstrated similar specificity when used in adoptive therapy studies. Mice with established FBL-3 or EL-4 tumors were cured by treatment on day 5, consisting of cyclophosphamide plus 2×10^7 immune spleen cells. Mice given 2×10^7 normal cells or cells sensitized to the other tumor did not demonstrate cures. The *in vivo* specificity of adoptively transferred cells strongly suggested that specific antigens expressed by each tumor were being targeted.

To generate effector cells with better tumor specificity, enhancement of primary immune cells by secondary IVS was investigated. Early studies relied on mixed lymphocyte and tumor cultures for secondary IVS. Typical of these studies was a report by Cheever et al., who examined the generation of therapeutically effective cells during secondary IVS of FBL-3–immune splenocytes. IVS of FBL-3–immune cells with FBL-3 tumors generated lytic cultures with improved therapeutic activity. The generation of maximum lytic activity and maximum therapeutic activity were chronologically disparate, suggesting different effector-cell populations mediating each function. Greenberg et al. (29) eventually showed that therapeutic efficacy was largely mediated by transfer of Lyt-1⁺2⁻ (CD8⁻) T cells, whereas *in vitro* cytotoxicity was derived from the Lyt-2⁺ (CD8⁺) subset. Thus, when effector cells were derived using this *in vitro* culture system, the predominant cell required to eradicate FBL-3 *in vivo* was not cytolytic to the tumor *in vitro.* In retrospect, secondary IVS alone rarely added much to primary immunization for highly immunogenic tumors, such as FBL-3. For weakly or nonimmunogenic tumors, however, IVS dramatically improved the efficacy of adoptively transferred cells.

The identification of T-cell growth factor (30) and the subsequent production of recombinant IL-2(31), its active component, facilitated IVS and improved the effectiveness of lymphocyte cultures in treating established tumors. Using the FBL-3 tumor model, Eberlein et al. (32) demonstrated that adoptive immunotherapy could result in curing mice of the established local tumor, as well as the established disseminated tumor. These authors showed for the first time that when immune splenocytes were secondarily sensitized to the FBL-3 tumor *in vitro*, they could be expanded in IL-2 and grown for multiple generations while retaining their ability to cure mice. Shu et al. (33) used IVS with IL-2 to examine adoptive immunotherapy of experimentally induced pulmonary metastases from the weakly immunogenic MCA-105 sarcoma. Using IL-2 during IVS, nonimmune or MCA-105–immune spleen cells increased in numbers up to 94-fold in 15 days. Only the IVS cultures of animals primed *in vivo*, however, were therapeutically effective. Immunotherapy with expanded MCA-105–immune cultures led to the reduction of established 3-day-old pulmonary metastases, prolongation of survival, and tumor cure in the majority of animals. Administration to tumor-bearing hosts of exogenous IL-2 improved the efficacy of the adoptive cellular therapy with cultured, but not fresh, immune cells. On a per-cell basis, the IVS-immune cells were eight to tenfold more effective when compared with fresh, noncultured MCA-105–immune cells in eliminating established pulmonary metastases (Fig. 12-5).
FIGURE 12-5. *In vitro* sensitized (IVS)-immune splenocytes are more effective in adoptive immunotherapy of pulmonary metastasis than fresh splenocytes. Mice with established 3-day-old MCA-105 pulmonary metastases were treated with the indicated number of fresh or IVS splenocytes from immune or normal mice. Three to 9 days later, mice received twice-daily interleukin-2 (IL-2) administration. Pulmonary metastases were counted on day 14. Lines of linear regression are shown for different types of cells. (From Shu S et al. *In vitro* sensitization and expansion with viable tumor cells and interleukin-2 in the generation of specific therapeutic effector cells. *J Immunol* 1986;136:3891, with permission.)

Many other studies reported improved adoptive immunotherapy using IVS cells. Peng et al. (34) reported on the eradication of subcutaneous MCA-205 sarcoma by immune T cells. Successful therapy in this difficult treatment model was dependent on transfer of a large number of secondary IVS-immune T cells, as well as pretreatment of the tumor-bearing mice with radiation. Additionally, the therapeutic effect of the adoptively transferred T cells was eliminated if CD4 cells or CD8 cells were depleted. In another difficult treatment model, the T-cell subsets mediating therapy of the nonimmunogenic MCA-102 sarcoma were identified (35). IVS of immune cells with IL-2 was required to generate therapeutically effective cultures. Selective depletion of T-cell subsets *in vivo* was used to show a

requirement for CD4+ (L3T4+) and CD8+ (Lyt-2+) T cells in mediating tumor regression. The depletion of CD4+ cells was circumvented by administration of exogenous IL-2 in this model. Taken as a group, these studies indicated that IVS of immune cells and culture expansion with IL-2 significantly increased therapeutic efficacy of immune cell cultures. The number of cells available for adoptive transfer and the "per cell" therapeutic efficacy of the transferred cells were improved by IVS methods.

Selection of Effector-Cell Attributes Impacts Therapeutic Efficacy

Lymphocytes are a highly heterogeneous group of cells. Questions remain regarding which T-cell traits should be selected and which T-cell traits should be abandoned for optimum efficacy in adoptive transfer. Specific tumor lysis by IVS cultures has been widely used as a surrogate marker of the therapeutic value of T-cell cultures. Direct evidence for a correlation between lytic ability and therapeutic effectiveness was collected by Matsumura et al (36). In this study, cloned T-cell lines were generated by IVS with tumor and IL-2. Experiments using these clones demonstrated that the *in vitro* cytotoxic specificity of the clones correlated with their *in vivo* infiltration into metastatic tumor deposits, as well as their *in vivo* antitumor specificity.

Specific cytokine secretion by transferred cell cultures may be a more valuable surrogate marker for therapeutic efficacy than lysis. Several reports document the capability of T-cell cultures from cancer patients to specifically secrete cytokines when stimulated with autologous tumor cells. For instance, Schwartzentruber et al. (37) described T-cell lines derived from tumor-infiltrating lymphocytes (TILs) from two melanoma patients and one breast carcinoma patient that specifically secreted interferon-γ (IFN-γ), tumor necrosis factor–α, and granulocyte-macrophage colony-stimulating factor when stimulated with the autologous tumor. Similarly, Maccalli et al. (38) reported that tumor-specific T-cell clones derived from melanoma patients exhibited heterogeneous lytic activity and expressed multiple cytokines. Importantly, cytokine secretion has been implicated in the antitumor mechanisms used by T-cell cultures in the elimination of metastatic tumor deposits in mice. Barth et al. (39) investigated the mechanisms whereby adoptively transferred murine CD8+ lymphocytes mediate tumor regressions. They found that noncytolytic CD8+ cultures from TILs eradicated pulmonary metastasis in irradiated mice. Many of these cultures specifically secreted IFN-γ and tumor necrosis factor when stimulated with tumor cells *in vitro.* The *in vivo* effectiveness of cultures for treatment of mice bearing pulmonary micrometastases correlated better with specific cytokine secretion than with cytotoxicity *in vitro.* Only 8 of 15 therapeutically effective TILs were cytolytic, whereas 14 of 15 therapeutically effective TILs specifically secreted IFN-γ *in vitro.* Additionally, antibodies to IFN-γ abrogated the ability of four different CD8+ cultures to mediate tumor regression, indicating that secretion of IFN-γ was an essential part of their mechanism of action. Nagoshi et al. (40) investigated the role of cytokine secretion *in vivo* during adoptive immunotherapy of pulmonary metastases of the MCA-105 murine sarcoma. T-cell cultures were transferred into Thy-1 congenic mice and immunohistochemistry was performed to identify donor cells that produced cytokines. The authors propose a model in which cytokine secretion by the transferred tumor-specific effector cells caused tumor inflammation and recruitment of host cells. Host cells, especially dendritic cells and macrophages, were essential for therapeutic efficacy. Additional work needs to be done to understand the roles played in tumor eradication by host immune cells and inflammatory cytokines produced by transferred cells.

Other T-cell phenotypes may also predict therapeutic efficacy, including tumor-specific proliferation of transferred cells. Klarnet et al. (41) described helper cell–independent cytotoxic T lymphocytes (CTLs). These cloned, antigen-driven, helper cell–independent CTL cells were specifically cytolytic to FBL-3. Furthermore, activation with FBL-3 induced secretion of IL-2, expression of IL-2 receptors, and *in vitro* proliferation. Cloned helper cell–independent CTL cells administered to cyclophosphamide-treated tumor-bearing mice were effective in the elimination of disseminated FBL-3. Even 125 days after therapeutic transfer, the cloned cells in these mice could be recovered. Similarly, Rosenstein and Rosenberg (42) examined T-cell clones that exhibited lytic activity and proliferation when stimulated by the syngeneic FBL-3 lymphoma. T-cell clones exhibiting proliferation and cytotoxic activity were more effective in adoptive therapy of FBL-3 tumors than clones exhibiting lytic activity but no proliferation.

Summary of Adoptive Transfer Using Immune Splenocytes

In summary, several qualities of T-cell cultures measured *in vitro* were correlated with the outcome of adoptive transfer therapy *in vivo.* First, virtually all models of adoptive transfer, including those described here, demonstrated a direct correlation between the number of transferred cells and their therapeutic efficacy. Second, the *in vitro* specificity of effector cells for tumors was generally correlated with their therapeutic efficacy. *In vitro* specificity of T cells has been measured by several criteria, including tumor-specific proliferation, cytokine secretion, and lysis. The most relevant of these *in vitro* characteristics for prediction of therapeutic efficacy in a clinical setting remains to be determined. Third, for most murine tumor models, including large, established, and poorly immunogenic tumors, IVS and culture with IL-2 increased immune cell numbers, as well as therapeutic efficacy of the cultured cells. Other important features of the effector cells may include the CD4/CD8 phenotype, the ability to traffic to tumors, and the capability of recruiting host cells into an antitumor inflammatory response.

Nonspecific Lymphocyte Activation and Lymphokine-Activated Killer Cells

Part of "12 - Cell Transfer Therapy: Basic Principles and Preclinical Studies "

The models of adoptive transfer in mice discussed so far have in common the prior immunization of donor mice to obtain immune splenocytes for transfer. Immunization of patients to obtain antitumor immune cells, however, was not technically

feasible. The application of adoptive transfer therapy to a clinical setting relied on the development of other sources of autochthonous cells. The availability of recombinant IL-2(31) allowed for the activation and *ex vivo* expansion of large numbers of lymphocytes. Grimm et al. (43) examined human peripheral blood lymphocytes from cancer patients and normal donors that were cultured in a high concentration (1,000 U per mL) of IL-2. Within 2 to 3 days, these cultures exhibited cytotoxicity toward 20 of 21 natural killer (NK)-resistant, fresh tumor cells tested. The cells mediating this nonspecific cytotoxicity were termed *lymphokine-activated killer* (LAK) *cells.* LAK-cell lysis was not major histocompatibility complex restricted, and LAK cells mediated lysis of autologous tumors and allogeneic tumors derived from multiple histologies (43 ,44 and 45). Low-level lysis of cultured fibroblasts and cultured normal cell lines were also observed, but fresh, unstimulated peripheral blood mononuclear cells (PBMC) from humans were not lysed (Table 12-1).

