A randomized trial conducted with only 45 patients compared ALT with observation for the adjuvant treatment of RCC (58). A significant difference was found in favor of ALT versus observation for the overall median time to progression of disease. In addition, further subgroup analysis revealed an advantage in median time to recurrence of disease in patients with stage T3 and node-positive disease (59). Updated results from this trial continued to show a delay in progression of disease in the ALT group (18.5 months) compared with the observation group (11.9 months) (60). Even with these results, no randomized trial comparing ALT with high-dose IL-2 therapy has been implemented to validate the feasibility of ALT to improve survival in patients with mRCC.

Tumor-Infiltrating Lymphocytes

Part of "13.2 - Renal Cell Carcinoma "

The continued interest in adoptive cellular immunotherapy led to the evaluation of more potent lymphoid cells, designated *tumor-infiltrating lymphocytes*, for the treatment of mRCC. The biologic principles and preclinical aspects of TILs have been discussed earlier. Human RCC possesses a high number of TILs that can be cultured *ex vivo* from surgically resected tumors (61). The preparation of TILs involves the digestion of the tumor specimen mechanically and enzymatically to grow a single-cell suspension. After several weeks in culture, the tumor cells died, leaving a culture of pure lymphocytes, predominantly T lymphocytes (10 ,62 ,63). TILs can be selectively grown in single-cell tumor suspensions when cultured with IL-2. These activated TIL cells proliferate and induce the destruction of RCC tumor cells, resulting in a pure culture of TILs (63).

In preclinical studies, murine tumor models with pulmonary and liver micrometastasis tumors exhibited from 50- to 100-fold greater effectiveness of TILs when compared with LAK cells (64). TILs and LAK cells also differ in their *in vitro* tumor-lytic specificity. LAK cells react nonspecifically to a broad spectrum of tumors. In contrast, TILs display tumor-specific reactivity to distinct murine tumors (62,64,65). Numerous TIL cultures have been successfully established from different human tumors, including RCC, melanoma, colon and breast cancer, lymphoma, and other tumor types. These TIL cultures have shown *in vitro* antitumor reactivity (11,63,66). Most of the bulk TILs contain a heterogeneous population of cells, consisting of $CD3^+CD8^+$ cytotoxic/suppressor T cells, $CD3^+CD4^+$ helper/inducer T cells, and natural killer cells (67). The subset of TILs responsible for tumor lysis is debatable, but all subsets have been active against RCC in *in vitro* studies (68). Several studies have determined that $CD8^+$ TILs possess most of the antitumor effect, and studies have shown the same for RCC (69 ,70 and 71), demonstrating that antigen-specific cytotoxicity against autologous tumors does exist within RCC tumors.

The preparation of TILs for adoptive cellular immunotherapy is conducted in a sterile fashion (72). The primary tumor from patients' radical nephrectomy specimens are mechanically and enzymatically disrupted to obtain single-cell suspensions containing viable mononuclear and tumor cells. The cells are expanded *ex vivo* in the presence of IL-2. After approximately 2 weeks in culture, the tumor cells die, and the TIL cells continue to proliferate and overgrow. After 3 to 5 weeks in culture, the initial 10^8 to 10^9 mononuclear cells proliferate and expand to approximately 10^{10} to 10^{11} TIL cells. During this time, the patients have recovered from their surgery, and the TILs can be infused into patients together with IL-2.

Treatment of mRCC with TILs is still in its early stages. Only a limited number of patients are receiving this therapy. Table 13.2-2 summarizes some of the clinical studies using TILs in mRCC (73 ,74 ,75 ,76 ,77 ,78 and 79). The two largest studies were conducted at the Cleveland Clinic and the University of California at Los Angeles (UCLA). At the Cleveland Clinic, patients were treated according to two types of clinical protocols. The first protocol involved 18 patients and the second protocol involved 16 patients. In the first protocol, TILs were obtained from the primary tumor or metastatic sites and infused into the patients using three different IL-2 doses (0.0, 3.0, and 4.5×10^6 U per m^2). The second protocol involved 16 patients with mRCC treated with TILs isolated from the primary tumor, activated, and expanded in IL-2 and IL-4. The response rate was 0% (0 out of 18 patients) and 25% (4 out of 16 patients) in the first and second trials, respectively. The overall response rate at the Cleveland Clinic for both groups was 12% of the 34 patients who had mRCC. In the large study conducted at UCLA, a different regimen and technique for cell expansion were used, and the results were encouraging. The UCLA study was a single trial that involved 55 patients with mRCC, and their primary tumor in place, and TILs were obtained from primary tumors. A total of 23 patients received TILs that had been generated and expanded after enrichment in the $CD8^+$ population of cells using CD8 capture flasks (i.e., flasks coated with anti-CD8 monoclonal antibody). The other 32 patients received TILs that were primed *in vivo*, expanded *in vitro*, and harvested for infusion. The *in vivo* priming of the TILs was conducted by administering cytokines to the patients

before their nephrectomies. Of these 32 patients, 15 received IFN-α, four received TNF-α, four received IL-2, four received IL-6, and five received IFN-γ. All the patients received intravenous IL-2 during the treatment period, and an additional 48 patients also received IFN-α. Complete response was achieved in five (9.1%) patients and a partial response in 14 (25.5%) patients, for an overall response in 19 (34.6%) patients. The results are shown in Table 13.2-3 and Figure 13.2-1 . Figure 13.2-1 shows computed tomographic scans of complete response in a patient who presented with mRCC involving the lung parenchyma, pleural base, hilar, and vena caval extension. The patient underwent radical nephrectomy and thrombectomy, followed by immunotherapy with TILs, IL-2, and IFN-α. The patient remains disease free at 5-year follow-up. These responses were noted to be durable with a median duration of response of 14 months (range, 0.8+ to 64+ months). The overall median survival was 22 months (range, 2 to 70+ months) with actuarial survival rates at 1 and 2 years as 65% and 43%, respectively (Fig. 13.2-2A and Fig. 13.2-2B). This study also demonstrated promising results with the use of low-dose IL-2 with or without IFN combined with TILs for adoptive immunotherapy for mRCC. The overall response rate of 34.6% in 55 patients compares favorably with those seen with high-dose IL-2. At UCLA, we have also studied the effect of adoptive immunotherapy in a subgroup of patients with sarcomatoid RCC tumors (80). Sarcomatoid RCCs have been found to be associated with local aggressiveness, high metastatic potential, and poor prognosis (81 ,82). In this evaluation of nine patients with sarcomatoid RCC, an 11% complete response rate and 22% partial response rate were seen when patients were treated with TILs, IL-2, and IFN-α. In a separate study at UCLA, 23 patients received CD8+ lymphocytes selected by using CD8 capture flasks coated with anti-CD8 antibodies. The flasks positively selected adherent CD8+ cells by immunogenicity. The expanded cells were harvested and suspended in 10% human serum albumin. One hour after IL-2 therapy, patients received a single intravenous infusion of purified CD8+ lymphocytes. Of the 23 patients who received therapy, the overall response rate was 43.5% (83). A multicenter phase 3 trial has been conducted by Rhône-Poulenc Rorer (Agoura, CA) to compare CD8+ TILs plus low-dose IL-2 with low-dose IL-2(84). Patients with mRCC were randomized to receive low-dose IL-2 plus CD8+-selected TILs or low-dose IL-2 alone. In this study, a total of 178 patients with mRCC were initially enrolled and underwent radical nephrectomy. One hundred-sixty patients were randomized to the two groups—81 patients in the TIL and IL-2 group, and 79 patients in the

IL-2–alone group. Each group had comparable characteristics. From these two groups, 20 patients could not receive IL-2 because of surgical complications or failure to meet eligibility criteria. Results were thus analyzed in the remaining patients, 72 of whom received TIL and IL-2 and 68 of whom received IL-2 alone. On initial intent to treat analysis, the overall response rate, according to the Eastern Cooperative Oncology Group (ECOG) performance status (ps), showed eight responders in the TIL and IL-2 group. Three (7.9%) of the patients had ECOG ps = 0 and five (11.6%) had ECOG ps = 1 with an overall response rate of 9.9%. In the IL-2–alone group, nine patients responded. Five (14.3%) patients had ECOG ps = 0 and four (9.1%) patients had ECOG ps = 1, for an overall response rate of 11.4%. Statistical analysis of the two groups revealed no significant difference between the two treatment groups (p = .894), as well as an odds ratio of 0.851, indicating a similar likelihood of response regardless of TIL treatment or ECOG ps. Overall survival rates were also similar for both groups with 1-year survival rates of 55% for the TIL and IL-2 group and 47% for the IL-2–alone group, showing median survival of 12.8 months and 11.5 months, respectively (Fig. 13.2-3`). In addition, only 39 of the 81 patients randomized to the TIL and IL-2 group actually received TILs because of technical problems encountered with TIL generation. The study was therefore terminated early because of lack of efficacy, as determined by the Data Safety Monitoring Board; thus, long-term results are not available. Although the 1-year survival rates in both groups in this study compared favorably with other studies, no demonstrable difference was found in response rate or survival between the TIL and IL-2 group and the low-dose IL-2–alone group.

FIGURE 13.2-1. Computed tomographic scans (A–D) of complete response in a patient who presented with metastatic renal cell carcinoma involving the lung parenchyma, pleural base, hilar, and venal caval extension. The patient underwent radical nephrectomy and thrombectomy, followed by immunotherapy with tumor-infiltrating lymphocytes, interleukin-2, and interferon-α. The patient remains disease free at 5-year follow-up.

CR, complete response; PR, partial response.

Table 13.2-3 Clinical Response, Duration of Response, and Duration of Survival in Responding Patients with Metastatic Renal Cell Carcinoma Treated with Nephrectomy, Tumor-Infiltrating Lymphocytes, and Interleukin-2

Variable	Total	Primed TILs	CD8[+] TILs	p Value[a]
No. of CR (%)	5 (9.1)	3 (9.4)	2 (8.7)	—
No. of PR (%)[b]	14 (25.5)	6 (18.8)	8 (34.8)	—
No. of overall response (CR + PR)	19 (34.6)	9 (28.1)	10 (43.5)	0.26 (Fisher's two-tailed test)
Median duration of response (range)	14 (0.8-64+)	24 (0.8-64+)	12 (3-48+)	0.73 (Log rank test)
Median overall survival (range)	22+ (2-70+)	24+ (3-53+)	21 (2-70+)	0.94 (Log rank test)

CR, complete response; PR, partial response; TILs, tumor-infiltrating lymphocytes.

[a]p values are for comparison between primed TILs and CD8[+] TIL results.

[b]Two cases of partial response were converted to complete surgical remission and pathologic remission, respectively, on surgical resection.

Interest in the role of radical nephrectomy in the presence of metastatic disease has increased in the 1990s, especially with the advance of modern of immunotherapy. In an analysis at UCLA, 203 patients were consecutively treated with IL-2(85). The study compared patients without nephrectomies who received IL-2 therapy with patients who had nephrectomies performed less than 6 months before or more than 6 months after administration of IL-2 or TIL. The results are summarized in Table 13.2-4 . Overall, the median survival was 18 months, which is comparable with that reported with the 255-patient database of bolus IL-2 treatment alone. Survival at 1, 2, and 3 years was 61%, 40%, and 31%, respectively. Patients who had nephrectomies more than 6 months before IL-2 therapy had a 46% 3-year survival rate compared with 9% for patients who underwent nephrectomies less than 6 months before

IL-2 therapy, and 4% for patients who received IL-2 therapy and had no nephrectomies. The 3-year survival for patients treated with TIL was 38%, which was significantly better than the 3-year survival for patients treated with IL-2 who had no nephrectomy or a nephrectomy less than 6 months before treatment. To receive TIL therapy, patients must undergo radical nephrectomy to obtain tumor specimens for TIL generation. The question remains, however, whether surgery and its associated morbidities allow any further therapeutic benefits. Studies from other institutions have shown that as many as 40% of patients with mRCC undergoing nephrectomy are unable to receive adjuvant systemic immunotherapy because of morbidity, mortality, and deterioration caused by progressive disease (86 ,87). At UCLA, we have reported more favorable results for patients with mRCC undergoing cytoreductive surgery and subsequent TIL and IL-2 therapy (88). Of the 63 patients, 56 (88%) were able to receive TILs. Seven patients were unable to receive treatment with TILs because of postoperative complications—including myocardial infarction, transient ischemic attack, mild chronic renal failure, and deterioration of ps—in five patients. The other two patients were excluded because TILs could not be grown in one patient, and the other patient had transitional cell carcinoma. In addition, many of these patients underwent extensive and complicated operations, including resection of caval thrombus, partial hepatectomy, and splenectomy. The results revealed an overall response of 33.9% (12.5% complete response and 21.4% partial response), as well as a 43% and 38% survival rate at 2 and 3 years, respectively (see Table 13.2-4). Although these results do not explain these observations (i.e., whether nephrectomy alone or the combination of nephrectomy and cellular therapy was responsible for the responses), radical nephrectomy before systemic immunotherapy is still an attractive alternative in select patients. The overall contribution of adjuvant nephrectomy for the therapy of patients with metastatic disease must be determined by prospective randomized trials. One such study is being addressed in a randomized phase 3 Southwest Oncology Group trial comparing IFN-α alone versus nephrectomy followed by

IFN-α therapy. Another aspect of surgery and adjuvant TIL and IL-2 treatment is being studied by Ridolfi et al. (89), who are evaluating the feasibility of TIL and IL-2 therapy in patients who undergo resection of metastatic disease. The initial report on 22 patients with metastatic disease, including one patient with mRCC, shows the latter patient to be disease free at 22 months. The question of extensive surgery for metastatic disease coupled with postoperative adjuvant immunotherapy, including TIL therapy, has also been studied at UCLA (90). We identified 31 patients with the primary tumor in place and extension of the tumor into the inferior vena cava, as well as other metastatic sites. These patients all underwent radical nephrectomy and inferior vena cava thrombectomy followed by adjuvant immunotherapy. Of the 31 patients, a total of 80% received received IFN plus isotretinoin (Accutane). The overall survival was 17% with a mean follow-up of 18 months (range, 1+ to 88+ months). The correlation between survival and the ability to administer postoperative immunotherapy was statistically significant on univariate and multivariate analysis (p = .0037), as shown in Figure 13.2-4 . Similar analysis also demonstrated a positive correlation between survival and site of metastases or histologic grade of tumor (Table 13.2-5). In addition, multivariate analysis based on the Cox Proportional Hazards model also suggested that the use of immunotherapy (p = .042) acts independently in reducing the risk of death in these patients. This result indicates that patients with inferior vena cava tumor and metastatic disease can benefit from thrombectomy and immunotherapy with survival, which is comparable to previous survival data in patients who underwent caval thrombectomy without other metastases (91). We therefore continue to favor the use of aggressive treatment with tumor debulking and immunotherapy, including adoptive cellular therapy (TILs), for advanced RCC. We believe that selected patients immunotherapy, 42% received IL-2, 26% received TILs, and 10%exhibit an overall improved survival with this treatment.

FIGURE 13.2-4. Percent of survival with or without immunotherapy administration in patients with inferior vena cava tumors who underwent surgery.

Table 13.2-4 Response and Survival to Interleukin-2 Plus TILs for Treatment of Metastatic Renal Cell Carcinoma with or without Nephrectomy at the University of California at Los Angeles

Treatment Received	No. of Patients	No. of Overall Response (%)	% Survival at 2 Years	% Survival at 3 Years
TILs and nephrectomy	56	19 (35)	43	38
No nephrectomy	24	4 (17)	13	4
Nephrectomy >6 months[a]	76	15 (19)	60	46
Nephrectomy <6 months[a]	47	10 (21)	21	9
All patients	203	48 (24)	40	31

TILs, tumor-infiltrating lymphocytes.

[a]Nephrectomy performed either less than or more than 6 months before administration of interleukin-2 therapy.

Table 13.2-5 Multivariate Analysis: Prognostic Factors for the Occurrence of Death After Treatment

	p Value	Relative Risk of Death
With or without immunotherapy	.042	3.18
Pulmonary vs. extrapulmonary metastasis	.058	3.38
Low-grade vs. high-grade tumor	.077	2.68

Tumor-Draining Lymph Node Lymphocytes

Part of "13.2 - Renal Cell Carcinoma "

Another intriguing approach to adoptive cellular therapy is the use of lymphocytes obtained from tumor-draining lymph nodes (TDLNs). Preclinical studies have established methods to activate and expand tumor-reactive T cells from lymph nodes, and these cells demonstrated the ability to cure visceral tumors in animals (92 ,93 ,94 and 95). In view of these results, a clinical study was initiated by Chang et al. (96) in patients with advanced RCC (all had prior nephrectomies) and melanoma. Patients were initially vaccinated with irradiated autologous tumor cells admixed with bacille Calmette-Guérin. After 7 days, TDLNs were removed and activated with anti-CD3 antibody and cells expanded with IL-2. The activated lymph node cells were then infused into the patients with concomitant IL-2. Of the 12 patients with advanced RCC, complete and partial responses were seen in two patients with an overall response of 33%, with duration of 12+ to 36+ months and 12 to 20 months, respectively. This study shows the feasibility of using vaccines with adoptive immunotherapy—using cells from other sites when no primary tumor is available.

Future Prospects of Cellular Therapy

Part of "13.2 - Renal Cell Carcinoma "

Dendritic Cells

DCs are the primary antigen-presenting cells responsible for *in situ* stimulation of T-cell mediated immune response, including antitumor immunity (97 ,98). DCs are leukocytes derived from bone marrow and lack cell surface markers typical for B cells, T cells, natural killer cells, or monocyte and macrophage lineage. DCs are derived in large numbers from PBMCs with the aid of the cytokines GM-CSF and IL-4 (97 ,99 ,100). GM-CSF and IL-4 allow the proliferation and maturation of DCs from monocyte precursors (Fig. 13.2-5). As many as 8% of circulating mononuclear cells can be recovered as functional DCs using these cell-culturing techniques. These cultured cells possess all the necessary functional, morphologic, and phenotypical antigen-presenting cell features and are crucial for the stimulation of T-cell subsets CD4 and CD8. More specifically, they express high levels of MHC classes I and II, adhesion molecules ICAM-1 and LFA-3, as well as other important costimulatory molecules, such as CD40, CD80, and CD86, that are essential to the process of proper antigen presentation. A phase 1 trial at UCLA showed that DCs can also be generated *in vivo* by administering GM-CSF plus IL-4 subcutaneously to patients with advanced cancer (101). This trial showed that patients had minimally detectable DCs at baseline and a marked increase in circulating DCs after 7 days of cytokine administration. An interesting point of these results may be the application of forming an antigen-based vaccination trial without the need for *ex vivo* processing of PBMCs to generate DCs.

FIGURE 13.2-5. Schematic diagram of dendritic cell (DC) generation and activation for application in the treatment of metastatic renal cell carcinoma. (GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-4, interleukin-4.)

The discovery of DCs has stimulated interest in using DCs for the treatment of cancer. This interest stems from the ability to induce a specific antitumor response using DCs isolated from patients loaded with tumor antigens. Phase 1 clinical trials using DCs have already shown promising results in patients with B-cell lymphoma, melanoma, and prostate cancer (102 ,103 and 104). Interest in DCs also lies in the ability to pulse DCs with various forms of antigens, including peptide-specific antigens, whole proteins in the form of tumor lysates (103 ,105), and even RNA encoding for antigens (106). At UCLA, large numbers of functional DCs have been generated from the PBMCs of patients with mRCC using IL-4 and GM-CSF(107). These DCs induce a rapid proliferation of CD8[+] and CD4[+] T lymphocytes, cytokine release, and enhancement of autologous tumor lysis in a TIL-based culture system on loading with unfractionated RCC tumor proteins in the form of crude tumor lysate (TuLy). This *in vitro* data led to a phase 1 clinical trial for patients with mRCC using TuLy obtained from the patients' primary RCC. The protocol is shown in Table 13.2-6 . The TuLy is used to produce an autologous lysate-loaded DC vaccination (108). Thus far, DC cultures have been consistently obtained from patients' PBMCs for 3 consecutive TuLy-loaded DC vaccinations without any dose-limiting toxicities.

Table 13.2-6 Protocol Outline for Phase 1 Study at the University of California at Los Angeles Implementing Dendritic Cell Therapy for Metastatic Renal Cell Carcinoma

Cohort	No. of Patients	Immunization	Route	Day
A	6	Irradiated autologous TuLy[a]	i.d.	0
		Irradiated autologous TuLy-loaded DCs[b]	i.d.	7
		Irradiated autologous TuLy-loaded DCs	i.d.	14
		Irradiated autologous TuLy-loaded DCs	i.d.	21
B	6	Irradiated autologous TuLy[a]	i.v.	0
		Irradiated autologous TuLy-loaded DCs[b]	i.v.	7
		Irradiated autologous TuLy-loaded DCs	i.v.	14
		Irradiated autologous TuLy-loaded DCs	i.v.	21

DCs, dendritic cells; TuLy, tumor lysate.

[a]Amount of TuLy irradiated depends on the number of DCs, usually 30% of the amount of DCs generated.

[b]Ideal number of DCs is 9×10^6.

The capability to arm DCs with target-specific tumor-associated antigens (TAAs) has been the basis of many ongoing studies. The association of DCs and TAAs has led to efforts in discovering TAAs in RCC because of common antigenic determinants demonstrated in RCC that can be expressed and are recognized by MHC-restricted cytotoxic T lymphocytes. Isolation of TAAs is a laborious process that involves classification of antigens that can be used *in vitro* to generate an MHC-restricted cytotoxic T-lymphocyte response (109), followed by peptide mapping and cloning. A number of TAAs have been identified and are being assessed for their frequency of expression in human RCC. The possible TAAs include RAGE-1, PRAME, gp75 messenger RNA, and, most recently, G250. These are expressed in adequate, although heterogeneous, frequency in surgically removed tumor specimens, but not in the adjacent normal epithelium (110 ,111). The RCC-TAA G250 has gained increased interest for use as possible target immunotherapy for RCC. Studies have shown that monoclonal antibody G250 reacts with more than 75% of primary and metastatic RCCs with no cross-reactivity to normal kidneys. In addition, further imaging studies using biodistribution of iodine-131–labeled chimeric monoclonal antibody G250 in patients with RCC revealed several areas of previously unrecognized metastases and also excellent tumor localization (112). These findings suggest that monoclonal antibody G250 can recognize RCC-TAA and

may be applied in strategies for adoptive immunotherapy or vaccine therapy in the treatment of RCC.

Future Trends in Gene Modification

One of the major problems encountered with cellular therapy involves the generation and expansion of adequate numbers of potent effector cells. To overcome this problem, genetic approaches have been implemented to alter tumor cells to enable enhanced cellular immune response to TAAs expressed on the primary tumor. The majority of the work has focused on the use of cytokine genes introduced into tumor cells. Animal studies using genetically modified tumor cells that secrete IL-4 or IFN-γ have shown tumor regression in established tumors when administered as a vaccine for active specific immunotherapy (113 ,114 and 115). These early animal studies led to the development of gene-modified tumors that can be used to generate various cells for adoptive cellular therapy. Two of these cell types are TILs and vaccine-primed lymph node cells or TDLNs that have been generated using gene-modified tumors.

Tumors that are genetically engineered to produce certain cytokines, such as IFN-γ and TNF-α, have been discovered to contain TILs with enhanced antitumor activity *in vitro* and *in vivo*, even in poorly immunogenic tumors (116 ,117). These TILs showed increased antitumor activity when compared with TILs generated from wild-type tumors. Another cytokine, IL-7, has also been shown to enhance recovery of TILs from tumors and showed a fivefold increase in T cells, as well as enhanced *in vitro* cytotoxicity (118). In the case of vaccine-primed lymph node cells, antitumor activity is accomplished by secondary activation *in vitro* by coculturing with irradiated tumors and IL-2 or by sequential activation with anti-CD3 monoclonal antibody and expansion with IL-2(93 ,94 ,119 ,120). These cells have antitumor effects with immunogenic tumors, but not with nonimmunogenic tumors. To overcome this problem, draining lymph nodes are primed by potent immunologic adjuvants, like *Corynebacterium parvum*, and then secondarily activated *in vitro*, leading to an increased antitumor effect (121). This increased activity has encouraged the exploration of genes to modify sensitization of T cells in TDLNs. Transfection of tumor B16-Bl6 melanoma with allogeneic MHC class I genes and then activation of TDLNs in anti-CD3 monoclonal antibody and IL-2 have significant antitumor effects compared with parental TDLNs when adoptively transferred into animals with pulmonary metastases (122). Genetic modification of tumor cells with other cytokines, such as IL-4, GM-CSF, and IFN-γ, have generated TDLNs that have mediated significant regression of established, poorly immunogenic tumors (123 ,124 and 125). These results show a promising avenue in enhancing antitumor activity of TILs and TDLNs that can be applied in clinical studies using cell transfer therapy for RCC.

Another path involving genetic modification in adoptive immunotherapy is to enhance the therapeutic efficacy of the cells being transferred. Initial application was addressed by Rosenberg et al. (126) using retroviral transduced TILs in patients with advanced melanoma. The ability of TILs to induce *in vitro* cytolysis or cause tumor regression was not affected. Moreover, TILs were detected in tumor deposits for as many as 64 days and in the circulation for as many as 189 days. The other strategies involve the use of various promoters and modification of cytokines such as TNF-α and IL-2 to enhance secretion of these cytokines. Possible methods that may be implemented in the future include modification of effector cells with signal transduction to enhance propagation or the introduction of chimeric receptor genes to specifically redirect TIL cells to specific tumors. Finally, the future in enhancing the efficacy of cellular transfer therapy may lie in the genetic engineering of naïve cells to become immunocompetent effector cells. These methods are still in their early stages but may provide future directions in the application of cellular transfer therapy in RCC.

- Future Prospects

Introduction

Part of "13.3 - Allogeneic Graft-versus-Leukemia and Antitumor Effects "

Perhaps the only positive outcome after the use of atomic bombs in 1945 was the stimulus given to research aimed at protecting individuals from the lethal effects of ionizing radiation. This research paved the way for bone marrow transplantation (BMT) (1). In 1951, two investigators, Jacobson and Lorenz, independently showed that infusions of hematopoietic tissues could rescue rodents from bone marrow failure induced by radiation. It was subsequently found that transplanted cells from different mouse strains or different species could cause a lethal "secondary" disease, called *graft-versus-host disease* (GVHD). Although details of the immune mechanisms involved were unknown, Barnes and colleagues in Harwell, England, suspected that the GVHD reaction induced by the use of "foreign" (i.e., alloreacting) transplants might also affect malignant cells. In 1956, these investigators were the first to prove the existence of a graft-versus-leukemia (GVL) effect (2). They showed that transplants of hematopoietic cells and splenic lymphocytes into mice delayed death from a transplanted lymphosarcoma. In Paris, Georges Mathé carried out similar experiments and went on to apply the adoptive transfer of alloimmune reactivity as a form of immunotherapy for cancer and leukemia. He used bone marrow transplants and lymphocyte transfusions in attempts to obtain a GVL effect in patients with advanced malignancies with some early but inconclusive successes (3). At that time, it became apparent that the GVHD induced after allogeneic BMT was a highly dangerous complication, requiring prophylactic immunosuppression and intensive treatment of established disease. Because GVL appeared to be inseparably linked to GVHD, its deliberate induction was considered to be impracticable in a clinical setting. This perception changed at the beginning of the 1990s, after the publication by the International Bone Marrow Transplant Registry (IBMTR) of a large analysis that showed that a GVL effect mediated by T lymphocytes was demonstrable in the absence of GVHD (4). Any doubts about the clinical potential of the GVL effect were dispelled by reports from Slavin, working in Israel, and Kolb, working in Germany, who showed that adoptively transferred donor lymphocytes given to patients relapsing with leukemia after transplant could induce stable remissions, sometimes without any accompanying GVHD (5). The cellular mechanisms mediating GVL responses have become better defined in the 1990s, as a result of animal experimental research and clinical studies. We are beginning to identify the antigens presented by major histocompatibility complex (MHC) molecules on malignant cells that serve as the target of T-cell attack. A natural killer (NK) cell alloresponse to leukemia is also beginning to be defined. With these developments, it is reasonable to anticipate the successful treatment of otherwise refractory malignant diseases, using alloreacting lymphocytes from closely matched healthy donors specifically targeted against the malignant cell. In this chapter, we describe the experimental and clinical basis of the GVL effect, the cellular mechanisms and antigens involved in the GVL response, and clinical results and developments in the application of GVL and graft-versus-tumor (GVT) effects.

Immunology of the Graft-versus-Leukemia Effect

Part of "13.3 - Allogeneic Graft-versus-Leukemia and Antitumor Effects "

Experimental Evidence for Graft-versus-Leukemia in Animal Models

Research into the GVL effect progressed rapidly after the introduction of transplantable leukemias, such as the AKR leukemic mouse, and the establishment of cell lines, such as EL4 and L1210 leukemia. Rodent GVL models using these well-defined malignancies have been used to elucidate the major features of the GVL response (6). These experiments have repeatedly shown that allogeneic lymphocytes have a powerful antileukemic effect. This GVL effect is greatest in the presence of strong allogeneic differences and is least, or absent, in syngeneic transplant models. Depending on the experimental conditions, T

lymphocytes and NK cells can be shown to exert GVL reactivity. Experimental leukemias and lymphomas differ widely in their susceptibility to alloimmune attack. Using a mouse AKR leukemia transplant model, Bortin and colleagues (who coined the term *graft-versus-leukemia*) were the first to show that it was possible to generate leukemia-specific T cells capable of inducing GVL without GVHD (7). The ability to separate antihost alloresponses from antileukemic responses varies: Leukemias induced by viruses are good models for leukemia-specific GVL reactions, whereas a rat model of acute myelogenous leukemia showed only GVHD-induced GVL activity (8 ,9). The role of cytokines, such as interleukin-2 (IL-2) in GVL and GVHD reactions, has been extensively studied in murine transplant models (10). The effect is schedule-dependent, inducing tolerance and GVL. Studies have focused on the role of T-cell subsets in GVL and GVHD reactions and on methods to separate the two by delayed T-cell add-back, induction of specific tolerance, use of specific lymphocyte subsets and leukemia-specific T-cell clones. Two techniques have further increased the potential of animal models for the study of GVL. First, gene knockout mice have given insight into the cytokines and surface molecules critical for the alloresponse (11). Second, the severe combined immunodeficiency disease nonobese diabetic mouse strain accepts transplanted human malignancies and malignant cell lines and allows the *in vivo* expansion of human lymphocytes. Immunodeficient mice can therefore be used to develop *in vivo* immunotherapy models of human malignancies (12).

Cellular and Cytokine Basis of the Graft-versus-Leukemia Response

The mechanisms involved in the generation of the alloresponse after bone marrow stem-cell transplantation form the basis for understanding GVL. The process, traced from the initiation of the alloresponse through a phase of clonal expansion to the effector phase, involves interactions between many cell types and the cytokines they produce (13) (Fig. 13.3-1).

FIGURE 13.3-1. Cellular and cytokine mechanisms of the immune response.

Initiation of the Alloresponse

The allogeneic T-cell response involves the interaction between class I and class II MHC on antigen-presenting cells with CD8+ and CD4+ lymphocytes, respectively. MHC molecules interact with the CD3 and CD4/8 molecules on the T cell and present

their antigens to the T-cell receptor. The antigens seen by T cells are peptides brought to the cell surface bound to MHC molecules. Just as antigens interact with their specific antibody, these peptide antigens interact with specific T cells bearing a specific matching configuration of the hypervariable CDR3 region of their T-cell receptor. Antigens can be presented by many cell types, including leukemia cells and donor and host antigen-presenting cells. Some myelogenous leukemias can differentiate into functional dendritic cells and monocyte macrophages to become competent antigen-presenting cells. Furthermore, donor macrophages and dendritic cells can present leukemia antigens derived from engulfed or disintegrating leukemia cells.