Table 12-1 Lymphokine-Activated Killer Cells Activated by Interleukin-2 Lyse a Variety of Fresh Natural Killer–Resistant Tumor Targets

LAK, lymphokine-activated killer; PBML, peripheral blood mononuclear leukocyte; SEM, standard error of the mean.

From Rayner AA et al. Lymphocyte-activated killer (LAK) cells. Analysis of factors relevant to the immunotherapy of human cancer. *Cancer* 1985;55:1327, with permission.

IL-2 was determined to be the only lymphokine absolutely required for elaboration of LAK cells (46). LAK-cell precursors were virtually ubiquitous in lymphoid tissues; lymphocytes from mouse and human sources, including PBMC, lymph nodes, spleen, thymus, and even solid tissue digests, could evolve LAK-cell activity (46 ,47). Human LAK cells could be readily generated in culture with recombinant IL-2 grown for several months without loss of activity and expanded *in vitro*, potentially to more than 10^{20} cells (44). LAK cells fulfilled one prerequisite for clinical trials of adoptive transfer therapy by providing a potent effector-cell population from the autochthonous source. LAK cells abrogated the need for a second, immune host as a source of transferred cells.

Demonstration of the therapeutic potential of LAK cells *in vivo* was accomplished using mouse metastatic tumor models. Mazumder and Rosenberg (48) showed that established pulmonary metastases of the B16 melanoma were successfully treated and survival time was increased in mice that received 1×10^8 LAK cells. LAK cells generated from tumor-bearing mice were equally effective as cells from naïve mice. With this experimental model, the therapeutic effect of LAK cells was independent of prior cyclophosphamide treatment of the host. IL-2 administered *in vivo* had a small therapeutic effect in reducing B16 pulmonary metastases, but IL-2 and LAK cells administered together were highly effective.

The therapeutic effect of LAK-cell administration with IL-2 support was characterized using mouse sarcomas, melanoma, and adenocarcinoma metastatic to the lungs or liver (48 ,49 ,50 and 51). In murine tumor models metastatic to the liver, IL-2 alone also had a significant effect at high dose, but only a small effect at lower doses. LAK cells alone were ineffective. The combination of LAK cells with IL-2 treatment, however, mediated significant reductions in the number and size of liver nodules (Fig. 12-6). In a lung tumor model, IL-2 administration alone also had a dose-dependent effect on lung metastasis. When LAK cells and IL-2 were administered together, LAK cells added significantly to tumor reduction at all doses of IL-2. High-dose IL-2 may act by supporting the growth of transferred cells and by inducing the formation of host LAK-like cells *in vivo*, even in the absence of

transferred cells (52). IL-2 administration at low doses was shown to support the growth of transferred LAK cells. Using a DNA labeling technique for monitoring cell proliferation *in vivo*, Ettinghausen et al. (53) showed that transferred LAK cells failed to proliferate *in vivo* in the absence of IL-2. When IL-2 was administered after LAK-cell transfer, however, increased proliferation of the transferred cells was seen in the lungs and liver and, to a lesser extent, at other sites.

FIGURE 12-6. Lymphokine-activated killer (LAK) cells augment the effect of recombinant interleukin-2 (rIL-2) for therapy of MCA-38 adenocarcinoma liver metastases. Experimentally induced 3-day-old liver metastases of the MCA-38 adenocarcinoma were treated with rIL-2 three times a day at the indicated dose for 4 or 7 consecutive days, starting on day 3. LAK cells were administered at 1×10^8 cells per treatment on days 3 and 6. Each dot represents a measure of liver metastases in a single mouse. (HBSS, Hanks' balanced salt solution.) (From Lafreniere R and Rosenberg SA. Adoptive immunotherapy of murine hepatic metastases with lymphokine-activated killer (LAK) cells and recombinant interleukin-2 (rIL-2) can mediate the regression of both immunogenic and nonimmunogenic sarcomas and an adenocarcinoma. *J Immunol* 1985;135:4273, with permission.)

To improve LAK-cell efficacy, many studies attempted to identify a LAK precursor cell and determine the mechanism of LAK-cell antitumor activity *in vivo.* Using complement and antibody-mediated lysis, Yang et al. (54) demonstrated that the majority of LAK-cell precursor activity in mice resided in the "null" cell population (i.e., Thy-1⁻, CD3⁻, FcR⁺). Yang et al. suggested an NK precursor. This hypothesis was supported by additional studies, which showed that LAK-cell activity could be greatly reduced by depletion of splenocytes with anti-asialo-GM antibody before culture with IL-2. Similar studies using antibody depletion of human peripheral blood lymphocytes before culture in IL-2 concluded that LAK-cell precursors were found predominantly in the NK compartment. LAK-cell precursors manifested potent NK activity before IL-2 stimulation and expressed NK markers, including CD56 (55). In addition to NK-cell precursors, some contribution to LAK-cell activity was derived from CD3⁺ cells. Raynor et al. (56) examined limiting dilution clones of LAK-cell cultures and identified CD3⁻ clones with high LAK-cell activity and CD3⁺ clones with intermediate LAK-cell activity. Similarly, Roussel et al. (57) defined culture condition for the production of long-term LAK-cell cultures comprised predominantly of CD3⁺ large granular lymphocytes.

Studies of LAK-cell precursors *in vitro* were mirrored by studies of therapeutic efficacy in mouse metastatic tumor models. Mulé et al. (58) showed that LAK-cell cultures derived from Thy-1–depleted cells were as effective for treating sarcoma lung metastases as standard cultures, indicating that T cells were not a predominant LAK-cell precursor population. Furthermore, host T cells were not necessary for *in vivo* LAK-cell activity because irradiated mice and T-depleted bone marrow chimeric mice showed no diminution of LAK-cell effectiveness. Further experiments investigating LAK-cell activity *in vivo* were performed by depleting mice of LAK-cell subsets after transfer (59). These studies demonstrated that only the asialo-GM–sensitive cells were required for elimination of metastatic deposits from a nonimmunogenic tumor. In contrast, LAK-cell activity *in vivo* against a weakly immunogenic tumor was mediated by anti-asialo-GM–sensitive and Lyt-2–sensitive (CD8) components.

Principles of LAK-cell activity and LAK-cell behavior have translated well from murine models to the clinical setting (see Chapter 13). Investigators continue to probe the clinical potential of nonspecific LAK cells derived by the *ex vivo* activated of PBMC for tumor therapy. Augmentation of LAK-cell activity by coadministration of tumor-specific monoclonal antibodies *in vivo* is being studied. LAK cells demonstrated potent antibody-dependent cellular cytotoxicity *in vitro* (60). *In vivo*, antibody administration was shown to act synergistically with LAK cells and IL-2 treatment in some experimental tumor models (61 ,62 and 63). Other studies are focusing on a role for LAK cells in regional local therapy by isolated perfusion techniques (64 ,65). Preclinical models continue to guide the clinical application of these approaches.

In summary, the discovery and recombinant production of IL-2 provided the means to generate highly activated cells with nonspecific killer activity for adoptive transfer. Preclinical mouse models elucidated principles of LAK cells that were exploited for clinical adoptive transfer trials. LAK cells were generated from PBMC and other lymphocyte sources by culture in 1,000 U per mL of IL-2. LAK cells developed within 2 to 3 days and LAK-cell activity was manifested as nonspecific lysis of fresh and cultured tumor targets. Transfer of LAK cells could treat established murine liver and lung tumors in a dose-dependent manner, and treatment efficacy was dependent on or greatly enhanced by coadministration of IL-2. In most tumor models, prior immune

suppression of the transfer recipient by cyclophosphamide or radiation could greatly augment LAK-cell efficacy.

Tumor Antigen Specificity and Tumor-Infiltrating Lymphocytes

Part of "12 - Cell Transfer Therapy: Basic Principles and Preclinical Studies "

Studies of Murine Tumor-Infiltrating Lymphocytes

A major improvement to adoptive transfer therapy was obtained by using TILs as the precursor population for LAK-cell generation. Single-cell suspensions of mouse sarcoma digests cultured without IL-2 generated cultures in which the tumor cells grew, whereas the lymphocyte population rapidly disappeared. When cultured in the presence of 1,000 U per mL of IL-2, the tumor cells in the single-cell digest specifically disappeared, however, whereas the lymphocytes proliferated (Fig. 12-7) (66). Speiss et al. (67) used adoptive transfer into animals bearing 3-day-old established pulmonary micrometastases to investigate the *in vivo* specificity and therapeutic activity of mouse TILs. In this metastatic model, TILs were 50- to 100-fold more effective than LAK cells at mediating clearance of autologous tumors (Fig. 12-8). IL-2 was not required absolutely, but did enhance the therapeutic effect of transferred TILs approximately fivefold. Using the simple method of culturing tumor digests in high-dose IL-2, therapeutically effective TIL cultures were successfully established from mouse tumors of diverse histology, including sarcomas, a melanoma, a colon carcinoma, and a bladder tumor (Table 12-2). The *in vivo* specificity of TILs was determined by comparing the therapeutic capacity of TILs from two chemically induced sarcomas, MCA-105 and MCA-106, which did not cross-protect in immunization and challenge experiments. TILs from the MCA-105 sarcoma eliminated autologous MCA-105 lung metastases, but not MCA-106 metastases. TILs from MCA-106 eliminated MCA-105 metastases and autologous MCA-106 metastases. In these studies, TILs generated in 1,000 U per mL of IL-2 could show tumor-specific or nonspecific effects *in vivo.*

Table 12-2 Tumor-Infiltrating Lymphocytes From Five Different Tumors Efficiently Treat Pulmonary Metastases

Tumor	Mean No. of Metastases[a] for Treatment Groups[b] with:		
	HBSS	IL-2	TILs + IL-2 (*p* Value)
MCA-38 colon adenocarcinoma	≥250	>250	0 (<.01)
B16 melanoma	≥250	>250	3.2 (<.01)
1660 bladder carcinoma	63	64	0.2 (<.01)
MCA-105 sarcoma	≥250	248	0 (<.01)
MCA-106 sarcoma	≥250	≥250	1 (<.01)

HBSS, Hanks' balanced salt solution; IL-2, interleukin-2; TILs, tumor-infiltrating lymphocytes.

[a]Enumerated on day 15.

[b]Mice bearing 3-day-old pulmonary metastases were treated with either HBSS or 7,500 U IL-2 in 0.5 mL HBSS three times a day on days 3 through 8 or with a single i.v. injection of 4 × 10⁶ TILs in addition to IL-2.

From Spiess PJ, et al. *In vivo* antitumor activity of tumor-infiltrating lymphocytes expanded in recombinant interleukin-2. *J Natl Cancer Inst* 1987;79:1067, with permission.
FIGURE 12-7. Growth of nonimmunogenic MCA-102 sarcoma tumor-cell suspensions with or without T-cell growth factor (TCGF). 1 × 10⁴ cells were plated in microtiter plate wells with or without TCGF. At the indicated times, cells were counted. Each point represents mean ± standard error of eight replicates. Lymphocytes predominated in cultures with TCGF, whereas tumor cells grew in wells without TCGF. (CM, complete media.) (From Yron I et al. *In vitro* growth of murine T cells. V. The isolation and growth of lymphoid cells infiltrating syngeneic solid tumors. *J Immunol* 1980;125:238, with permission.)
FIGURE 12-8. Tumor-infiltrating lymphocytes (TILs) are 50- to 100-fold better than lymphokine-activated killer (LAK) cells at treating MCA-105 pulmonary metastases. Three-day-old pulmonary metastases of MCA-105 sarcoma were treated with infusion of TILs or LAK cells. LAK cells were given in one or two doses separated by 3 days. All mice received interleukin-2 three times a day for 5 days. (From Spiess PJ, Yang JC, and SA Rosenberg. *In vivo* antitumor activity of tumor-infiltrating lymphocytes expanded in recombinant interleukin-2. *J Natl Cancer Inst* 1987;79:1067, with permission.)