Clonal Expansion Phase

After antigen recognition, T-cell activation is required for the continuation of the immune response. The activation of the costimulatory molecules CD28 and CTLA4 on the T cell by B7.1 and B7.2 (CD80 and CD86) molecules on the stimulator cell governs whether the T cell undergoes clonal expansion or, in the absence of a signal, becomes anergic. Interaction of CD4$^+$ cells with dendritic cells activates CD40 and provides the signal for CD8$^+$ activation, whereas IL-2 and IL-12 production by CD4$^+$ cells provides the proliferative stimulus to CD8$^+$ cells and NK cells. The process of clonal expansion to alloantigens can be rapid; acute GVHD occurs within 7 to 10 days of the transplant. In contrast, the GVL process is slower: After donor lymphocyte transfusion (DLT), months may pass before an antileukemic response is seen. This may represent the time taken to expand an effector population from a low frequency of T-cell precursors.

Effector Phase

Three mechanisms appear to be responsible for the GVL effect:

- Direct killing of leukemia cells by perforin and granzyme attack from cytotoxic lymphocytes (CD4$^+$, CD8$^+$, and NK cells)
- Apoptotic death through the fas/fas ligand pathway (CD4$^+$ and CD8$^+$ T cells)
- Cytokine-mediated leukemia cell death or control of proliferation (CD4$^+$ and CD8$^+$ cells)

Leukemia-reactive T-cell clones derived from healthy donors responding to HLA-identical or closely identical leukemia cells have been used to study GVL mechanisms. Leukemia-specific T cells inhibit the clonal growth of leukemic progenitors in colony-inhibition assays and induce apoptosis in leukemia cells expressing fas through fas/fas-ligand interaction. T cells can inhibit leukemic proliferation by producing interferon-γ (IFN-γ) and tumor necrosis factor-α.

Lymphocyte Subsets and Graft-versus-Leukemia

The GVL response involves many effector cell types. After allogeneic BMT or DLT, an early rise in activated T cells and NK cells occurs and the frequency of leukemia-reactive cytotoxic T lymphocyte precursors increases (14 ,15). A general association exists between prolonged remission and full recovery of CD4$^+$ and NK cells (16). It is now clear that NK cells are capable of powerful but poorly characterized alloresponses to leukemia through recognition of foreign MHC molecules on the leukemia target (17). The relative contribution of CD4$^+$ and CD8$^+$ T cells to GVL has been studied in animal models and in humans. Mice receiving CD8-depleted marrow or marrow with addition of purified CD4$^+$ T cells had a low incidence of GVHD with high leukemia-free survival, supporting a role for CD4$^+$ cells in GVL. In other murine models, however, the addition of purified CD8$^+$ T cells to the graft had an antitumor effect and facilitated engraftment without inducing GVHD (13). We can conclude that CD4$^+$ and CD8$^+$ T-cell subsets contribute to GVL reactions. The dominant mechanism, however, is strain specific and varies with the degree of donor-recipient histocompatibility and the type of leukemia. In humans, CD4$^+$ and CD8$^+$ alloreactive cells with antileukemia activity have been generated *in vitro.*

Susceptibility of Leukemia to Graft-versus-Leukemia

To be immunogenic, leukemia cells must express critical surface molecules that render them susceptible to attack from donor lymphocytes. To be killed, they must be susceptible to apoptosis, induction, or lysis by perforin-granzyme systems of NK cells or T lymphocytes. To elicit T-lymphocyte responses, leukemia cells must express MHC class I or class II adhesion molecules, such as ICAM-1, and costimulatory molecules, such as CD80 and CD81 (13). Donor T cells recognize small peptide antigens presented by the leukemia cell through MHC class I and class II molecules. We can define three functional categories of antigens: ubiquitous, tissue-specific, and leukemia-specific (Table 13.3-1). The first two categories comprise the minor histocompatibility antigen (mHA) system (18). Although only a handful have so far been characterized, hundreds of mHA are believed to exist. They are allelic peptide sequences of numerous polymorphic proteins scattered throughout the genome. From analysis of natural peptides

present in MHC molecules, it appears that self peptides can be derived from all parts of the cell. Ubiquitous antigens are those that are widely distributed in recipient tissues, such as the gut, skin, liver, and marrow cells. Alloresponses against these antigens are thought to induce a nonspecific response, causing GVHD in addition to any GVL effect. In contrast, tissue-restricted antigens are derived from proteins with a limited tissue distribution (19). Three hematopoietic tissue-restricted mHA are known: HA-1, HA-2 (on lymphoid and myeloid cells), and HB-1 (on B lymphocytes) (20). These mHA are of particular interest because T-cell clones specific for these antigens should induce GVL responses without causing GVHD. The identification of tissue-restricted antigens is an active area of research because of their potential to initiate specific GVL responses.

Table 13.3-1 Antigens Inducing T-Cell-Mediated Graft-versus-Leukemia Responses

Minor histocompatibility antigens (mHA)

Ubiquitously distributed

HA-3, HA-4, HA-5, HA-6, HA-7

Y chromosome–derived proteins

Restricted to hematopoietic tissue

HA-1, HA-2, HB-1

Some Y chromosome–derived proteins

Normal but aberrantly expresses proteins restricted to hematopoietic tissue

PR-1 (proteinase-3), alleles of proteinase-2

PRAME

Leukemia-specific proteins

Fusion proteins from chromosomal translocation

(e.g., BCR-ABL, PML-RARA)

Single point or frame-shift mutations of oncogenes

(e.g., p53, RAS)

BCR-ABL, B-cell reactivity–antigen-binding lymphocyte.

The third category of leukemia antigens are those that are truly leukemia specific (21). These are antigens unique to the leukemia because they are derived from leukemia-specific chromosomal translocations and point and frame-shift mutations and deletions. Peptide sequences from the area of mutation or fusion region of translocations could function as neoantigens. Several translocations and mutations have been extensively studied, notably the BCR-ABL transcript from chronic myelogenous leukemia (CML) and mutations of the p53 gene in many myeloid malignancies. Despite almost a decade of research using fusion peptide sequences representing the recombined region of the gene, no definitive evidence exists proving fusion proteins or mutated genes induce GVL in stem-cell transplant recipients. From what is already known about tumor-specific antigens, overexpressed or aberrantly expressed normal tissue-restricted proteins (e.g., MAGE, MART, and tyrosinase in melanomas) represent a more likely category of potent leukemia-specific antigens. Peptides from these proteins induce autologous and allogeneic cytotoxic T-cell responses against the tumor. It is clear that similar overexpressed proteins occur in marrow-derived cells. PRAME, an antigen expressed by several solid tumors, is also expressed in some hematologic malignancies (22). Primary granule proteins, such as proteinase-3, overexpressed in many myeloid leukemias and in myelodysplastic syndrome, are the source of powerful leukemia-specific antigens. Cytotoxic T cells recognizing proteinase 3 peptides that show cytotoxicity specifically to leukemia cells and their progenitors but not to normal marrow cells can readily be produced *in vitro* from healthy individuals (23).

Nevertheless, despite great progress in the identification of target antigens on leukemia cells, it should be emphasized that no direct evidence exists that any of the antigens thus far described are instrumental in causing GVL responses after allogeneic stem-cell transplantation.

Graft-versus-Leukemia in Clinical Practice

Part of "13.3 - Allogeneic Graft-versus-Leukemia and Antitumor Effects "

Therapeutic Potential of the Graft-versus-Leukemia Response

An analysis by the IBMTR of 2,030 HLA-identical sibling transplant recipients demonstrated two clinical characteristics of the GVL effect (4): (a) GVL was greatest in CML, less in acute myeloid leukemia, and least in ALL; and (b) the relapse rate after T-cell depletion was significantly greater than that observed in a comparable patient group who received non-T-cell-depleted transplants and did not develop acute GVHD (Fig. 13.3-2). A further study from the IBMTR showed that relapse rates are higher in transplants between identical twin transplants compared with HLA-identical sibling transplants (24). These observations provide indisputable evidence for a GVL effect mediated by allogeneic, but not syngeneic, BMTs and implicate T lymphocytes in the mechanism. These studies were the first to quantitate the strength of the GVL response. Further evidence of the power of the GVL effect of allogeneic lymphocytes comes from widely confirmed observations by Slavin et al. (25) and Kolb et al. (26) that DLTs given after allogeneic BMT induce permanent remissions in patients whose leukemia relapses after allogeneic BMT. This finding is all the more striking because it implies that donor lymphocytes alone in these circumstances can be more effective at eradicating leukemia than the original transplant involving myeloablative chemoradiotherapy and a T-cell–replete

marrow transplant. It therefore appears that a major component of the curative potential of the allogeneic transplant is the establishment of a donor immune system that permits the survival of transfused alloreacting lymphocytes from the same donor, exerting a GVL effect. Figure 13.3-3 illustrates a complete remission of CML persisting after allogeneic BMT after transfusion of donor lymphocytes.

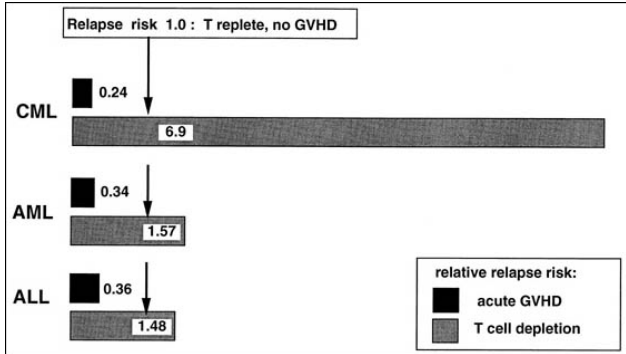

FIGURE 13.3-2. The graft-versus-leukemia effect in chronic myelogenous leukemia (CML), acute myelogenous leukemia (AML), and acute lymphoblastic leukemia (ALL). The bars indicate the relative relapse risk for each disease compared with the relapse rate of a T-cell-replete transplant not developing acute or chronic graft-versus-host disease. The figure illustrates the different impact of T-cell depletion in each disease (greatest in CML) and the powerful antileukemic effect of acute graft-versus-host disease. (Data adapted from Horowitz MM, Gale RP, Sondel PM, et al. Graft-versus-leukemia reactions after bone marrow transplantation. *Blood* 1990;75:555-562.)

FIGURE 13.3-3. Hematologic course after allogenic bone marrow transplantation for chronic phase chronic myelogenous leukemia in a 24-year-old woman. After a T-cell-depleted stem-cell transplant from an HLA-identical sibling and a planned delayed add-back of 1×10^7 per kg of CD3 donor lymphocytes, she entered hematologic remission. On day 100, however, the spleen was enlarged. The bone marrow appearance suggested chronic myelogenous leukemia, and karyotyping showed 50% Ph+ metaphases. She was treated by withdrawal of cyclosporine and a further donor lymphocyte transfusion (DLT) of 5×10^7 CD3+ cells per kg. Within 4 weeks, hematologic recovery occurred, the spleen returned to normal size, and she became Ph+ chromosome negative and negative for the B-cell receptor-antigen-binding lymphocyte marker by RT-PCR. At the same time, she developed skin and liver graft-versus-host disease (GVHD), which was successfully treated with prednisone. She remains in complete molecular remission 1 year posttransplant.

The realization that the GVL effect can be powerful is beginning to bring about a fundamental change in transplant strategy. First, the old perception that immunotherapy with lymphocytes can be successful only in eradicating malignancy at the level of minimal residual disease has been overturned by the observation that, after BMT, full hematologic relapse of leukemia can respond completely to DLT. Secondly, new transplant approaches are emerging based on the idea that in malignancies in remission or with slow progression, it may be possible to rely exclusively on the GVL effect to achieve disease control and subsequent cure. This is the basis for nonmyeloablative stem-cell transplants (27). Patients receive an immunosuppressive, but not myeloablative, preparative regimen (usually a combination of an alkylating agent and fludarabine or low-dose radiation), followed by a lymphocyte-rich peripheral blood stem-cell transplant and short posttransplant immunosuppression. After such low-intensity preparative regimens, the malignancy initially persists. Approximately 2 to 3 months posttransplant, regression of disease coincides with donor immune recovery. Experience with this type of stem-cell allograft is still limited, but it is already clear that the approach holds promise for cure of otherwise untreatable lymphoid and myeloid malignancies and, possibly, solid tumors.

Factors Determining the Strength of the Graft-versus-Leukemia Effect

Type of Malignancy

GVL effects are being demonstrated in a variety of hematologic malignancies. Table 13.3-2 lists the conditions where clinical evidence exists for a GVL effect. Two methods exist for measuring the strength of GVL effects from clinical data: comparisons of relapse rates between allogeneic transplants and syngeneic transplants (where no GVL effect is seen) and analysis of remission rate and duration after DLT to treat leukemia relapsing after BMT. Several factors govern susceptibility of leukemia to GVL effects:

- Disease progression—Early relapse is more favorable than later relapse or relapse of progressing leukemia. Thus, CML in molecular or cytogenetic relapse is more likely to respond than relapse into hematologic chronic phase. Relapse in accelerated or blast phase is the least likely to respond.
- Leukemia type—Myeloid leukemias are more susceptible to GVL effects than acute lymphoblastic leukemia after BMT and DLT.
- Pace of disease—Reports of responses of relapsed myeloma to DLT suggest that, together with CML, myeloma is susceptible to GVL effects because of a slower pace of proliferation and progression than the acute leukemias.

Table 13.3-2 Malignancies with Clinical Evidence of a Graft-versus-Leukemia Effect

Hematologic malignancies

Myeloid malignancies

Chronic myelogenous leukemia

Chronic phase >accelerated phase >blast phase

Acute myelogenous leukemia

Myelodysplastic syndrome

Myeloproliferative disorders

Lymphoid malignancies

Acute lymphoblastic leukemia

Chronic lymphocytic leukemia

Prolymphocytic leukemia

Non-Hodgkin's lymphomas, including mantle cell lymphoma

Multiple myeloma

Nonhematologic malignancies

Breast cancer

Renal cell cancer

Graft-versus-Host Disease

Numerous clinical observations have linked regression of leukemia with the onset of acute or chronic GVHD. The Seattle marrow transplant group were the first to study a large enough leukemia transplant series to show that leukemic relapse was significantly reduced in patients who developed acute or chronic GVHD (28). An IBMTR study came to similar conclusions: The relative risk of relapse in recipients developing acute or chronic GVHD was significantly reduced, and the combination of grade II or greater acute GVHD with any degree of chronic GVHD conferred the greatest protection against relapse in all leukemia types studied (4). A similar correlation of GVHD with leukemic relapse has been shown in patients given DLT to treat leukemia relapsing after BMT. In CML patients, the chance of achieving a further remission developing acute GVHD was 80% compared with 40% for those who did not (26).

Minor Histocompatibility Antigen Differences

The importance of mHA differences in exerting GVL effects can be studied by comparing outcome of HLA-identical sibling BMT in genetically homogeneous and genetically diverse populations. In this situation, patient and donor are genotypically matched at the MHC loci, but the genetically homogeneous group should have a lower diversity of the mHA gene repertoire. The effect of mHA disparity on GVL was studied in comparable CML patients transplanted with HLA-identical siblings in Japan (genetically homogeneous) and the United Kingdom (genetically diverse) (29). The U.K. BMT recipients had twice as much acute GVHD (50% vs. 25%) and became polymerase chain reaction negative for the BCR-ABL transcript more rapidly than comparable Japanese patients. The overall relapse rate, however, was low (10% vs. 12%) and comparable in the two groups.

Major Histocompatibility Antigen Differences

Comparison of relapse rates between HLA-identical siblings and haploidentical family transplants should define the contribution of MHC-antigen differences to the GVL effect. The preparative regimens and GVHD prophylaxis used, however, differ widely between HLA-matched and HLA-mismatched transplants. No comparative data exist to determine whether the degree of MHC disparity modulates the GVL effect.

HLA-Identical Unrelated Transplants

The GVL potential of HLA-identical unrelated donor transplants should be greater than that of HLA-identical sibling transplants because of a greater mHA disparity in the unrelated transplants, as well as differences in nonclassical MHC antigens and cryptic variations in DNA sequences of HLA molecules apparently identical by serotyping. The assumption that relapse rates after unrelated donor BMT are lower than comparable transplants from HLA-identical sibling donors remains unconfirmed. Comparisons are complicated by the greater degree of immunosuppression given to unrelated transplant recipients. Nevertheless, one report of T-cell-depleted unrelated BMT for leukemia suggests that the effect on GVL of histocompatibility differences outweighs the deleterious effect of T-cell depletion on relapse (30). A comparison of unrelated versus related donor DLT to treat relapse of CML showed a more rapid disappearance of residual disease but a similar overall response rate with the unrelated donor transplants, indicating that the GVL effect in unrelated donor BMT may be more rapid but has comparable strength to identical sibling BMT (31).

Immunosuppression

As indicated previously, GVHD is a two-edged sword that, while protecting against leukemic relapse, confers a high mortality. Inevitably, therefore, patients developing GVHD are given immunosuppression with steroids alone or in combination with other immunosuppressive agents. Furthermore, to prevent GVHD, patients receive cyclosporine, FK506, or mycophenolate mofetil, often in association with methotrexate, steroids, or ATG. Such powerful immunosuppressive regimens clearly impact on the ability of the transplanted donor immune system to recognize and respond to residual malignant disease in the BMT recipient. Good evidence exists that cyclosporine is permissive for leukemic relapse. Numerous observations link the disappearance of residual disease or the reversal of incipient relapse with the withdrawal of cyclosporine immunosuppression (32 ,33). The leukemic regression may occur without development of GVHD. Steroid treatment has not been clearly linked with relapse and the routine use of steroids to treat clinically significant GVHD does not seem to abrogate the powerful GVL effect associated with this complication.

Source of Transplanted Stem Cells

Allogeneic peripheral blood progenitor cells (PBPCs) and cord blood (CB) stem-cell transplants are increasingly used in leukemia treatment. PBPC transplants contain approximately tenfold more lymphocytes and at least as many stem cells as a BMT. PBPC transplants have similar rates of acute GVHD, but probably confer a greater risk of chronic GVHD. It has therefore been of interest to look for differences in leukemic relapse rates in bone marrow and PBPC transplants. Several uncontrolled comparative studies suggest that PBPC transplants confer a better GVL effect than BMT, but these results have not yet been confirmed in a large prospective trial (34). Even less experience exists in the use of CB transplants in leukemia; however, *in vitro* evidence exists suggesting that lymphocytes from CB have greater GVL reactivity than lymphocytes from older donors. Because few CB transplants have so far been carried out, it is not clear to what degree this stem-cell source differs in its GVL potential from BMT and PBPC transplant. Sustained remissions of CB transplants in high-risk leukemias do, however, suggest the presence of a strong GVL effect (35).

Stem-Cell Dose

Differences in the GVL potential of stem cells from different sources could be explained by differences in the quality or quantity of lymphocytes contained in the transplant. Evidence also

exists that the stem-cell dose itself affects relapse. Animal and clinical studies have shown a powerful effect of high CD34$^+$ cell doses, conferring resistance to leukemic relapse (36). Even patients at high risk have significantly lower relapse rates if given more than 3×10^6 CD34 cells per kg. The mechanism is independent of a GVL effect from transplanted lymphocytes. The protective effect against relapse is unknown.

Preparative Regimens, Chimerism, and Tolerance

The degree to which the donor T lymphocytes engraft depends in part on the efficiency of the preparative regimen to immunosuppress the recipient's immunity and in part on the number and alloreactivity of the lymphocytes given in the transplant. Consequently, poorly immunosuppressive preparative regimens and T-cell-depleted transplants predispose to a state of mixed chimerism in which donor and recipient lymphocytes coexist after transplant. Prolonged mixed chimerism is strongly associated with an increased rate of leukemic relapse (37 ,38). One reason that T-cell-depleted transplants incur a higher rate of relapse is that they predispose to mixed chimerism and a state of tolerance between donor and recipient, which abrogates the GVL effect.

T-Cell Depletion and Lymphocyte Add-Back

Although T-cell-depleted transplants increase the risk of relapse, the effect can be overcome by transfusing donor lymphocytes at the first sign of leukemic relapse or in a prophylactic approach to prevent relapse. Both strategies are effective. In CML, where residual disease can be easily monitored using a polymerase chain reaction technique to measure the BCR-ABL transcript, DLT reverses incipient relapse in more than 80% of cases (39). In another study, a scheduled DLT on days 45 and 100 after transplant successfully prevented leukemic relapse in 85% of transplanted CML patients (40). The method used to deplete the transplant of T cells also has an impact on relapse. Nonspecific techniques that remove NK cells and T cells indiscriminately have a greater risk of provoking relapse than more selective T-cell depletion (41). Depletion of CD8 cells alone, at least in CML transplants, results in strong protection against relapse with little GVHD (42).

Cytokines

Several investigators have used IL-2 to boost the antileukemic response in patients relapsing after transplant. Anecdotal evidence exists that IL-2 enhances GVL responses and, when given in conjunction with DLT, can induce remission in leukemias relapsing after transplant. IFN-α has been used with and without DLT to treat CML relapsing after BMT with some success, but it is not clear whether the regression of the leukemia is a result of an antiproliferative effect of IFN or an enhancement of the GVL response. A better understanding of the mechanisms whereby cytokines can alter the immunogenicity of the leukemia and the donor's immune response may permit the intelligent use of cytokine combinations to treat and prevent relapse (43).

Graft-versus-Leukemia and Leukemic Relapse after Bone Marrow Transplantation

Mechanisms of Relapse

Case reports in which leukemic relapse after BMT was reversed by stopping immunosuppression support the idea that residual leukemia is often under the control of a competent donor immune system. In other instances in which relapse follows rapidly after transplant, it is more likely that leukemic cytoreduction from the preparative regimen was inadequate and that residual leukemia outstripped the developing GVL response. A third possibility is that leukemic relapse after BMT represents a form of immune escape. Data supporting this possibility comes from a paired study of leukemia samples obtained before marrow transplant and at relapse posttransplant (44). Many of the relapsed leukemias showed alterations in surface phenotype, including downregulation of MHC class I and II antigens associated with a decreased ability to stimulate allogeneic proliferative T-cell responses and decreased susceptibility to lysis by cytotoxic T lymphocytes or NK cells. These findings, coupled with evidence of clonal progression in relapsed leukemias, suggested that the allograft selected leukemia subclones that were resistant to the GVL effect.

Treatment of Relapse with Donor Lymphocyte Transfusions

It is well established that DLT can induce remission in leukemia relapsing after BMT. Two large DLT series from Europe and North America have been reported (26 ,45). Both groups found that patients with CML in cytogenetic relapse or CML relapsing into chronic phase had the best response to DLT with complete cytogenetic remission rates of 84% and 76% for the European and American cohorts, respectively. These responses were not only complete at the cytogenetic level, but were also complete by molecular criteria because nearly all patients studied were negative for BCR-ABL messenger RNA by sensitive two-step polymerase chain reaction techniques. The majority of remissions were stable with second relapse rates of only 6% to 12%. The results for transformed-phase CML, however, were considerably worse in both series, with complete response rates of only 13% (European group) and 28% (American group). The time to cytogenetic remission after DLT is usually 3 to 4 months, but it may be longer. The delay between infusion of donor lymphocytes and hematologic response presumably reflects the period required for the activation and expansion of the GVL effector cells. More rapid responses occur when DLT is given for Epstein-Barr virus (EBV) lymphoproliferative disorders (46). This is presumed to be related to the high precursor frequency of EBV-specific cytotoxic T lymphocytes present in the donor.

In acute leukemias, the contribution of DLT to remission induction is unclear because many patients receive DLT and chemotherapy. Whatever approach is used, acute myeloid leukemia and myelodysplastic syndromes respond poorly to DLT. In the European and North American series, only 15% and 29% of patients given DLT achieved remissions, which were often short lived. Only a few patients have received DLT for myelodysplastic

syndrome, but only approximately 20% of patients respond. Individual case reports of successful therapy with DLT in acute lymphoblastic leukemia (ALL) exist, including the high-risk subtype Ph+ ALL. Overall, results of DLT in relapsed ALL are poor, with response rates of 3% to 18%. Donor lymphocytes also mediate an antitumor effect in chronic lymphoid disorders. Hematologic responses coinciding with the onset of GVHD have been observed in patients with persistent chronic lymphoid leukemia, prolymphocytic leukemia, and non-Hodgkin's lymphoma (47 ,48). A graft-versus-myeloma effect was demonstrated in three patients with progressive myeloma treated with DLT after T-cell-depleted transplants (49 ,50). Complete remission coincided with the development of GVHD. Responses are also reported in mantle cell lymphoma, as well as dramatic regressions of EBV lymphoproliferative disease. DLT, however, has little efficacy in non-Hodgkin's lymphoma and Hodgkin's disease. The antileukemic effect of DLT may be enhanced by cytokines and growth factors. IFN-α may increase the rate of hematologic remission in CML; IL-2 and granulocyte-macrophage colony-stimulating factor may improve responses in ALL and acute myeloid leukemia relapse, respectively. The T-lymphocyte dose also determines the response rate. For CML relapse, approximately 10^7 CD3+ cells per kg are needed to achieve remissions (39).

Separating Graft-versus-Leukemia and Graft-versus-Host Disease

Allogeneic stem-cell transplants require some method of preventing GVHD. Both T-cell depletion and posttransplant immunosuppression, however, are nonselective, diminishing GVL as much as GVHD reactions. To optimize the GVL effect, techniques that selectively reduce GVHD while conserving or enhancing GVHD are needed. Several approaches are being explored.

Delayed T-Cell Add-Back

In animal experiments, T-cell depletion followed by delayed add-back of immune-competent donor cells confers GVL with only a low incidence of acute GVHD. Clinical studies confirm experimental predictions: Although DLTs used to treat leukemia relapsing after BMT can cause GVHD, approximately 25% of patients with CML achieve a remission without clinical GVHD. In HLA-matched sibling BMT for CML, T-cell depletion followed by cyclosporine treatment and graded add-back of donor T cells from as early as day 30 confers protection from relapse with a low incidence of severe acute GVHD (40). Smaller T-cell doses given after 100 days from BMT without cyclosporine cover also achieve a GVL effect with a low risk from GVHD (51).

T-Cell Subset Depletion

Some promising results of selective CD8 depletion of donor marrow have been reported in transplants for CML. In clinical trials in CML using CD8-depleted marrow transplants, the presence of CD4 cells alone prevented relapse after BMT. In one report, CD8-depleted DLT were also effective in treating CML relapsing after BMT with 60% complete remission and only a 20% incidence of clinically significant GVHD (42). Although this technique has produced some favorable results in CML patients, it is possible that other hematologic malignancies require CD4 and CD8 T cells for the GVL effect. Because CD4+ and CD8+ subsets are involved in GVHD and GVL reactions, selective T-cell subset depletion does not appear likely to completely separate GVL from GVHD.

Thymidine Kinase "Suicide Genes"

In this approach, T cells marked with a "suicide gene" (viral thymidine kinase) that renders the cells susceptible to elimination by ganciclovir are given to the recipient to induce a GVL effect (52). At the onset of a serious GVHD reaction, the alloreacting T cells can be eliminated by administering ganciclovir to the recipient. Although this strategy appears attractive, it remains to be seen whether GVL responses can be effective in the brief window between the infusion of gene-marked T cells and their removal at the onset of the GVHD reaction.

Selective Depletion of Alloreacting Donor T Cells

Selective depletion of alloreacting donor T cells involves the *in vitro* stimulation of donor T cells with nonleukemic cells from the recipient (usually lymphocytes). Responding donor cells are eliminated by the addition of antibodies to CD25 activation markers coupled to toxins or immunomagnetic beads. Remaining cells conserve reactivity to recipient leukemia, EBV-transformed B cells, and third-party stimulators. Clinical trials with this selective immunodepletion are under way (53).

Generating Leukemia-Specific T Cells

It is technically possible to generate leukemia-specific donor T-cell clones in many, but not all, HLA-matched donor-recipient pairs. One group of investigators in Leiden, Netherlands, have successfully generated sufficiently large numbers of leukemia-specific donor-derived T-cell lines by expanding them *in vitro* using the patient's leukemia cells as stimulators. They have successfully used these T-cell lines to induce permanent remission in patients relapsing with CML after BMT. Although this is clear proof of principle, better and more reliable techniques for selecting and expanding leukemia-specific T cells are needed before this approach can have general application (54).

Graft-versus-Tumor Effects

By extension, it can be hypothesized that an allogeneic GVT response analogous to the GVL effect could be used to treat solid tumors. Evidence supporting the possibility of an allogeneic GVT effect is summarized in Table 13.3-3 . Malignancies arising in skin, the gastrointestinal tract, and biliary tree, which are targets of the GVHD response, might be similarly susceptible to immune damage from donor immune cells. Conversely, tissues uninvolved in GVHD reactions (e.g., muscles and the nervous system) may, by the same argument, be immune to GVT effects. A useful

approach to identifying susceptible tumors would be the demonstration that allogeneic cytotoxic T lymphocytes or NK cells and lymphokine-activated killer cells are cytotoxic to the tumor cells. The tumor characteristics required for a GVT response would include slow proliferation (matching the relatively slow pace of the T-cell response) and surface expression of MHC class I and II, costimulatory molecules (CD80, CD86) and adhesion molecules, such as the ICAM molecules and fas. Many malignancies possess some or all of these characteristics. It should also be noted, however, that many solid tumors have developed mechanisms to escape immune-mediated killing. Locus or allele-specific downregulation of MHC molecules is a common mechanism used by tumor cells to escape T-cell attack. In addition, aberrations in the number of MHC molecules on the surface of melanomas affect their susceptibility to lysis by cytotoxic T lymphocytes. Solid tumors may escape host immune surveillance by upregulating fas-ligand expression, leading to direct cytotoxicity of those lymphocytes that may have targeted the tumor.

Table 13.3-3 Arguments For and Against a Graft-versus-Tumor Effect

Arguments in favor of a graft-versus-tumor effect:

Tumors arising in tissues that are targets of cytotoxic damage in graft-versus-host disease could also be susceptible to immune-mediated apoptosis.

Tumors possessing major histocompatibility class I and class II, ICAM-1, B7.1, and fas should be targets of T-cell attack.

Evidence exists of autologous antitumor immune responses in some malignancies. Alloresponses are likely to be at least as powerful.

Alloreacting T cells can recognize a wide range of antigens on the recipient's malignant cells (e.g., minor histocompatibility antigens, alleles of tissue-specific antigens).

Clinical graft-versus-malignancy effects are being demonstrated in a widening range of diseases (e.g., leukemias, lymphomas, myeloma, and some solid tumors).

Arguments against a graft-versus-tumor effect:

Tumors arising in tissues not involved in graft-versus-host disease are less likely to be suitable targets of alloreacting T cells.

Tumors are notoriously adapted to escape from immune control.

Posttransplant immune deficiency may favor tumor progression.

Graft-versus-tumor effects may be abrogated after the establishment of tolerance posttransplant.

Large tumor masses may limit complete infiltration by tumor-infiltrating lymphocytes.

Delayed second malignancies develop after bone marrow transplants.

ICAM-1, intracellular adhesion molecule-1.

Malignant melanoma and renal cell carcinoma deserve special consideration. The occurrence of autologous T cells that recognize and kill the tumor in these malignancies strongly supports the possibility of a therapeutic effect from a T-cell allograft.

Stem-Cell Transplants for Solid Tumors in Humans

The clinical experience of stem-cell allografts in solid tumors is limited and, at best, anecdotal. At this stage, proof that clinically measurable GVT effects occur is scanty. Inevitably, in these experimental techniques, patients with advanced disease with no other conventional treatment options have been selected for treatment. The following accounts provide the first proof of principle that allogeneic GVT effects may have a place in the treatment of cancer.

Breast Cancer

To evaluate the feasibility of allogeneic PBPC transplantation and to assess GVT effects in patients with metastatic breast cancer, investigators at the M. D. Anderson Cancer Center evaluated allogeneic PBPC transplantation in ten women (median age, 42 years) with metastatic breast cancer involving the liver or bone marrow. The patients were prepared with a myeloablative regimen of cyclophosphamide, carmustine, and thiotepa. GVHD prophylaxis was achieved with cyclosporine or tacrolimus. All patients engrafted with full hematologic recovery. Three patients developed grade II acute GVHD, and four patients had chronic GVHD. After transplantation, one patient was in complete remission, five patients achieved a partial remission, and four patients had stable disease. In two patients, metastatic liver lesions regressed in association with skin GVHD after withdrawal of immunosuppression. The regression of tumor associated with GVHD suggests a GVT effect. Because of the slow progression of some patients with metastatic breast cancer, however, longer follow-up and larger studies are required to fully evaluate a beneficial effect of PBPC allografts in this disease (55). A further case report of a regression of breast cancer metastases coincident with acute GVHD has been reported in Germany (56).