The ease of generation of TIL cultures and their striking therapeutic potential in murine models suggested that TILs from human tumors could be a useful effector-cell population for adoptive therapy. To investigate clinically relevant questions, investigators turned to more difficult tumor models. Rosenberg et al. (68) examined the effectiveness of systemic treatments of tumor-bearing animals for enhancement of TIL activity. These studies showed that murine TILs could mediate the treatment of large established lung and liver metastases of transplantable sarcomas in mice. In this setting, TILs were not effective alone, but TILs could enhance the effects of cyclophosphamide and IL-2 to promote complete tumor regression (Table 12-3). Another model was developed by Yang et al. (69) to address the problem that TILs were not routinely generated from nonimmunogenic murine tumors. They optimized the culture conditions for generating tumor-reactive lymphocyte cell lines, including IVS, with irradiated autologous tumor and growth in low-dose IL-2 (10 U per mL). These culture changes increased the *in vivo* efficacy of TILs from the weakly immunogenic carcinoma, MC-38, and the sarcoma, MCA-105 (Fig. 12-9). When used with the nonimmunogenic sarcoma, MCA-102, the improved culture conditions enabled the generation of therapeutically effective TILs, whereas standard bulk-culture conditions did not.

Table 12-3 Treatment of Liver Metastases From the MC-38 Colon Adenocarcinoma with Tumor-Infiltrating Lymphocytes

| Treatment | | | Experiment 1 No. of Mice | | | | Experiment 2 No. of Mice | | | |

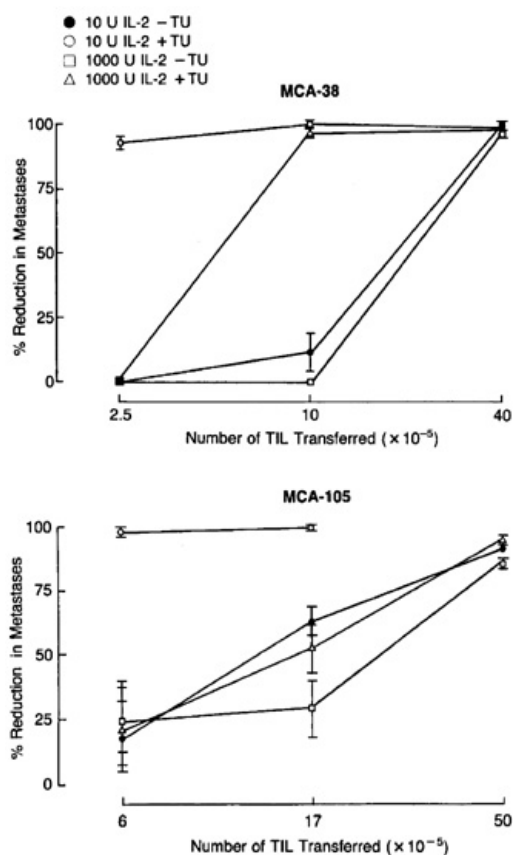

FIGURE 12-9. The effect of tumor and interleukin-2 (IL-2) doses during culture of tumor-infiltrating lymphocytes (TILs) on therapeutic efficacy. Three-day-old pulmonary metastases of MCA-105 or MCA-38 tumors were treated with TILs grown under different conditions. Pulmonary nodules were enumerated on day 14. Results are reported as the reduction in metastasis by mice given the indicated number of TILs and IL-2 compared with mice given IL-2 alone. The greatest antitumor effect was obtained with TILs grown in low-dose IL-2 with tumor stimulation. (Filled circles, 10 U per mL IL-2, no tumor; open circles, 10 U per mL IL-2 with tumor; open squares, 1,000 U per mL IL-2, no tumor; open triangles, 1,000 U per mL IL-2 with tumor.) (TU, tumor.) (From Yang JC et al. An improved method for growing murine tumor-infiltrating lymphocytes with *in vivo* antitumor activity. *J Biol Response Mod* 1990;9:149, with permission.)

TILs constitute a unique source of T cells in terms of cell trafficking and persistence because, by definition, TILs are derived from lymphocytes that found their way into and persisted within the tumor. It is possible that TILs express cell surface receptors or other features that render them well suited to the tumor microenvironment compared with other lymphocytes. Ames et al. (70) provided support for this hypothesis with evidence that TILs preferentially home to tumor deposits in mammary tumor-bearing mice. TILs, normal splenocytes, or LAK and NK cells from splenocytes were labeled with indium-111 and injected via a tail vein into female mice bearing one or more mammary tumors. Only TILs were found to be more concentrated in tumors than in corresponding normal mammary tissue. Wong et al. (71) studied the uptake of a radiolabeled thymidine analogue into the DNA of dividing cells to study the *in vivo* proliferation and migration patterns of transferred TILs. Twenty hours after injection of label, tissues were removed and radioactivity was determined. Animals receiving TILs and high-dose IL-2 showed high-level of label uptake in the lungs, liver, kidneys, and spleen compared with controls. Experiments with TIL transfer in Thy-1 congenic mice confirmed that TILs were localized in these organs. These studies in mice indicate that TILs can traffic into and persist in solid tissues of mice and may preferentially home to tumor.

Human Tumor-Infiltrating Lymphocytes

Based on the results in mouse models, a host of experiments to characterize the *in vitro* reactivity of human TIL cultures were performed. Unique among human tumors investigated, TILs from human melanoma consistently and reproducibly exhibited specific lysis of autologous tumors. In contrast, when single-cell digests from nonmelanoma human tumors were cultured with IL-2 to generate TILs, specific recognition of autologous tumor by lysis or cytokine-release assays could only rarely be demonstrated.

Sporadic reports of specific TILs have been published for tumors of many different histologies, including ovarian carcinoma (72), colon carcinoma (73 ,74), breast carcinoma (75), cervical carcinoma (76), renal cell carcinoma (77 ,78), and gastric carcinoma (79). Even when specificity to the autologous tumor was documented, in many cases the responsible TIL was not typical of mouse TIL lines. And, despite these sporadic reports of specific TIL recognition, most reports indicate that TILs from nonmelanoma tumors are nonlytic or express LAK-like nonspecific lysis. In fact, even LAK-cell activity has been difficult to generate from some tumors. Low TIL-derived LAK-cell activity has been directly attributed to a low LAK-cell precursor, low "null" cell components, or both, in several reports. Lymphocytes infiltrating carcinomas of the lung and colon were low in CD16+ (NK) cells and deficient in their ability to generate LAK-cell activity compared with PBMC (80 ,81). Similarly, TILs from breast carcinoma exhibited poor proliferation when stimulated with IL-2 compared with PBMC and were low in LAK-cell precursors (82 ,83). The examples cited reflect a broad spectrum of different experimental approaches and conclusions. In general, most human tumors do not harbor a highly selected and highly reactive population of lymphocytes.

In marked contrast to TILs from most tumor histologies, TILs derived from melanoma exhibited nonspecific LAK-cell activity and specific autologous tumor recognition. Almost unique among human tumors, TILs from melanomas matched the general immunologic features of lymphocytes cultured from mouse transplantable tumors. Itoh et al. (84) reported that four of nine TIL cultures from melanoma lesions generated typical nonspecific LAK-cell activity, but five of nine TILs were preferentially lytic for autologous tumors. In this report, autologous tumor-specific TIL cultures expressed typical T-lymphocyte markers, including CD8, but not the NK marker, CD16. Autologous tumor lysis was blocked by antibodies specific for the major histocompatibility complex or the T-cell receptor. Similarly, Muul et al. (85) reported that six of six TILs from melanoma patients preferentially lysed autologous melanoma. Three TIL cultures were specific for autologous tumors and failed to lyse allogeneic tumors or fresh cells, whereas three TIL cultures demonstrated specific autologous tumor lysis and some lysis of nonautologous tumor cells. These trials and subsequent studies indicated that melanoma TILs cultured in IL-2 could consistently evolve CD8+ CTLs that were readily expanded in culture and demonstrated specific lysis of autologous tumors. These features indicated that TILs from melanoma constituted an ideal effector-cell population for clinical adoptive transfer studies. In fact, melanoma TIL cultures have been clinically evaluated for efficacy in treatment of metastatic melanoma and were shown to be therapeutically effective in some patients (see Chapter 13).

The reasons for the unique immunologic properties of melanoma compared with other human tumors are not clear. One possibility is that some melanomas are more immunogenic than tumors from other tumor histologies and can mediate immune priming against melanoma antigens *in situ.* In fact, TIL-like activity could be derived from PBMC of melanoma patients after repeated *in vitro* stimulations with tumors (86), suggesting that systemic immunization against tumor antigens had occurred. Similarly, Marincola et al. (87) concluded that melanoma patients exhibited evidence of *in vivo* priming against melanoma antigens based on secondary *in vitro* stimulation of patient and normal donor peripheral blood lymphocytes with defined melanoma antigens. Whatever the mechanism of *in vivo* priming in melanoma patients, the high frequency of tumor-reactive cells in melanoma TILs served as an excellent source of cells for adoptive transfer.

The specific recognition of autologous melanomas by TIL cultures invited the exploration of the tumor antigens recognized by TIL-derived T cells. A fair number of melanoma-associated

antigens were discovered and their genes identified by the ability to stimulate melanoma TILs. These and other tumor antigens are described in Chapter 16 . TILs from melanoma patients continue to provide a rich source of reagents for tumor antigen discovery. One possibility for future research involves identification using melanoma TILs of antigens expressed not only by melanomas, but also by tumors of other histologies. The first example of such an antigen was reported by Wang et al. (88), who demonstrated that a TIL-derived, T-cell clone specific for an epitope of the NY-ESO-1 protein also recognized HLA-31[+], ESO-1[+], melanoma, and breast carcinoma cells.

The diversity of TIL-recognized tumor antigens presents an embarrassment of riches and a conundrum for adoptive transfer therapy: Which tumor antigen should be targeted? Therapeutically effective TILs from human and mouse tumors were shown to recognize shared, as well as unique, tumor antigens. Shared antigens (i.e., antigens expressed in common by multiple HLA-matched tumors) are generally derived from nonmutated genes. These are tempting targets for immunotherapy because of the logistical ease of administering a single therapeutic agent to multiple patients. Questions about the absolute strength and persistence of an immune response against an antigen from a normal "self" protein, however, remain a vexing problem for approaches that target shared antigens. In contrast, uniquely expressed tumor antigens would require herculean efforts for clinical application because each new patient requires an essentially new therapeutic agent. Uniquely expressed antigens, however, might prove beneficial by provoking a strong inflammatory response that is not muted by self tolerance.