Renal Cell Cancer

In renal cell cancer, some evidence exists that autologous T lymphocytes exert an immune antitumor response: Tumor-infiltrating lymphocytes can be readily isolated from some renal cell carcinomas and have been shown *in vitro* to have HLA-restricted specific cytotoxicity against tumor cells (57). Because renal cell cancer has been shown *in vitro* to be a target for T-cell cytotoxicity and potential renal tissue-restricted mHAs have been described, we carried out an experimental study of allogeneic PBPC transplants in patients with advanced metastatic renal cell carcinoma (58). To minimize the complications of transplantation, we used a nonmyeloablative preparative regimen of cyclophosphamide (120 mg per kg), followed by fludarabine (125 mg per m^2), to immunosuppress, but not myeloablate, the recipient. Three patients with metastatic renal cell cancer have received PBPC transplants from HLA-identical or near-identical siblings. All three patients showed a response with diminution of pulmonary and hepatic metastases beginning approximately 2 to 4 months posttransplant. Figure 13.3-4 illustrates the resolution of pulmonary metastases in the first patient treated. Two patients are currently well and disease free; the third patient continues to show tumor regression on successive computed tomography scans. The preparative regimen was well tolerated, and GVHD was readily controlled with combinations of steroids and cyclosporine. These promising results

suggest that some patients with renal cell carcinoma may benefit from allogeneic stem-cell transplantation. The results encourage further exploration of a GVT effect from allogeneic stem-cell transplantation in the treatment of other advanced malignant diseases.

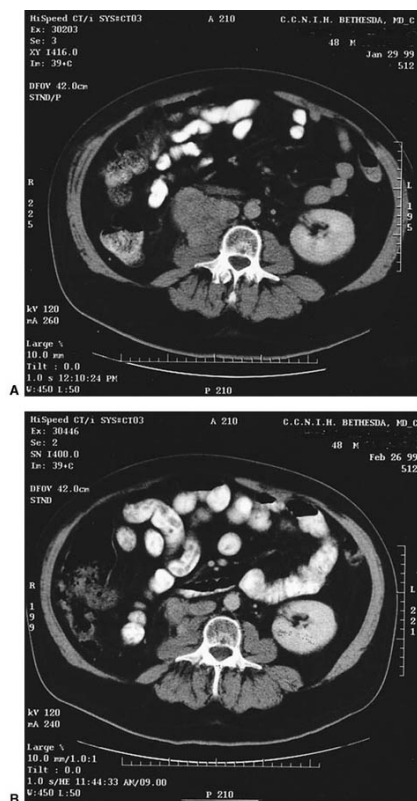

FIGURE 13.3-4. Regression of metastatic renal cell carcinoma after nonmyeloablative stem-cell transplant in a 48-year-old man. A: Computed tomography scan on day 100 posttransplant with stable retroperitoneal disease. (The original tumor in the right kidney was surgically removed 1 year previously.) At this point, cyclosporine treatment for graft-versus-host disease was withdrawn. B: Repeat computed tomography scan at the same level on day 129 shows marked tumor regression.

Future Prospects

Part of "13.3 - Allogeneic Graft-versus-Leukemia and Antitumor Effects "

The GVL effect is emerging as the most powerful form of T-cell–mediated immunotherapy in use in clinical practice. Furthermore, the full potential of alloreacting lymphocytes to control an increasing variety of malignant diseases is becoming apparent. The challenge for the future is to characterize the nature of the alloimmune response against the malignant disease, to refine the approach to alloimmunotherapy, and to avoid the unwanted aspect of GVHD. Ultimately, it should be possible to use healthy donors to provide *in vitro*-expanded lymphocytes, specific for a given malignancy to augment the immune response to the disease after transplant. It is also possible that, in the future, improved transplant preparative regimens will allow the use of adoptive T-cell immunotherapy without the toxicity associated with intensive myeloablative transplants.

Introduction

Part of "13.4 - Adoptive Cellular Immunotherapy for Epstein-Barr Virus-Associated Malignancies "

Epstein-Barr virus (EBV) is a latent herpesvirus that infects more than 90% of the world's population. The primary infection usually begins in the oropharynx, where mucosal epithelial cells become productively infected. The virus produced in these cells may then infect neighboring epithelial cells and B cells circulating through the mucosa-associated lymphoid tissues (MALTs). Primary infection most often results in a mild, self-limiting illness that is followed by lifelong virus latency in oral epithelial cells and in B cells (1 ,2). B cells infected with EBV *in vitro* undergo transformation as a result of the expression of latency-associated transforming protein (2). In normal seropositive individuals, B cells that express these proteins are tightly controlled by the abundant EBV-specific T cells present in the circulation (3). Although cell-mediated responses to the immunogenic proteins prevents outgrowth in the immunocompetent host, reactivation of EBV in severely immunocompromised individuals can lead to uncontrolled lymphoproliferation and the development of frank B-immunoblastic lymphoma (2 ,4). The proliferating EBV-infected B cells seen in lymphoproliferative disease (LPD) have a phenotype and pattern of EBV gene expression identical to that of lymphoblastoid cell lines generated by infecting normal peripheral blood mononuclear cells (PBMCs) with EBV. This type III latency (Table 13.4-1 and Table 13.4-2) involves the expression of nine latency-associated viral proteins: Epstein-Barr nuclear antigens (EBNAs) 1, 2, 3a, 3b, 3c, and EBNA leader protein (EBNA-LP); the latent membrane proteins (LMP)1, 2a, and 2b; and the cytosolic protein RK-BARFO. Because the cells express viral antigens and are rich in cell adhesion and costimulatory molecules, they are highly immunogenic (Fig. 13.4-1) and are normally susceptible to immune-mediated killing.
Immunogenicity of LCLs

FIGURE 13.4-1. Phenotype and pattern of Epstein-Barr virus (EBV) gene expression of a lymphoblastoid cell line (LCL) that is identical to the cells that outgrow in EBV lymphoproliferative disease after bone marrow transplant. These cells express all latent cycle EBV antigens [Epstein-Barr nuclear antigens (EBNA)1, EBNA2, EBNA3A, EBNA3B, EBNA3C, latent membrane protein (LMP)1, LMP2a, and LMP2b], as well as a number of adhesion and costimulatory molecules that enhance cytotoxic T lymphocyte (CTL) generation and target recognition. (ICAM-1, intracellular adhesion molecule-1; LAK, lymphokine-activated killer cell; LFA, lymphocyte functional antigen; TCR, T-cell receptor.)

Table 13.4-1 Types of Epstein-Barr Virus (EBV) Latency

EBV Genes	Latency Type
LMP2a	0
EBNA1, BARTs, EBERs, ± LMP2a	I
EBNA1, BARTs, EBERs, LMP1, LMP2a	II
EBNA1, 2, 3a, 3b, 3c, LP; LMP1 and 2; BARTs and EBERs	III

BARTs, a rightward transcript encoding at least one protein (RK-BARFO); EBERs, EBV small RNAs; EBNA, EBV nuclear antigen; LMP, latent membrane protein.

Table 13.4-2 Epstein-Barr Virus (EBV)—Associated Diseases

EBV-Related Disease	Cell Type	Latency Type	Reference
Burkitt lymphoma	B lymphocyte	I	83
Gastric carcinoma	Mucosal epithelium	I	84
Nasal natural killer lymphoma	Natural killer	II	85,86
Pleural cavity lymphoma	B lymphocyte	I/II	87
Parotid carcinoma	Mucosal epithelium	II	88
Hodgkin's lymphoma	B lymphocyte	II	89
Nasopharyngeal carcinoma	Mucosal epithelium	II	90
T-cell lymphoma	T lymphocyte	II	91
Midline granuloma	T lymphocyte	II	86
Thymic carcinoma	Epithelium	III	92
Pyothorax-associated lymphoma	B lymphocyte	III	93
Infectious mononucleosis	B lymphocyte	III	94
Lymphoproliferative disorders	B lymphocyte	III	95
Leiomyosarcoma	Smooth muscle	N/A	5
Sjögren's syndrome	—	N/A	97
Adrenal lymphoma	B lymphocyte	N/A	96

N/A, not applicable.

In immunocompetent individuals, latent EBV is associated with other types of malignancy (see Table 13.4-2). In approximately 50% of patients with Hodgkin's disease, EBV antigens can be detected in the pathognomonic Reed-Sternberg cells (5), whereas patients with endemic nasopharyngeal carcinoma express EBV antigens in the epithelial tumor cells. In both of these malignancies, a more restricted array of EBV antigens (EBNA1, RK-BARFO, LMP1, 2) are expressed in a pattern termed *type II latency* (see Table 13.4-1). A number of other virus-associated malignancies—in particular, carcinomas of mucosal epithelium and mucosa-associated lymphoid tissue (MALT) lymphomas—also express type II EBV-latency antigens. In endemic Burkitt lymphoma

(West and North Africa, Papua New Guinea), the B cells are also infected with latent EBV but express only two latency-associated antigens, EBNA1 and RK-BARFO, and are termed *type I latent cells* (see Table 13.4-1). Other malignancies, such as smooth muscle leiomyosarcomas common in children with acquired immunodeficiency syndrome and in organ transplant recipients, also carry the EBV genome, although their latency type is unclear (4). In principle, all of these tumors should be suitable targets for immunotherapy directed against the appropriate EBV-associated latency antigens. In this chapter, we describe the successes and limitations of this strategy.

Epstein-Barr Virus–Related Lymphoproliferative Disease

Part of "13.4 - Adoptive Cellular Immunotherapy for Epstein-Barr Virus-Associated Malignancies "

Pathogenesis

The onset of EBV-LPD seems to be preceded by a large increase in EBV load, as well as the proliferation of EBV-infected B cells. Rises in EBV levels have been observed before the onset of LPD in solid organ transplant patients (6 ,7 and 8) and in stem-cell transplant patients; a 2- to 3-log increase in EBV DNA was found to be highly predictive of the subsequent development of EBV-related lymphoproliferation (9). These observations were confirmed by Lucas et al. (10), who reported high EBV-DNA levels (>40,000 copies per μg DNA) in the peripheral blood leukocytes of patients with T-cell–depleted transplants, as compared with low levels (40 to 4,000 copies per μg) in recipients of unmanipulated stem-cell transplants and healthy seropositive individuals. The increase in EBV load was associated with an increased risk of LPD. The disease begins as a polyclonal lymphoproliferation but may evolve into an oligoclonal or even a monoclonal true immunoblastic lymphoma.

Several viral factors that may be important in the pathogenesis of LPD have been elucidated. The transforming protein EBNA2 functions through interaction with the cellular DNA-binding protein human C protein-binding factor (CBF1) to control the expression not only of viral genes, but also of cellular genes, such as CD21, CD23 (11), and c-fgr (12). EBNA3a, 3b, 3c, and LP appear to be important in regulating the activity of EBNA2. The growth-promoting effect of LMP1 in LPD was

shown to be mediated by binding to cytoplasmic tumor necrosis factor receptor–associated factors, leading to activation of the NF-κB transcription factor (13 ,14). The constitutive activity of LMP1 can replace activation of CD40 ligand, upregulating the epidermal growth factor receptor and preventing apoptosis (15). EBV relies on a number of mechanisms for modulating host immune responses, some of which may play a role in the pathogenesis of LPD. Viral interleukin-10 (IL-10) expressed as a late protein and cellular IL-10 induced in B cells by LMP1 not only act as autocrine growth factors for B cells but also inhibit the activation of macrophages and inflammatory responses (16 ,17 and 18). The CD8[+] T-cell response to EBV includes γ-interferon-secreting cytotoxic T lymphocytes (CTLs) and cells secreting the type II cytokines IL-4 and IL-13, which can activate EBV-infected B cells (19). Thus, although the CTL response to EBV is an important factor in host control of EBV infection and the proliferation of EBV-infected B cells (2), the virus may also manipulate the immune response, allowing viral persistence. In the setting of transplantation and immunosuppression, this complex regulatory balance is disturbed, allowing uncontrolled growth of EBV-infected B cells and reactivation of latent EBV infection (20 ,21).

Incidence and Risk Factors

In general, the incidence of EBV-LPD rises as the level of host immunosuppression increases (Table 13.4-3). For example, after stem-cell transplantation, EBV-LPD is highest in recipients of grafts from mismatched family members or closely matched unrelated donors, when the stem-cell preparations have also been depleted of donor T cells to prevent graft-versus-host disease (GVHD), a severe and frequent complication of such transplants. The incidence of EBV-LPD is lowest in recipients of autologous stem cells. Several reports, however, suggest an increasing incidence of EBV-LPD in these patients because of more ablative preparatory regimens used in conjunction with stem-cell transplants depleted of T cells by procedures such as CD34 selection (22) or *in vitro* purging (23). There has even been a documented case developing after intensive chemotherapy for a B-cell malignancy, not followed by transplantation (24). After solid organ transplantation, the incidence of LPD is highest in recipients of heart–lung or gut grafts and lowest in those with renal transplants. Overall, the incidence after T-cell depletion ranges from less than 2% to as high as 26% (see Table 13.4-3), representing a devastatingly frequent and lethal problem in some groups of patients (10 ,21 ,25 ,26 and 27). After allogeneic stem-cell transplantation, the proliferating B cells are almost always of donor origin (>95%), and methods that deplete not only donor T cells but also donor B cells appear to reduce the disease incidence. In a large review of patients whose transplants were treated with the Campath series of antibodies, the incidence of EBV-LPD was less than 2% (28). A similar low incidence was seen after elutriation, which removes more than 90% of B cells from the donor graft (29). In a French series, addition of a monoclonal antibody-depleting B cells to the T-cell-depletion regimen resulted in no cases of EBV lymphoma in 19 patients compared with 7 in 19 historical controls (30). After solid organ grafting, EBV-related lymphomas more often derive from host B cells and are correspondingly harder to prevent by manipulation of the graft (31).

Table 13.4-3 Incidence of Epstein-Barr Virus–Related Lymphoproliferative Disease after Different T-Cell Depletion Methods

Center	T-Cell Depletion Method	Incidence (%)	Reference
Memorial Sloan-Kettering Cancer Center	E-rosetting	11.0	21
St. Jude Children's Research Hospital	CD6/CD8 or T10/B9 monoclonal antibodies	11.5	26
Indiana University School of Medicine	E-rosetting or CD34 selection	26.0	10
University of Wisconsin, Madison, Medical School	CT-2 antibody	11.0	22
Medical College of Wisconsin	CD3 monoclonal antibodies and complement	8.0	98
Leiden University	E-rosetting	14.0	21
Multicenter (Europe)	CAMPATH (CD52) antibody	<2.0	28

Conventional Treatment

Because EBV-induced LPD is driven by latent virus, drugs such as acyclovir that interfere with viral replication have been of little benefit in prevention and of no benefit in treatment. Indeed, several reports suggest that in fact the EBV thymidine kinase gene does not phosphorylate acyclovir to the active agent, although this drug clearly inhibits virus replication *in vivo* and *in vitro*(32 ,33 ,34 and 35). In organ transplant recipients, the disease usually involves transmission of donor virus to recipient B cells, so that this transmission phase should be susceptible to inhibitors of virus replication. The timing of drug administration may be critical.

Because of the limitations of drug therapy, the treatment of EBV-LPD has largely been focused on strategies that boost the immune response to EBV. In solid organ transplant patients, simply withdrawing immunosuppressive therapy has proven effective but carries a high risk of graft rejection (31 ,36). Because of the more pronounced immunodeficiency after bone marrow transplantation, withdrawal of immune suppression does not usually result in a rapid enough immune recovery to eradicate EBV-infected B cells, although anecdotal reports of responses occurred in some patients who had developed lymphoma as their immune response was recovering (37 ,38). Therapy with interferon-α plus intravenous immune globulin after solid organ grafting and in a small number of hemopoietic stem cell recipients have elicited responses in some cases (31 ,38).

Anti-B-cell antibodies, a third approach for treating LPD, have been used clinically with some success in hemopoietic stem cell and organ transplant patients (39), although responses were often incomplete or transient. The anti-CD21 and anti-CD24 antibodies used in these studies are not clinically available, but anti-CD20 conjugated to ritoxylin has

been approved for clinical use and may be warranted in some patients (40). Hydroxyurea and EBV-specific ribozymes are two other agents used in preclinical studies (41 ,42). Low concentrations of hydroxyurea eradicated latent EBV infection and inhibited proliferation of EBV-infected cell lines *in vitro* (41). Because hydroxyurea has been used clinically for other applications and has an acceptable toxicity profile at the doses suggested, it may be useful in patients for whom adoptive immunotherapy is not available. Adenoviral vectors encoding a ribozyme directed to EBNA1, an EBV protein required for viral replication, inhibited the growth of EBV-infected cells *in vitro* and in severe combined immunodeficiency disease mice (42). This strategy would likely be limited *in vivo*, however, because of low gene transfer efficiency.

Unmanipulated Donor T cells

Part of "13.4 - Adoptive Cellular Immunotherapy for Epstein-Barr Virus-Associated Malignancies "

Overall, the failure of available treatments for EBV-LPD, coupled with an improved understanding of the biology of the disease, has stimulated interest in cellular immunotherapies. Most people infected with EBV have persistent infections, so that a significant proportion of peripheral blood T lymphocytes (from 1 in 300 to 1 in 4,000) are specific for the virus. It was therefore postulated that adaptively transferred PBMCs would include small numbers of EBV-specific T lymphocytes, which may proliferate *in vivo* and restore the patients' ability to respond to the virus and extirpate the lymphoma. Papadopoulos et al. (43) from Memorial Sloan-Kettering Cancer Center originally reported on five patients with EBV-LPD, all of whom responded to donor leukocyte infusion. These patients received less than 10^7 total T cells per kg, so that their response can be credited to EBV-specific T cells that originally numbered only in the tens of thousands and presumably underwent massive expansion *in vivo.* Although the percentage of EBV-specific T cells in peripheral blood is relatively small, a much higher proportion of T lymphocytes may be alloreactive, and these, too, can expand if the host expresses the relevant alloantigens. As might be predicted, therefore, three of these patients developed GVHD. Unexpectedly, two died from respiratory insufficiency (43), presumably because of the inflammatory reactions that occurred when EBV-specific T cells entered pulmonary tissue infiltrated by large numbers of EBV-positive immunoblasts. In an update of the Sloan-Kettering experience, 17 out of 19 patients responded to donor T cells (21). Other centers have also reported success with this strategy (10 ,44 ,45) while emphasizing the risk of GVHD (10 ,44). Still, others have had only poor rates of response to donor T cells (Table 13.4-4). Lucas et al. (10) described the Indiana University experience in treating LPD (10). In a comparison of outcomes among recipients of T-cell-depleted allogeneic stem-cell transplants who were treated with donor leukocytes or ten patients treated by observation, interferon-α plus intravenous immune globulin, chemotherapy, or surgery (10), only one of the control patients (surgery only) survived. By contrast, complete responses were induced in 4 out of 13 (31%) patients in the group receiving donor leukocytes, although 31% also experienced severe GVHD. One of the two patients who survived was actually treated with EBV-specific CTLs (see the section Virus-Specific Cytotoxic T Lymphocytes later in this chapter) (10). The Indiana investigators noted that five of the nine patients with disease progression died within 10 days of receiving donor leukocytes, most likely because of advanced LPD at the time of treatment, and therefore advocated earlier diagnosis and therapy. Two case reports from Japan describe patients who failed to respond to donor T cells (46 ,47), and none of three patients treated at the University of Minnesota responded (38). The reasons for these differences in response rate are unclear, but they may reflect different types of disease or a better outcome with early diagnosis.

Table 13.4-4 Therapy for Epstein-Barr Virus (EBV) Lymphoproliferative Disease with Donor T Cells or EBV-Specific Cytotoxic T Lymphocytes (CTLS)

Cell Product	Responses	GVHD	Reference
Therapy			
Donor T cells	17/19	3 acute, 8 chronic	21
Donor T cells	1/1	1/1	44
Donor T cells	0/3	Not reported	38
Donor T cells	4/13[a]	4/13	10
Donor T cells	0/1	0/1	46
EBV-specific CTLs and donor T cells	0/1	0/1	45
EBV-specific CTLs	2/3	0/3	58
Prophylaxis			
EBV-specific CTLs	0/39 developed LPD	1/39	58

GVHD, graft-versus-host disease; LPD, lymphoproliferative disease.

[a]One responder received EBV-specific CTLs.

Two strategies have been used to reduce the risk of GVHD after immunotherapy with donor T cells. The first, evaluated by Bonini and colleagues (48), is to transduce T cells with a "suicide gene," so that cell death may be induced if adverse effects occur after treatment of EBV-LPD or leukemic relapse (48). After a brief 24- to 48-hour primary stimulation with antigen, lymphocytes were transduced with a construct containing the thymidine kinase gene, which phosphorylates ganciclovir and renders host cells sensitive to the cytotoxic effects of the active drug. The construct also encoded a truncated version of the low-molecular-weight nerve growth factor gene, whose expression on the lymphocyte surface allows its use as a selectable marker. Eight patients have been reported, and, in three, ganciclovir treatment abolished the signs and symptoms of GVHD (48). A multicenter trial is in progress. The second strategy, adopted by our own center, is to administer EBV-antigen-specific CTLs (26) rather than unmanipulated polyspecific donor T cells with the intent of avoiding alloreactivity.

Virus-Specific Cytotoxic T Lymphocytes

Part of "13.4 - Adoptive Cellular Immunotherapy for Epstein-Barr Virus-Associated Malignancies "

Virus-specific CTLs were first used by investigators in Seattle, who administered cytomegalovirus-specific CD8 T-cell clones to three recipients of matched sibling grafts (49 ,50). No adverse effects from the adoptive transfer of these clones occurred. Moreover,

cytomegalovirus-specific immune responses were reconstituted, and none of the patients developed cytomegalovirus disease (49). Because the tumor cells of posttransplant EBV-LPD express all latent-cycle virus-encoded antigens (EBNA1, 2, 3a, 3b, 3c, and LMP1, 2a, 2b), it should be an excellent model in which to evaluate the efficacy of adoptively transferred antigen-specific CTL therapy. Moreover, EBV-transformed B-lymphoblastoid cell lines (LCLs) can readily be prepared from any donor and could provide a source not only of antigen-presenting cell expressing the appropriate viral antigens, but also of autologous target cells bearing the tumor antigens for CTL testing. Finally, most donors are immune to EBV, and because the virus persists in latent form, the EBV-specific CTL precursors persist long term in higher frequency than precursors specific for acutely infectious viruses. All of these features simplify the technical aspects of preparing EBV-CTL.

Functional CTL epitopes have been identified in seven of the nine EBV latency-associated proteins (51 ,52) and could be used to generate T-cell clones specific for each epitope. We elected to prepare polyclonal T-cell lines, however, because we did not know which epitopes are protective *in vivo* and because of fear that mutations in single viral epitopes would permit escape from monospecific T-cell clones. Hence, donor-derived EBV-specific CTL lines were generated by culturing donor T cells with donor-derived EBV-infected LCLs using techniques that have been described in detail (53). To determine how long these cells would persist in the recipient and to evaluate adverse or therapeutic effects, we marked the CTLs with a retroviral vector encoding the neomycin resistance gene.

Since our study opened, we have been able to establish cell lines from the CTLs of more than 120 normal donors, failing in only two cases (one seronegative and the other a recent seroconversion). CTL lines were predominantly CD3+ (median, 99%) and contained CD4+ and CD8+ T cells. Both subsets were retained in the infused lines because CD4+ cells may play an important role in maintaining long-term CD8+ cytotoxic effector cells (54). The median percentages of CD4+ and CD8+ cells were 19% and 75%, respectively, but with wide variation among individual lines (55). All lines readily killed autologous LCL but showed variable activity against HSB-2 cells, targets of activated natural killer cells (55).

Clinical Trial of Cytotoxic T Lymphocytes as Prophylactic Therapy

We determined if adoptively transferred EBV-specific CTLs might be effective in preventing or treating EBV-LPD in recipients of mismatched or unrelated donor transplants who were at high risk for this complication (56). Patients were eligible for the study beginning at day 45 posttransplantation if they had engrafted, did not have severe GVHD (>grade II), had normal liver function, and had no severe intercurrent infection. The initial design was a dose-escalation study, but after six patients had been treated at the first two dose levels (4×10^7 and 1.2×10^8 cells per m^2 over 4 weeks), evidence existed of both persistence and efficacy (58). The study was then modified so that the remaining patients received just two injections of 2×10^7 cells per m^2 4 weeks apart. Subsequently, a single injection proved effective, emphasizing how few EBV-specific T cells are needed to reconstitute the host defense against EBV.

Safety and Toxicity

As of January 1999, 54 patients were enrolled on the prophylaxis arm of this study. No immediate adverse effects of CTL administration occurred. Of particular importance, no evidence existed of acute GVHD within the first 3 months after CTL administration. This is significant because CTLs that recognize certain EBV-derived peptides in the context of a particular HLA molecule can cross-react with alloantigen (58). In two patients, preexisting GVHD continued; however, a biopsy specimen from one patient who had received gene-marked CTLs showed no evidence of selective accumulation of marked cells. Four other patients developed limited chronic GVHD, although the incidence was somewhat lower than in a comparable transplant group who did not receive CTLs (57).

Persistence of Immune Response

Reconstitution of immunity to EBV after adoptive transfer of CTL lines was demonstrated by a rise in virus-specific CTL activity in peripheral blood and by an increase in CTL precursor frequencies to the high end of the normal range (59). The level of marker gene detection in CD4+ and CD8+ components ranged from 0.1% to 1%, corresponding to levels in the infused lines. T cells in peripheral blood that were positive for the neo marker gene were not detectable by polymerase chain reaction (PCR) at 18 weeks' postinfusion. Antigen-reactive precursors persisted at a subthreshold level, however, and readily could be expanded to a detectable level by stimulation with EBV-LCL *in vitro.* Indeed, in these studies, it was possible to detect CTLs by this method more than 4 years after their administration (26). Additional evidence for long-term persistence of *in vivo* immunity is available from a boy with late reactivation of EBV (more than a year after CTL infusion) (59). He presented with fever and had an elevated EBV-DNA level in his peripheral blood. The marker gene, which had been undetectable in peripheral blood for 9 months, reappeared at this time, suggesting that the transferred CTLs had expanded in response to an increased viral load. The patient received no specific therapy, EBV-DNA levels returned to baseline, and the neo signal again disappeared from peripheral blood. The long-term persistence of antigen-specific CTLs may relate to the continued presence of EBV antigen and to the presence of CD4+ cells and CD8+ cells in the infused line.

Clinical Effects

None of the 54 patients in the prophylaxis study developed EBV-LPD, compared with 6 (11%) of 52 controls ($p <.03$) (58). The latter group consisted of patients who received T-cell–depleted marrow from mismatched-related or matched-unrelated donors but not prophylactic CTLs, owing to transplantation before the current study opened, ineligibility, or refusal to participate. Additional data also suggest the efficacy of CTL prophylaxis. We and others have shown that high EBV-DNA levels in peripheral blood are

strongly predictive of the development of EBV-LPD (6 ,7 ,9). Thus, the initial presence of such levels in seven patients scheduled to receive CTLs might be expected to produce a high incidence of EBV-LPD. But, in fact, the EBV-DNA level in each of these patients returned to normal within 1 to 2 weeks after CTL infusion, and none of this subgroup developed EBV-LPD (58). These findings suggest that EBV-specific CTLs are effective therapy for "incipient" lymphoma, in addition to preventing the disease in patients without unfavorable presenting features.

Cytotoxic T Lymphocytes for Established Epstein-Barr Virus–Related Lymphoma

We also treated four patients who did not receive CTLs prophylactically and who subsequently developed frank EBV-related immunoblastic lymphoma. In three cases, CTL infusion produced disease resolution. Two of the patients presented with nodal disease and attained remission uneventfully after receiving 1.2×10^8 or 2×10^7 CTLs per m^2 (74 and *unpublished data*). A third patient presented with high fever and bulky cervical and nasopharyngeal disease causing respiratory compromise at 7 months after transplantation of cells from an unrelated donor (58). After the diagnosis of EBV-LPD was confirmed, he received 2×10^7 CTLs per m^2. Over the next week, cervical and oropharyngeal swelling increased, necessitating tracheostomy. A biopsy of sample nasopharyngeal tumor taken at that time showed an infiltrate of small lymphocytes, the majority of which stained with antibodies to T-cell markers; a few residual B cells were also found. Both *in situ* PCR and semiquantitative PCR analysis of DNA extracted from nasopharyngeal tissue showed that 1% of the infiltrating lymphocytes were positive for the neo marker gene, a marking efficiency similar to that in the adoptively transferred line. These data suggest that the gene-marked EBV-specific T cells had selectively accumulated at the tumor site. Because of evidence that the tissue swelling represented an inflammatory response during therapy rather than disease progression, this boy received no further specific therapy and remains in remission 3 years later. The complexity of this case provides a clear illustration of why prophylactic or early treatment (i.e., when elevated EBV-DNA levels are detected) is more desirable than treatment of established disease.

The fourth patient in this series illustrates another reason why CTL prophylaxis is preferable to treatment of overt disease. This 17-year-old girl received a T-cell–depleted unrelated donor transplant. She was admitted to the hospital on day 45 with fever, and repeated computed tomography scans showed progressive pulmonary infiltrates and nodules (61). Her EBV-DNA levels were high, and she received CTLs on day 56. Her lung disease progressed, and a lymph node biopsy revealed persisting lymphoblasts. She died on day 80 with an autopsy showing widespread EBV-positive lymphoma. Why did treatment fail? Analysis of her CTL line showed that almost all activity was directed towards a single EBV antigen, EBNA3b, and to two epitopes within that antigen (61). Sequencing of the viral DNA within the tumor revealed a deletion affecting precisely those two epitopes recognized by the CTL line. The loss of the two immunodominant epitopes thereby caused resistance to killing by the CTLs (61). The occurrence of escape mutants argues for treating patients when they have a low viral/tumor burden and, hence, a lower probability of mutation. The result also argues against attempting to substitute T-cell clone(s) for polyclonal lines because the escape phenomenon is more likely to occur when there is a limited range of target epitopes to be recognized.

Cytotoxic T Lymphocytes for Recipients of Solid Organ Transplants

The successful use of anti-EBV CTL in solid organ recipients requires identification of recipients at high risk of disease. Several groups fall into this category:

- Seronegative recipients are at particularly high risk of posttransplant lymphoma because they frequently fail to mount an effective primary immune response to virus associated with the graft or other blood products. Although it is not possible to generate anti-EBV CTL from the T cells of seronegative recipients using EBV-transformed B-cell lines as antigen presenters, dendritic cells have the capacity to induce primary immune responses *in vitro*, and thus may be able to recruit naive CTL precursors *in vitro* to become EBV-specific effector cells. For example, dendritic cells can be induced to express EBV peptides by transducing them with recombinant vectors or pulsing them with apoptotic LCL, after which they are capable of inducing EBV-specific CTL, even from naive donors (CM Rooney, *unpublished data*).
- Patients whose grafts (e.g., pancreas or intestine) contain high B-cell numbers are also at high risk of EBV-LPD.
- Individuals who have received prolonged or intensive immunosuppression to overcome repeat rejection episodes may be at exceptionally high risk if they are also in the first two categories. Of note, CTLs can still be generated from such patients by *ex vivo* culture, even when the patients are receiving intensive immunosuppressive therapy.
- Few reports of treatment of organ recipients with anti-EBV CTLs exist, but Comoli et al. (personal communication, 1999) have shown that liver transplant recipients with EBV-LPD respond to autologous CTL infusions with dramatic decreases in virus load and tumor regression. As with bone marrow recipients, the successful use of CTLs in organ recipients requires careful monitoring of virus load and may work best with early or prophylactic administration. Although most investigators who have studied CTL therapy after solid organ transplantation propose using autologous T cells, two alternative treatments, EBV-reactive CTLs from HLA-matched or haploidentical related donors, are being evaluated at the Johns Hopkins Medical School (61).

Improving the Feasibility of Cytotoxic T Lymphocyte Therapy

The feasibility of making CTL treatment available for patients with active EBV-LPD would be increased if it were possible to shorten the time required to prepare the activated lymphocytes. Four to 6 weeks are needed to generate LCL lines and an additional 4 to 6 weeks to generate specific CTLs. It may be possible to simplify and accelerate the production of CTLs by substituting

dendritic cells expressing EBV antigens for the LCLs. Because dendritic cells can be prepared in only 3 to 7 days (63), their use would markedly reduce the total preparation time. Moreover, dendritic cells can be used to stimulate CTL responses to the more restricted set of EBV antigens expressed by Hodgkin's disease and nasopharyngeal carcinoma cells (64). Their value would therefore be especially high in extending adoptive immunotherapy to the EBV-related malignancies described below (see the section Immunotherapy for Epstein-Barr Virus–Related Hodgkin's Disease).

Immunotherapy for Epstein-Barr Virus–Related Hodgkin's Disease

Part of "13.4 - Adoptive Cellular Immunotherapy for Epstein-Barr Virus–Associated Malignancies "

Although the origin of Hodgkin's disease remains unclear, approximately 50% of cases in North America and Europe are associated with EBV (4). In South America, Kenya, and parts of Asia, a 90% to 100% association exists. Thus, CTLs could prove a valuable addition to conventional therapy for EBV and Hodgkin's disease, if they could be marshaled against this disease as effectively as against EBV-LPD. Although 80% or more of patients with Hodgkin's disease are cured with available treatments, 50% of the minority who relapse do not respond to salvage chemotherapy or relapse a second time. Furthermore, the unacceptably high level of therapy-related secondary malignancies (18% at 5 years) and other serious medical complications in those who are "cured" also underscores the need to improve current therapeutic options (65).

A number of obstacles could diminish the effectiveness of EBV-specific CTLs in Hodgkin's disease. First, the malignant cells express a restricted set of viral genes, namely, EBNA1, RK-BARFO, and LMP1 and 2 (66). In the majority of cases, memory CTL responses are preferentially directed against the highly immunogenic EBNA3a, 3b, and 3c antigens, irrespective of the patient's HLA type. By comparison, EBNA-1, RK-BARFO, and LMP1 and 2 are poorly immunogenic. EBNA1 contains a repeating glycine-alanine amino acid sequence that inhibits its ubiquitination and subsequent processing and presentation of EBNA1 peptides by HLA class I antigens (67). RK-BARFO-specific CTLs can be generated *in vitro* from seropositive individuals, but they do not kill target cells naturally expressing the protein (68). The mechanism for this immune evasion is unclear. The reason for the limited immunogenicity of LMP1 and 2 is similarly unclear, because LMP1 or 2 epitopes are presented in the context of the HLA A2.1, B24, B40, B51, and B55 alleles (51 ,69). This lack of immunogenicity is particularly disappointing because EBV and Hodgkin's tumors express costimulatory molecules, such as HLA DR, CD40, CD80, and CD86, and should therefore be excellent antigen-presenting cells. They also secrete the Th2 cytokines IL-10 and tumor growth factor–β, however, as well as thymus and activation-regulated chemokine (TARC), a chemoattractant for CD4+ T cells of the Th2 biotype (70). This overwhelmingly Th2 phenotype likely helps the antibody response and inhibits the CTL response. IL-10 may also act as an autocrine growth factor for Reed-Sternberg cells. Patients with Hodgkin's disease also have T-cell abnormalities, such as low expression of the zeta chain of the T-cell receptor (71), which further reduce the effectiveness of the host immune response to the tumor (72).

To assess the feasibility of using EBV-specific CTLs as therapy for Hodgkin's disease, we generated EBV-specific CTLs from the peripheral blood of patients with this lymphoma, with the notion of expanding the cells *in vitro* in the absence of *in vivo* immunosuppressive effects. We then compared them phenotypically and functionally with CTLs generated from normal donors (53). To discover whether autologous EBV-specific CTLs could persist and produce antiviral activity *in vivo*, we genetically marked the cells and then adoptively transferred them to three patients with relapsed disease.

Cytotoxic T Lymphocytes from Patients with Hodgkin's Disease Compared with Those from Healthy Epstein-Barr Virus–Positive Donors

In the presence of IL-2 and B-LCL, cell counts of cultures from healthy donors (n = 15) typically increased by tenfold every 2 weeks, so that after 16 weeks in culture, CTLs from normal donors had expanded approximately 1,500-fold. During the same 16-week period, CTL cultures from patients in remission expanded by only approximately 150-fold, whereas those from patients with relapsed disease increased by just 80-fold. In more than 75% of patients, however, it was still possible to generate at least 10^8 CTLs, a number suggested by previous studies of EBV-LPD to be well in excess of that required to establish EBV immunity (59 ,60). Phenotypically, the patient lines were essentially identical to the lines from normal donors, except that the level of the T-cell receptor-zeta chain was abnormally low (73). The cytoplasmic portion of the T-cell receptor-zeta chain is involved in signal transduction and subsequent activation and proliferation of T cells, so that downregulation of this chain may contribute to the decreased proliferative response of patient T cells. Nonetheless, the lines produced had strong activity against HLA-matched EBV-positive targets. Of particular note, lines from Hodgkin's disease patients had activity against cells expressing Hodgkin's-associated viral antigens, including LMP1 and LMP2. This effect was demonstrated by the cells' ability to kill HLA-matched fibroblasts infected with vaccinia recombinants, each expressing one of the EBV-latent cycle proteins. Both HLA class I- and class II–restricted CTLs could be detected. The presence of the class II–restricted cells may be of benefit because approximately 50% of Hodgkin's tumor cells downregulate HLA class I molecules, and may therefore be protected from conventional CTL killing. They generally maintain class II major histocompatibility complex (MHC) expression, however.

Biologic and Clinical Study of Cytotoxic T Lymphocytes

Encouraged by our ability to generate CTLs with activity against at least one of the Hodgkin's-associated antigens, we asked whether these cells would have antiviral and antimalignant properties *in vivo*. To track the persistence of infused CTLs, we marked the cells with a neo-containing retroviral vector. The neo gene was detectable in PBMCs for 4 to 12 weeks after the initial dose of 3.2×10^7 EBV-specific CTLs (73). The

levels of marking indicated that approximately 1 of every 1,000 circulating PBMCs was derived from the infused cell line.

The infused CTLs had cytotoxic antiviral activity. Thus, the proportion of circulating EBV-specific cytotoxic precursor cells was increased 10- to 100-fold, indicating an enhanced cell-mediated immune response to EBV. The number of MHC-unrestricted cytotoxic effector precursors remained constant, as demonstrated by the minimal change in the proportion of cytotoxic precursor cells that killed HLA-mismatched LCLs. In addition to the rise in cytotoxic precursor cell frequency, the CTL activity tested after 2 weeks of culture with the autologous LCLs also increased *in vivo*, from less than 3% killing of autologous LCLs at an effector:target ratio of 40:1 to more than 25% killing at the same effector:target ratio. Again, little effect on the activity of MHC-unrestricted cytotoxic effector cells occurred, suggesting that an increase in classical MHC-restricted CTL activity was responsible for the observed increase in autologous LCL target killing.

The observed increase in cytotoxic function was associated with measurable antiviral activity. We used semiquantitative PCR analysis to calculate the viral burden in peripheral blood before and after CTL infusion. The number of EBV-DNA genomes in normal donors ranges from less than 20 to 2,000 copies per 10^6 PBMCs (9). Before CTL infusion, the level of EBV DNA in patient 1 was 30,000 EBV genomes per 10^6 PBMCs, which is 15-fold higher than in normal individuals and within the range seen for stem-cell transplant recipients with immunoblastic lymphoma (9 ,58). After CTL infusion, the level of EBV DNA decreased dramatically and was undetectable at 4 weeks' postinfusion. Associated with this drop in EBV DNA, the patient showed improvement of stage B symptoms with increased appetite and resolution of fever and sweats; stabilization of his pulmonary disease also occurred. These effects were apparent even though the patient had received no chemotherapy for 4 weeks before or 6 weeks after infusion. In fact, the viral load in the peripheral blood of this patient increased only during readministration of chemotherapy at 6 weeks' postinfusion (the end of the evaluation period). Patient 2 had insufficient blood counts to allow measurement of EBV-DNA levels but also showed improvement in stage B symptoms before the institution of further chemotherapy and disease progression. Although the EBV burden was not supranormal in the third patient, an initial level of 400 EBV genomes per 10^6 PBMCs fell to undetectable levels by 19 days after the first infusion. These effects were again produced in the absence of chemotherapy (>6 weeks before and after). This patient had an initial worsening of his pleural effusion, and gene-marked CTLs were detected in pleural biopsies of diseased areas (73). His disease then stabilized and no further pleural effusions occurred for more than a year. The tumor ultimately progressed in all three patients, who died of their disease 10 to 13 months later.

Improving the Clinical Outcome

These preliminary studies show:

- It is feasible to obtain substantial *ex vivo* expansion of EBV-specific T cells from patients with advanced Hodgkin's disease.
- These cells have *in vivo* cytotoxic activity against EBV-infected cells and are detectable *in vivo* for up to 12 weeks.
- These cells can be targeted to Hodgkin's disease-associated antigens.

Our efforts are directed at enhancing the component of the anti-EBV response that is directed to the Hodgkin's-associated antigens LMP1 and 2 by using dendritic cells expressing the appropriate proteins (see the section Cytotoxic T Lymphocytes for Recipients of Solid Organ Transplants). The CTLs generated will be given to patients with minimal residual disease to reduce the immunosuppressive effects associated with bulky tumors. An alternative approach is to develop CTL clones directed against Hodgkin's-associated antigens. Such an approach is possible (74) but is time consuming because the frequency of cells with such specificity is low. Moreover, many Hodgkin's tumors have mutations within the 3" region of the LMP1 oncogene, including a 30-base pair deletion and a high frequency of nonrandom point mutations (75 ,76). As we have already found in our EBV-LPD patients, these mutations may destroy the epitopes recognized by CTLs specific for wild-type LMP1, a problem that can only be accentuated if monospecific CTL clones, rather than polyspecific CTL lines, are used. It may also be possible to vaccinate patients directly using polypeptides, DNA, or dendritic cells as immunogens. The capacity to induce an immune response *in vivo*, however, may be limited by tumor-mediated immune escape mechanisms that subvert the induction or expansion of a cytotoxic response.

Other Epstein-Barr Virus–Associated Malignancies

Part of "13.4 - Adoptive Cellular Immunotherapy for Epstein-Barr Virus-Associated Malignancies "

EBV is associated with an increasing number of frequently rare and geographically associated malignancies (see Table 13.4-2). Lethal midline granulomas involving natural killer–like T-cell lymphomas, gastric carcinomas, and pyothorax-associated lymphoma seem to have an increased frequency in Japan, whereas parotid carcinomas are found predominantly in American Eskimos. EBV-positive smooth muscle tumors (leiomyosarcomas) are the second most prevalent malignancy of children with acquired immunodeficiency syndrome, and have an increased frequency after organ transplantation. In nonimmunosuppressed individuals, leiomyosarcomas rarely carry the EBV genome. EBV has also been found in carcinomas of the thymus and salivary gland. With the exception of gastric carcinoma and pyothorax-associated lymphoma, these tumors all express the intermediate type II latency and therefore are potential targets for immunotherapies targeting viral proteins, although the success of such therapies may depend on the immune-evasion strategies used by the tumor.

The type I tumors, Burkitt lymphoma and gastric carcinoma, pose a greater challenge for immunotherapy. The only viral proteins expressed in type I tumors are EBNA1 and RK-BARFO, which, as described in the preceding paragraph, do not provide target epitopes for HLA class I-restricted CTLs. Burkitt lymphoma cells have been shown to use additional antiimmune response mechanisms. They have defects in their expression of TAP I transporter proteins and HLA class I molecules (77 ,78).

Moreover, they have the immunophenotype of a resting B cell and do not express costimulatory molecules necessary for the induction of an effective immune response. It may be possible to use CD4+ HLA class II–restricted EBNA-1 or RK-BARFO-specific CTL to target tumor cells expressing type-I latency (81 ,82).

Conclusions

Part of "13.4 - Adoptive Cellular Immunotherapy for Epstein-Barr Virus-Associated Malignancies "

EBV-associated malignancies provide an investigational bridge between viral diseases and classic malignancies. As increasing numbers of tumor-associated antigens are identified, the effectiveness and limitations of CTL therapies in EBV-related diseases should provide an invaluable guide for improving immunotherapies for an ever broader range of cancers.

Acknowledgments

Section III
Principles and Practice of Monoclonal Antibody Therapy

14
Monoclonal Antibodies: Basic Principles

14.1

Basic Concepts and Antigens Recognized

Kenneth A. Foon

Introduction

Part of "14.1 - Basic Concepts and Antigens Recognized "

This chapter is designed to overview basic concepts of monoclonal antibody diagnosis and therapy. The focus of this chapter is on those targeted antigens that have been used in the clinic for diagnostic and therapeutic applications. Monoclonal antibodies have emerged as the dominant reagent for *in vitro* diagnostics and immunohistopathology. Serologic assays, such as carcinoembryonic antigen (CEA) levels, CA125, and the prostate-specific antigen, are such examples. Monoclonal antibody reagents are used for flow cytometry in immunodiagnostic laboratories and for immunohistochemistry and have a critical role in the classification of leukemias and lymphomas.

Monoclonal Antibodies for Diagnosis and Therapy

Part of "14.1 - Basic Concepts and Antigens Recognized "

The concept of monoclonal antibody-guided therapy and diagnosis has been studied for more than 20 years. One of the major limitations for *in vivo* diagnostics and therapeutics has been that murine antibodies generate immune response in immunocompetent patients. Therefore, the vast majority of patients injected with murine antibodies generate immunity that neutralizes the antibodies for future injections. A variety of strategies to overcome this obstacle are discussed in the section Genetic Engineering of Monoclonal Antibodies .

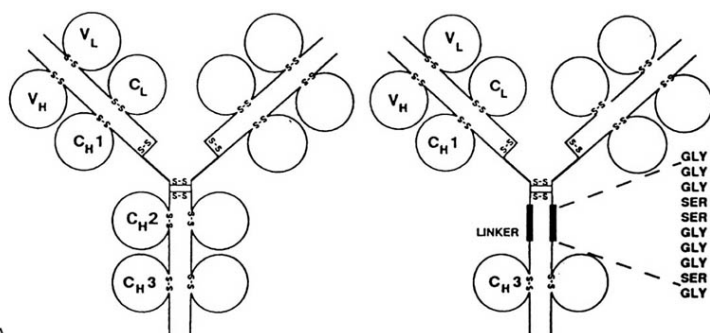
Another feature of the immunoglobulin molecule is size. Comparisons of the intact immunoglobulin G (IgG) and the F(ab")₂, Fab, and sFv molecules have been studied in animal models (Fig. 14.1-1). The concept is that the smaller molecules leave the circulation more rapidly and penetrate tumors more evenly than the whole immunoglobulin (1). The longer residence in the blood of whole IgG, however, has advantages in that the longer the antibody is in the blood, the greater opportunity for delivery of a higher percent of the injected dose to the tumor. This might be an advantage for unlabeled antibodies, but for the purposes of delivering radiolabeled antibodies to tumor, smaller molecules appear to be advantageous. Radiolabeled F(ab")₂, Fab, and sFv are cleared from the bloodstream much more rapidly than the whole immunoglobulin, and this should lead to less bone marrow toxicity. The more rapid serum clearance, however, could lead to less uptake in the tumor. Another approach for more rapid clearance of the immunoglobulin is to remove the CH2 domain (Fig. 14.1-2), which allows the immunoglobulin to clear from the bloodstream more quickly than the intact IgG (2 ,3). Other characteristics of the various immunoglobulin molecules are that the Fab₂, Fab, and sFv molecules accumulate in kidney tubules; IgG does not accumulate in the kidneys (4). These patterns must be considered when conjugating antibodies to toxins, drugs, and isotopes.
FIGURE 14.1-1. Binding regions and domains of an immunoglobulin molecule.


FIGURE 14.1-2. Diagram of an intact immunoglobulin molecule **(A)** and CH2 domain-deleted molecule **(B).**

Antibody administration has typically been by the intravenous route. Other approaches have been considered—in particular, the peritoneal route when tumors are primarily confined to the peritoneal cavity, such as ovarian cancer. The peritoneal route targets smaller peritoneal tumors more efficiently than does the intravenous route, and also the injected dose per gram in the blood pool is reduced, leading to potentially less systemic toxicity (5).

A variety of toxins, radionuclide drugs, and cytokines have been coupled to monoclonal antibodies. Diagnostic isotopes, such as indium-111 (¹¹¹In) and technetium-99m (⁹⁹ᵐTc) conjugated to monoclonal antibodies, have been used in clinical trials (6 ,7 ,8 and 9). For the intraoperative hand-held probe, iodine-125-labeled monoclonal antibodies are typically used (10). Most therapeutic trials have included iodine-131 (¹³¹I)-labeled monoclonal antibodies because of its low cost, wide availability, and relatively simple chemistry. Disadvantages of ¹³¹I include its long-range gamma emissions requiring lead-lined rooms and longer inpatient treatment. In addition, iodine is volatile and special hood precautions are required. Other isotopes, such as yttrium-90, lutetium-177, and rhenium-186, offer advantages because of the abundance of beta-emitting versus gamma-emitting energy. Patients can be treated as outpatients and special precautions are less stringent. Alpha emitters, such as bismuth-212 and copper-67, which have short half-lives and short path lengths, also have distinctive advantages. A variety of linker

chemistries have been developed to couple these isotopes to monoclonal antibodies. No ideal isotope or linker system exists, and a variety of approaches continue to be studied.

Ricin is probably the most widely studied toxin conjugated to monoclonal antibodies. Ricin has both an A and B chain. The B chain is responsible for binding cell receptors but can be removed so that the A chain is coupled directly to the monoclonal antibody. Other toxins that have been studied in animal models and in the clinic include gelonin, saporin, and *Pseudomonas* exotoxin. Patients recognize these toxins as foreign, however, and antitoxin immune responses are common. Antibodies coupled to chemotherapy agents are also under investigation but have been less successful in animal models. Passive immunotherapy with unconjugated or naked monoclonal antibodies has been focused primarily on chimerized or humanized antibodies. Two monoclonal antibodies approved for therapy by the U.S. Food and Drug Administration are rituximab, which is a human-chimerized anti-CD20 antibody (11 ,12) used for the treatment of follicular low-grade lymphomas, and herceptin, a humanized anti-Her-2/neu antibody, which is used in combination with chemotherapy for the treatment of advanced breast cancer (13). Unlabeled murine monoclonal antibodies are being studied in the clinic in the form of antiidiotype antibodies to generate active immunity in patients. This is discussed in the section Antiidiotype Monoclonal Antibodies .

Tumor-Associated Antigens

Part of "14.1 - Basic Concepts and Antigens Recognized "

This section focuses on three separate areas of tumor-associated antigens: (a) epithelial tumor-associated antigens, (b) melanoma-associated antigens, and (c) hematopoietic tumor-associated antigens. The antigens that are focused on are those that are most commonly used in clinical and laboratory studies.

Epithelial Tumor-Associated Antigens

The Her-2/neu oncogene protein is a member of the tyrosine kinase family of growth factor receptors (14 ,15). It is frequently overexpressed in adenocarcinomas of the breast, ovary, and colorectum and other histologies for which overexpression appears to correlate with a poor prognosis (16). A number of studies have demonstrated the importance of Her-2/neu in the tumorigenic and metastatic phenotype (17 ,18 and 19). It has therefore become an attractive target for cancer immunotherapy. A small subset of patients develop IgG antibody responses to Her-2/neu and, in some cases, CD4[+] T-cell responses have been demonstrated (20 ,21).

Herceptin is a humanized monoclonal antibody that has been approved by the U.S. Food and Drug Administration for treatment of metastatic breast cancer (13). Her-2/neu is a growth factor receptor and herceptin mediates cell killing by apoptosis.

Another antigen that has been commonly targeted for immunotherapy is the nonsecreted MR40,000 glycoprotein CD17-1A antigen, which is overexpressed on most epithelial tumors. The murine monoclonal antibody that binds to this antigen, designated *171A*, is an IgG2A antibody that has been studied in patients with a variety of cancers, particularly colorectal cancers. Rare clinical responses have been described after the intravenous infusion of unlabeled murine 171A antibody in patients with metastatic disease (22 ,23 and 24). The mechanism remains unknown, but it has been hypothesized that responses were secondary to activation of the idiotypic network or antibody-dependent cellular cytotoxicity (ADCC), or both.

The most impressive and important 171A clinical trial was reported in 189 patients with Dukes' C colorectal cancer who were assigned to postoperative observation or treatment with 500 mg of 171A antibody, followed by four 100-mg monthly infusions. After a median follow-up of 7 years, the antibody-treated patients had an improved survival by 30% over patients in the control arm (25 ,26). Studies are underway in the United States and Europe to confirm these results.

The murine monoclonal antibody L6 is an IgG2A antibody that binds to a poorly characterized antigen on adenocarcinoma cells and is expressed on more than 90% of breast, colorectal, and non-small-cell lung cancer (27 ,28). This antibody has also been shown to mediate ADCC and complement-dependent cytotoxicity. Unlabeled chimeric antibody did not have clinical responses, whereas responses were seen in three of four patients treated with ^{131}I-labeled chimeric L6 (29).

Monoclonal antibody D612 is a murine IgG2A antibody directed at a membrane glycoprotein expressed on gastrointestinal tumors (30 ,31). This antibody has also been shown to mediate ADCC and its effects could be enhanced when combined with macrophage colony-stimulating factor (32).

TAG72 is expressed on most epithelial tumors, including colorectal cancer, ovarian cancer, and prostate cancer. The B72.3 monoclonal antibody binds to TAG72 and has been studied in a number of clinical trials. ^{111}In-B72.3, termed *Oncoscint*, has been approved for commercial use for the detection of colorectal cancer (6 ,7 and 8). This immunoconjugate was demonstrated to improve the detection of intraabdominal sites of tumor over computed axial tomography of the abdomen and pelvis.

The CEA gene has been sequenced and is part of the human immunoglobulin supergene family located on chromosome 19 (33 ,34). CEA is highly expressed on colorectal cancers and a variety of other epithelial cancers and is thought to be involved in cell-cell interactions. CEA is considered an adhesion molecule and may play an important role in the metastatic process by mediating attachment of tumor cells to normal cells (35 ,36). CEA has been a target for passive immunotherapy by monoclonal antibodies, monoclonal antibody imaging, as well as vaccine therapy. A Fab" antibody fragment of an anti-CEA antibody, designated *IMMU-4*, labeled with ^{99m}Tc has been approved commercially for radioimaging colorectal cancer (9). Similar to ^{111}In-B72.3, ^{99m}Tc-IMMU-4 Fab" was superior to conventional diagnostic modalities in the extrahepatic abdomen and pelvis and complemented conventional modalities in the liver.

MUC1 is a highly glycosylated high-molecular protein abundantly expressed in human cancer of epithelial origin (37 ,38 and 39). The MUC1 gene is overexpressed and aberrantly glycosylated in a variety of cancers, including colorectal cancer, breast cancer, and ovarian cancer. Much of the glycosylation is found within regions of tandemly repeated sequences of 20 amino acids per repeat (40 ,41 and 42). Tumors derived from cells of epithelial origin often lose the carbohydrate side chains exposing the tandemly repeated protein core, resulting in antigenically active epitopes exposed to the cell surface membrane (40). A closely related antigen is the human milk fat globule antigen, which has the same tandemly repeated sequences of 20 amino acids as MUC1 (43). Both of these antigens have been the target of passive serotherapy, radioimmunoimaging, and vaccine therapies.

The monoclonal antibody OVB3 reacts with an ovarian cancer–associated antigen and has been linked to the pseudomonas exotoxin (44). Dose-limiting toxicity occurred as a result of reactivity with neural tissues, and no responses were reported.

A variety of clinical trials using antiferritin monoclonal antibodies and polyclonal sera have been reported for patients with hepatocellular carcinoma (45 ,46). Shrinkage of unresectable tumors has been reported.

A number of trials have been reported for monoclonal antibodies that target to the epithelial growth factor receptor (47 ,48). The epithelial growth factor receptor, similar to Her-2/neu, is a growth factor receptor and, therefore, binding to this receptor leads to apoptosis.

Melanoma Tumor-Associated Antigens

Gangliosides are sialic acid–containing glycosphingolipids and have increased surface membrane expression on cancers of neuroectodermal origin, including malignant melanoma. A number of immunotherapy studies have been targeted to gangliosides (49 ,50). The R24 antibody that targets the disialoganglioside GD3 has been the most widely studied with seven partial responses and one complete response among 58 patients (51 ,52 ,53 and 54). No response was reported among eight patients treated with the MG21 antibody that also recognizes the disialoganglioside GD3 (55). A number of studies with the disialoganglioside GD2 either alone or combined with R24 also reported two partial responses among nine patients with the 3F8 anti-GD2 antibody, but none of the other studies reported responses (56 ,57 and 58). Four partial and seven complete responses were reported, however, using the L72 antibody that also recognizes the disialoganglioside GD2 when injected intralesionally (59 ,60). Similar results were reported with intralesional injections of antibodies that bind to the GM2 and GM3 gangliosides (61 ,62). The high-molecular-weight melanoma-associated antigen, designated *mCSP*, is identified by a number of monoclonal antibodies, including 9.2.27. No responses were reported among 21 patients treated with intravenous therapy (63 ,64 and 65). Melanoma vaccines generated to a variety of melanoma-associated

antigens recognized by T lymphocytes are presented in another chapter.

Hematopoietic Tumor-Associated Antigens

A variety of antigens that identify antigens on non-Hodgkin's lymphoma have been used as unlabeled monoclonal antibodies. The antigens targeted are the CD19, CD20, and CD22 antigens; the CD5 antigen has been targeted for chronic lymphocytic leukemia (CLL) and cutaneous T-cell lymphoma and the CD25 antigen [interleukin-2 (IL-2) receptor] has been targeted for certain non-Hodgkin's lymphoma and adult T-cell leukemia (66 ,67 ,68 ,69 ,70 ,71 and 72). Rare responses have been reported using these unlabeled murine antibodies. Antiidiotype antibodies that are custom made for individual patients that target the immunoglobulin on the surface of B-cell lymphomas have also been used as therapeutics. Antiidiotypes have been the most successful form of unlabeled murine monoclonal antibody therapy in that 40% of patients respond to antiidiotype antibodies with approximately 10% complete responses (73 ,74). Because of the difficulty of tailor-making individual antibodies for patients, this approach has largely been abandoned.

The most successful trials with unlabeled antibodies have been with chimerized and humanized antibodies. The anti-CD20 chimerized antibody rituximab has been the most extensively studied unconjugated antibody, and is the only antibody approved for therapy by the U.S. Food and Drug Administration for lymphomas (11 ,12). This antibody consists of a murine variable region from the parent antibody grafted onto a human IgG1 constant region backbone. The CD20 antigen is a more ideal target for unconjugated antibody therapy because it is not expressed on precursor B cells or stem cells but has high-density expression on mature B cells, including malignant B cells. CD20 does not shed and does not undergo modulation after antibody binding. *In vitro* data suggest that rituximab binding to CD20 may trigger apoptosis, as well as mediate complement-dependent cytoxicity and ADCC. Patients with follicular center cell low-grade lymphomas respond to rituximab in the 50% range with approximately 10% complete responses. Another monoclonal antibody that has been studied in the clinic is CAMPATH-1, which targets the CD52 antigen that is expressed on lymphocytes, monocytes, and granulocytes, but is not found on stem cells. The humanized version of this antibody, designated *CAMPATH-1H*, has shown responses in CLL and lymphoma (75 ,76 and 77).

Antibodies conjugated to radioisotopes have had considerable success. The most impressive responses have been with the ^{131}I-labeled anti-B1, which is an anti-CD20 antibody (78 ,79 ,80 and 81). Complete responses were reported in the majority of previously treated lymphoma patients. Another promising antibody is Lym-1, which binds to a DR-related antigen. ^{131}I-labeled Lym-1 therapy had excellent responses in the majority of treated lymphoma patients (82). Similar responses have been reported for ^{131}I-labeled OKB7 and LL2 (83 ,84).

Immunotoxins involve the linkage of monoclonal antibodies to a protein toxin. Growth factors and other ligands, such as IL-2, can also carry toxins (85 ,86). Toxins, such as ricin and diphtheria toxin, are natural products that disrupt protein synthesis. Immunotoxins must be internalized after antigen binding to allow the toxin entry into the cytosol for cell death. One methodology to fuse the toxin protein to the monoclonal antibody is to eliminate the binding domain of the toxin and to link the toxic domain directly to the antibody. Thus, without the nonspecific binding domain of the native protein, the antibody directs the toxin to the tumor cell. Another approach is to retain but modify the binding domain (87). An alternative approach is to fuse the DNA sequences that encode a toxin to the DNA elements that encode the antigen-binding site (Fv). This creates a small molecule that retains binding and cytotoxic properties (88 ,89 and 90). Clinical trials with immunotoxins have shown tumor cell cytoreduction in a variety of hematologic malignancies but with limited responses (91 ,92 ,93 ,94 and 95). Toxicity is characterized by a vascular leak syndrome with peripheral and pulmonary edema, hypotension, and hypoalbuminemia (91 ,92). There is also a high incidence of host immune responses to the antibody and the toxin.

More limited literature exists on monoclonal antibody studies with unconjugated and radiolabeled antibodies for the treatment of acute myelogenous leukemia (AML). In one trial, using the unlabeled humanized HuM195 antibody that targets the CD33 antigen, one of 13 patients had a transient clinical response with decreased circulating blasts (96). ^{131}I-labeled monoclonal antibody M195 demonstrated three complete responses among 24 AML and blastic chronic myelogenous leukemia patients treated with antibody alone (97). When combined as a conditioning regimen with chemotherapy before allogeneic bone marrow transplantation, 18 of 19 patients had complete remissions (98).

Immune Flow Cytometry

Part of "14.1 - Basic Concepts and Antigens Recognized "

Immune flow cytometry using monoclonal antibodies has become a critical tool in the diagnosis of leukemias and lymphomas. Correlating immunophenotype with molecular and cytogenetic data has delineated biologically important subgroups. This data was reviewed by Jennings and Foon in 1997 and is briefly discussed (99). Critical requirements for flow cytometry are viable cells that can be prepared in a single-cell suspension. This, of course, is not a problem for liquid tumors that invade the peripheral blood and bone marrow, but it may be a problem for certain solid tumors where it is more difficult to prepare single-cell suspensions. Lymphomas have generally not been a problem, even when they do not invade the peripheral blood and bone marrow, as a lymph node is more easily separated into a single-cell suspension. For AML, the critical antigenic markers that differentiate the Fab subtypes M0, M1, M2, M3, M4, M5, M6, and M7 include DR, CD13, CD14, CD15, CD33, and CD34. These markers help differentiate myeloid from monocytic leukemias. The M7 megakaryoblastic leukemia is differentiated by the CD41 and CD61 platelet-associated antigens. Detection of the cytoplasmic enzyme myeloperoxidase is more sensitive than CD13 and CD33 combined to detect AML, and may be particularly useful in differentiating M0 from acute lymphoblastic leukemia (ALL) (100). For the B-cell ALL, the critical markers are DR, CD10, CD19, CD20, CD22, CD24, and CD34. Markers for surface and cytoplasmic immunoglobulin differentiate more mature from more primitive B cells. T-ALL

is differentiated by T-cell antigens, which include CD1, CD2, cytoplasmic and surface membrane CD3, CD5, CD7, CD4, CD8, CD10, and CD34. Using combinations of the above markers, it is extremely rare for ALL to be confused with AML. To differentiate the B-lymphoproliferative disorders, the same monoclonal antibodies that differentiate the B-cell ALL are used. Subtle differences exist between some of these disorders. For instance, CLL shares many of the same markers with mantle cell lymphoma, including the B-cell antigens, CD19, CD20, and the putative T-cell antigen CD5. In mantle cell lymphoma, however, the CD5 antigen, as well as CD20, are much more intensely expressed than is typically seen with CLL. Follicular lymphomas typically express B-cell markers in addition to CD10, which is not typically expressed by the other B-lymphoproliferative disorders. Hairy cell leukemia expresses B-cell markers but also expresses CD103, which is unique to hairy cell leukemia among the B-cell disorders. T-cell lymphoproliferative disorders also incorporate the same surface markers as T-ALL, but again, subtle differences may differentiate subclassifications. For instance, adult T-cell leukemia lymphoma expresses the T-cell markers CD3, CD4, and CD5, but also have a bright CD25 expression, which is uncommon for the other T-cell malignancies. Natural killer cell lymphocytic leukemias are subclassified by their expression of the natural killer–associated antigens CD16, CD56, and CD57.