Another critical question involves the role of CD4[+] cells in antitumor therapeutic efficacy. Many TILs administered to patients in the Surgery Branch of the National Cancer Institute exhibited a CD4[+], HLA class II–restricted recognition of autologous tumors (89). Antigens stimulating several CD4[+] TILs have been identified and their genes have been cloned. These genes include shared antigens from the tyrosinase protein (90 ,91), as well as unique antigens, such as a mutation in the triosephosphate isomerase gene (92), a mutated form of human CDC27 (93), and a novel fusion protein derived from the translocation of the LDLR and FUT genes (94). The identification of unique and shared antigens recognized by CD4[+] TILs, as well as other evidence (95), indicates that the CD4[+] T-cell response to melanoma may be as diverse as the CD8[+] response. The individual contributions of CD4[+] and CD8[+] T cells and their potential for synergy in the treatment of solid tumor deposits are actively being investigated.

A final question concerns whether TILs in humans preferentially traffic back to tumor deposits. In a large series of patients treated with indium-111–labeled TILs in the Surgery Branch of the National Cancer Institute, TIL localization and *in vivo* kinetics were analyzed (96). In these studies, TILs from responsive and nonresponsive patients showed preferential homing to tumor deposits. TIL trafficking to tumors was significantly correlated with patient objective responses. No objective responses were seen in patients who received nontrafficking TILs. Trafficking to tumor deposits was also significantly correlated with the dose of TILs administered and the prior administration of cyclophosphamide. These and additional studies in melanoma patients receiving TILs provided evidence that therapeutically effective TILs preferentially trafficked to the tumor, participated in tumor destruction, and persisted in the patient.

Summary of Preclinical Experience with Tumor-Infiltrating Lymphocytes

For immunogenic tumors, such as transplanted mouse sarcomas and human melanoma, TILs have proven to be a rich source of tumor-specific lymphocytes. Isolation of efficacious TILs from nonimmunogenic tumors was only variably successful. Culture of tumor digests in IL-2 resulted in tumor destruction and lymphocyte outgrowth with concomitant elaboration of tumor-specific T-cell functions, including lysis and cytokine secretion. Mouse TILs exhibited greatly improved specific lysis of autologous tumors when cultured under conditions of IVS to tumors. Adoptive transfer of specific TIL cells could mediate destruction of metastatic tumor deposits in the lung and liver from a variety of tumor types in mouse models. Adoptive transfer of TILs in melanoma patients was associated with objective responses (see Chapter 13). Therapeutic benefit in mouse models was directly dependent on the transferred cell number. T cells from therapeutic TILs homed to tumor deposits and persisted *in vivo.* TIL treatment was augmented by pretreatment of tumor-bearing mice with cyclophosphamide or radiation and by systemic IL-2 support.

In Vitro-Sensitized T-Cell Clones

Part of "12 - Cell Transfer Therapy: Basic Principles and Preclinical Studies "

T cells that mediate tumor destruction are crucial to the success of adoptive therapy approaches in mouse models and in the clinic. Rapid advances in tumor immunology and molecular genetics have identified a host of tumor-specific genes that potentially encode T-cell recognizable tumor antigens. The discovery of these genes and their production as synthetic peptides and recombinant proteins provides possibilities for adoptive transfer therapy. Patients could be primarily sensitized *in vivo* by antigen immunization. Then, peripheral blood lymphocytes or vaccine-draining lymph nodes could be secondarily sensitized *in vitro* with the same antigen. To improve the tumor reactivity of bulk IVS cultures, T-cell clones with the appropriate characteristics, such as antigen specificity and tumor reactivity, could be identified. Once isolated from bulk cultures, these clones could be expanded *in vitro* to therapeutic levels and finally transferred to the autologous patient. Several reasons exist to believe that cloned T cells can be highly effective for adoptive transfer. First, cloned T cells were effective in elimination of tumors in several mouse models (97 ,98). Second, the technical feasibility of growing clones for patient treatment has been proven in a clinical trial for prophylaxis of cytomegalovirus-associated disease in bone marrow transplant recipients (99). Third, the phenotype of the transferred cells can be manipulated by selecting a clone for transfer with the appropriate phenotype. Thus, the potential for transfer of cloned T cells for cancer therapy incorporates many features of previously successful adoptive transfer approaches.

The ability to select a specific T-cell phenotype for adoptive transfer led to the initiation of a clinical trial with gp100:209-217 (referred to as *g209*) peptide-specific T-cell clones for treatment

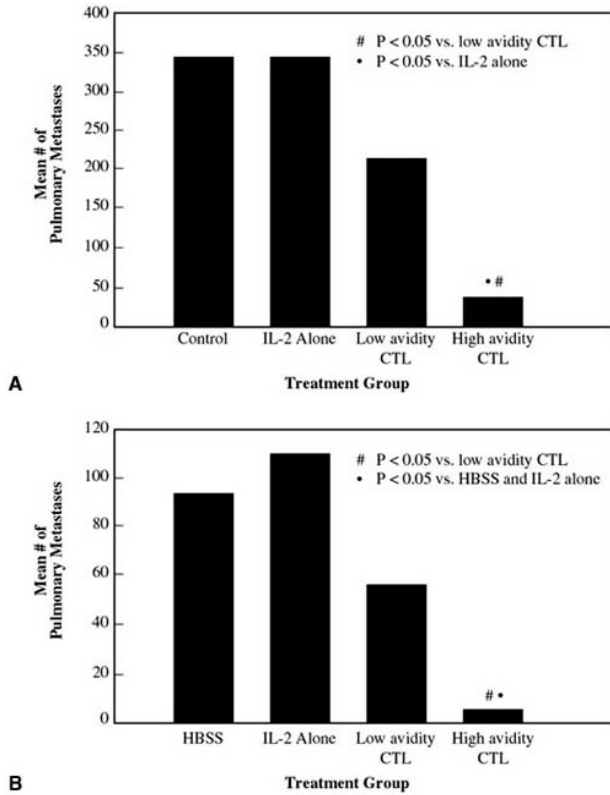
of patients with metastatic melanoma. Using defined antigens in mouse models, several reports have shown a correlation between T-cell avidity *in vitro* and efficacy on adoptive transfer *in vivo* (100 ,101 and 102). For instance, Zeh et al. (100) used different concentrations of defined peptide antigens expressed by B16 melanoma to generate CTL cultures. CTLs expanded in low concentrations of purified antigens demonstrated higher avidity for peptide-pulsed targets and better tumor recognition when compared with CTLs generated in the presence of high concentrations of antigens. More important, high-avidity CTLs demonstrated superior *in vivo* efficacy in adoptive transfer experiments (Fig. 12-10). These results suggest that selection and expansion of a clone with high avidity could generate a highly therapeutic CTL culture.


FIGURE 12-10. Treatment of day 4 pulmonary metastases of B16 melanoma by high- and low-avidity cytotoxic T lymphocyte (CTL) lines. Mice were injected intravenously with B16 melanoma on day 0 to induce pulmonary micrometastases. On day 4, 3×10^6 TRP-2-specific CTL (A) or 7×10^4 p15E-specific CTL (B) were given intravenously and interleukin-2 (IL-2) was given three times a day for 3 days. On day 14, pulmonary metastases were counted. Only the high-avidity CTLs significantly treated the tumor. (HBSS, Hank's balanced salt solution.) (From Zeh HJ III et al. High avidity CTLs for two self-antigens demonstrate superior *in vitro* and *in vivo* antitumor efficacy. *J Immunol* 1999;162:989, with permission.)

Patients who received a primary immunization with a modified 9-amino acid peptide, gp100:209-217(210M) (referred to as *209-2M*), exhibited increased frequency of g209-specific, tumor-reactive T cells (103). Tumor-reactive, g209-specific CTLs were cloned by limiting dilution. Their function was then analyzed. Individual CD8[+] clones displayed wide diversity in peptide-antigen avidity and tumor recognition (Fig. 12-11). Clones differed by more than two logs in the minimum concentration of antigens that they recognized. Clones displayed a similar variation in their ability to recognize tumor cells (104). This functional variation was mirrored at the structural level, whereas sequence analysis of T-cell receptor β chains revealed 11 different receptors from 13 clones analyzed in one patient. The analysis of functional activity of individual clones confirmed that the ability to recognize tumors is highly correlated with the recognition of the native gp100:209-217 epitope. In all patients examined, the cells that demonstrated the highest avidity for peptide antigens also exhibited the best tumor recognition. In addition, although the apparent frequency of high-avidity clones varied from patient to patient, all patients examined had at least one clone that was high avidity. Clinical evaluation of the therapeutic potential of high-avidity clones is under way.
FIGURE 12-11. Cloned T-cell lines from a patient immunized with g209-2M were tested for peptide avidity. Interferon-γ (IFN-γ) secretion (pg per mL per 10,000 cells) by individual clones in an overnight assay is plotted as a function of the concentration of g209 peptide pulsed onto the T2 stimulators. Clones differ by two orders of magnitude in the minimum peptide concentration recognized. (From Dudley ME et al. High-avidity CTLs for two self-antigens demonstrate superior *in vitro* and *in vivo* antitumor efficacy. *J Immunotherapy* 1999;22:288, with permission.)

The approach outlined above could be used with virtually any synthetic peptide or recombinant protein identified as a tumor antigen. Antigen-specific CTLs could potentially be derived from each patient after immunization. Clones with the most suitable characteristics, such as high avidity for tumor antigens, could be expanded and administered by adoptive transfer. The generation of CTLs for adoptive immunotherapy

from nonimmunized patients presents additional technical challenges. Its feasibility remains to be evaluated. CTL epitopes have been identified for a large number of tumor-encoded proteins, including her2/neu, CEA, and p53 (105 ,106 ,107 ,108 and 109). Although the therapeutic potential of each of these antigens is unproved, any of these antigens could be used for IVS of patient lymphocytes for clone isolation and adoptive transfer therapy.

Recipients of allogeneic bone marrow transplants for treatment of leukemia constitute another patient population that could benefit from clonal adoptive transfer. The evaluation of patients who have undergone allogeneic bone marrow transplants provides some of the strongest evidence that adoptive transfer can cure patients with advanced cancer. Graft-versus-host disease in these patients is a serious problem; however, patients with this condition may actually benefit from the development of concomitant graft-versus-leukemia (110). This observation led to strategies for augmenting the graft-versus-leukemia effect of allogeneic donor cells without aggravating graft-versus-host disease. One such strategy involves immunizing the marrow donor before marrow harvest. Several reports indicate that CTL immunity is transferred with marrow transplantation in mouse models (111 ,112). Another strategy involves the cloning of IVS donor lymphocytes to identify T cells that are specific for leukemia cells or purified leukemia antigens but do not react with recipient normal tissues. Tumor-specific antigens in this setting would include clonotype-specific immunoglobulins produced by some B-cell malignancies (111), the unique junction sequences of translocation fusion proteins (113), or the viral proteins produced by Epstein-Barr virus in some leukemias. Some of these potential applications for adoptive transfer therapy are presented in detail in Chapter 13 .

Summary

Part of "12 - Cell Transfer Therapy: Basic Principles and Preclinical Studies "

Transplantable tumors of mice represent an imperfect but highly useful model to elucidate the basic principles of adoptive cellular therapy. Small, recently transplanted, and highly immunogenic mouse tumors were artificially "easy" targets for immunotherapy, but were useful for testing novel technologies and poorly understood principles. Large, established, and poorly immunogenic tumors in mice were more representative of human disease and comprised a gold standard of adoptive therapy. Whether tumors were actively interfering with immune effector-cell function or passively subverting the existing host mechanisms for maintenance of self tolerance, immunosuppressive treatment of the tumor-bearing transfer recipient generally augmented adoptive cellular transfer. Similarly, administration of systemic IL-2 to tumor-bearing mice supported the transferred cells and improved therapeutic outcome.