Immunohistochemistry

Part of "14.1 - Basic Concepts and Antigens Recognized "

Traditional morphology is not always adequate for poorly differentiated tumors. For decades, pathologists have relied on histochemical techniques to differentiate a variety of tumors using enzymes, mucin, reticulum, and so forth. Monoclonal antibodies have greatly expanded this specificity. This section only presents examples of some of the more useful differentiation markers studied by immunohistochemistry, and the reader is referred to reference 101 .

One common problem is diagnosing poorly differentiated lymphomas and carcinomas. The leukocyte common antigens distinguish hematopoietic malignancies from nonhematopoietic malignancies (102). A variety of antibodies that can be used in paraffin-embedded tissue to differentiate lymphomas have been described, including L26, which identifies the CD20 antigen common to B-cell malignancies (103). Immunoglobulins are the most reliable B-cell markers and can be used in paraffin-embedded tissue. CD3 identifies the T-cell receptor (104) and differentiates T-cell malignancies. Leu-M1 identifies the CD15 antigen common to Reed-Sternberg cells (105), CD30 identifies the Ki-1 antigen found in Reed-Sternberg cells and anaplastic large-cell lymphoma cells. Anti-T6 (CD1a) reacts with cortical thymocytes and Langerhans' cells and identifies Langerhans' tumors (106).

Common epithelial tumor antigens include the epithelial membrane antigen (107), keratin (108 ,109), and CEA (110). Monoclonal antibodies against lung tumor cells may be useful in differentiating lung cancers and may also be useful for the detection of metastasis. For example, the monoclonal antibody SM-1 reacts with small-cell carcinoma of the lung and can be used to detect bone marrow metastasis (111). The HMB-45 is widely used in the diagnosis of malignant melanoma (112). This antibody reacts with immature melanosomes and stains cutaneous melanocytes, retinal pigment epithelium, and melanocytic tumors (113). Antibodies to the S100 protein identify malignant melanoma, neurogenic tumors, chondrosarcomas, meningiomas, tumors of the breast and salivary glands, and neuroendocrine tumors. The demonstration of S100 protein, vimentin, and HMB-45 in the absence of staining for keratin distinguishes malignant melanoma from poorly differentiated carcinomas (114). Some antigens, such as prostate-specific antigen and thyroglobulin, are specific markers for prostate cancer and thyroid cancer, respectively.

Genetic Engineering of Monoclonal Antibodies

Part of "14.1 - Basic Concepts and Antigens Recognized "

Genetically modifying murine immunoglobulin molecules to enhance desired characteristics and eliminate undesirable characteristics is common practice (115 ,116 and 117). One approach is chimerization of the immunoglobulin molecules in which the murine variable region is linked to a human Fc molecule. This involves the inclusion of possible immunogenic mouse sequences (Table 14.1-1). Another approach is CDR grafting in which the six murine hypervariable regions or CDRs are grafted onto a human antibody (118 ,119 and 120). This procedure may lead to loss of affinity. A second approach involves veneering the murine immunoglobulin (121). The murine sequences of the immunoglobulin molecule are analyzed via computer programs, and potential sequences distinguishing mouse from human immunoglobulins are eliminated and substituted with humanlike sequences. Another approach is the derivation of completely human antibodies with an expected minimal immunogenicity in humans using phage-display technology (122). Repertoires of human sFv or Fab fragments are cloned for display on the surface of filamentous phage, and antigen-specific "phage antibodies" are enriched on immobilized antigen (123). From libraries of millions to a few billion antibody fragments derived from an IgM pool of naïve human B cells, it is possible to isolate high-affinity human antibodies. One approach to enhance this methodology is using cells from

patients that are immunized with specific tumor-associated gene products. Another approach to generate human antibodies is to use transgenic mice that generate human immunoglobulin. These animals can be immunized with any desired antigen.

Table 14.1-1 Genetic Modification of the Immunoglobulin Molecule

Recombinant Immunoglobulin	Purpose
Chimeric	Reduce immunogenicity
CDR grafting	
Veneering	
Phage display technology	
Deletions in At 2 domain	Alter size
F(ab")2 or Fab"	
sFv	
Hinge alterations	Increase affinity
CDR modification	
Changes in glycosylation	

CDR, complementarity-determining regions.

Another advantage of genetic manipulation of monoclonal antibodies is to alter pharmacokinetic properties, metabolic properties, and affinity. Advantages may exist for immunoglobulins to have shorter half-lives, which would lead to more rapid clearance from the body, more rapid tumor penetrance and, possibly, lower immunogenicity. Deleting the CH2 domain (see Fig. 14.1-2) results in enhanced clearance of immunoglobulin from the plasma with a limited loss of tumor uptake (2 ,3). sFv molecules (Fig. 14.1-3) have the advantage of reduced size, more rapid clearance, and better tumor penetration (4 ,124). Other genetic modifications include hinge modifications, modifications of single domains, and alterations in V regions.

FIGURE 14.1-3. Single-chain antigen-binding protein (sFv) shows a linker connecting the V_L and V_H.

Another genetic modification is ligating of genes coding for various biologic response modifiers to the immunoglobulin molecules. Molecules such as interferon-α, interferon-γ, and IL-6 upregulate certain tumor antigens. Such molecules have been constructed using IL-2. Engineering recombinant Fv immunotoxins was reviewed by Reiter and Pastan in 1996 (125). The antigen-binding and targeting domains in recombinant immunotoxins are typically single-chain sFv or Fab connected by a flexible peptide binder and fused directly to a bacterial toxin. Because of problems with stability and binding of some sFv immunotoxins, new recombinant Fv immunotoxins have been developed, in which the targeting variables of the Fv are stabilized by an interchain disulfide bond located in framework positions of the V_H and V_L domains.

Antiidiotype Monoclonal Antibodies

Part of "14.1 - Basic Concepts and Antigens Recognized "

The idiotype network hypothesis of Lindenmann (126) and Jerne (127) offers an elegant approach to transforming epitope structures into idiotypic determinants expressed on the surface of antibodies. According to the network concept, immunization with a given tumor-associated antigen will generate production of antibodies against this tumor-associated antigen, which are termed *Ab1;* Ab1 is then used to generate a series of antiidiotype antibodies against the Ab1, termed *Ab2*. Some of these Ab2 molecules can effectively mimic the three-dimensional structure of the tumor-associated antigen identified by the Ab1. These particular antibodies, called *Ab2B*, fit into the paratopes of Ab1 and express the internal image of the tumor-associated antigen. The Ab2B can induce specific immune responses similar to those induced by the original tumor-associated antigen and, therefore, can be used as surrogate tumor-associated antigens. Immunization with Ab2 can lead to the generation of anti-antiidiotypic antibodies (Ab3) that recognize the corresponding original tumor-associated antigen identified by Ab1. Because of this Ab1-like reactivity, the Ab3 is also called *Ab1"* to indicate that it might differ in its other idiotopes from Ab1. The putative immune pathways for antiidiotype vaccines are presented in Figure 14.1-4 . The antiidiotype antibody represents an exogenous protein that should be endocytosed by antigen-presenting cells and degraded to 14- to 25-MER peptides to be presented by class II antigens to activate CD4 helper T cells. Activated Th2 CD4 helper T cells secrete cytokines, such as IL-4, which stimulate B cells that have been directly activated by the Ab3 to produce antibody that binds to the original antigen identified by the Ab1. In addition, activation of Th1 CD4 helper T cells secrete cytokines that activate T cells, macrophages, and natural killer cells, which directly lyse tumor cells and, in addition, contribute to ADCC. Th1 cytokines, such as IL-2, also contribute to the activation of a CD8 cytotoxic T-cell response. This represents a second putative pathway of endocytosed antiidiotype antibody. The antiidiotype antibody may be degraded to 9/10-MER peptides to present in the context of class I antigens to activate CD8 cytotoxic T cells (128 ,129), which are also stimulated by the IL-2 from Th1 CD4 helper T cells.

FIGURE 14.1-4. Antiidiotype antibodies are endocytosed by antigen-presenting cells (APCs). They may be degraded to 14/25-MER peptides and presented on major histocompatibility complex (MHC) class II molecules to CD4 helper T cells. Activated Th2 CD4 helper T cells secrete Th2 cytokines that stimulate B cells that have been directly activated by the antiidiotype antibody to produce the anti-antiidiotypic antibody or Ab3 (Ab1") that binds directly to tumor cells. This antibody can mediate complement- and antibody-dependent cellular cytotoxicity (ADCC), as well as a direct antimetastatic effect by opsonization. In addition, Th1 CD4 helper T cells secrete Th1 cytokines that activate T cells, natural killer cells, and macrophages. The activated macrophages and lymphokine-activated killer (LAK) cells may also serve as effector cells for ADCC. All of these cells may mediate direct tumor lysis. Data also suggest that exogenously processed proteins can be degraded to 9/10-MER peptides that can be presented by MHC class I molecules to activate CD8 cytotoxic T cells. This is enhanced by Th1 cytokines, such as interleukin-2 (IL-2). Activated CD8 cytotoxic T cells make contact with tumor cells, leading to direct tumor cell lysis. (TCR, T-cell receptor.)

Several antiidiotype antibodies that mimic tumor-associated antigens on colorectal cancer cells have been reported. One such antibody was generated against the murine 17-1A antibody, described in the section Epithelial Tumor-Associated Antigens . After surgery for colorectal cancer, six patients were immunized with this human antiidiotype antibody, which mimics the GA733-2 antigen (130). All of the patients developed a long-lasting T-cell immunity against GA733-2 and five mounted a specific IgG antibody response against GA733. Another group, using a rat antiidiotype antibody generated to the 17-1A antibody, immunized nine colorectal cancer patients with aluminum hydroxide–precipitated 17-1A; none of the nine patients developed specific antibodies, although four patients developed delayed-type hypersensitivity (131). Another group of investigators has developed both murine and human monoclonal antiidiotype antibodies that mimic the gp72 antigen (132 ,133 ,134 and 135). They demonstrated delayed-type hypersensitivity reactions when murine antiidiotype antibody was injected without adjuvant (135). When the antiidiotype was linked to keyhole limpet hemocyanin in the presence of Freund's adjuvant, anti-gp72 antibodies were detected. Using the human equivalent antiidiotype antibody precipitated in aluminum hydroxide, 9 of 13 patients with advanced colorectal cancer produced blastogenic responses to gp72-expressing tumor cells or produced detectable levels of IL-2 in their plasma (133). They suggested that survival correlated with immune responses. In another study with the same human antiidiotype antibody, six patients with rectal cancer were immunized preoperatively (134). This study demonstrated significant killing of autologous tumor cells using cryopreserved lymphocytes or lymph node cells from patients 1 to 2 weeks postimmunization.

CeaVac is an antiidiotype murine monoclonal antibody to an antibody designated *8019*, which identifies a specific epitope on CEA that is highly restricted to tumor cells and is not found on normal tissues (136). CeaVac generated antiidiotypic (Ab3)

responses that recognize CEA in mice, rabbits, and monkeys, and had a major antitumor effect in a murine tumor model (137). Among 23 patients with advanced colorectal cancer, 17 generated anti-antiidiotypic Ab3 responses (138 ,139).

Thirty-two patients with resected colorectal cancer were treated with 2 mg of CeaVac every other week × 4, then monthly until recurrent disease (140). Four patients were Dukes' B2, 11 were Dukes' C, eight were completely resected Dukes' D, and nine were incompletely resected Dukes' D. The incompletely resected Dukes' D were those with positive margins after surgery. Fourteen of the patients received 5-fluorouracil–based chemotherapy regimens (11 leucovorin, 3 levamisole) concurrently with CeaVac. Two of nine patients with Dukes' B and C disease progressed at 19 and 24 months, and one patient developed a second primary at 18 months. Seven of eight patients with completely resected Dukes' D remain on study from 10 to 31 months; one resected Dukes' D patient relapsed at 9 months. Two patients with incompletely resected Dukes' D remain on study at 12 and 29 months without evidence of progression; seven progressed at 6 to 30 months. All 32 patients had high-titer polyclonal anti-CEA responses (50 to 300 µg per mL) that mediated ADCC. The predominant Ab3 immunoglobulin was IgG, and the major subclasses were IgG1 and IgG4. All 32 patients generated idiotypic-specific T-cell responses, and 75% were CEA-specific. A linear peptide derived from the CDR2 light-chain region stimulated a Th1 CD4 proliferative response *in vitro* (141). These data demonstrate that 5-fluorouracil–based chemotherapy regimens do not adversely affect the immune response to CeaVac. In addition, high-titer anti-CEA immunoglobulin and Th1 helper-cell response can be maintained indefinitely with monthly boosts with CeaVac. Injections were well tolerated with only minor local reactions and minimal systemic side effects. Although longer follow-up is required, a biologic effect on tumor progression is apparent, suggested by the ten patients with resected and incompletely resected Dukes' D disease who continue on study from 10 to 31 months.

A number of antiidiotype antibody vaccines exist for malignant melanoma. Two of these have been the gangliosides GD2 and GD3 (142 ,143). Immune responses with high-titer anti-GD2 polyclonal responses were reported in one study using an antiidiotype antibody designated *TriGem* that mimics the disialoganglioside GD2 (142). Forty-seven patients with advanced melanoma received four weekly injections with TriGem and then monthly injections until disease progression. Hyperimmune sera from 40 of 47 patients revealed an anti-anti-Id (Ab3)

response (144). The isotypic specificity of the Ab3 antibody consisted of predominantly IgG with only minimal IgM. All of the IgG subclasses were represented with IgG1 as the most abundant. A T-cell clone-specific for the idiotypic portion of TriGem was identified that was a Th2 CD4$^+$ cell as it secreted IL-4 and IL-10. One patient had a complete response to the TriGem vaccine. Seventeen patients are stable on study from 8+ to 34+ months (median, 13+ months). Twenty-seven patients have progressed on study from 1 to 9 months (median, 13+ months), and 20 have died from 1 to 16 months (median, 6 months). The Kaplan-Meier-derived overall median survival has not been reached but, at 16 months, was 52%. For the 26 patients with soft tissue-only disease, the median survival has not been reached. For 18 patients with visceral metastasis, the median survival was 15 months. Toxicity consisted of local reaction at the site of the injection, mild fever, and chills. No additional toxicity, such as abdominal pain, that was seen previously with infusion of murine monoclonal anti-GD2 antibody occurred.

Another trial with antiidiotype antibodies that mimic the melanoma-associated chondroitin sulfate proteoglycan (MPG) have been used. In one study, 26 patients with metastatic melanoma were treated with an antiidiotype antibody that mimics the MPG antigen (145). These authors did not report whether an anti-MPG immune response was identified in these patients, but they did correlate antiidiotypic responses with clinical responses. Similar results were reported for another antiidiotype antibody that mimics MPG (146 ,147).

Antiidiotype vaccines are capable of inducing prophylactic and therapeutic immunity in animal models (148 ,149). It has been suggested that they may not be ready for the clinic because murine antibodies induce neutralizing antibody responses in humans, idiotype vaccines do not induce long-lasting immunity, and the predominant immune response to antiidiotypes is IgM (150). These data clearly demonstrate that monthly injections of murine antiidiotype antibodies can generate and maintain high-titer IgG antibody and proliferative T-cell responses (151).

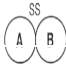
Introduction

Part of "14.2 - Immunotoxins and Recombinant Immunotoxins "

Approximately 100 years ago, Paul Ehrlich first suggested the concept of targeted drug delivery (1). By linking a tumor-specific antibody to a toxin, these magic bullets would seek out and kill cancer cells without being toxic to normal tissues. It was not until 1975, with the invention of the hybridoma technique by Kohler and Milstein (2), that monoclonal antibodies (MAb) with well-defined specificity and purity could be obtained in large amounts and used for the production of these magic bullets.

MAb coupled to bacterial or plant toxins are termed *immunotoxins*. Much progress has been made in the field since the first *in vitro* study was reported in the 1970s (3). First-generation immunotoxins were made by chemically coupling MAb to a native plant or bacterial toxin. The experience gained from laboratory and clinical studies using these first-generation molecules led scientists to produce more specific and potent molecules that are now being tested in humans. Two major advances in the immunotoxin field have been the use of the recombinant DNA technique to produce recombinant toxins with better clinical properties and the production of single-chain immunotoxins by fusing the DNA elements encoding combining regions of antibodies, growth factors, or cytokines to a toxin gene.


In this chapter, we give a brief overview of the current status of immunotoxins and recombinant toxins in cancer therapy. The structure and function of plant and bacterial toxins and advances in design and manufacture of immunotoxins are reviewed. A summary of major clinical trials and their problems are presented. The rationale and approaches used to design the new generation of recombinant toxins (single-chain immunotoxins and disulfide-linked immunotoxins) and prospects for the future are discussed.

Toxins—Structure and Function

Part of "14.2 - Immunotoxins and Recombinant Immunotoxins "

Several plant and bacterial toxins have been used in the construction of immunotoxins (Table 14.2-1). These toxins belong to a group of polypeptide enzymes that catalytically inactivate protein synthesis leading to cell death. Some of these toxins have been shown to induce apoptosis (4 ,5).

Table 14.2-1 Common Toxins Used in the Construction of Immunotoxins

Toxins	Source	Molecular Weight	Intracellular Target	Structure
Plant Toxins				
Ricin	Seeds of castor bean	62 kd	Inactivates 28s rRNA	
	Ricinus communis			
Saporin	*Saponaria officinalis*	30 kd	Same	
PAP	*Phytolacca americana* pokeweed	30 kd	Same	
Bacterial Toxins				
Pseudomonas exotoxin	*Pseudomonas aeruginosa*	66 kd	Adenosine diphosphate–ribosylation of EF2	
Diphtheria toxin	*Corynebacterium diphtheriae*	58 kd	Adenosine diphosphate–ribosylation of EF2	

Plant Toxins

Ricin, or the ricin A chain fragment, has been a commonly used toxin for conjugation to antibodies. Ricin is synthesized as single polypeptide chains and processed posttranslationally into two subunits, A and B, linked though a disulfide bond. Ricin is a 65-kd glycoprotein purified from the seeds of the castor bean *(Ricinus communis)*. It is composed of an A subunit, which kills cells by catalytically inactivating ribosomes. The A subunit is linked by a disulfide bond to a B subunit, which is responsible for cell binding. The B chain is a galactose-specific lectin that binds to galactose residues present on cell-surface glycoproteins and glycolipids (6). Once the B subunit of ricin binds to the cell membrane, the protein enters the cell through coated pits and endocytic vesicles. The A and B subunits of ricin are separated by a process involving disulfide bond reduction. The A subunit of ricin translocates across an intracellular membrane to the cell cytosol, probably with the assistance of the B subunit. In the cytosol, it arrests protein synthesis by enzymatically inactivating the 28S subunit of eukaryotic ribosomes (7 ,8). Because native ricin is highly toxic and lacks specificity, several modified forms of ricin have been developed to prepare immunotoxins that are better tolerated by patients.

Ricin A Chain

To decrease the nonspecific binding of whole ricin, the A chain alone has been coupled to antibodies. The A chain is obtained by reducing the disulfide bond that links it to the B chain. Immunotoxins composed of the ricin A chain coupled to well-internalized antibodies can be highly cytotoxic (9). In the absence of B chain (the binding subunit), however, immunotoxins made with poorly internalized antibodies are not cytotoxic.

Deglycosylated Ricin A Chain

Immunotoxins containing ricin A chain are rapidly cleared from the circulation by the liver by the binding of mannose and fucose residues of the A chain to receptors present on the reticuloendothelial system and hepatocytes. To circumvent this problem, these carbohydrate residues were chemically modified (10), resulting in a deglycosylated A chain (dgA) molecule. In preclinical studies, dgA-containing immunotoxins were found to have longer half-lives in the circulation and better antitumor efficacy *in vivo* (11). Also, recombinant A chain produced in *Esherichia coli* can be used in place of dgA because it is devoid of carbohydrate and is not rapidly cleared by the liver.

Blocked Ricin

Another strategy to decrease the nonspecific toxicity of native ricin is to block the galactose-binding sites of the B chain by cross-linking with glycopeptide (12) or to use short cross-linkers to connect the antibody to the toxin so that the galactose-binding site is sterically blocked by the antibody (13). Blocked ricin retains a low affinity for galactose-binding sites, which enhances internalization and cytotoxicity of an antibody that binds to a poorly internalized antigen.

Other plant toxins commonly used for clinical immunotoxin construction are also shown in Table 14.2-1 . Saporin and pokeweed antiviral protein are single polypeptide chains that inactivate ribosomes in similar fashion to ricin. Because these toxins lack the binding chain (B chain), they are relatively nontoxic to cells and are used for immunotoxin production (14 ,15 ,16 and 17).
Bacterial Toxins

Both *Pseudomonas* exotoxin (PE) and diphtheria toxin (DT) have been used in constructing immunotoxins (18 ,19). PE is a 613–amino acid (66 kd) single-chain protein secreted by *Pseudomonas aeruginosa*. X-ray crystallography (20) and mutational studies (21) have shown that PE is composed of three major structural and functional domains (see Table 14.2-1): an amino terminal cell-binding domain (domain Ia, composed of amino acids 1 through 252), a central translocation domain (domain II, amino acids 253 through 364), and a carboxyl terminal domain (domain III, amino acids 395 through 613). The latter catalyzes the adenosine diphosphate ribosylation and inactivation of elongation factor 2 and thereby inhibits protein synthesis and leads to cell death. Domain III contains a carboxyl terminal sequence (REDLK). After lysine is removed, the REDL binds within the cell to the KDEL receptor, which directs endocytosed toxin to the endoplasmic reticulum. Substitution of REDLK with a KDEL sequence, which is known to retain newly synthesized proteins in the endoplasmic reticulum (22), results in a PE molecule that is more toxic to cells (23). Domain Ib is composed of amino acids 365 to 395 and has no known function; deleting part or all of this domain results in no loss of activity.

Cell killing is initiated when PE binds to a multifunctional high-molecular-weight cell-surface glycoprotein. This protein is

the receptor for α_2-macroglobulin and a low-density lipoprotein (24). PE is then internalized by the pathway of receptor-mediated endocytosis (25). Either before entry into the cell or on reaching the endocytic compartment, the PE proenzyme is activated by a cleavage between amino acids 279 and 280, followed by reduction of a disulfide bond connecting amino acids 265 through 287. This generates a 37-kd fragment composed of a portion of domain II and all of domain III. The 37-kd fragment is ultimately translocated to the cytosol, where it inactivates elongation factor 2 and produces cell death (26). Translocation to the cytosol probably occurs from the endoplasmic reticulum. The structure and activity of various recombinant toxins and immunotoxins derived from PE are depicted in Table 14.2-2 .

Table 14.2-2 Structure and Activity of Recombinant Toxins Derived from *Pseudomonas Aeruginosa*

Name	Structure	Target Cells	Size (Molecular Weight)	Reference
PE		Most mammalian cells	66 kd	20,21
PE40/PE38		—	40/38 kd	21
B3-LysPE38 (LMB-1)		Lewis Y carbohydrate carcinomas: gastrointestinal, breast, lung, ovary, bladder	200 kd	74,75
B3(Fv)PE38 (LMB-7)		Same	65 kd	76
B3(dsFv)PE38 (LMB-9)		Same	65 kd	79
e23(dsFv)PE38		Her2/neu carcinomas: breast, gastric, lung, ovary	64 kd	83,84
AntiTac (Fv)PE38 (LMB-2)		Human IL-2 receptor	65 kd	41,76
		Leukemia/lymphomas		
RFB4(dsFv)-PE38 (BL22)		CD22	65 kd	48
		Leukemia/lymphomas		
TGF-PE40/38		Epidermal growth factor receptor	46 kd	88,92,93
		Epidermoid carcinoma		
		Adenocarcinoma		
		Glioblastoma		
IL-4(38-37)-PE38KDEL		IL-4 receptor	56 kd	102,103
		Glioblastoma		

IL, interleukin; PE, *Pseudomonas* exotoxin.

DT is produced by *Corynebacterium diphtheriae*. It is a single-chain polypeptide of 535 residues. Like PE, it is also made up of three domains (27). Fragment A, the 21-kd amino terminal catalytic domain, catalyses the transfer of the adenosine diphosphate-ribosyl group of NAD$^+$ to elongation factor 2, arresting protein synthesis and, thus, killing the target cell. Fragment B (37 kd) consists of two domains, a receptor-binding domain (amino acids 386 to 535) and a transmembrane domain (amino acids 205 to 378), which is responsible for membrane insertion and translocation of the A fragment to the cytosol. After binding to a receptor on the cell surface, DT is internalized through coated pits into endocytic vesicles, where it is proteolytically cleaved into A and B fragments. The low pH in the vesicular compartment (approximately pH 5) initiates the translocation process, but reduction of the disulfide bond is required for translocation into the cytosol (28 ,29).

Construction of Immunotoxins

Part of "14.2 - Immunotoxins and Recombinant Immunotoxins "

How Immunotoxins Are Attached to Antibodies

First-generation immunotoxins were constructed by coupling toxins to MAb or antibody fragments using a heterobifunctional cross-linking agent. All the immunotoxins containing plant toxins that are described in this review have been produced in this manner. Subsequently, it was discovered that

genetic engineering could be used to replace the cell-binding domains of bacterial toxins with the Fv portions of antibodies or with growth factors (30 ,31). Because bacterial toxins have no carbohydrates and are naturally produced by bacteria, production of recombinant immunotoxins and growth factor toxin-fusion proteins in *E. coli* has been successful. Initially, single-chain Fvs were used to fuse to toxins in which the heavy and light chains are connected together by a peptide linker. Because the majority of single-chain Fvs cloned from MAb are unstable and cannot be used to make recombinant immunotoxins, it was necessary to find a method of stabilizing the Fvs. This was accomplished by replacing the peptide linker with a disulfide bond connecting framework residues in the V_H and V_L. Residues that can be used to introduce disulfide bonds for almost all antibodies were identified by protein modeling (32). Recombinant immunotoxins containing truncated PE are most commonly 38 kd in molecular weight and include B3(Fv)-PE38, anti-Tac(Fv)-PE38, etc., or if a growth factor is used, transforming growth factor-α (TGF-α)-PE38, etc. The mechanism of cell killing by a single-chain immunotoxin containing an Fv fragment and a portion of PE is depicted in Figure 14.2-1 . With DT, the ligand is inserted at the carboxyl end of the toxin and the number of amino acids in the toxin (including the initiator methionine) is noted [e.g., DAB_{486},-interleukin-2 (IL-2) or DAB_{389}-IL-2].
FIGURE 14.2-1. Mechanism of cell killing by a single-chain immunotoxin containing an antibody Fv fragment and a portion of *Pseudomonas* exotoxin. Domain I (the binding domain of *Pseudomonas* exotoxin) is replaced with the variable regions of an antibody. *T* indicates translocation domain (II) and *A* indicates the adenosine diphosphate ribosylation domain (III) of *Pseudomonas* exotoxin. After binding to a cell-surface antigen, the toxin-receptor complex is internalized via coated pits into the endocytic vesicle and trans Golgi compartments, where the low pH environment causes toxin unfolding and facilitates proteolysis; the cleaved toxin is then reduced into two fragments. The 37-kd carboxyl terminal fragment is transported to the endoplasmic reticulum and from there to the cytosol. The toxin fragment inactivates elongation factor 2, arrests protein synthesis, and causes cell death.

Recombinant immunotoxins have several advantages over chemical conjugates with antibodies or antibody fragments. One is that they are homogeneous with respect to the toxin-ligand junction, whereas chemical conjugates are heterogeneous. Second, they are less immunogenic. Third, they are less costly to produce. Their most important attribute, however, is that they are often more active than chemical conjugates, probably because they closely resemble the parental toxin from which they are derived and are activated by the target cell more efficiently.

Clinical Trials

Part of "14.2 - Immunotoxins and Recombinant Immunotoxins "

Immunotoxins Targeting Hematologic Malignancies

Many of the initial immunotoxins were directed toward hematologic tumors, which are easier to target than solid tumors for several reasons, including direct access of the immunotoxin to intravascular tumor cells and better penetration into lymphomatous tumor-cell masses. Moreover, fresh cells can be obtained and tested for immunotoxin binding and cytotoxic activity. Immunotoxins also have been developed for the indirect treatment of malignancies by targeting T cells that mediate graft-versus-host disease (GVHD) in the setting of allogeneic transplantation. Table 14.2-3 summarizes some of the immunotoxin clinical trials in hematologic malignancies from the mid-1990s.

Table 14.2-3 Results of Clinical Trials of Targeted Toxins in Hematologic Malignancies

Target Toxin	Phase	Target	Patients	Response	Frequent Toxicities	References
H65-RTA	2	CD5	41	GVHD prevention	N/A	35
Anti-CD6-bRicin	1	CD6	5	CTCL	Ongoing	54
DAB_{389}IL-2	1-3	IL-2R	144	13 CR, 24 PR	Asthenia, mild VLS	38,39
Anti-Tac(Fv)-PE38(LMB-2)	1	CD25	32	1 CR, 7 PR	Transaminases, fever	37,41
RFT5-dgA	1	CD25	20	2 PR	VLS	43
RFB4-IgG-dgA	1	CD22	42	1 CR, 9 PR	VLS	44,46
Bispecific αCD22/αSAP	1	CD22	5	0 PR	Preliminary data	118
RFB4(dsFv)-PE38 (BL22)	1	CD22	—	—	Ongoing	48
B43-PAP	1	CD19	17	4 CR, 1 PR	Preliminary data	51
HD37-dgA	1	CD19	40	1 CR, 2 PR	VLS	52
Anti-B4-bRicin	1-2	CD19	95 Measurable	4 CR, 5 PR	Transaminases, platelets	53,54
Anti-B4-bRicin	1-3	CD19	143 Adjuvant	DFS unchanged	N/A	55,56
Ber-H2-Sap6	1	CD30	12 HD	4 PR	—	57
Anti-My9-bRicin	1	CD33	18 AML	0 PR VLS	Platelets	54

AML, acute myelogenous leukemia; CTCL, cutaneous T-cell lymphoma; CR, complete remission; DFS, disease-free survival; dgA, deglycosylated A chain; GVHD, graft-versus-host disease; HD, Hodgkin's disease; IL-2, interleukin-2; IL-2R, interleukin-2 receptor; N/A, not applicable; PE, *Pseudomonas* exotoxin; PR, partial remission; VLS, vascular leak syndrome.

Immunotoxins Targeting CD5

CD5 is a T-cell antigen that is present in T-cell and some B-cell malignancies, particularly B-cell chronic lymphocytic leukemia (CLL) (33). In one of the earliest clinical trials of immunotoxins, the anti-CD5 MAb T101 was conjugated to ricin A chain (RTA) and T101-RTA was tested in patients with GVHD and CLL with some responses reported (34). A related immunotoxin H65-RTA (also called *XomaZyme-CD5*), showed some activity in patients with GVHD and other autoimmune disorders. A randomized double-blind trial comparing steroids with or without H65-RTA in 243 patients with acute GVHD, however, showed control of clinical manifestations of GVHD for the first 5 weeks but no lasting significant difference in the complete response rate, incidence of chronic extensive GVHD, or survival (35). Toxicities included fever and vascular leak syndrome (VLS), and patients treated for GVHD had a high mortality rate from infections because of the late return of CD4- and CD8-positive T cells (36).