Several effector-cell populations demonstrated therapeutic benefit in mouse adoptive transfer studies. The potent lytic activity of LAK cells *in vitro* emphasized the inherent antitumor destructive power of immune effector cells when removed from *in vivo* regulatory constraints. LAK-cell therapeutic efficacy in some preclinical models demonstrated the importance of effector-cell activation for adoptive transfer. The use of TILs extended the power of *ex vivo* lymphocyte activation to include tumor-specific cells that were primed *in vivo.* Specificity of transferred cells by *in vitro* measures correlated with their efficacy *in vivo.* Different *in vitro* effector-cell functions, including lysis, cytokine secretion, and proliferation, have been accented in different studies. *In vivo,* TILs may act through direct tumor-cell destruction or through the elaboration of inflammatory cytokines and the recruitment of host immune effectors to the tumor site. Therapeutically effective TILs from mouse tumors and human melanomas are a highly enriched source of reagents for tumor-antigen identification.

Cloned T cells represent the ultimate in antigen specificity for adoptive transfer. Cloning of tumor antigen-specific lymphocytes from mice produced monospecific cultures that were effective in adoptive transfer experiments. High-avidity cloned T cells with defined *in vitro* characteristics can be obtained from immunized cancer patients. These reactive clones can be expanded *in vitro* and evaluated in clinical trials. In addition, T-cell clones with different *in vitro* qualities need to be further evaluated in preclinical models to resolve basic questions of tumor immunology. The therapeutic value of different antigens, the role of CD4 cells in tumor immunity, and the importance of inflammation at the tumor site are a few examples of the unsettled issues that adoptive transfer experiments could address. The ability to immunize patients with synthetic tumor antigens provides the capability of extending clinical studies of adoptive transfer from melanoma to other tumor types. Preclinical and basic studies in mouse models of adoptive transfer should continue to guide clinical practice and resolve the underlying biology of tumor immunotherapy.

Cell Transfer Therapy: Clinical Applications

13.1
Melanoma

Steven A. Rosenberg

- Introduction
- Brief Historical Perspective
- Tumor-Infiltrating Lymphocytes
- Cellular Immunotherapy with Lymphokine-Activated Killer Cells
- Other Cells Used in Cell Transfer Therapy

Introduction

Part of "13.1 - Melanoma "

Cell transfer therapy (or *adoptive immunotherapy*) refers to the transfer of immune cells with antitumor activity that can mediate, directly or indirectly, antitumor effects in the tumor-bearing host. The successful application of cell transfer therapy for the treatment of patients with cancer depends on a variety of factors, including the lymphocyte subtype used for cell transfer, the presence on the tumor cell of the target antigen to which the lymphocytes are reactive, the avidity of the lymphocytes for recognition of the target antigen, the ability of lymphocytes to traffic to tumor deposits, the specific effector function of immune lymphocytes necessary for tumor destruction, and the ability of lymphocytes to overcome any suppressive or tolerizing factors that might exist in the host or at the tumor site to prevent the transferred cells from reacting with the tumor.

Most studies of cell transfer therapies in cancer have involved patients with melanoma because of the relative ease of generating immune cells directed against melanoma antigens, as well as the substantial progress made in the identification and characterization of melanoma antigens that can serve as targets for this therapy. A variety of cell types have been used for cell transfer, including tumor-infiltrating lymphocytes (TILs), peripheral lymphocytes sensitized *in vitro* to tumor antigens, and lymphocytes obtained from sites of tumor vaccinations. Cells with major histocompatibility complex (MHC)–restricted or non–MHC-restricted recognition of tumor cells have been used. Although these treatments remain experimental, antitumor effects have been seen in patients receiving the adoptive transfer of cells. These studies provide important biologic information about the functional characteristics of lymphocytes, as well as the target antigens required for tumor destruction.

Brief Historical Perspective

Part of "13.1 - Melanoma "

In the early 1960s, increasing information from immunologic studies indicated that the cellular arm of the immune response was a predominant factor in the *in vivo* rejection of tissue, such as organ allografts and experimental tumors, in mice. These findings led to attempts to transfer cells to tumor-bearing patients with the hope of mediating antitumor effects (1). Moore and Gerner developed techniques for the large-scale cultivation of human B lymphocytes and treated 28 patients with 1 to 236 g of allogeneic-cultured B cells without therapeutic benefit (2).

Many workers attempted to treat cancer patients with fresh cells immunized against cancer tissue. Nadler and Moore cross-immunized cancer patients by reciprocal subcutaneous implantation of tumor into the thigh (3 ,4). Leukocytes were then cross-transfused between the patients daily for 3 weeks. Similar cross-immunization studies were also performed by Marsh et al. (5). Feneley et al. treated patients with lymph node cells from pigs immunized with tumor (6). Cheema and Hersh treated 15 patients with injections of phytohemagglutinin-activated autologous lymphocytes directly into cutaneous cancer nodules (7), and Frenster and Rogoway described techniques for activating large numbers of human lymphocytes with phytohemagglutinin before infusion into patients (8). Although minor antitumor responses were claimed, no reproducible antitumor effects were seen. These approaches to immunotherapy were therefore largely abandoned.

The ability to grow lymphocytes *in vitro* using interleukin-2 (IL-2) and other cytokines and the ability to identify lymphocytes with unique antitumor activity opened new possibilities for the development of highly specific cell transfer therapies for the treatment of patients with cancer. These developments have renewed interest in the application of this approach.

Tumor-Infiltrating Lymphocytes

Part of "13.1 - Melanoma "

TILs are lymphoid cells that infiltrate solid tumors and can be grown from single-cell suspensions of tumors by incubation in IL-2-containing media. Interest in the use of TILs for the adoptive immunotherapy of patients with metastatic melanoma was stimulated by the study of TILs obtained from transplantable mouse tumors (9 ,10). TILs able to recognize specific tumor-associated antigens from a variety of experimental tumors could

be expanded in culture and exhibited specific killing, as well as specific cytokine secretion, when cocultivated with the syngeneic tumor (11 ,12). *In vivo* studies using the adoptive transfer of syngeneic murine TILs, often in association with cyclophosphamide administration or whole-body irradiation, demonstrated that established lung and liver metastases from a variety of murine tumor models could be successfully treated (9 ,10). In these studies, there was a correlation between the therapeutic effectiveness of TILs and the ability of TILs to specifically lyse or secrete cytokines, such as interferon (IFN)-γ, when cocultivated with syngeneic tumor (13).

These studies of murine TILs lead to attempts to derive TILs from a variety of histologic types of human cancer, including metastatic melanoma, lung cancer, breast cancer, colon cancer, renal cell cancer, and ovarian cancer (14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 and 24). TILs grown from approximately 50% of patients with melanoma exhibit specific tumor lysis or specific cytokine secretion when stimulated *in vitro* with tumor from the autologous patient (25). A variety of techniques were developed for the expansion of TILs *in vitro* to the large numbers required for the adoptive therapy of cancer patients (25 ,26 and 27). In one study, 206 melanoma biopsies were processed from a variety of metastatic sites, and attempts were made to grow TILs to therapeutic levels (25). TIL cultures were initiated from single-cell suspensions of tumors obtained by enzymatic digestion. These cultures were first grown in culture plates. Later, when sufficient numbers were reached, the cultures were grown in gas-permeable bags. Of these 206 biopsies, 124 (60%) grew to levels of more than 10^{10} cells, usually within 45 days of initiating the culture. Eighty-nine TIL cultures were grown to levels of 10^{11} cells or more. TILs could be successfully grown from tumors obtained from a variety of metastatic sites, including involved lymph nodes, lungs, muscles, intestines, and subcutaneous tissues. The cytotoxicity of 115 TIL cultures were tested. Preferential lysis of autologous tumor cells was seen in 43 cultures (25). This preferential lysis of fresh autologous tumor cells was obtained more frequently from subcutaneous tumors (50%) than tumor-involved lymph nodes (18%) (p <.05). In another study, melanoma metastases were harvested from 82 patients for the purpose of growing TILs (28). Cells were incubated in IL-2 followed by repeated exposure to tumor and, in some cases, by the use of anti-CD3 monoclonal antibody bound to plastic culture vessels. In this study, more than 10^{10} cells could be grown in 23 of 26 attempted cultures (88%).

TILs from melanoma patients recognize a wide variety of melanoma-associated antigens, including melanoma and melanocyte differentiation antigens (i.e., MART-1, gp100, tyrosinase, TRP-1, TRP-2), antigens that represent unique mutations of intracellular proteins (i.e., beta-catenin), and proteins that are expressed in a variety of cancers, as well as the testes (i.e., NY-ESO-1 antigen) (29 ,30 and 31). Antigens have been identified that are encoded not only by the primary open reading frame of the gene, but by alternative open reading frames, as well as intronic regions. A list of the class I- and class II–restricted antigens recognized by TILs is shown in Table 13.1-1 . Each of these antigens is recognized by TILs in an MHC-restricted fashion. TILs can recognize a broad array of epitopes, even within a single protein. All MART-1 reactive TILs thus far obtained from patients with melanoma recognize the MART-1:27-35 peptide, AAGIGILTV, although ten different peptides are recognized by TILs reactive with the gp100 antigen (32 ,33).

Table 13.1-1 Melanoma Antigens Recognized by Tumor-Infiltrating Lymphocytes

Name of Antigen	TILs Used for Identification	HLA Restriction	Immunodominant Epitopes	Characteristics
MART-1	1235 and others	A2	AAGIGILTV	Normal differentiation antigen
gp100	1200 and others	A2	KTWGQYWQV	Normal differentiation antigen
			ITDQVPFSV	
			YLEPGPVTA	
	1351	A3	LIYRRLMK	
	888	A24	VYFFLPDHL	Intronic sequence
Tyrosinase	1138 and 1374	A2	YMDGTMSQV	Normal differentiation antigen
	1138	A1	SSDYVIPIGTY	
	888 and 1413	A24	AFLPWHRLF	
	1088	DR4	QNILLSNAPLGPQFP	
p15	1290	A24	AYGLDFYIL	Posttranscriptional control
TRP-1	586	A31	MSLQRQFLR	Translated from alternate open reading frame

LDL-FUT	1363	DR1	WRRAPAPGA	Chromosomal rearrangement
			PVTWRRAPA	

TILs, tumor-infiltrating lymphocytes.

TILs have been identified that recognize melanoma antigens restricted by HLA-A1, HLA-A2, HLA-A3, HLA-A24, HLA-A31, B44, DR1, and DR4 (34 ,35 ,36 ,37 ,38 ,39 ,40 ,41 ,42 ,43 ,44 ,45 and 46). A study of TIL cultures grown from 123 patients with melanoma is shown in Table 13.1-2 (34). Six of 38 TILs that express HLA-A1 recognized shared antigens, including one TIL that recognized gp100, one TIL that recognized tyrosinase, and four TILs that recognized

unidentified antigens. The HLA-A2 molecule is found in approximately 50% of whites. Thirty-two of 57 TILs that expressed HLA-A2 recognized shared melanoma antigens. Twenty-two of these cultures recognized MART-1, 13 recognized gp100, two recognized tyrosinase, and two recognized unidentified antigens. Similar observations were made for TILs restricted by HLA-A3, HLA-A24, and HLA-A31 (as shown in Table 13.1-2).