Immunotoxins Targeting Interleukin-2 Receptor

The IL-2 receptor (IL-2R) binds IL-2 with high affinity ($kd = 10^{-11}$ M) if all three subunits of the receptor are present (α, β, γc). IL-2 binds with intermediate affinity ($kd = 10^{-9}$ M) to the complex of β and γc and with low affinity ($kd = 10^{-8}$ M) to α

(CD25) alone. CD25 is overexpressed on the malignant cells in adult T-cell leukemia, peripheral T-cell leukemia/lymphomas, cutaneous T-cell lymphoma (CTCL), B-cell non-Hodgkin's lymphomas, Hodgkin's disease (HD), hairy cell leukemia, and CLL, as well as on activated T cells (37).

The high-affinity IL-2R has been targeted using single-chain fusions of truncated DT with IL-2. DAB₄₈₆IL-2 contains the first 485 amino acids of DT; it was tested in 112 patients with hematologic malignancies in several phase 1 trials (38). Responses (mostly partial) were observed in 4 of 46 patients with B-cell non-Hodgkin's lymphoma, one of nine patients with HD, 5 of 36 patients with CTCL, 1 of 13 patients with CLL, and no patients with Kaposi's sarcoma, adult T-cell leukemia, acute myelogenous leukemia, prolymphocytic leukemia, and acute lymphocytic leukemia. Dose-limiting toxicity when given as bolus injections was usually from transaminase elevations, and when given as a 90-minute infusion, toxicity was caused by renal insufficiency, hemolysis, and thrombocytopenia.

An improved derivative, DAB₃₈₉IL-2, containing the first 388 amino acids of DT, was subsequently produced. In a phase 1 trial, it produced five complete remissions (CRs) and eight partial remissions (PRs) in 35 patients with CTCL, one CR and two PRs in 17 patients with non-Hodgkin's lymphoma, and no responses in 21 patients with HD (39 ,40). The maximum tolerated dose (MTD) was 27 µg per kg per day × 5 days, and the dose-limiting toxicity was asthenia. Common toxicities included transaminase elevations (62%), hypoalbuminemia (86%), hypotension (32%), rashes (32%), other allergic reactions (21%), and mild VLS comprised of hypotension, hypoalbuminemia, and edema (8%). The average overall half-life was 72 minutes. A phase 3 trial of DAB₃₈₉IL-2 was performed in 71 patients with CTCL who were randomized between receiving 9 and 18 µg per kg per day × 5. Overall, seven CRs and 14 PRs were observed (39). Slightly more responses occurred in the high-dose arm (36% vs. 23%), which became more significant (10% vs. 38%, *p* = .03) when patients with at least stage IIb disease were considered.

An alternative strategy for IL-2R targeting is to target CD25 directly, and this is particularly useful for targeting malignant cells that express CD25 alone or with low expression of the other IL-2R chains. Anti-Tac(Fv)-PE38 (LMB-2) is a recombinant immunotoxin that targets CD25. It is composed of the V_H domain of anti-Tac fused via a 15-amino acid linker to V_L, which, in turn, is fused to a PE38 (30 ,37 ,41). In a phase 1 trial, 35 patients with chemotherapy refractory hematologic malignancies have been treated with doses of LMB-2 ranging from 2 to 63 µg per kg q.o.d. × 3. One CR and seven PRs were observed in 19 evaluable patients treated with 30 to 63 µg per kg q.o.d. × 3, including four of four patients with hairy cell leukemia, one of three patients with CLL, one of one patient with CTCL, one of two patients with adult T-cell leukemia, and one of six patients with HD. One hairy cell leukemia patient had a clinical CR lasting longer than 9 months. The MTD of LMB-2 is 40 µg per kg q.o.d. × 3 with the most common toxicities being transient transaminase elevations and fever. A phase 2 trial is planned for 1999. LMB-2 is also being developed for the prevention of GVHD. One strategy is to react donor T cells with radiated patient cells to selectively upregulate CD25 only on those donor T cells that are potentially reactive with patient cells. Using LMB-2 *ex vivo*, these patient-reactive donor T cells are killed, leaving a graft more suitable for haplotype-mismatched transplantation (42). This should represent an improvement over nonspecific T-cell depletion from the donor graft, which has been associated with impaired engraftment when antigens, such as CD3, are targeted. A chemical conjugate of the anti-CD25 MAb RFT5 with dgA has also been tested in a phase 1 trial in which 2 of a total of 20 patients with HD responded (43). This immunotoxin, RFT5-dgA, is also being administered to patients immediately after allogeneic transplantation in an effort to prevent GVHD.

Immunotoxins Targeting CD22

Because approximately 70% of B-cell lymphomas and leukemias are CD22⁺, these disorders have been targeted by a variety of

immunotoxins, the most successful of which have contained the anti-CD22 MAb RFB4 or its Fab" fragment conjugated chemically to dgA (44 ,45 and 46). RFB4-Fab"-dgA produced PRs in 5 of 13 patients and RFB4-IgG-dgA produced one CR and nine PRs in 30 evaluable patients. Another durable CR was reported with RFB4-IgG-dgA (47). The dose of RFB4-dgA is limited by VLS, which in several cases has been fatal (44 ,45 and 46). RFB4(dsFv)-PE38 is a PE-based recombinant immunotoxin targeted at CD22 (48) that has just entered clinical trials. It contains the Fv portion of the RFB4 antibody, so it targets the same epitope as RFB4-dgA. It could potentially have fewer side effects than RFB4-dgA, however, because PE38 is much less toxic than dgA toward human endothelial cells (49) and RFB4(dsFv)-PE38 is well tolerated in preclinical studies done in mice and monkeys.

Immunotoxins Targeting CD19

CD19 is the most ubiquitously expressed protein in the B-lymphocyte lineage and is present on B cells from the time stem cells begin B-cell commitment until the time of plasma-cell differentiation (50). Pokeweed antiviral protein has been targeted using the anti-CD19 MAb B43. In a phase 1 trial in relapsed patients with childhood acute lymphocytic leukemia, the MTD was found to be more than 1.25 mg per kg, and toxicities included VLS and myalgias. To date, responses in 17 evaluable patients have been reported, including four CRs and one PR (51). Another anti-CD19 antibody, HD37, was conjugated to dgA and administered to lymphoma patients in various schedules. HD37-dgA produced one CR and two PRs in 40 evaluable patients. Dose-limiting toxicity was caused by VLS (52). The anti-CD19 MAb anti-B4 was conjugated to blocked ricin (bR). When anti-B4-bR was administered by five daily bolus injections or by continuous infusion, a total of three CRs and five PRs were observed in 59 patients, but, in a follow-up phase 2 trial, no responses were observed (53). Anti-B4-bR was also tested by continuous infusion in patients with B-cell lymphoma in CR after autologous bone marrow transplantation, where residual disease was minimal. Although phase 1 and 2 trials appeared promising, in a phase 3 trial, 82 patients randomized to anti-B4-bR showed no benefit in disease-free survival (54 ,55 and 56).

Immunotoxins Targeting Other Hematologic Antigens

The T-cell antigen CD6 is present on CTCL cells, and a clinical trial of anti-CD6-bR is under way in this disease (54). Because CD30 is expressed in HD, an anti-CD30 immunotoxin was made by coupling MAb Ber-H2 to saporin. Ber-H2-Sap6 produced four PRs in 12 patients (57). CD33 is expressed on acute myelogenous leukemia cells and has been targeted using the chemical conjugate anti-My9-bR, but it produced no major responses in 18 patients in a trial in which the dose was limited by VLS and thrombocytopenia (54). Recombinant toxins targeted at the granulocyte-macrophage colony-stimulating factor receptor on acute myelogenous leukemia (58) and CD40 on B-cell malignancies (59) are under development with the former agent, DT_{388}-granulocyte-macrophage colony-stimulating factor, already in clinical testing.

Immunotoxins Targeting Solid Tumors

Although encouraging results have been observed in the treatment of patients with leukemia and lymphomas, the efficacy of immunotoxins in the treatment of epithelial carcinomas has been limited. A major obstacle has been the difficulty in finding MAb without cross-reactivity to essential normal tissues. The first immunotoxin studies designed to target breast and ovarian carcinomas were hampered by unexpected neurotoxicities as a result of cross-reactivity with cells of the central nervous system (60 ,61). Another barrier has been the inability of these macromolecules to reach the target cell in adequate quantities because of physiologic factors well described by Jain et al (62). The heterogeneous blood supply, elevated interstitial pressure within the tumor, and large transport distances in the interstitium (63) play a role in decreasing the therapeutic window of these agents. These physiologic barriers do not represent a problem for treating leukemias, lymphomas, and micrometastasis in which the interstitial pressure is low and diffusion distances are small (64).

Valuable clinical experience was gained from first-generation immunotoxins. They are listed in Table 14.2-4 (60 ,61 ,65 ,66 ,67 ,68 ,69 ,70 and 71). Progress in the understanding of tumor physiology and biology has also led to the development of newer-generation recombinant immunotoxins with better properties. The advent of computer protein design and modeling has been instrumental in many of these improvements. Some of the new-generation immunotoxins developed during the past few years are described.

Table 14.2-4 Clinical Trials of Immunotoxins and Recombinant Immunotoxins for Solid Tumors

Immunotoxin	Target/Toxin Moiety	Disease (Mode of Delivery)	Major Side Effect	Reference
Systemic Delivery				
Xomazyme-Mel	Proteoglycan/A chain	Melanoma (i.v.)	VLS	65,66,67
Xomazyme-791	gp72/ A chain	Colon cancer (i.v.)	VLS, renal, neurologic	68,69
260F9-rRTA	Anti-gp55/rA chain	Breast cancer (i.v.)	Neuropathy, VLS	60,70
N901-bB	Anti-NCAM/blocked R	Small-cell lung cancer (i.v.)	VLS, hepatic, hematologic	85
LMB-1 (B3LysPE38)	Anti-Le^y/PE38	Epithelial carcinoma (i.v.)	VLS	75
LMB-7 (B3FvPE38)	Anti-Le^y/PE38	Epithelial carcinoma(i.v.)	Gastrointestinal	78
LMB-9 (B3dsFvPE38)	Anti-Le^y/PE38	Epithelial carcinoma (i.v.)	Ongoing	Ongoing
erb-38	Her2-neu/PE38	Her2neu-positive tumors (i.v.)	Hepatic	84
$DAB_{389}EGF$	EGF/DT	EGF-positive tumors (i.v.)	Hepatic	86,87
Regional Immunotoxin Delivery				
454A12-rRTA	Anti-transf./r A chain	Epithelial cancer (i.p.)	VLS, encephalopathy	71
OVB3-PE	OVB-3/PE	Ovarian cancer (i.p.)	Encephalopathy	61
TP40	EGF/ PE40	Bladder cancer (intravesical)	None	93
45A12-rRA	Anti-transf./r A chain	Leptomeningeal carcinomatosis (intrathecal)	Neurologic	95
TF-CRN1-7	Transferrin/DT (CRM107)	Brain tumors (intratumoral)	Hepatic, neurologic	99
IL-4(38-37)-PE38KDEL	IL-4 receptor/PE38	Glioblastoma (intratumoral)	Ongoing	102,103 and 104

Anti-transf./r A, anti-transferrin ricin A; DT, diphtheria toxin; EGF, epidermal growth factor; PE, *Pseudomonas* exotoxin; VLS, vascular leak syndrome.

Anti-Lewis Y Recombinant Immunotoxins

MAb B3 is a murine antibody that reacts with several human epithelial carcinomas with limited expression in normal tissue (72). The hybridoma that produces MAb B3 (IgG1k) was isolated from the spleen of a mouse immunized with MCF-7 (human breast carcinoma) cells. Immunohistochemical studies of a panel of human carcinomas show that MAb B3 react strongly and homogeneously in more than 90% of the colorectal carcinomas. Other gastrointestinal malignancies, such as esophageal (80%) and gastric carcinomas (75%), showed similar strong reactivity, as do 70% of non-small-cell carcinomas of the lung. MAb B3 also reacts strongly with as many as 70% of breast carcinomas tested and mucinous adenocarcinomas of the ovary.

Peroxidase immunohistochemistry with frozen sections of normal tissues demonstrated that MAb B3 reacts with the glands of the stomach, the differentiated cell layer of the esophagus, and the epithelia of the trachea and bladder. One of the important characteristics of this antibody is that similar reactivity was found in normal monkey and normal human tissues, so that monkeys could be used for toxicology studies. Biochemical analysis indicated that MAb B3 reacts with a carbohydrate antigen of the Lewis^y (Le^y) family that is present on many cell-surface glycoproteins. These range in molecular weight from more than 200,000 kd to less than 40,000 kd. Because many of these glycoproteins are internalized, they represent good targets for immunotoxin therapy.

LMB-1 (B3-LysPE38) is an immunotoxin in which MAb B3 is chemically coupled to LysPE38 (73 ,74). Thirty-eight patients with advanced solid tumors were entered in a phase 1 clinical trial (16 male, 22 female) with a mean age of 47 years (age range, 30 to 70 years). All patients had B3 antigen on the surface of their tumor cells and no preexisting neutralizing antibodies to LMB-1 (75). Twenty-six patients had colorectal cancer, eight had breast cancer, one had cancer of the esophagus, one had cancer of the stomach, one had ovarian cancer, and one had cancer of the ampulla of Vater. LMB-1 was administered intravenously over 30 minutes on days 1, 3, and 5. Patients received doses ranging from 10 mg per kg per day to 100 mg per kg every day. The MTD is 75 mg per kg given on days 1, 3, and 5. The dose-limiting toxicity is VLS, manifested by hypoalbuminemia, fluid retention, and peripheral edema. In severe cases, hypotension and pulmonary edema were observed. Other side effects include "flulike" symptoms, fever, malaise, skin rash, headache, and nonspecific electrocardiogram changes. Antitumor activity was observed in four patients (one CR, one PR, two minor responses), 20 patients had stable disease, and 15 patients progressed. Thirty-three of 38 (90%) patients developed antibodies against LMB-1 3 weeks after treatment.

The evidence of antitumor activity observed with LMB-1 proves that it is possible to target epithelial malignancies in humans. Although immunotoxin therapy has been shown to be active in hematologic malignancies, this is the first time that objective antitumor activity against metastatic colon and breast cancers has been documented. At the MTD, side effects of LMB-1 were well tolerated and transient. The major side effect, VLS, is secondary to targeting of LMB-1 to antigen-positive endothelial cells (49).

Single-Chain Immunotoxins [B3(Fv)-PE38 and B3(dsFV)-PE38]

LMB-7

Inadequate distribution of drug within tumors is probably one of the major obstacles for the efficacy of LMB-1 and other high-molecular-weight immunotoxins. Although this is a problem that affects drugs in general, it is particularly troublesome for macromolecules, such as LMB-1 (molecular weight, approximately 200 kd). The differences in the blood flow within the tumor and the elevation of interstitial pressure greatly slows the penetration of molecules like LMB-1 into the interior of tumors. Successful therapy may not be possible, unless this barrier can be circumvented. The production of small, genetically engineered single-chain (Fv) immunotoxins (65 kd) helps overcome the tumor distribution problem (76). B3(Fv)-PE38 or LMB-7 is a single-chain immunotoxin composed of the variable regions (Fvs) of the light (V_L) and heavy (V_H) chains of B3, connected by a flexible linker to form a single-chain antigen-binding protein B3(scFv), which, in turn, is fused to PE38 (77). It has a molecular weight of 63 kd. Because LMB-7 lacks the Fc portion of the murine MAb and is smaller in size, it was expected to be less immunogenic than LMB-1.

Fifty-one patients were entered into a phase 1 clinical trial at doses ranging from 2 μg per kg per day to 48 μg per kg per day given as a 30-minute bolus on days 1, 3, and 5 (78). At 7 μg per kg, the first signs of nausea, vomiting, and diarrhea were noted. The dose-limiting toxicity was 30 μg per kg, and the MTD was defined as 24 μg per kg. Upper gastrointestinal endoscopy revealed severe gastritis and ulcers. This side effect was expected because the B3 antigen is also expressed on the surface of the human gastric mucosa. The etiology of the diarrhea is unclear. Our hypothesis is that the targeting of the gastric mucosa by LMB-7 leads to increased gastric secretion, which, in turn, stimulates intestinal movement. Based on this hypothesis, the clinical protocol was amended to circumvent the gastrointestinal toxicity. Patients are now pretreated with antiemetics and omeprazole to suppress gastric acid secretion. Loperamide is administered to patients as needed. Using this regimen, the LMB-7 dose has been escalated up to 48 μg per kg with marked improvement of the gastrointestinal symptoms. Other non–dose-limiting side effects thus far include VLS, transient elevation of transaminases, and

transient elevation of creatinine. A minor response (<50% tumor shrinkage) was observed in one patient with colon cancer (78).

Preliminary pharmacokinetic data indicates that LMB-7 is cleared monoexponentially from the circulation with a half-life of 60 minutes (± 38); the area under the curve, 2.2 µg per hour per mL (± 14); the Vd = volume of distribution, 3.2 liters (± 1.6); and the Cl = clearance, 2.2 liters per hour (± 0.6). LMB-7 is cleared from the circulation more rapidly than the chemical conjugate LMB-1 (half-life, 1 hour vs. 8 hours). Sixty-five percent (33 of 51) of the patients developed neutralizing antibodies against LMB-7 after one cycle of treatment. This result indicates that, as predicted, LMB-7 is less immunogenic than the chemical conjugate LMB-1.

LMB-9

Single-chain (Fv) immunotoxins, such as LMB-7, were created to overcome the poor tumor penetration of large immunotoxins made with whole IgG. Although LMB-7 is smaller in size than LMB-1 and should penetrate more readily into tumor, LMB-7 is unstable in serum. When incubated at 37°C in human serum, it loses 50% of its activity after 2 to 4 hours. Dissociation of V_L and V_H leads to aggregation and inactivation. To overcome the instability of LMB-7, a method was developed to stabilize the Fv fragment of the B3 antibody by producing genetically altered forms of V_L and V_H in which a disulfide bond connects the two chains (79). LMB-9 was synthesized using this new approach. B3(dsFv)PE38 or LMB-9 is extremely stable (80). When incubated at 37°C in phosphate-buffered saline or human serum, it remains fully active for more than 14 days. This property renders LMB-9 superior to LMB-7. Because LMB-9 is much more stable in physiologic conditions than LMB-7, LMB-9 should remain active within the tumor interstitium as it slowly distributes and binds to the cancer cells. Preclinical experiments indicate that, when given by slow intraperitoneal infusion, LMB-9 has superior antitumor activity than LMB-7 (81).

Preclinical pharmacokinetic studies of LMB-7 and LMB-9 indicate that these molecules are cleared rapidly from the circulation in mice (half-life, 20 to 23 minutes) and Cynomolgus monkeys (half-life, 30 to 180 minutes). The plasma clearances of LMB-7 and LMB-9 in humans are expected to be similar. Because of the improved stability of LMB-9, however, its behavior within the tumor interstitium is expected to be superior. A phase 1 clinical trial using the improved disulfide-stabilized immunotoxin LMB-9 is ongoing.

Recombinant Immunotoxins Targeting Her2/neu (Erb-38)

To exploit the overexpression of erbB-2 in many human cancers (breast, stomach, lung, and ovary), a recombinant immunotoxin was made using MAb e23 (82) that reacts with erbB-2. Erb-38 is a recombinant immunotoxin in which the Fv portion of an MAb recognizing erbB2 is fused to a 38-kd fragment of PE A. This immunotoxin is specifically cytotoxic to cells expressing erbB-2 and causes regression of the human gastric cancer cells (N87) growing as tumors in immunodeficient mice (83). We conducted a phase 1 study of erb-38 in adult cancer patients with carcinomas that express Her2/neu (84). Erb-38 was administered as a 30-minute intravenous bolus on days 1, 3, and 5. Six patients (five breast, one esophageal cancer) were entered at doses of 1 or 2 µg per kg. Transient transaminase elevation was observed in all patients. Erb-38 was cleared monoexponentially from the circulation with a half-life of 2.4 to 10.3 hours at 2 µg per kg; the maximum plasma concentration achieved was 47 to 105 ng per mL. One of five patients developed antibodies against erb-38 (84). The toxicity observed with erb-38 is most likely caused by the presence of erbB2 on hepatocytes. This finding led us to conclude that the toxicity observed with erb-38 is most likely caused by the presence of erbB2 on hepatocytes because recombinant immunotoxins targeting other antigens (Le^y or CD25) did not produce the same liver toxicity when given much higher doses. The targeting of tumors with antibodies to erbB2 that are armed with radioisotopes, chemotherapy drugs, and other toxic agents may also result in unexpected organ toxicities caused by erB2 expression on normal tissues.

Immunotoxin for Small-Cell Lung Cancer (N901-bR, anti-NCAM-Blocked Ricin)

bR was coupled to N901, a murine IgG anti-NCAM (CD56), which is expressed in more than 95% of small-cell lung cancer cell lines. This antigen is also present in cardiac muscle, peripheral nerve, and human natural killer cells. In preclinical toxicity studies, monkeys were able to tolerate up to 1 mg per kg of intravenous N901-bR, but myocardial inflammation and mild nerve conduction alterations were observed in animals treated with N901-bR. In a phase 1/2 study, N901-bR was given by continuous intravenous infusion × 7 days to 21 patients with small-cell lung cancer who had failed standard therapy (85). Patients were treated with doses ranging from 5 to 40 µg per kg per day. The MTD was 30 mg per kg lean body weight per day with VLS as the dose-limiting toxicity. Other side effects included transaminase elevation, fever, myalgia, weight gain, and thrombocytopenia. Fifteen of the 21 patients were evaluated pre- and posttreatment with detailed neurologic examinations, electromyelogram, and nerve conduction studies. No clinical symptoms or changes in the neurologic examination were noted, although there was a trend for amplitude decline in nerve conduction for both sensory motor and motor neurons. No evidence of clinically significant myocardial dysfunction was observed, but cardiac events occurred in three patients: one patient had a "silent" myocardial infarction with a change of ejection fraction from 66% to 36%, one patient with a previous history of fibrillation had an episode of atrial fibrillation, and one patient had an asymptomatic elevation of creatine phosphokinase. Sinus tachycardia was noted in 15 of 21 patients. These events were probably related to the specific binding of the antibody to neural and cardiac cells. Specific binding of the immunotoxin to tumor cells in bone marrow, liver, and lung was documented. One patient achieved a PR. Fifty percent of the patients developed human antimouse antibody (HAMA) and 85% developed human antiricin antibody. A phase 2 study after induction radiochemotherapy in patients with small-cell lung cancer

will address the role of N901-bR in patients with a small tumor burden.

Epidermal Growth Factor Immunotoxin (DAB$_{389}$ Epidermal Growth Factor)

Two phase 1 studies using DAB$_{389}$ epidermal growth factor (EGF) (86) in patients with EGF receptor (EGF-R) expressing solid tumors has been conducted in patients with EGF-R-expressing malignancies. Two different dosing schedules repeated every 28 days (daily, 1 to 5 and days 1, 8, 9, 15, and 16) were examined. A total of 52 patients with metastatic disease were entered, receiving doses ranging from 0.3 to 15 µg per kg per day. The dose-limiting toxicity was renal tubular acidosis and back and chest pain. The toxicities include reversible hepatic transaminase elevation, renal toxicity, hypoalbuminemia, fever, chills, nausea, blood pressure alterations, and anorexia.

A PR was observed in one patient with lung cancer (6 µg per kg per day on the episodic schedule) (38 ,87). A phase 1/2 study is ongoing for patients with non-small-cell lung cancer with a starting dose of 6 µg per kg per day every other day for three doses.

Regional Immunotoxin Delivery

Part of "14.2 - Immunotoxins and Recombinant Immunotoxins "

Regional drug delivery is an approach designed to exploit dose-response effects by delivering more drug to locally confined tumors. When compared with intravenous administration, regional delivery of drugs can presumably increase drug concentration at tumor sites, decrease systemic exposure and, therefore, decrease toxicities. Modes of regional delivery include administration into an existing cavity (e.g., cerebrospinal, peritoneal, bladder, pleural) and direct instillation of drug into a tumor or intraarterial infusion. The general pharmacokinetic principles guiding regional therapy is that the rate of drug clearance from the local compartment is smaller than total body clearance, resulting in a higher drug concentration at the tumor site for a longer period. Regional delivery of immunotoxins might therefore help overcome the physiologic resistance to therapy of solid tumors and minimize systemic toxicities.

Intravesical Therapy of Transitional Cell Carcinoma with TP40

To exploit the EGF-R overexpression on neoplastic cells, the DNA encoding TGF-α has been fused to PE40 to form the chimeric toxin TGFα-PE40 (88). TGFα-PE40 specifically kills cells that overexpress EGF-Rs (89 ,90). Because several normal organs and, particularly, the liver express the EGF-R, the therapeutic window for TGFα-PE40 is narrow when delivered systemically. To circumvent liver toxicity, this agent has been used for the regional therapy of superficial bladder cancer in patients. Transitional cell cancer of the bladder is known to overexpress EGF-Rs, and tumors with a high density of EGF-R have been shown to correlate with poor clinical outcome (91). A phase 1 trial using a genetically modified form of TGFα-PE40, termed *TP40* (92), was carried out in patients with superficial bladder cancer. Forty-three patients were entered in this study (93). Therapy was given weekly × 6 by intravesical administration at doses ranging from 0.15 mg per 60 mL to 9.6 mg. No toxicities were observed in this study. Eleven patients had evaluable Ta or T1 lesions, 19 patients had resected Ta or T1 lesions, seven patients had carcinoma *in situ* only, and six patients had mixed carcinoma *in situ* and Ta/T1 disease. One CR occurred in a patient with carcinoma *in situ*; five of seven (70%) patients with carcinoma *in situ* were found to have visual resolution of the lesions during follow-up cystoscopy. None of the patients in this trial developed antibodies against TP40. The absence of systemic toxicity and antibody formation against the toxin indicate that TP40 is not absorbed through the bladder mucosa. Further trials using prolonged bladder irrigation, daily intravesical administrations, or other schemes of delivery might help improve the efficacy of this agent for patients with superficial bladder cancer.

Treatment of Central Nervous System Malignancies with Immunotoxins

Several immunotoxins and recombinant immunotoxins are being tested in clinical studies for the treatment of malignancies of the central nervous system. Although normal blood-brain barrier represents an impediment for the delivery of large molecules, such as immunotoxins, it is known that this barrier is frequently disrupted at the tumor site. Although systemic administrations might have potential benefit for treatment of central nervous system malignancies, regional delivery of immunotoxins in this "self-contained" compartment is appealing, particularly in the setting of meningeal carcinomatosis. Furthermore, the immunoprotective environment of the central nervous system may also allow for repeated administration of immunotoxin without the development of neutralizing antibodies frequently observed in systemic delivery.

Anti-Transferrin-Ricin A Chain Immunotoxin

454A12-rRA is an immunotoxin made of an MAb against the human transferrin receptor and ricin A chain (94). Eight patients with leptomeningeal carcinomatosis were treated in a pilot study of intraventricular therapy (95). Patients received doses ranging from 1.2 to 1,200 µg. Doses of more than 120 µg were associated with headache, vomiting, and altered mental status. More than 50% reduction of tumor cell counts in the lumbar cerebrospinal fluid was observed in four of eight patients; however, no patients had their cerebrospinal fluid cleared of tumors, and clinical or magnetic resonance imaging evidence of tumor progression was demonstrated in seven of eight patients. Tumoricidal concentrations of 454A12-rRA were obtained. Pharmacokinetic studies showed that the early phase half-life in the cerebrospinal fluid was 44 ± 21 minutes and the late phase half-life was 237 ± 86 minutes.

LMB-1 and LMB-7

A mouse model of human meningeal carcinomatosis was developed by Bigner et al. using athymic rats bearing the human epidermoid carcinoma A431. The efficacy of anti-Lewis Y immunotoxins LMB-1 and LMB-7 were evaluated using this model (96 ,97).

Immunotoxins were injected intrathecally 3 days after tumor implantation. Without treatment, median survival was 10 days. When LMB-1 was administered at 40 or 200 μg given on days 3, 6, and 8, significant increase in median survival was observed (40.5 and 33 days, respectively). With two long-term survivors in each group (191-day survival), non-tumor-bearing athymic rats showed no toxicity with a single dose of either 40 μg or 200 μg, or three doses of 40 μg. Weight loss, neurologic deficit, and death (two of eight patients) occurred. LMB-1 had no therapeutic effect on the treatment of two B3 antigen-negative neoplastic meningitis models. Similarly, CR and long-term survivors were observed in animals given 10 μg of LMB-7 on days 3, 5, and 7. A phase 1 clinical study to determine the MTD and side effects of LMB-7 in patients with meningeal carcinomatosis is being carried out.

Treatment of High-Grade Astrocytomas with Immunotoxins

Glioblastoma multiforme is the most malignant tumor of the glial series. Despite technical advances in neurosurgery and radiation therapy, the median survival for glioblastoma multiforme remains dismal. Presently available chemotherapy agents provide little to no survival advantage. The average survival of patients with this tumor ranges from 6 to 12 months. Because death is most often caused by local failure after conventional therapy, regional delivery with highly potent agents, such as immunotoxins, is an attractive treatment modality that warrants consideration.

Clinical Trial with Transferrin-CRM107

Human transferrin (Tf) chemically coupled to a mutant of diphtheria toxin (CRM107) (98) has been evaluated and tested in a clinical trial in patients with recurrent malignant tumors. Tf-CRM107 was delivered by interstitial infusion in a dose-escalation schedule (99). After a computed tomography-guided tumor biopsy, one to three silastic infusion catheters were placed at selected sites in the tumor using stereotactic guidance. To distribute the immunotoxin in the tumor and the infiltrated brain surrounding the tumor, Laske and colleagues adapted a microinfusion technique in which a pressure gradient was maintained during interstitial brain infusion to establish convective flow in the extracellular space (100 ,101). Eighteen patients (ten male, eight female) ages 24 to 61 years (median, 48 years) with confirmed radiographic evidence of tumor progression were entered in the trial. Ten patients had glioblastoma multiforme, five patients had anaplastic astrocytoma, two patients had adenocarcinoma of the lung, and one patient had oligodendroglioma. The primary variables of this clinical trial were the drug concentration and the volume infused. Patients received doses ranging from 0.1 to 3.2 μg per mL (total dose, 0.5 to 199 μg). The total volume infused varied from 5 to 180 mL (duration of infusion, 2 to 15 days). Drug concentration and volume were escalated as tolerated. Doses of 1 mg per mL or more resulted in local toxicity, specifically peritumoral local brain injury, attributed to binding of the immunotoxin to transferrin receptors on endothelial cells. Objective tumor response was observed in 9 of 15 evaluable patients. Seven PRs (≥50% decrease in the enhancing volume of the tumor) and two CRs occurred. Tumor shrinkage occurred no earlier than 1 month. Time to maximum response was observed from 6 to 14 months in four patients after the first treatment. The median time to progression was 38 weeks. Transient worsening of neurologic deficit occurred three times in a total of 44 infusion treatments. This was attributed to increased cerebral edema in patients with preexisting significant edema and mass effect caused by the tumor. Four patients with history of seizure had seizure during infusion. Systemic toxicity included mild decrease in serum albumin (n = 12) and transient grade 1 to 3 elevation of transaminases (n = 14). Anti-DT antibody was detected in all patients before therapy. Six of 14 patients tested had more than a twofold increase in serum titers after treatment. Overall, at doses below 1 μg per mL, Tf-CRM107 was well tolerated with transient local and systemic toxicities.