Table 13.1-2 Summary of Tumor-Infiltrating Lymphocyte Recognition of Shared Melanoma Antigens

| HLA Class I Restriction Element | Number of Shared Antigen-Specific CTLs/Total TILs Expressing HLA (%) | Number of CTLs that Recognized Melanocyte Antigens | | | | | |
		MART-1	gp100	Tyrosinase	TRP-1	TRP-2	Unidentified
HLA-A1	6/38 (16)	0	1	1	0	0	4
HLA-A2	32/57 (57)	22	13	2	0	0	2
HLA-A3	2/28 (7)	0	1	0	0	0	2
HLA-A24	3/23 (13)	0	1[a]	2	0	0	1
HLA-A31	3/11 (27)	0	0	0	1[b]	1	2

CTLs, cytotoxic T lymphocytes; TILs, tumor-infiltrating lymphocytes.

[a]Peptide encoded by an intron sequence of the gp100 gene was recognized by TILs.

[b]Peptide encoded by an alternative open reading frame of the TRP-1 gene was recognized by TILs.

Clinical Effect of Transfer of Tumor-Infiltrating Lymphocytes to Patients with Metastatic Melanoma

The largest reported series of patients with melanoma treated with TILs included 86 patients with metastatic melanoma treated in the Surgery Branch at the National Cancer Institute (NCI) with TILs plus high-dose intravenous bolus IL-2 at 720,000 IU per kg every 8 hours (47). Two treatment cycles were administered approximately 2 weeks apart. Fifty-seven of the 86 patients received a single intravenous dose of 25 mg per kg cyclophosphamide before the infusion of TILs plus IL-2 based on data from animal models indicating that immunosuppression before adoptive transfer could improve the immunotherapeutic effect (48 ,49 and 50). The characteristics of the patients in this trial, as well as the characteristics of the adoptively transferred TILs, are shown in Table 13.1-3 . In this study, the overall objective clinical response rate was 34% and was similar in patients receiving TILs and IL-2 alone (31%) or in conjunction with cyclophosphamide (35%) (Table 13.1-4 and Table 13.1-5). The objective response rate was similar in patients who received prior treatment with high-dose IL-2 (32%) compared with patients not previously treated with IL-2 (34%). This overall response rate of 34% was approximately twice the response rate seen in 134 consecutive melanoma patients treated using the same regimen of high-dose IL-2 alone, although the duration of responses was often short (51).

Table 13.1-3 Treatment with Tils Plus Interleukin-2

Patient Characteristics	No. (%)		TIL Characteristics		Total (%)	
Total	86		Days of growth	11-20	1	(1)
Sex:				21-30	17	(20)

A collaborative study from multiple institutions of 21 patients with metastatic melanoma who received adoptive transfer of TILs plus IL-2 was published by the National Biotherapy Study Group (28). TILs were grown in IL-2 followed by repeated exposure to tumor antigen and, sometimes, with stimulation by immobilized anti-OKT3 monoclonal antibody. Patients received 1 g per m² of cyclophosphamide and 36 hours later began a constant infusion of 18 × 10⁶ IU per kg of IL-2 daily for 4 days. Four hours after initiation of IL-2, TIL cells were infused. Some patients with stable or responding disease were retreated at 3- to 4-week intervals. Objective responses were seen in 24% of patients. Two of ten patients who had previously failed treatment with IL-2 exhibited a response compared with 3 of 11 patients who had not previously received IL-2.

Kradin et al. reported the treatment of 13 patients with melanoma treated by TILs in conjunction with relatively low doses of IL-2 administered by constant infusion (1 to 3 × 10⁶ IU per kg for 24 hours) (52). Objective responses were seen in three patients. The doses of IL-2 used in this trial would not be expected to mediate antitumor responses when administered alone. In a study by Arienti et al., 12 evaluable patients with metastatic melanoma were treated by the adoptive transfer of TILs followed by the administration of IL-2 by continuous infusion at 12 × 10⁶ IU per kg for 5 days (53). In this study, patients also received 3 × 10⁶ IU of IFN-α as an intramuscular injection for 3 consecutive days and a single intravenous injection of 350 mg per m² of cyclophosphamide 1 day before TIL administration. Four of these 12 evaluable patients exhibited an objective response to treatment. Similarly, Queirolo et al. saw two complete responses in 19 melanoma patients treated with TILs plus IL-2 and IFN-α (54). The small number of patients in these trials makes it difficult to determine whether the antitumor effects were attributable to the TILs or to the administration of IL-2 and IFN-α.

Although one large study suggested that the response rates of patients with metastatic melanoma receiving the adoptive transfer of TIL cells plus IL-2 is twice that of patients treated with IL-2 alone (47), a prospective randomized trial in which patients with metastatic melanoma receive TIL cells plus IL-2 or the identical regimen of IL-2 alone is required to determine the clinical effectiveness of TILs. Several other factors, however, suggest that TIL cells played a therapeutic role in these patients. In the NCI Surgery Branch study (47) and the National Biotherapy Study Group trial (28), similar response rates were seen after treatment with TIL cells plus IL-2, regardless of whether patients had previously failed treatment with IL-2. This result is in contrast to reports that repeat treatments with IL-2 alone could not mediate therapeutic responses, even in patients who previously responded to IL-2 and then recurred (55 ,56). Thus, the responses to TILs plus IL-2 in patients who previously did not respond to IL-2

strongly suggest that TILs were a factor in the beneficial response. Furthermore, several characteristics of TILs strongly correlate with their ability to manifest therapeutic responses. The specific reactivity of TILs, the reactivity of TILs against particular antigens, and the ability of TILs to traffic to tumor sites are correlated with clinical response. Although it is possible that patients who give rise to TILs with these characteristics are patients more likely to respond to IL-2 alone, it appears more likely that TILs play a direct role in the antitumor responses. Definite resolution of this question must await prospective randomized trials.

Characteristics of Tumor-Infiltrating Lymphocytes Associated with Antitumor Responses in Patients

In a detailed study of melanoma patients who underwent treatment with TILs and IL-2, multiple patient and treatment characteristics were evaluated for correlation with clinical response (Table 13.1-6 and Table 13.1-7) (47 ,56). TIL characteristics, such as doubling time, cell surface phenotype, autologous tumor lysis, and cytokine secretion after autologous tumor stimulation, were assayed within 7 days of infusion. A statistically significant increase in clinical response was seen when TILs were obtained from subcutaneous sites compared with TILs obtained from lymph nodes (p_2 = .006). TILs that were cultured for a shorter duration and TILs with shorter doubling times also were associated with higher responses (p_2= .0001 and .03, respectively). A significant increase in clinical response was seen for TILs able to lyse autologous tumor cells (p_2 =.0008). In another study, clinical response was associated with the ability of TILs to secrete cytokines (especially granulocyte-macrophage colony-stimulating factor) when cocultivated with autologous tumor cells (p = .04) (57). The correlation of clinical response with the ability of TILs to specifically recognize tumors was a major factor that stimulated attempts to clone individual TIL populations with high levels of antitumor reactivity for use in cell transfer therapies.

The molecular identification of antigens recognized by transferred TILs has enabled an analysis of the specific reactivity of TILs against known antigens and their correlation with clinical response (34). Twenty-one HLA-A2 patients were treated with TIL cells that recognized shared melanoma antigens. Twelve of these TILs recognized the gp100 antigen, 16 recognized the MART-1 antigen, and two recognized the tyrosinase antigen. Nine TIL populations recognized gp100 and MART-1. A significant correlation existed between gp100 recognition by TILs and objective tumor regression after the adoptive transfer of TILs plus IL-2 (p = .024). No correlation of clinical responsiveness existed with recognition by TILs of the MART-1 antigen (p = .61).

Traffic of Adoptively Transferred Tumor-Infiltrating Lymphocytes to Tumor Sites

Although the mechanism of action of TILs in mediating antitumor effects is not known, it is hypothesized that adoptively transferred TILs traffic to tumor sites and, on encountering

tumor antigens, directly lyse tumor cells or secrete cytokines, or both, which can amplify local antitumor immune responses. Studies to determine whether transferred TILs can traffic to sites of tumors have used TILs radiolabeled with indium-111-oxine (58, 59 and 60). In a study of 38 patients with metastatic melanoma receiving high-dose IL-2 and TILs labeled with indium-111, significant localization of TILs to metastatic tumor deposits was seen in 26 of 38 patients (68%), as measured by gamma camera imaging or biopsies of tumors and normal tissue (60) (Table 13.1-8 and Fig. 13.1-1). In a univariate analysis of factors influencing TIL traffic, administration of cyclophosphamide (25 mg per kg) 24 to 36 hours before TIL infusion was significantly associated with the ability to localize to tumors. Twenty-one of 26 (80.8%) treatment courses given with cyclophosphamide demonstrated tumor localization compared with 5 of 12 (41.7%) treatment courses given without cyclophosphamide (p_2 = .026). Biopsy of cutaneous tumors, as well as nearby normal skin, showed a significantly greater accumulation of indium-111-labeled TILs at tumor sites (p_2 >.001) (Fig. 13.1-2). Clinical response was also correlated with localization of TILs to sites of tumors (60) (Table 13.1-9). Ten of twenty-six (38.5%) patients who exhibited tumor localization by radionuclide scans had an objective clinical response, whereas no responses were noted in 12 patients whose tumors did not image (p_2 = .022). It thus appears that the traffic of TILs to tumor deposits is an important part of the mechanism involved in the antitumor response of TILs in melanoma patients.
FIGURE 13.1-1. Nuclear scan of a patient infused with indium-111-labeled tumor-infiltrating lymphocytes. Areas of tumor show enhanced uptake of labeled cells.

FIGURE 13.1-2. Results of sequential biopsies of patients receiving indium-111-labeled tumor-infiltrating lymphocytes. An increased accumulation of tumor-infiltrating lymphocytes with time was found in tumor deposits, but not in normal tissue.

Table 13.1-8 Factors Influencing Indium-111-Labeled Tumor-Infiltrating Lymphocyte Localization to Tumor

The short half-life of indium-111 (2.8 days) and the spontaneous loss of indium-111 from lymphocytes made it difficult to determine the long-term survival of TIL cells. Adoptive transfer studies of T cells in patients with acquired immunodeficiency syndrome suggested that the limited survival of transferred lymphocytes was a result of rapid apoptosis of the infused cells (61). Other studies in recipients of allogeneic bone marrow transfer who received T-cell clones directed against cytomegalovirus suggested that CD4+ cells were important for maintaining the prolonged survival of transferred CD8+ cells that recognized the same antigen (62). Similar data have been obtained in animal models, indicating the importance of CD4+ cells for the survival of CD8+ cells (63). Other factors, such as the expression of L-selectin on the T-cell surface, may impact on the traffic and survival of these cells (64).

To study the long-term survival of T cells after adoptive transfer, ten patients with metastatic melanoma received autologous TIL cells retrovirally transduced with the gene for neomycin phosphotransferase (65). Polymerase chain reaction assays demonstrated that the transferred TILs persisted in the circulation

of patients for 3 weeks and, in some cases, for as long as 2 months, although only a small fraction of the infused cells could be detected. Cells bearing the neomycin phosphotransferase gene could also be recovered from tumor deposits. The unique rearranged sequences of the T-cell receptor can also be used to follow the survival of transferred cloned lymphocytes (62).