Interleukin-4 Toxin

IL-4(38-37)-PE38KDEL (102 ,103) is a fusion protein consisting of a circularly permuted form of IL-4 fused to PE38KDEL. This chimeric toxin, composed of IL-4 residues 38-129, the linker GGNGG, and IL-4 residues 1-37, is highly cytotoxic to glioblastoma cell lines, as determined by clonogenic and protein synthesis inhibition assay. The IL-4 ligand in this toxin was circularly permuted to allow the toxin-ligand junction to be switched from the carboxyl terminus of IL-4, where the toxin interferes with IL-4R binding to residue 37 of IL-4. Human glioblastoma cells express high-affinity IL-4 receptors. IL-4 toxin, when administered directly into U251 tumors implanted in the flank of athymic mice, was capable of causing complete regressions (104). Significant antitumor activity was also observed in mice when IL-4 toxin was administered via intraperitoneal or intravenous routes. The potential advantage of IL-4 toxin over less tumor-specific immunotoxins is that IL-4R is not expressed on normal brain tissue (102), which allowed high concentrations to be well tolerated after intrathecal injections in monkeys or after intracerebral injection in rats. IL-4(38-37)-PE38KDEL is being tested in a phase 1/2 study in patients with glioblastoma, where the drug is administrated intratumorally.

Transforming Growth Factor-α-PE40 and Transforming Growth Factor-α-PE38

To exploit the overexpression of EGF-R in glioblastoma (105 ,106), we tested the activity of TGFα-PE40 (87) on tumor cells derived from patients diagnosed with glioblastoma multiforme. These cells were found to be highly sensitive to the recombinant toxin with an IC_{50} of 0.4 ng per mL for U-251 and 1.5 ng per mL for the T-98G cell line (90). Most significant, when given by continuous infusion over 7 days, TGFα-PE40 caused significant tumor regressions in nude mice bearing U-215 human glioblastoma xenografts (90). Preclinical toxicity experiments using a close derivative TGFα-PE38 indicate that this agent is well tolerated by rats (MTD, 666 ng) and monkeys (MTD, 2,000 ng) when administered intracerebrally. Higher doses lead to necrosis with microhemorrhage in the region of infusion. A phase 1 clinical study is being planned for patients with high-grade astrocytomas using TGFα-PE38.

Problems

Part of "14.2 - Immunotoxins and Recombinant Immunotoxins "

Several problems that limit the clinical efficacy of immunotoxins have been identified. One is toxicity caused by antigen present on essential normal tissues. This can be circumvented by the selection of antibodies or growth factors that are more specific for tumor cells. A second is nonspecific toxicity caused by an uptake of the immunotoxin by antigen-negative cells, such as in the liver or kidney. This can occur because of low-affinity binding of the immunotoxin to normal cells. For example, bR retains some affinity for normal liver cells and causes liver damage. In addition, nonspecific dose-limiting toxicities have been observed with several agents. The most severe is VLS (see next section). Immunogenicity is another problem. The toxins are products of plants of bacteria, which are immunogenic in humans. Finally, it is important to have molecules that are small and stable because proteins that are the size of antibodies or larger penetrate into tumors poorly.

Vascular Leak Syndrome

Damage to endothelial cells that manifest as VLS is a major dose-limiting toxicity for several immunotoxins presently in clinical trials. This syndrome has been observed with immunotoxins made of various toxins, including ricin, saporin, pokeweed antiviral protein, and PE. This toxicity was observed in the preclinical testing of some, but not all, of these agents in rodents and monkeys. VLS in humans is characterized by a decreased serum albumin and accumulation of fluid in the interstitial space, leading to weight gain and edema. In the most severe cases, excess fluid accumulates in the lungs, resulting in pulmonary edema. Acute and severe fluid leakage into the interstitium leads to intravascular depletion with hemodynamic consequences, such as sinus tachycardia, hypotension, oliguria, and prerenal azotemia. Similar toxicity has been reported in patients after administration of IL-2 therapy (107), although the mechanisms of action of IL-2 and immunotoxins are probably different.

The mechanisms involved in immunotoxin-mediated VLS are complex and poorly understood. *In vitro* and animal studies indicate that several different mechanisms might be involved in endothelial cell damage; furthermore, the pathogenesis of the endothelial cell damage may also differ from immunotoxin to immunotoxin. Soler-Rodriguez et al. have shown that human umbilical vein endothelial cells undergo rapid and dramatic changes in morphology after treatment with ricin A chain and ricin A chain containing immunotoxins (108). Rounding of the endothelial cells results in the formation of gaps between them; subsequently, protein synthesis is arrested and the cells die. VLS caused by LMB-1 appears to be due in large part to the presence of a small amount of Le^Y on endothelial cells and is a specific effect of the immunotoxin (49). Because LMB-1 leaves the circulation slowly (half-life in humans is 8 ± 2 hours), endothelial cells are exposed to a high concentration of LMB-1 for extended periods. Smaller recombinant immunotoxins (e.g., LMB-7 and LMB-9) that leave the circulation more rapidly may not produce this side effect.

In vitro and animal studies have shown that leukocytes (109,110) and cytokine and inflammatory mediators (111) are involved in endothelial cell damage. In 1998, Rafi et al. showed that perforin and Fas ligand may actively participate in IL-2-induced endothelial cell injury and induction of VLS in a variety of organs (112). It is possible that these mechanisms might also play a role in immunotoxin-mediated toxicity in humans. Prophylactic administration of corticosteroids and nonsteroidal antiinflammatory drugs has been shown to prevent PE-immunotoxin-mediated VLS in rats (113).

Clinical management of the capillary leak syndrome is mainly supportive. Pulmonary edema and hypotension are the most troublesome toxicity and have produced major morbidity and mortality in some trials. These patients require close monitoring, oxygen supplementation, fluid reconstitution, and, if necessary, ventilatory support and vasopressors. Judicious use of diuretics if hypotension is not present may be warranted. Serum albumin and steroids have been given to occasional patients in the event of acute VLS with no clear beneficial effects (44,45).

In an attempt to study the usefulness of corticosteroids in preventing immunotoxin-induced VLS, eight cancer patients received immunotoxin LMB-1 at 60 µg per kg on days 1, 3, and 5 and oral prednisone at 60 mg per m^2 for 2 weeks starting 4 days before the first dose of LMB-1. Eight patients received immunotoxin alone. No statistical differences were observed in the incidence of VLS, maximum decrement of serum albumin, weight gain, or development of HAMA/human antitoxin antibody (HATA) among the two groups.

Immunogenicity

Murine antibodies and toxins are highly immunogenic foreign proteins. HAMA and HATA can generally be detected 7 to 14 days after the initial exposure. Approximately 90% of patients with epithelial carcinomas and 30% of lymphoma patients have detectable HAMA and HATA after one cycle of immunotoxin. These antibodies neutralize the activity of the immunotoxin, precluding a multiple course therapy. Although the formation of HAMA is overcome by the use of single-chain recombinant immunotoxins, formation of antitoxin antibodies continues to represent a major problem.

Traditional immunosuppressive agents have been evaluated as a means of decreasing the antibody formation to the immunotoxins. Cyclophosphamide and cyclosporin (66,67) have been tested and were unsuccessful in reducing antibody formation at the doses administered. Newer agents, such as 15-deoxyspergualin, a metabolite of *Bacillus laterosporus,* were tested in a phase 1 study as immunosuppressive agent on HAMA formation (114,115) with encouraging effectiveness. The effectiveness of these agents was in part limited by the dose that could be administered without significant systemic toxicity.

A phase 2 study to explore the ability of the anti-CD20 antibody rituximab to suppress HAMA and HATA formation after treatment with immunotoxin LMB-1 is being conducted at the National Cancer Institute. Rituximab is used to treat B-cell lymphomas (116). It mediates complement and antibody-dependent cell-mediated cytotoxicity (ADCC) and has direct antiproliferative effects against malignant B-cell lines (117). In addition, a single dose of rituximab is able to completely clear normal B cells from the peripheral circulation. By giving an immunotoxin at the time of maximum B-cell depletion post-rituximab,

it might be possible to reduce or eliminate the host antibody response to the immunotoxin LMB-1, which permits repeated cycles to be administered. It is clear that to improve the efficacy of the immunotoxins and their clinical usefulness, this and other strategies to inhibit the immune response to foreign proteins need to be explored.

Conclusion

Part of "14.2 - Immunotoxins and Recombinant Immunotoxins "

The concept of targeting cancer cells with toxins attached to antibodies is more than two decades old. Several clinical trials have clearly documented antitumor activity in humans. The most promising and exciting results have been with hematopoietic tumors and in brain tumors using direct intratumoral infusion. Progress in the treatment of epithelial tumors has been slower because tumor-specific antibodies have been more difficult to identify, and first-generation immunotoxins have had difficulty penetrating into solid tumor masses because of their large size. Ongoing clinical trials using recombinant immunotoxins that are smaller, more active, and more stable in human circulation (e.g., LMB-9) may prove to be superior to the first-generation immunotoxins. Future clinical trials should select patients with minimal residual disease in whom target therapy with immunotoxin should be most effective. Strategies to reduce the immunogenicity and nonspecific toxicity are presently explored. These obstacles need to be overcome before immunotoxins can become an effective treatment modality for cancer.

Introduction

Part of "14.3 - Radioisotope Conjugates "

In this review, we focus primarily on the emerging promise of radiolabeled antibodies as therapeutic agents. Long-lasting major responses have been observed using radiolabeled antibody as the sole treatment in hematopoietic tumors refractory to chemotherapy. Responses to solid tumors have been fewer. Progress in this area depends on the success of new approaches under investigation, such as the use of alpha emitters for intracavitary therapy and micrometastases. Advances in the radiochemistry of antibody labeling, genetic engineering-based production methods, and better understanding of tumor and normal tissue dosimetry provide a strong, fundamental, scientific basis for the development of new reagents and approaches to improve treatment applications in human tumors.

Historical Perspective

Part of "14.3 - Radioisotope Conjugates "

Radioisotopes can be conjugated to antibodies to tumor-specific antigens, and when administered parenterally, the radoimmunoconjugates serve as a carrier for radioactivity, targeting tumor sites deep within the human body. The specific antibody binds to its antigen at the tumor site, much like a key fits into a lock and, over time, there is progressive concentration at the antigen-binding site with catabolism and clearance of conjugate through non-antigen-bearing tissues. In this way, a radioactivity concentration gradient can be developed between tumor and surrounding tissue, serving as a basis for focused radiation therapy to the tumor site.

An attractive feature of radioimmunotherapy is that most normal tissues are spared intensive radiation. In addition, the same radiolabeled antibody may be initially used to determine appropriate dosimetry and subsequently used for radioimmunotherapy labeled with larger quantities of radioisotope. Furthermore, because most tumor types have been shown to have characteristic tumor-associated antigens, such targeted radiotherapy can, in principle, be applied broadly to human cancers.

Pressman and collaborators discovered the elegant principle of immune-specific targeting of tumors in the late 1940s and 1950s (1 ,2 and 3). Over the next 50 years, many challenges were overcome to permit clinical applications. Throughout the 1960s and 1970s, incremental advances in immunologic methods gradually led to more reproducible methods of preparation of radiolabeled (polyclonal) antitumor antibodies, and targeting of human tumors significantly improved (4 ,5).

Interest in this field is largely due to the development of the hybridoma technology of Kohler and Milstein (6), whereby monospecific antibodies (monoclonal) can be produced. The hybridoma method of producing antibody lends itself readily to the manufacture of pharmaceutical grade reagents. Also based on these methods, it is likely that, in the future, still greater improvements in tumor targeting will be achieved through the use of specially tailored hybrid antibodies that have been created through genetic engineering. Examples of such molecules include humanized antibodies, genetically engineered sFv fragments, Fab", $F(ab)"_2$, diabodies, and minibodies (7).

Radioisotope conjugates of antitumor antibodies are being slowly introduced for diagnosis and therapy of human neoplasms. In regard to diagnostic use, four new drug applications have been issued by the U.S. Food and Drug Administration in the last 5 years for radiolabeled antibodies: an indium-111- (^{111}In) labeled form of B72.3 for colorectal and ovarian cancer imaging (satumomab pendetide, Cytogen Corp.); an ^{111}In-labeled antibody against the prostate-specific membrane antigen for imaging of prostate cancer (capromab pendetide, Cytogen Corp.), a technetium-99m (^{99m}Tc)-labeled anti-CEA Fab" fragment (arcitumomab, Immunomedics Inc.), and Tc-99m–labeled

NR-LU-10 ("Verluma," an anti-small-cell lung cancer Fab" antibody, NeoRx Corp.).

The toxicity associated with radioimmunotherapy has been predominantly hematopoietic and relatively mild under the conditions of use. As doses are increased in clinical trials, however, "second organ" toxicities are likely to emerge in radiosensitive organs, such as the lungs, or along the route of excretion of the radionuclide, in the gut and kidney. Principal problems encountered have been the rapid development of immunity against the murine antibodies used and the fact that only a relatively small fraction of the total radioactivity injected is actually concentrated in tumor. Technical problems associated with radioimmunotherapy include inaccurate dosimetry for estimating radiation-absorbed dose to tumor and radiation-sensitive tissues, such as red marrow. Symposia address dosimetry (8) and other technical issues (9 ,10). Dosimetric considerations are presented in detail in the section Modeling and Dosimetry for Radioimmunotherapy . Reviews have appeared (11 ,12 ,13 and 14).

No radiolabeled antibodies have yet been approved by the Food and Drug Administration for therapeutic use. Pivotal clinical trials leading to Food and Drug Administration approval have nearly been completed for therapy of non-Hodgkin's lymphoma using radiolabeled anti-CD20 antibodies [iodine-131 (^{131}I)-labeled anti-B1, Bexxar, Coulter Pharmaceuticals, and Y-90 IDEC-Y2B8, IDEC Laboratories]. Although both of these antibodies are of murine origin, they do not evoke an antimurine antibody response in most patients with established disease, presumably because the B lymphocyte is the principal modulator of the immune response.

Radioisotope-Antibody Conjugates

Part of "14.3 - Radioisotope Conjugates "

Future prospects for improving radioimmunotherapy are based on firmly conjugating relatively nonimmunogenic antibodies with nuclides with especially favorable radioactive decay properties. Radionuclides that offer specific advantages due to their nuclear decay properties, including auger emitters, negatron (beta) emitters, and alpha emitters, are being explored.

The special chemistry for preparation of radioisotope-antibody conjugates is a branch of applied chemistry (15). Some radioisotopes, such as iodine and other halogens, can be directly attached to the antibodies; the most commonly used for this purpose are the radioiodine isotopes, particularly ^{131}I and ^{125}I. Other radioisotope-antibody conjugates are formed by indirect labeling, in which a linker is first attached to the antibody and the radioisotope is conjugated to the antibody by binding via the linker. This approach is widely used for radiometals [e.g., ^{111}In and yttrium-90 (^{90}Y)] (15 ,16). Alpha-emitting radionuclides have been linked to monoclonal antibodies and should be excellent for some applications (17 ,18 and 19). The recent implementation of the alpha-emitting radionuclides, bismuth-213 (^{213}Bi) and astatine-211 (^{211}At) (a halogen), into clinical trials is important because of the enormous potency of radiation delivery by alpha emission over the range of a few cell diameters. This offers the prospect of killing single tumor cells and greatly increases the chances that radioimmunotherapy will be useful in treating leukemia and solid tumor micrometastases. These agents are discussed more completely in the section Alpha Particle Emitters .

Radiolabeling by whatever method should be optimized so the immunobiologic properties of the antibody are retained because the ability of the radioisotope conjugate to bind to antigen (radioimmunoreactivity) is of major importance to optimal *in vivo* tumor uptake (20).

Radionuclides for Radioimmunotherapy

Part of "14.3 - Radioisotope Conjugates "

Table 14.3-1 lists some of the radioisotopes that are being used for radioimmunotherapy. Therapeutic nuclides may be broadly divided into beta-minus emitters, which deposit low-level radiation over relatively long (millimeter) distances, and alpha emitters, which deposit high-level radiation over short (micron) distances. Auger emitters, such as ^{125}I, fall into the latter category; these have been rarely explored, presumably because they are cytocidal only when they decay in the nucleus. Beta-plus or positron emitters are useful for quantitative imaging of targeted therapy, particularly when the radionuclide is an isotope of a therapeutic radionuclide, such as ^{124}I, copper-64 (^{64}Cu), or ^{86}Y.

Table 14.3-1 Selected Radioisotopes for Radioimmunotherapy

Radionuclide	Decay Mode (Energy, MeV)	Half-Life
Iodine-131 (^{131}I)	Beta minus (0.182)	8.0 d
Yttrium-90 (^{90}Y)	Beta minus (0.934)	64.0 hr
Iodine-124 (^{124}I)	E.C., beta plus (0.188)	4.2 d
Copper-64 (^{64}Cu)	E.C., beta plus (0.656)	12.8 hr
Copper -67 (^{67}Cu)	Beta minus (0.142)	62.0 hr
Gallium-67 (^{67}Ga)	E.C.	3.3 d
Iodine-125 (^{125}I)	E.C.	60.2 d
Rhenium-188 (^{188}Re)	Beta minus	17.0 hr
Rhenium-186 (^{186}Re)	E.C., beta minus (0.323)	3.8 d
Bismuth-212 (^{212}Bi)	Alpha (2.17), beta minus (0.492)	1.0 hr
Bismuth-213 (^{213}Bi)	Alpha and beta (multiple)	45.0 mo
Actinium-225 (^{225}Ac)	Alpha (multiple)	10.0 d
Astatine-211 (^{211}At)	Alpha decay (2.447)	7.2 hr

E.C., electron capture.

Note: For beta decay, average energy is given.

A limited number of beta particle emitters are suitable for the successful application of radioimmunotherapy. Beta particle emitters [e.g.,^{131}I, ^{90}Y, rhenium-188 (^{188}Re)] with long-range (1-10 mm) emissions are generally restricted to settings of large tumor burden or when bone marrow transplant is possible because of their considerable bystander cell killing. In contrast, the physical characteristics of alpha particle-emitting radionuclides make them attractive for radioimmunotherapy:

1. High linear energy transfer make alpha particles up to 100 times as potent as beta particles.
2. The nonspecific irradiation of normal tissue around the target cell is greatly reduced. The path lengths of typical alpha particles are on the order of 60 μm.
3. The damage to DNA and induction of apoptosis from alpha particle irradiation is difficult to repair, which makes alpha particles extremely cytotoxic.

The uses of alpha-emitting radionuclides for the treatment of disease have appeared in several reviews (21 ,22 and 23).

Alpha Emitters

Part of "14.3 - Radioisotope Conjugates "

Alpha particles are high-energy helium nuclei (He-4) with high linear energy transfer in the range of 100 keV per μm. The mean linear energy transfer value for the beta particle-emitting ^{90}Y is 0.2 keV per μm, whereas that of ^{211}At (an alpha emitter) is 97 keV per μm. Tissue penetration ranges differ greatly, from 70 μm for the ^{211}At alpha particle to 3,960 μm for the ^{90}Y beta particle. Therefore, the cytotoxicity induced by alpha particles is far more selective. Daughter nuclides that may be metabolized differently from the parent isotope must also be taken into account, especially if the daughter is long lived.

Using a two-step labeling method, Zalutsky et al. (24) have successfully attached [211]At to monoclonal antibodies and fragments. Only a few research centers have the capability for production of [211]At. This remains a potential drawback to the widespread use of this radionuclide. The 7.2-hour half-life, however, makes [211]At attractive for radioimmunotherapy. This half-life is appropriate for moderate diffusion of the targeting molecule to gain access to the tumor cells. The thorium-228 decay chain yields [212]Bi, an alpha particle-emitting radiometal with a short half-life (60 minutes). Bifunctional metal chelating moieties have been extensively investigated (25) that can be readily attached covalently to protein molecules, such as immunoglobulin G (IgG). These stably bind bismuth radionuclides.

This decay scheme also yields lead-212 ([212]Pb) (10.6-hour half-life). Both [212]Bi and [212]Pb nuclides can be produced using a radium-224 ([224]Ra) generator system. When administered clinically, a monoclonal antibody labeled with [212]Pb would serve as an *in situ* [212]Bi generator (25). One difficulty in chelating [212]Pb results from the electron capture branch in the decay scheme, which through the concomitant charge build-up after Auger electron emission would destroy the chelating moiety.

The natural decay of uranium-233 or the neutron irradiation of [226]Ra by successive n,ß capture decay reactions will yield actinium-225 ([225]Ac) (26). Six daughters of [225]Ac are produced in its cascade, and five alpha and three beta disintegrations are produced before stable [209]Bi is reached. The high-energy alpha particle emission, the favorable rapid decay chain to stable [209]Bi, and the 10-day half-life make [225]Ac an excellent candidate for use in cancer therapy. No suitable chelating agent exists, however, that is able to withstand the immense alpha particle recoil energies for the actinium ion. Thus, the major application of [225]Ac is a source for the generation of [213]Bi.

[213]Bi (45.6-minute half-life) is a decay product of [225]Ac. A clinically proven [213]Bi generator has been developed that provides up to 925 MBq (25 mCi) of pure chemically reactive [213]Bi (27). [213]Bi is bound to antibody with the C-functionalized *trans*-cyclohexyldiethylenetriamine pentaacetic acid moiety, CHX-A-DTPA (28). Clinical trials using a [213]Bi-labeled anti-CD33 construct are in progress. The [213]Bi 440-keV photon emission allows *in vivo* patient imaging, and detailed pharmacokinetic and dosimetry information in patients with leukemia have been obtained (29).

Modeling and Dosimetry for Radioimmunotherapy

Part of "14.3 - Radioisotope Conjugates "

Radiation damage is the result of ionization along the emitted particle track, which disrupts critical biomolecules. Tumor cell kill is most closely associated with damage to the nuclear material of the cell, so it is the nucleus and, more precisely, the DNA within the nucleus, which is the target for tumor killing. A single "hit" from an alpha particle emitter is usually sufficient to kill a cell (30). A variety of methods have been developed to estimate the amount of energy deposited in tissues; this is usually expressed in terms of rad or gray. Internally administered radioisotopes and the radiation-absorbed dose from their use is computed by the medical internal radiation dose (MIRD) schema, a method for obtaining whole body and organ radiation doses (31). This method is suitable for estimating doses when the distributions of radioisotopes are relatively homogeneous throughout volumes in the order of a few grams or greater.

A single alpha particle track, originating from the cell's surface and traversing the nucleus, is capable of resulting in cell death (32). Thus, the conventional methodologies for estimating mean absorbed dose may not always yield physically or biologically meaningful information when estimating alpha doses. Instead, stochastic or microdosimetric methodologies may be required. Pharmacokinetics of alpha particle emitters may not be extrapolated from experience obtained using ^{131}I or other longer-lived beta emitters. With longer-lived radionuclides, the pharmacokinetics are dominated by biologic clearance of the antibody. This is in contrast to [213]Bi (half-life = 45.6 minutes) (e.g., in which 94% of the total alpha particle emissions occur within the first 3 hours after injection).

Systemically administered radiolabeled antibodies against tumor cell-specific or tumor cell-associated antigen must equilibrate within a distribution volume that contains the tumor, bind to tumor cell antigen, and remain attached to tumor while excess unbound antibody clears from the body. If the antibody remains attached to the antigen for a sufficiently long period of time, a radionuclide with an appropriate half-life delivers most of the radiation dose to antigen-positive cells without delivering a toxic dose to normal organs. Selective irradiation of target cells is contingent on using a radiolabel with appropriately ranged emissions, so that the majority of the energy per radionuclide decay is delivered to antigen-positive cells rather than to adjacent normal tissue. If the absorbed dose delivered to all sites of a tumor meets the radiobiologic requirements for tumor kill without inducing intolerable normal tissue damage, then the radiolabeled antibody selectively targets and eradicates the tumor.

Three-Dimensional Dosimetry

To evaluate the effectiveness and potential hazard of a particular radionuclide-antibody combination, the absorbed dose to target and normal organs must be calculated. This requires estimation of the total energy emitted per decay of the radionuclide and the fraction of the emitted energy that is absorbed in a source or in another (target) tissue. Using an idealized representation of human anatomy to mathematically define the coordinates, volumes, and compositions of organs, the MIRD Committee has performed such calculations for a large number of radionuclide and source-target organ combinations (31). The results are compiled in a series of "S-factor" tables. Given the time course of radioactivity in a particular organ, the S-factor tables may be used to determine the absorbed dose to other organs from radioactivity in the source organ.

The S-factor formalism was developed in the early to mid-1970s. This approach has proved adequate because most internally administered radiolabeled agents have been used for imaging and diagnosis; the absorbed dose to critical organs has usually been far below the level associated with tissue damage. Those cases in which radionuclides are used for nonantibody therapy (e.g., radioiodine therapy of thyroid disease), exhibit a high target-to-normal tissue activity concentration ratio. In radioimmunotherapy, however, the high levels of administered activity and the biodistribution of labeled antibody may lead to normal tissue morbidity. In such cases, the average absorbed dose over the volume of an idealized organ are misleading because information regarding the maximum dose to the organ is not provided. The spatial distribution of absorbed dose for each patient's actual organ geometry is necessary to assess the potential for normal tissue morbidity.

To overcome these limitations, techniques that combine computed tomography and magnetic resonance images with single-photon emission computed tomography or positron emission tomography have been developed to account for each patient's anatomy and radioactivity distribution (32). The anatomic modalities, computed tomography, and magnetic resonance imaging are used to define tumor and normal organ geometry; single-photon emission computed tomography and positron emission tomography provide the spatial distribution of radioactivity. A series of images may be obtained by three-dimensional registration of these two image sets, such that the radioactivity distribution is superimposed on, and may be directly related to, patient anatomy (33). By way of illustration (Fig. 14.3-1), this approach has been combined into a dosimetry software package, called *3D-ID*, and is implemented for radiolabeled-antibody trials at Memorial Sloan-Kettering Cancer Center (34).
FIGURE 14.3-1. Dose contours. Patient with metastatic colon cancer received 90 mCi/m^2 iodine-131-CC49 intravenously. Coregistered computed tomography (left) and single-photon emission computed tomography (right) slices through the liver are shown; the box on the right demonstrates the dose received by tumor; most of the tumor received a relatively low dose.

Red Marrow Dose

The red marrow is the dose-limiting organ in most implementations of radioimmunotherapy. Marrow vasculature is fenestrated and does not present a significant barrier to antibody penetration. The red marrow is composed of cells that are continuously undergoing cell division, and are therefore

more radiosensitive. Early accessibility and enhanced radiosensitivity are two factors that account for the marrow toxicity that is observed in almost all radiolabeled antibody dose-escalation studies.

Red marrow dosimetry introduces a number of difficulties that are not shared by other organs. Because of the distributed nature of this organ, it is difficult to obtain a time-activity curve from external imaging that is representative of all sites of active marrow.

Marrow dosimetry falls into two situations depending on the targeting properties and expected distribution of the antibody and the nature of the disease. If the antibody is not bound to antigen in the marrow, the radioactivity is distributed passively to the marrow based in the blood (passive distribution). If the antibody actively binds to antigen, a buildup of a higher concentration occurs on cellular components in the marrow (active distribution). Both situations fall within the MIRD S-factor formalism (31); their difference lies in the approach used to determine the cumulated activity in marrow.

Passive Distribution

The time-activity curve for intravenously administered antibody that does not target cellular components of the marrow, blood, or bone is obtained by assuming that the red marrow radioactivity concentration is equal to the radioactivity concentration in blood multiplied by a correction factor. After a review of the literature, the American Association of Physicists in Medicine Task Group on the Dosimetry of Radiolabeled Antibodies has recommended that a factor between 0.2 and 0.4 be used, and these general values have been rationalized by Sgouros (35).

These correction factors apply to blood activity concentration, and cumulated activity estimate for blood must be converted to cumulated activity concentration before the correction factor may be applied. The result must then be multiplied by the red marrow volume to give red marrow cumulated activity.

Active Distribution

In targeting hematologic disease or when the radiolabeled antibody cross-reacts with antigen that is associated with a cellular component of blood, marrow, or bone, antibody kinetics in marrow may not be approximated by blood kinetics. In this case, the time-activity curve of bone marrow concentration must be measured directly. The most widely adopted approach for obtaining the time-activity curve in marrow combines planar imaging with a single bone marrow biopsy. By drawing a region of interest around a marrow-rich, low-background area (e.g., ball of the femur or humerus), imaging may be used to determine the kinetics. The absolute radioactivity concentration in a bone marrow biopsy may then be used to "fix" the time-activity curve obtained from imaging to an absolute scale.

An increasing number of radioimmunotherapy protocols include a bone marrow transplant component. In such protocols, the red marrow is no longer the dose-limiting organ, and preliminary results suggest that lung or liver morbidity may limit the total dose that can be administered.

Adjuvant Radioimmunotherapy

Part of "14.3 - Radioisotope Conjugates "

Although regional spread of cancer is associated with lymphatic invasion, distant metastases are generally thought to occur via hematologic spread. Such hematologic spread may arise from direct invasion of tumor vasculature or via the lymphatics to the thoracic duct and then into the circulation. That hematologic spread of micrometastatic cells is potentially important in the long-term course of the disease is suggested by studies that show a correlation between the number of tumor cells in marrow of breast cancer patients and their likelihood of developing distant metastases. The detection of hematologic micrometastases early in the course of disease has also been observed in prostate cancer. Although these studies have not demonstrated a cause-and-effect relationship, the possibility that radiolabeled antibody targeting of such cells may reduce distant metastases is enticing. The size distribution, number, and anatomic location of such micrometastases are critical in assessing the potential efficacy of radioimmunotherapy as an adjuvant treatment modality.

Using Monte Carlo-derived data regarding the size distribution and number of micrometastases that are present in a given prostate cancer patient population at the time of diagnosis and a mathematical model of antibody distribution and tumor cell cluster penetration, the potential efficacy of adjuvant radioimmunotherapy has been examined (27). The analysis suggests that a single administration of radiolabeled antibody could yield a potentially lethal dose ($\geq$20-38 Gy for ^{131}I) to 23% of micrometastases present at the time of initial diagnosis without inducing prohibitive red marrow morbidity (absorbed dose $\leq$2.5 Gy). Multiple courses of radioimmunotherapy designed to target micrometastases that are initially too small but that eventually reach a targetable size (i.e., 20 μm $\leq$$\mu$m radius $\leq$200 μm) yields a potentially lethal dose to 87% of micrometastases. These results indicate that approximately 25% of "high-risk" prostate cancer patients (i.e., patients with occult metastases at the time of diagnosis) making up the population used for the Monte Carlo simulation would benefit from a single course of radioimmunotherapy; multiple courses could benefit 75% of these patients.

Alpha Particle Emitters

Although the extensive experience and easy availability of ^{131}I have made it the most commonly used radionuclide for antibody therapy, it is not ideal for targeting disseminated disease. Given the number of antigen sites per cell for most antibodies, the achievable specific activity, and the limitations on the amount of ^{131}I that may be administered because of red marrow toxicity, ^{131}I-labeled antibodies are not capable of single-cell kill (27).

Alpha particles are effective cytotoxic agents, capable of single-cell kill without limiting morbidity (28). The effectiveness of alpha particles arises because the amount of energy deposited per unit distance traveled (linear energy transfer) is approximately 400 times greater than that of beta particles (80 keV per μm vs. 0.2 keV per μm). Each traversal of an alpha particle through the nucleus results in a highly ionizing track. Cell survival studies have shown that alpha particle-induced killing is independent of oxygenation state or cell cycle during irradiation and that a single

track across the nucleus may result in cell death (36 ,37 and 38). Most studies with alpha particle-emitting radionuclides for therapy have examined either ^{212}Bi or ^{211}At. Both radionuclides are short lived with 61-minute and 7.2-hour half-life, respectively. Both emit alpha particles whose range is 40-80 mm. In rapidly accessible, disseminated disease, these radionuclides have demonstrated a significant curative potential with minimal toxicity. In an ascites tumor mouse model, Macklis et al. (36) demonstrated specific targeting and 80% cure after injection of 5.6 to 8.5 MBq ^{212}Bi-labeled antibody. These results were observed after intraperitoneal administration.

The first human trial of an alpha particle emitter used systemically has been conducted with ^{213}Bi. ^{213}Bi is available in a generator system and has a half-life of 45.6 minutes. The highly stable CHXA-DTPA chelate has been used for labeling the antileukemia antibody, HuM195, with ^{213}Bi (19 ,21). Seventeen patients have participated in a phase 1 study of this agent without evidence of extra medullary toxicity. Dosimetry and pharmacokinetics associated with this trial have been described (27).