Cellular Immunotherapy with Lymphokine-Activated Killer Cells

Part of "13.1 - Melanoma "

Lymphokine-activated killer (LAK) cells are lymphocytes that develop the ability to lyse fresh tumors but not fresh normal cells after the incubation of lymphocytes in the lymphokine cells (66). In animal models, the adoptive transfer of LAK cells plus IL-2 was capable of mediating the regression of established micrometastases (67 ,68). Mechanistic studies indicated that the LAK cells could expand *in vivo* under the influence of IL-2 administration and maintain their antitumor activity (69).

Because IL-2 was available only in tiny amounts in the 1980s, studies began with the adoptive transfer of phytohemagglutinin-activated killer cells, a cell type quite similar to LAK cells (70). The adoptive transfer of these phytohemagglutinin-activated cells alone or in combination with cyclophosphamide or activated macrophages was performed in 21 patients between 1981 and 1983 (71). When recombinant IL-2 became available, a clinical trial was performed at the NCI Surgery Branch for patients with advanced cancer using the combined administration of LAK cells and IL-2. Published in 1985, this study provided evidence that adoptive immunotherapy with LAK cells and IL-2 could mediate antitumor effects (72 ,73). These clinical trials used a preinfusion of IL-2 for 3 to 5 days, which resulted in profound lymphocytosis when IL-2 administration ceased. Repeated leukophereses were performed during this period of lymphocytosis to increase the yield of lymphocytes. These harvested lymphocytes were then cultured in the presence of IL-2 for 3 to 4 days to produce LAK cells, which were then reinfused along with the administration of IL-2. In these studies, patients received IL-2 by intravenous bolus infusion every 8 hours, usually at a dose of 720,000 U per kg. In early trials, patients with renal cell cancer and melanoma showed the most significant anticancer responses, and, thus, patients with these diagnoses accounted for the majority of patients treated. The patients entering these trials had advanced cancer that did not respond to standard effective therapy, no treatment other than this protocol for 30 days before or throughout the follow-up period, evaluable disease, and life expectancies longer than 3 months.

After the initial reports of tumor regressions using LAK cells and IL-2 by the NCI Surgery Branch, other groups began clinical studies using LAK cells (Table 13.1-10). In these studies, responses were reported in patients with lymphoma, ovarian cancer, and lung cancer, although few patients with these histologies were treated.

As experience with the use of high-dose IL-2 evolved, significant responses were seen in cancer patients treated with high-dose IL-2 alone. To evaluate the role of LAK cells in antitumor responses, the Surgery Branch at the NCI conducted a prospective trial in 181 patients with advanced cancer randomized to receive LAK cells and IL-2 or IL-2 alone (74). The results of this trial were reported in 1993 with a median follow-up of 63.2 months. A trend toward improved survival was seen for patients with melanoma who received IL-2 plus LAK cells, compared with those who received IL-2 alone (24-month survival: 32% vs. 15%; 48-month survival: 18% vs. 4%; p_2 = .064). No difference in survival was seen in patients with renal cell cancer in the two treatment groups (p_2 = .52). Because of the suggestion that treatment with LAK cells and IL-2 improved survival in patients with metastatic melanoma, a second randomized clinical trial was initiated in the Surgery Branch at the NCI among 128 patients with melanoma comparing treatment with LAK cells and IL-2 or IL-2 alone. This trial did not reveal a difference in survival between the two treatment groups. Thus, systemic treatment with LAK cells is no longer recommended.

Clinical studies did not demonstrate that LAK cells traffic to tumor deposits. Therefore, attempts were made to administer LAK-cell therapy locally to increase the concentration of tumor-reactive cells at the tumor site (75, 76, 77, 78, 79 and 80). LAK cells were instilled

at the site of brain tumors by directly injecting the LAK cells into a tumor cavity after resection of recurrent disease. Jacobs et al. (75) treated 15 patients with recurrent glioblastoma by injecting LAK cells and IL-2 directly into the brain tissue surrounding the resection site intraoperatively. Others have instilled LAK cells and IL-2 through an Ommaya reservoir inserted intraoperatively or by using a plasma clot containing LAK cells placed into a resected tumor bed (76 ,77 ,78 and 79). Nitta et al. (80) reported tumor regression after the direct injection of LAK cells plus bispecific (anti-CD3-antiglioma) antibody into the tumor site after "debulking" surgery. In most of these studies, no measurable tumor was present at the time of treatment. Indications of successful therapy could be obtained only by following the survival of treated patients. It is difficult to interpret these studies because no randomized studies of patients receiving and not receiving LAK cells after resection of brain tumors have been performed.

Others have instilled LAK cells or IL-2 directly into a body cavity, such as the peritoneal or pleural space (81 ,82 ,83 and 84). Steis et al. (83) reported objective responses in patients with peritoneal carcinomatosis from ovarian and colorectal cancer who were treated with LAK cells and IL-2 administered intraperitoneally. Yasumoto et al. (85) reported the administration of LAK cells and IL-2 into the pleural cavity of patients with malignant pleural effusion. The intrathecal administration of IL-2 and LAK cells for the treatment of patients with leptomeningeal carcinomatosis has also been reported (86).

In an attempt to improve the traffic of LAK cells to tumor deposits, LAK cells have been infused directly into the hepatic artery of patients with liver metastases or introduced into the isolation-perfusion extracorporeal circulation of patients with intransit metastases from melanoma (87 ,88 ,89 and 90). Although these studies suggest that higher response rates are obtained, direct comparative studies using conventional modes of administration are required before conclusions can be drawn.

Other Cells Used in Cell Transfer Therapy

Part of "13.1 - Melanoma "

The TIL populations used for cell transfer therapy were heterogeneous populations grown from the lymphocytes infiltrating into tumor deposits, many of which may have been bystander cells with no reactivity against tumors. Attempts to transfer improved populations of cells with increased antitumor activity have used a variety of *in vitro* and *in vivo* techniques. Sporn et al. treated 14 patients with metastatic melanoma using autologous peripheral blood lymphocytes that had been cocultured with irradiated autologous tumor cells for 1 week followed by expansion in IL-2–containing medium (91). These lymphocytes were then infused into patients followed by the administration of IL-2 at relatively low doses (2×10^6 IU per kg per day). Patients received a single dose of 300 mg per m^2 of cyclophosphamide 4 days before each treatment. In this protocol, approximately 10^9 cells were given per treatment and from one to five cell infusions were given to patients. The infused lymphocytes exhibited some degree of specificity for the autologous target cell in only 2 of the 14 patients. No significant therapeutic responses were seen in this trial.

Chang et al. attempted to increase the effectiveness of adoptively transferred cells by obtaining lymphocytes from lymph node draining sites of vaccination (92 ,93). These studies were based on preclinical studies in mice showing that immune T cells from lymph nodes primed by *in vivo* vaccination could be successfully used for the immunotherapy of transplantable tumors (94). In this study, irradiated autologous tumor cells mixed with bacillus Calmette-Guérin were used to vaccinate patients. Seven days later, draining lymph nodes were removed, activated with anti-CD3 monoclonal antibody, and expanded in IL-2. Eleven patients were treated with a mean of 3.4×10^{10} expanded lymphocytes and the bolus administration of IL-2 at 360,000 IU per kg every 8 hours for up to 5 days. Three of these melanoma patients developed delayed-type hypersensitivity skin tests to autologous tumor. One of the 11 melanoma patients had an objective tumor response.

Techniques for the effective immunization of patients using immunodominant peptides from tumor antigens have improved the prospects for isolating cells with specific antitumor reactivity. After immunization of melanoma patients with the modified gp100 peptide [gp100:209-217(210M)], more than 80% of patients developed circulating peripheral blood lymphocytes capable of reacting with unique melanoma antigens (95). Techniques for cloning these cells have been developed (96 ,97), and more than 1,000-fold differences in the affinity of these cells for tumor antigens were seen when individual clones were examined (98). In addition, techniques for the isolation of specifically reactive cells using peptide-MHC tetramers have enabled the rapid identification and isolation of lymphocytes with high levels of antitumor activity (99 ,100 and 101) that can potentially be used for cell transfer. This represents an exciting area for the future development of cell transfer therapies. The T-cell receptors from antitumor immune cells have been characterized and successfully transferred into OKT-3-stimulated human lymphocytes (102). These lymphocytes then exhibit the antitumor activity conveyed by the retrovirally transduced T-cell receptors and represent cells suitable for therapy.

Introduction

Part of "13.2 - Renal Cell Carcinoma "

Adoptive immunotherapy has evolved with improved understanding of tumor biology, as well as the rapid growth in genetic engineering. This mode of treatment involves the transfer of soluble messengers and cytolytic cells that stimulate the host immune system toward tumor cells. The activation of the immune system leads to tumor regression by direct antitumor effects or by an indirect cytokine-mediated pathway that ends in tumor destruction (1). Most methods use four distinct forms of cellular immunotherapy: lymphokine-activated killer (LAK) cells, autolymphocyte therapy (ALT), tumor-infiltrating lymphocytes (TILs), and dendritic cell (DC)-based therapy.

The basis of cellular immunotherapy began with mice models immunized with chemically induced tumors, which prevented the growth of transplanted tumors (2). The mechanism for this process involves T lymphocytes, which have been shown to cause the rejection of not only virally or chemically induced tumors in murine mice (3), but also allogeneic tumors in normal mice (4). T lymphocytes have also been implicated in the antitumor activity seen with cytokine therapy (5,6). These findings have also led to the notion that suppressive factors are present around the tumor, preventing an effective immune response (7). Adoptive immunotherapy has overcome this problem by infusing the host with cells capable of mediating tumor regression. These cells have the capability to cause tumor regression by cytokine-mediated mechanisms (i.e., using host cells to destroy tumor cells) or by direct antitumor effects.

Another major advancement in adoptive cellular immunotherapy has been the discovery of interleukin-2 (IL-2) (discussed in Chapter 2), which has shown enhanced therapeutic effect when administered in conjunction with cellular therapy (8,9). IL-2 has not only allowed the expansion of *in vitro* lymphocytes, but has also been shown to cause *in vivo* proliferation and prolonged survival of cells used in adoptive immunotherapy (10). Thus, IL-2 is routinely administered with some form of cellular therapy.

Difficulties with adoptive cellular therapy in humans include the identification of specific cells that have antitumor effects

and the generation of these cells in numbers large enough for clinical use. Over the years, however, more information on specific cellular immunology and biotechnology has evolved, opening the avenue for application of cellular therapy for renal cell carcinoma (RCC) in the clinical setting.

Lymphokine-Activated Killer Cells

Part of "13.2 - Renal Cell Carcinoma "

One of the first cell types to be implemented for adoptive immunotherapy were LAK cells. LAK cells were described in the 1970s by Rosenberg et al., who were investigating lymphoid cells capable of lysing neoplastic cells at the National Cancer Institute (NCI) (11). LAK cells appear to be part of the primitive immunosurveillance system and are capable of recognizing and destroying altered cells (12). LAK cells cause a nonspecific natural killer–like cytotoxicity in contrast to cytotoxic T lymphocytes because LAK-cell activity is major histocompatibility complex (MHC)–nonrestricted and causes lysing of tumor target cells derived from syngeneic, allogeneic, or xenogeneic sources regardless of target expression of MHC antigens (13).

The distinct characteristic of LAK-cell activity is the ability to differentiate tumor cells and normal cells. The characteristics and mechanisms of LAK-cell effects have been described in another chapter, as have preclinical studies. Preclinical studies using LAK cells and IL-2 demonstrated that this form of adoptive cellular therapy was capable of mediating tumor regression of micrometastases. Preclinical studies also demonstrated that both treatments provided better antitumor effects than either therapy alone (14 ,15 ,16 and 17). In addition, these studies exhibited the effect of IL-2 on LAK cells by causing *in vivo* expansion and proliferation of LAK cells and the death of LAK cells when IL-2 was discontinued (18). Further studies also showed that LAK cells were effective in the treatment of immunogenic and nonimmunogenic murine tumors (19). These animal studies led to the first clinical use of LAK cells and recombinant IL-2 in six patients and proved cell transfer to be feasible with only a few side effects (20).

The feasibility of LAK cells and IL-2 led to a clinical trial at the NCI in patients with advanced cancer (21). Of the 25 patients, 11 had an objective tumor response (1 complete response and 10 partial responses). These responses were seen in metastatic disease to the lung, liver, and subcutaneous tissues in patients with RCC, melanoma, lung adenocarcinoma, or colorectal carcinoma who did not respond to standard therapy. On follow-up, it was noted that patients with RCC and melanoma had the most significant tumor response and accounted for the majority of patients receiving this treatment (22 ,23). Of the 178 patients, 72 had metastatic kidney cancer. Complete regression of metastases was seen in eight patients, as well as a partial regression in 17 patients, with a combined response of 35%.

LAK cells are generated by initially treating patients with IL-2 to induce lymphopenia, followed by rebound lymphocytosis 2 to 3 days after infusion of high-dose (23) and low-dose IL-2(24). Leukopheresis is then performed at the peak of the rebound lymphocytosis. Peripheral blood mononuclear cells (PBMCs) are then isolated. The cells are cultured *in vitro* using high concentrations of IL-2 (400 to 1,000 IU per mL) to generate approximately 10^{10} to 10^{11} LAK cells and are then infused into the patient together with high- or low-dose IL-2. The high-dose IL-2 is administered by intravenous bolus infusion every 8 hours for 4 to 5 days, whereas the low-dose IL-2 is administered by continuous intravenous infusion over 4 or more days. Most of the side effects of concomitant therapy with LAK cells plus IL-2 were from toxicities related to the dose of IL-2. The optimal dose and schedule of IL-2 administration with LAK cells are not clearly defined. Studies have found less clinical toxicity with lower-dose continuous intravenous IL-2 infusion regimens when compared with bolus IL-2 infusions (25). In addition, schedules using continuous infusion of IL-2 also showed an improved response rate (26). A randomized phase 2 trial by the NCI Extramural IL-2/LAK Working Group, however, found equivalent anticancer activity and toxicity when using high-dose IL-2 as a bolus or continuous infusion in the treatment of patients with metatastic RCC (mRCC) (27). Gold et al. (28) have also shown that continuous infusion of IL-2 is associated with less toxicity than high-dose bolus IL-2.

The favorable results reported by early NCI studies led to a number of subsequent clinical studies at various institutions using LAK cells plus IL-2 for the treatment of mRCC. These trials used a variety of preparative and treatment regimens with response rates ranging from 9% to 35% and a combined objective response rate of approximately 22%. A list of studies is shown in Table 13.2-1 (22 ,26 ,27 ,28 ,29 ,30 ,31 ,32 ,33 ,34 ,35 ,36 ,37 ,38 ,39 ,40 and 41 ,44). Randomized trials have also been conducted to determine whether adoptive cellular therapy with LAK cells plus IL-2 could improve the clinical response rather than the use of IL-2 alone. In one study by investigators from the Modified Group C Program, a total of 167 patients from 13 institutions, including 69 patients with mRCC, were enrolled (42). The response rates for the treatment of mRCC with LAK cells and IL-2 and IL-2 alone were 13% and 8%, respectively. These results suggested that LAK cells did not contribute to higher response rates than IL-2 alone. The Surgery Branch at the NCI conducted another prospective randomized study. In this study, 181 patients with advanced cancer were randomized, including 97 patients with mRCC, to receive LAK cells plus IL-2 or IL-2 alone. The results for the 46 assessable patients with mRCC showed complete response in eight patients and a partial response in seven patients who received LAK cells plus IL-2. For the patients who received IL-2 alone, only four complete responses and six partial responses occurred. The overall response rate was 33% for LAK cells plus IL-2 versus 24% for IL-2 alone, showing no statistical difference between the two therapies. Moreover, no statistically significant difference was seen in survival at 48 months; 29% for LAK cells plus IL-2 versus 25% for IL-2 alone (*p* = .52) (23). Similarly, in Bajorin and colleagues' trial of 49 patients randomized to receive IL-2 with or without LAK cells reinfused on days 13 through 15, no significant difference was found (43). Two responses occurred (one complete response and one partial response) in 21 patients randomized to receive IL-2 plus LAK cells. Three responses occurred (one complete response and two partial responses) in 28 patients who received IL-2 alone. Results from a study by Law et al. (44) involved 71 randomized patients with advanced RCC; 36 patients received IL-2 alone and 35 patients received LAK cells plus IL-2. Of the 66 eligible patients, objective responses (complete responses and partial responses) were seen in 9% and 3% of patients receiving IL-2 alone and

LAK cells plus IL-2, respectively. No significant differences were found in the overall median survival for the two groups (IL-2-alone arm, 11 months; LAK-cell-arm, 13 months; p = .47). Gold et al. reported results that confirmed these findings. Although not randomized, this report included 123 patients with mRCC who received recombinant IL-2 and 76 patients who received LAK cells. In the patients who were treated with LAK cells plus IL-2, the overall response rate was 22% with six complete responses (8%) and 11 partial responses (14%). The overall survival at 5 and 9 years was 19% and 17%, respectively, with a median survival of 22 months (range, 1.5 to 109+ months). Comparing these results with those of the patients treated with IL-2 alone, the overall response rate was 13% (three complete responses and partial responses). The overall survival rate was 28% at 4 years with a median survival of 14 months (range, 1 to 49+ months). Although the influence of each study on its own is not convincing, the overall data available strongly suggest that the combination of LAK cells plus IL-2 does not offer any significant advantage over IL-2 therapy alone in the treatment of mRCC.

Table 13.2-1 Studies and Response Results Using Lymphokine-Activated Killer Cells and Cytokine Immunotherapy for the Treatment of Metastatic Renal Cell Carcinoma

Source	No. of Patients	No. of CRs	No. of PRs	No. of Overall Responses (CR + PR) (%)
Schoof et al. (26)	10	1	4	5 (50)
Rosenberg et al. (22)	54	7	10	17 (54)
Weiss et al. (27)[a]	48	2	5	7 (15)
Thompson et al. (29)	42	4	10	14 (33)
Margolian et al. (30)	35	2	3	5 (16)
West et al. (31)	6	—	3	3 (50)
	12	2	2	4 (33)
Paciucci et al. (32)	9	—	1	1 (11)
Negrier et al. (33)	51	5	9	14 (27)
Stahl et al. (34)	14	—	3	3 (21)
Davis et al. (35)	31	3	11	14 (39)
Fujioka et al. (36)	10	1	3	4 (40)
Palmer et al. (37)	102	5	12	17 (18)
Parkinson et al. (38)	47	2	2	4 (9)
Gold et al. (28)	76	6	11	17 (22)
Foon et al. (39)	23	2	4	6 (17)
Kruit et al. (40)[b]	51	6	13	19 (37)
	17	3	2	4 (24)
Law et al. (44)	32	1	3[c]	4 (13)
Tomita et al. (41)	9	3	4[d]	7 (78)
Total	679	55	114	169 (25)

CR, complete response; PR, partial response.

[a]From the IL-2/LAK Working Group: IL-2/LAK Working Group included six institutions: City of Hope, CA; Albert Einstein College of Medicine of Yeshiva University, NY; Loyola University of Chicago Stritch School of Medicine, Chicago; New England Medical Center, Boston; University of California, San Francisco School of Medicine; and University of Texas Medical School at San Antonio.

[b]Results of two protocols. Protocol 1 involved 17 patients treated with interleukin-2 and lymphokine-activated killer cells. Protocol 2 involved 51 patients treated with interleukin-2, interferon-α, and lymphokine-activated killer cells.

[c]These are the patients with minor responses. No partial responses were seen.

[d]Includes one patient with minor response.

Autolymphocyte Cellular Therapy

Part of "13.2 - Renal Cell Carcinoma "

ALT is a form of adoptive immunotherapy based on the activation and expansion of autologous memory T cells in patients with metastatic cancer. The memory T cells are presumed to have been exposed to tumor antigens and thus may have the potential for mediating tumor regression after nonspecific activation (45). Memory T cells are activated *ex vivo* by mitogenic monoclonal antibody directed against the invariant region of the CD3 component of the T-cell antigen receptor in a combination of autologous cytokines, resulting in polyclonal activation of heterogeneous memory T cells (46 ,47).

The preparation of autolymphocytes for immunotherapy involves two steps (48). The first step involves the preparation of an autologous cytokine mixture by harvesting approximately 2×10^9 PBMCs by pheresis from patients. These cells are then exposed to anti-CD3 monoclonal antibody and incubated for 3 days. Supernatant fluid is then collected and frozen. The supernatant is important because it contains a variety of cytokines, including a number of ILs, tumor necrosis factors (TNFs), interferon (IFN)-γ, and granulocyte-macrophage colony-stimulating factor (GM-CSF). The second step consists of *ex vivo* activation of the memory T cells 2 weeks after initial pheresis. Patients undergo another pheresis to collect PBMCs that contain the memory T cells for activation. The cells are incubated for 5 days in media containing 25% supernatant, indomethacin, and cimetidine, then irradiated. Indomethacin, cimetidine, and radiation are used to decrease the suppressor T-cell activity (49 ,50 and 51). The activated T cells are then infused back into the patients

with oral cimetidine on a monthly outpatient basis over 6 months.

The initial clinical use of ALT in the treatment of mRCC has proved this form of adoptive cellular therapy to be safe and feasible (52 ,53). In a phase 2 trial for treatment of mRCC using ALT and cimetidine, Krane et al. (54) showed a delayed progression of disease in 33% of the patients. The median survival was 32 months, with a survival estimate of 56% and 36% at 1 and 2 years, respectively. These early results have prompted a multicenter phase 3 trial comparing ALT plus cimetidine with cimetidine alone in patients with mRCC (55). Initial results from this trial reported a 2.5-fold survival advantage for the ALT group (21 months vs. 8.5 months). Updated results showed a median survival of 29% at 46 months for the patients who received ALT. This phase 3 trial also revealed some interesting findings in the patients treated with ALT. First, a fourfold survival advantage was seen only in men, whereas women showed no advantage. This survival advantage was seen only in patients with anti-CD3–activated supernatant containing high levels of IL-1. Secondly, a lack of correlation existed between response (21%) and survival, and these were only partial responses. The results from these clinical trials initiated the use of ALT in the clinical practice setting at three sites: Boston; Orange, California; and Atlanta (56 ,57). The results from 335 patients with mRCC treated with ALT and cimetidine continued to show a survival advantage.