Dosimetry-Based Design of Radioimmunotherapy Trials

Part of "14.3 - Radioisotope Conjugates "

Seminal studies carried out in human melanoma demonstrated the concept of using an initial tracer dose of radioactivity to predict organ-specific dose-limiting toxicity for subsequent calculation of maximum tolerated doses that could be safely administered. These studies also showed that there was an optimal mass amount of antibody for achieving the highest tumor radiation dose relative to the critical organ, which in most instances is the bone marrow (39). Using this same concept, Press et al. (40) and Kaminski et al. (41) showed that calculation of radiation-absorbed dose to the whole body (as a surrogate for red marrow) or to the next critical normal organ (42) permitted delivery of patient-specific amounts of radioactivity conjugated to antibody. All of these studies were possible in large part due to the relatively low immunogenicity of Fab murine fragments in the melanoma patients or to whole antibodies in patients with B-cell lymphoma using ^{131}I-labeled antibodies that permitted external measurement of whole-body radioactivity. In solid tumors, dosimetry-based measurements of optimum, patient-specific, therapeutic amounts of radioactivity were not possible because of the invariable development of an antimurine antibody response when whole antibody was used. Phase 1 solid tumor radioimmunotherapy trials with murine antibodies have used a radioactivity dose-escalation design based on weight or body surface area. Most ^{131}I-labeled antibody studies showed a maximum tolerated dose of 75 mCi per m^2, and comparable agreement was found in trials with other radionuclides, suggesting that estimation of radioactivity based on weight or body surface area was an adequate measure of maximum tolerated dose. Evaluation of these data, however, have conclusively shown that the amount of radioactivity administered is indeed a poor predictor of toxicity. Toxicity has been shown to be dependent, not surprisingly, on radiation-absorbed dose to the whole body and, correspondingly, to the red marrow (43). Adequate prediction of toxicity, therefore, demands the estimation of clearance of radioactivity from each patient so that radiation-absorbed dose to critical normal organ(s) may be determined.

The development of relatively nonimmunogenic forms of antibody have allowed the possibility of treatment based on radiation-absorbed dose to critical normal organs. Clinical trials are increasingly based on estimation of whole body, red marrow, and other normal critical organ radiation-absorbed dose estimates to determine appropriate patient-specific amount of radioactive antibody that would deliver predictable toxicity to a known normal organ. These treatment schema are similar to those used to determine the maximum safe dose of ^{131}I for thyroid carcinoma (44), and to those used for ^{131}I-labeled antibody therapy for lymphoma (41). An initial dose of radiolabeled antibody is used to determine the biodistribution and pharmacokinetics of the radiolabeled antibody in the particular patient. These data are then used to determine the radiation-absorbed dose to normal organ(s) and a patient-specific radioactivity amount calculated. Initial prospective studies at the Memorial Sloan-Kettering Cancer Center have already demonstrated the wide range of radioactivity that would deliver comparable whole-body radiation-absorbed doses.

For such a schema to be feasible, however, the radionuclide needs to be measurable *in vivo* using external measuring devices; this is feasible for most nuclides with therapeutic potential, including ^{131}I, ^{186}Re, ^{188}Re, and lutetium-177 (^{177}Lu). For nuclides like ^{90}Y and ^{67}Cu, which cannot be measured in this manner, suitable surrogates need to be identified. Developments in radiochemistry have permitted the use of ^{111}In as a surrogate in most cases. Moreover, developments in cyclotron chemistry have allowed the use of the positron emitters ^{124}I, ^{86}Y, and ^{64}Cu as "true" surrogates; positron emission tomography of positron-labeled antibodies permits *in vivo* quantitation (45). It seems likely, therefore, that future radioimmunotherapy trials will increasingly use radiation-absorbed dose estimates for determination of toxicity, allowing optimal therapeutic delivery with minimal and predictable toxicity.

Single Large-Dose and Fractionated Radioimmunotherapy

The conventional wisdom that low-dose rate radiation, such as that delivered by radioimmunotherapy, is best administered as a single large dose may have important caveats. The twin limitations of antigen density and specific activity, for example, necessitate multiple treatments in radioimmunotherapy with ^{213}Bi-huM195 therapy. Studies by DeNardo et al. (46) have suggested that specific activity with ^{90}Y-labeled antibodies is also an important factor in therapy delivery that may necessitate fractionation.

Xenograft studies carried out, notably by Schlom et al. (47), Buchsbaum et al. (48), and Buchegger et al. (49), have suggested that fractionated radioimmunotherapy may have greater efficacy than single-dose therapy. This may be due to variability in tumor interstitial pressure and vascular flow, among other poorly understood factors. As in external beam

radiotherapy, fractionated radioimmunotherapy may also permit recovery of radiation-injured normal cells. Theoretical models developed by O'Donoghue at the Memorial Sloan-Kettering Cancer Center (50) have suggested that although the tumor cell survival fraction is less after single large-dose radioimmunotherapy, repopulation of cells occurs at a slower rate after fractionated radioimmunotherapy. To test this hypothesis clinically, our group, in conjunction with colleagues at the Ludwig Institute for Cancer Research, are undertaking simultaneous radioimmunotherapy trials using the single large-dose and the fractionated models based on whole-body (or red marrow) radiation-absorbed dose. These studies should provide important information regarding the relative merits of each schedule of radioimmunotherapy. Needless to say, both methods have been made possible by the development of relatively nonimmunogenic antibody constructs, especially in nonlymphoid malignancies, as both require multiple administration of antibody.

Clinical Trials

Part of "14.3 - Radioisotope Conjugates "

To a certain extent, the development of radioimmunotherapy depends on the stepwise application of newly established biologic principles in the fields of radiation biology, immunology, and hematopoiesis to ongoing clinical protocols. The basic principles have been developed for *in vitro* systems and animal models in the laboratory and have progressed to clinical trials. The reader is referred to prior editions of this book for historical aspects. Review of progress since the last edition of this textbook is emphasized in this section, followed by examples from the experience of our group at the Memorial Sloan-Kettering Cancer Center. In particular, applications of ^{131}I-, ^{90}Y-, and ^{213}Bi-labeled huM195 (against CD33) in leukemia; ^{131}I-3F8 (against GD$_2$) in neuroblastoma; ^{131}I CC49 (against TAG-72) in prostate cancer; and ^{131}I-chimeric G250 in renal cancer illustrate the problems and promise of radioimmunotherapy.

Lymphomas/Leukemia

Reviews of the treatment of lymphomas/leukemia have appeared, which summarize the early history of treatment of lymphomas and leukemias (51 ,52). From the earliest studies, there were major responses in a variety of lymphoma types and clinical situations. Studies have been performed with ^{131}I, ^{90}Y, and ^{67}Cu (53). Antibodies have been used which target the differentiation antigens for white cells, CD5 (54), CD19, CD20, CD21, CD22 (55), CD33, and CD45 (56), as well as the HLA-DR (53) antigens. Each of these cellular targets provides tissue specificity to various subpopulations of myeloid and T-cell lineage and, as such, each cluster differentiation antigen has its proponents and detractors for the purpose of immune-specific targeting. In this review, we focus on radioimmunotherapy using anti-CD20 and anti-CD33 antibodies, which have been studied more extensively with less emphasis on CD37- and HLA-DR–targeting antibodies (57).

Treatment of Non-Hodgkin's Lymphoma: Myeloablative Dose Regimens and Autologous Bone Marrow Rescue

CD20 and CD37 Targeting

CD20 is a pan B-cell antigen that is broadly expressed on most B cells, whereas CD37 is an antigen found in late pre–B-cell precursors. Initial studies (40) used high doses of ^{131}I-labeled B1 and 1F5 anti-CD20 antibodies, as well as a few patients with anti-CD37 MB1 antibody. The study plan involved:

1. An antibody mass dose escalation in individual patients to determine "favorable dosimetry," defined as *tumor radiation-absorbed dose*, greater than the highest normal tissue (usually the lung)
2. Single massive doses of ^{131}I requiring hospitalization
3. Autologous bone marrow rescue

A tracer dose of ^{131}I B1 or MB1 was administered in patients with relapsed non-Hodgkin's lymphoma and radiation-absorbed dose to liver, lung, and kidney estimated by MIRD techniques (29). Favorable distribution was interpreted as preferential radiation dose to tumor compared with normal organs. Twenty-four (56%) patients showed preferential targeting of radioantibody to tumor ("favorable dosimetry"). Major responses were seen in 86% of patients, including 79% complete responses (CRs). Nonhematopoietic dose-limiting toxicity was cardiopulmonary with the estimated maximum tolerated radiation dose being 23.75 Gy (42).

Unmaintained CR has been seen in almost one-half of the patients for more than 7 years after therapy. The most common late toxicity was biochemical thyroid insufficiency in 60% of patients.

Nonmyeloablative Dose Regimens

Using smaller but multiple doses of ^{131}I B1 antibody in non-Hodgkin's lymphoma, ten patients (five low-grade lymphoma, five intermediate-grade lymphoma) were treated with a tracer dose to determine the optimal milligram amount of coadministered cold B1 to result in a whole-body dose of 25-45 cGy per injection. Thereafter, nine patients received 1–2 doses of 24-66 mCi ^{131}I B1, administered at 6- to 8-week intervals. Six of nine patients responded to the treatment; there were four CRs of 8, 11+, 9+, and 8+ months' duration. In this study, all known tumor greater than 2 cm was scan positive, and there was mild or no myelosuppression (41).

A summary of the experience with this nonmyeloablative regimen has been published using ^{131}I B1 antibody in doses that give whole-body radiation doses of 45-75 cGy. Fifty percent of the patients in the phase 1 trial of patients refractory to chemotherapy achieved a CR, and thrombocytopenia was dose limiting. The whole-body dose of 75 cGy is the maximum tolerated dose in patients who have not had a bone marrow transplant, and durable CRs were more likely to be seen in patients treated with the higher dose of radiation (65-75 cGy to whole body). Patients with low-grade and transformed

low-grade non-Hodgkin's lymphoma appear most likely to respond (58).

This approach has developed into a phase 2/3 clinical trial, and initial results appear favorable. Of special interest was the fact that the ^{131}I-labeled B1 could be prepared centrally with the immunoreactivity maintained and shipped to clinical investigators around the country. Figure 14.3-2A demonstrates targeting of ^{131}I B1 to known nodal disease.
FIGURE 14.3-2. A: Therapy with iodine-131 (^{131}I)-anti-B-1. Anterior spot view of the pelvis (inset) and coronal single-photon emission computed tomography slices of the pelvis a week after therapy calculated to deliver no more than 0.75 Gy to whole body. There is excellent targeting to the right femoral lesion, as well as to the right inguinal adenopathy. **B:** Anterior and posterior whole body images 2 hours after ^{131}I-huM195 in a patient with acute promyelocytic leukemia. Targeting to marrow is clearly demonstrated.

Yttrium-90 Anti-CD20 Antibodies in Lymphoma

^{90}Y is a high-energy beta emitter that may be more effective than ^{131}I for irradiating large tumor masses because of a longer mean range of beta particle penetration into tumor tissue *in vivo*. On a per-millicurie basis, ^{90}Y delivers 2.3 times as much radiation to tissue as ^{131}I. A phase 1/2 trial has been performed with an ^{90}Y-labeled anti-CD20 antibody in recurrent B-cell

lymphoma. Again, myelosuppression was dose limiting, and the maximum tolerated dose was 50 mCi in this group of patients. Eighteen patients were studied with a major response rate of 72%, approximately one-half being CRs (59). In a phase 2 study using ^{111}In as a surrogate for ^{90}Y, the median bone marrow dose at the maximum tolerated dose of ^{90}Y was estimated to be 0.53 Gy. An overall response rate of 82% in low-grade non-Hodgkin's lymphoma was reported with 27% CRs (60). A phase 3 study is ongoing.

Monoclonal Antibody M195 (Anti-CD33)

Monoclonal antibody M195 (anti-CD33) is a murine IgG$_{2a}$ monoclonal antibody that reacts with most myeloid leukemic cells, monocytes, and hematopoietic progenitors. This antibody does not react with the pluripotent stem cell. ^{131}I M195 was studied as a therapeutic agent in acute and chronic leukemia. The chapter in the prior edition details phase 1 studies, which showed prompt targeting to tumor elements in the bone marrow; relatively low doses of antibody (4-6 mg) appeared to be optimal for targeting, presumably because of the low number of CD33 receptors per cell (61). ^{131}I M195 showed antileukemic activity in a subsequent phase 1/2 study; the invariable development of human antimouse antibody (HAMA), however, precluded multiple therapies, limiting efficacy (62).

Another group of patients studied were in clinical remission from acute promyelocytic leukemia after treatment with all-*trans*-retinoic acid in whom the status of the marrow was followed with a polymerase chain reaction technique designed to detect the particular gene translocation [t(15;17)] associated with acute promyelocytic leukemia. Disease-free survival appears to be increased by the use of the ^{131}I M195 at nonmyeloablative doses (50 mCi per m^2) to eliminate minimal disease. In relapsed patients with acute myelocytic leukemia for first transplants, patients were prepared for bone marrow transplant with ^{131}I-M195 cytoreduction instead of whole-body radiation therapy. Seven patients studied have achieved CR (initial doses were 120 mCi per m^2). Four patients were alive at 24 months after follow-up, and this approach compared favorably with prior treatment regimens (63). Figure 14.3-2B demonstrates targeting of ^{131}I-M195 to bone marrow in a patient with acute promyelocytic leukemia.

Humanized M195 consists of the murine complementarity-determining regions grafted to a human IgG1 backbone by genetic engineering methodology. Affinity of the humanized variant is approximately one order of magnitude higher than the murine monoclonal M195. In initial studies, biodistribution of the ^{131}I huG$_1$-M195 was similar to ^{131}I murine M195, and an anti-antibody response was absent (64).

Because the CD33 antigen is internalized subsequent to interaction with antibody, a phase 1/2 trial to evaluate the use of ^{90}Y-huM195 is being carried out at the Memorial Sloan-Kettering Cancer Center. The maximum tolerated dose of ^{90}Y-huM195 appears to be 0.25 mCi per kg body weight. Considerable cytoreduction has been seen in the majority of patients with no nonhematopoietic toxicity. Dose modifications are being continued for evaluation of toxicity and efficacy. No antihumanized antibody responses have been seen thus far.

Human trials with the short-lived ^{213}Bi required construction and operation of a ^{225}Ac/^{213}Bi generator capable of producing 25–100 mCi of ^{213}Bi suitable for clinical antibody labeling (65). A generator has been designed to have an effective lifetime of several weeks and produces up to four therapeutic doses of radionuclide per day.

A phase 1 trial to determine the safety, pharmacology, dosimetry, and biologic activity of ^{213}Bi-HuM195 was completed (27). Eighteen patients with relapsed (n = 14) or refractory (n = 3) acute myelogenous leukemia or chronic myelomonocytic leukemia (n = 1) were treated with 0.28, 0.42, 0.56, 0.7, or 1 mCi per kg of ^{213}Bi-HuM195 in 3-6 fractions over 2–4 days. Total ^{213}Bi doses ranged from 17 mCi to 96 mCi; no acute toxicity was seen. Delayed toxicity was limited to myelosuppression, lasting 8 to 34 days. Biodistribution and dosimetry data were obtained by serial gamma camera images and blood samples after injection of ^{213}Bi-HuM195. Uptake of ^{213}Bi in the bone marrow, liver, and spleen occurred within 10 minutes of administration and was maintained throughout the half-life of the isotope. No significant uptake was seen in any other organ. Radiation doses to the bone marrow or spleen were up to 40,000 times higher than the estimated radiation doses to the kidneys or whole body. The absorbed-dose ratios between marrow, liver, and spleen and the whole body for ^{213}Bi-HuM195 were 1,000–10,000 times greater than those seen with beta-emitting nuclides, such as ^{131}I or ^{90}Y. Ten of 12 evaluable patients had reductions in peripheral blood leukemia cells, and 13 of the 18 patients had decreases in the percentage of bone marrow blasts. No CRs have been observed. This was the first study to show that systemic, targeted alpha particle therapy is safe and feasible in humans and has antileukemic activity.

Solid Tumors

One advance in this field has been the development of methods for assessing dosimetry of radioimmunotherapy based on quantitative imaging approaches. At Memorial Sloan-Kettering Cancer Center, for example, we have developed a three-dimensional dosimetry technique, 3D-ID (32). Using this method, we estimated that doses of up to 80 Gy could be delivered to selected tumor deposits using nonmyeloablative doses of ^{131}I-labeled CC49. HAMA occurs in virtually all patients by 3 weeks after a single injection of this murine IgG, however, and repeat injections were ineffective because the radioantibody is neutralized by the HAMA, and clearance into the reticuloendothelial system is accelerated. Moreover, even after a single injection, the uptake seen in the tumor is decidedly heterogeneous with a majority of the tumor volume receiving significantly less than the mean dose (32). Thus, it appears from these data that, to be successful in the treatment of solid tumors, repeated doses in this same range would be required. This depends on the development of less immunogenic reagents, probably humanized antibodies or some form of antibody fragment (66).

CC49 is one of the most widely studied of antibodies, and this antibody targets a mucinlike antigen, TAG-72, which is widely expressed on colon cancer (67) and a variety of other tumor types, including prostate. The chapter in the prior edition of this textbook details the experience with ^{131}I-CC49, an antibody directed against the sialyl-Tn antigen in colon and breast

cancer. The antibody, conjugated with[177]Lu using a stable chelate, was subsequently studied in colon cancers by Carrasquillo et al.; as with the iodinated antibody, myelotoxicity was dose limiting, and responses were few and transient (68). A myeloablative regimen with ^{131}I CC49 was studied by Tempero et al.; they too found that responses were not lasting, and that at high doses of radioantibody, autologous rescue was not successful, precluding the use of this antibody even in a myeloablative setting (69). The development of an antimurine response precluded repeat therapies in these trials (66), although the response could be mitigated with immunosuppressive drugs (70).

Meredith et al. studied ^{177}Lu-CC49 in ovarian cancers (71). Administered via the intraperitoneal route, complete responses were seen in a few patients treated at the maximum tolerated dose. Rosenblum et al. similarly used ^{90}Y-labeled B72.3 (the "first-generation" anti-sialyl Tn antibody) intraperitoneally in patients with ovarian cancer (72). Again, an antimurine antibody response precluded multiple therapies; the study, however, confirmed the advantages of loco-regional delivery of radioimmunotherapy. Humanized CC49 is being developed and is expected to enter clinical trials shortly.

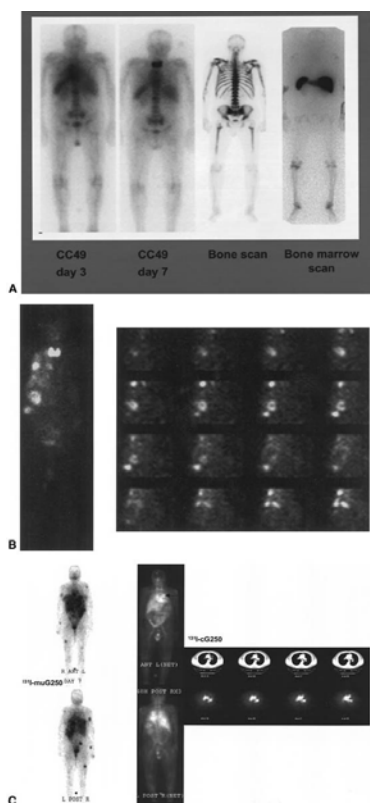
We (73) and others (74) have studied radiolabeled CC49 in prostate cancer (Fig. 14.3-3A). We used interferon to upregulate the antigen and to assess targeting and toxicity in phase 2 trials. Although targeting was good and minor responses, including pain relief, were seen in some patients, the results were not sufficiently promising to serve as a basis for more extensive clinical trials with these agents. A number of biologic insights have been offered from this work, however, including the extensive nature of bone marrow involvement of prostate cancer and the replacement of normal intramedullary marrow by tumor (see Fig. 14.3-2).


FIGURE 14.3-3. **A:** Anterior whole-body (left) and coronal slices through the thorax and liver in a patient with metastatic colon carcinoma treated with 140 mCi iodine-131 (^{131}I)-murine A33. Targeting to liver metastasis and pleural-based lung metastases is excellent; the patient had resolution of several pleural lesions with significant drop in serum carcinoembryonic antigen. Human antimouse antibody precluded further therapy. **B:** Posterior whole-body images in a patient with hormone-refractory prostate cancer treated with 140 mCi ^{131}I-CC49 administered after interferon therapy to upregulate antigen. From left: images 3 and 7 days after treatment with ^{131}I-CC49; bone marrow scan with technetium-99m-sulfur colloid. **C:** Treatment of metastatic renal cell carcinoma with ^{131}I-G250. Left: anterior (top) and posterior (bottom) images a week after 90 mCi ^{131}I-murine G250. Targeting to lesions in liver, lung, lymph nodes, bone, and subcutaneous lesions is excellent. Right: anterior and posterior whole body images and coregistered thoracic computed tomography and single-photon emission computed tomography images in a patient treated with ^{131}I-chimeric G250.

Pastan et al. have completed a phase 1 trial with ^{90}Y-labeled anti-Lewis[y] (Le[y]) antibody B1 (Carrasquillo J, *personal communication*, 1999). As with other radiolabeled antibodies, dose-limiting toxicity has been myelosuppression; as with other murine antibodies, the invariable occurrence of an antimurine antibody response has led to the development of humanized anti-Le[y] antibody, and we and other groups are initiating therapeutic trials with ^{90}Y-labeled humanized anti-Le[y] antibodies. Because the Le[y] complex is internalized, radiometals may be more suitable than radioiodine for therapy (75). Welt et al. developed A33 (Fig. 14.3-3B), an antibody against an antigen found in virtually all colon cancers with normal tissue reactivity limited to normal colon (76). Mixed responses were seen in patients treated with ^{131}I-murine A33, which had a maximum tolerated dose comparable with other iodinated antibodies, with myelosuppression being dose limiting; development of HAMA again precluded multiple therapies (77). Unlike CC49, A33 is internalized subsequent to interaction with antigen. A33 internalization occurs by macropinocytosis (78); this allows the use of radioiodine as a therapeutic conjugate. We also carried out a study using ^{125}I-labeled murine A33; no toxicity was seen at ^{125}I doses of up to 400 mCi per m[2](79). Even at these dose levels, however, the overall response rate was not different from that observed earlier. Serial external imaging was possible because of the large amounts of administered radioactivity; these showed that retention of radiolabeled antibody in tumor was significant for up to 6 weeks with concomitant clearance from normal tissue, particularly large bowel. No bowel toxicity has been seen. The antibody has been humanized, and clinical trials with ^{131}I-A33 are under way.

G[D2] as Tumor Target

Gangliosides are acidic glycosphingolipids found on the outer surface of most cell membranes; they are particularly concentrated in gray matter and synaptic junctions in the nervous system, especially during brain development. During oncogenesis, major changes in the composition and distribution of cell-surface gangliosides can occur in tumors, including those of the central nervous system. G_{D2} and G_{D3} have been found in a wide spectrum of human tumors, including neuroblastoma, small-cell lung cancer, and brain tumors (80 ,81). In contrast, the only normal tissues with high ganglioside expression are restricted to tissues of the central nervous system and some peripheral nerves. A number of anti-G_{D2} antibodies have been produced by hybridoma technique. 3F8 is a murine IgG$_3$ monoclonal antibody (80). In preclinical studies, [131]I-3F8 targeted to human neuroblastoma xenografts with exceptionally high %ID per gm (20%-40%). Intravenous ^{131}I-labeled murine IgG$_3$ 3F8 produced a substantial dose-dependent shrinkage of established neuroblastoma in preclinical studies. Dose calculations suggested that tumors that received more than 42 Gy rads were completely ablated.

Neuroblastoma

The biodistribution of [131]I-3F8 has shown excellent tumor targeting in patients with neuroblastoma (82), detecting more tumor sites than ^{131}I-MIBG (metaiodobenzylguanidine), ^{99m}Tc-MDP (technetium-labeled methylene diphosphonate) bone scan. The uptake that was observed was surgically confirmed to be in active neuroblastoma, and tumor uptake was high: 0.08%-0.1% injected dose per gm (83 ,84). This high tumor uptake was probably the result of the high antigen density (10[7] per cell) (85).

Radioimmunotherapy of Neuroblastoma

Next to lymphoid and brain tumors, neuroblastoma is the most common solid tumor of childhood. Large primaries and widespread metastatic disease at diagnosis, coupled with the early emergence of resistance to chemotherapy, magnified its management difficulties. Because neuroblastoma is a radiosensitive tumor, clinical applications of local radiotherapy and total-body irradiation have been incorporated into most "curative" strategies. Hyperfractionation at 150 cGy b.i.d. (total of 2,100 cGy) appears to be quite effective, especially for local control of microscopic disease. Long-term effects on growth and organ function plus the 1,200-cGy limit on total-body irradiation are two compelling reasons to develop alternative methods to deliver selective radiotherapy, both for bulky and microscopic disease. Neuroblastoma is suitable for testing radioimmunotherapy because:

1. The shed antigen G_{D2} has not interfered with antibody delivery, especially in patients with small tumor load.
2. The tumor cells have a limited ability to repair radiation damage.
3. These tumors are generally vascular and their sites of metastases (liver, bone marrow, lymph nodes) are usually not perfusion limited.
4. Tumoricidal levels of radiation can be delivered by ^{131}I-labeled monoclonal antibody despite dehalogenation *in vivo*. A radiation dose of more than 40 Gy is curative for neuroblastoma xenografts (86).
5. Radiolabeled antibodies with minimal extramedullary toxicities can be given over a short time to exploit the steep dose response of radiosensitive tumors, as long as the marrow can be rescued.

Toxicities

Acute side effects of pain, hypertension, hypotension, urticaria, and fever occur but can be controlled by appropriate premedication.

No lethality has been reported in patients undergoing treatment with nonradioactive antibodies directed at G_{D2}. Severe, though reversible, neuropathy, however, was observed with the anti-G_{D2} antibodies 14.2a and ch14.18, thought to be associated with HAMA (87). This toxicity probably derived from antibody cross-reactivity with myelinated nerve fibers. More than 150 children have been treated with 3F8, and many have been followed for more than 4 years (maximum, 12 years) after treatment. None of the pediatric patients had obvious signs or symptoms of neuropathy, despite the finding of G_{D2} on peripheral nerves and previous reports of cross-reactivity of 3F8 with neurocellular adhesion molecule. This difference in toxicity spectrum may be caused by differences in antibody biodistribution in the child versus the adult. Because anti-G_{D2} antibodies may differ in their spectrum of reactivity with various gangliosides and their O-acetylated derivative, their fine specificities may determine their relative efficacy and toxicity.

The radiation toxicities of ^{131}I-3F8 were defined in a phase 1 dose-escalation study. Twenty-three patients (12 male and 12 female, 0.3 to 24.2 years of age at diagnosis) with refractory neuroblastoma (23, stage IV; 1, stage 3u) were treated with ^{131}I-3F8 at seven dose levels, namely 6, 8, 12, 16, 20, 24, and 28 mCi per kg. Radiation dose to the blood was calculated based on blood clearance, total-body dose based on MIRD, and the tumor/organ dose on regions of interest calculations from serial imaging. Twenty-two of 24 patients were rescued with cryopreserved autologous bone marrow; one patient received granulocyte-macrophage colony-stimulating factor and one patient died of progressive disease before marrow reinfusion. Marrow was infused when blood radioactivity decreased to less than 0.01 μCi per mL in the first 17 and less than 1 μCi per mL in the last five patients. Acute toxicities of ^{131}I-3F8 treatment included pain (20 of 24) during the infusion, fever (20 of 24), and mild diarrhea. All developed grade 4 myelosuppression. Thyroid uptake despite oral saturated solution of potassium iodine (SSKI), levothyroxine sodium (Synthroid), or liothyronine sodium (Cytomel) (or both) led to biochemical hypothyroidism in the majority. Among the six who survived more than 20 months after antibody treatment, no delayed extramedullary toxicities were encountered. Ten patients were evaluable for response to ^{131}I-3F8. There were two partial responses of soft tissue masses and two CRs of bone marrow disease. Average

tumor dose was calculated to be 150 rad per mCi per kg. Thus, when ^{131}I-3F8 was administered intravenously (6–28 mCi per kg), significant toxicities were encountered, including myelosuppression, and their infectious complications—pain, fever, and hypothyroidism. Autologous marrow rescue could reverse marrow aplasia. Although extramedullary toxicities in the acute phase were not severe, the late effects of this treatment modality have not yet been definitively defined (88 ,89).

In a subsequent study, the acute and delayed toxicities of this modality were confirmed in 25 patients with high-risk neuroblastoma treated with the N7 protocol (90). The N7 protocol uses dose-intensive chemotherapy for induction; surgical resection and 2,100 cGy hyperfractionated radiotherapy for local control; and, for consolidation, targeted radioimmunotherapy with ^{131}I-labeled anti-GD2 3F8 and immunotherapy with unlabeled/unmodified 3F8 (400 mg per m^2). Intravenous ^{131}I-3F8 was given at 4 mCi per kg daily for 5 days (maximum, 1,000 mCi). Approximately 18 days after antibody treatment, autologous marrow or peripheral blood stem cells were infused. Among the first 25 consecutive previously untreated patients older than 1 year at diagnosis, 22 were stage 4 and two were unresectable stage 3 with n-myc amplification. Chemotherapy achieved complete or very good partial responses in 22 of 25 patients. All 25 patients engrafted, the major complications being myelosuppression plus infections with no lethal complications. Hypothyroidism was again noted despite aggressive thyroid protection using oral SSKI, liothyronine sodium, and Perchloracap. For dosimetry of both imaging (tracer) and therapeutic doses of ^{131}I-3F8, plasma time-activity curve was integrated over time to yield cumulated activity. Antibody clearance in normal organs generally closely followed that of blood. The plasma cumulative activity concentration was used to calculate activity in the liver, spleen, lungs, and red marrow according to each organ's extracellular fluid volume, which were estimates adjusted for body weight. Conjugate planar images obtained on the day of injection (day 0) and on days 1, 2, and 4 were used to calculate tumor time-activity curves. Total-body cumulated activity obtained from imaging was within 5% of estimates based on external survey meter data. Computed tomography-based volume estimation technique was used to determine tumor volume. Using the DOSCAL program developed at Memorial Sloan-Kettering Cancer Center that implements the S-factor formalism, absorbed dose could be estimated (90). Figure 14.3-4 depicts the chest computed tomography scans of a patient before and after treatment with 24 mCi per kg of ^{131}I-3F8. Based on tracer dosimetry, the absorbed doses to liver, spleen, red marrow, lung, total body, and tumor were 537, 574, 445, 454, 499, and 4,926 cGy, respectively. The average cGy per mCi were 2.3, 2.5, 2, 2, 1.9, and 13.7, respectively.
FIGURE 14.3-4. Computed tomography before and after therapy with iodine-131-3F8 (24 mCi per kg) in a patient with neuroblastoma.

Monoclonal Antibodies Against Renal Cancer

Monoclonal antibody G250 reacts against a cell surface antigen expressed in virtually all clear-cell renal carcinomas, and normal tissue expression is limited to large bile ducts and gastric epithelium. A presurgical study showed excellent tumor localization with uptake being among the highest reported in solid tumor. A phase 1/2 therapy study with murine ^{131}I-mG250 showed excellent targeting with mixed responses; development of an antimurine response precluded repeat therapy, underscoring the need for development of less immunogenic forms (91).

Chimeric G250 (cG250) was developed to circumvent the immunogenicity observed with mG250 and showed comparable targeting characteristics without immunogenicity (92). Radioimmunotherapy trials are being carried out to assess safety and efficacy; these have shown that the relative lack of immunogenicity of this chimeric antibody allows calculation of therapeutic dose based on radiation-absorbed dose to marrow estimated by measurement

of clearance kinetics of an initial "scout" infusion of ^{131}I-cG250. Experimental data suggests that multiple administrations of radiolabeled antibody may have greater therapeutic effect than a single infusion; this has led to the study of single large-dose and fractionated radioimmunotherapy studies. Initial results indicate that calculation of absorbed dose based on scout data is reliable and that the low immunogenicity of cG250 permits multiple therapies (see Fig. 14.3-3C).

Intracavitary and Direct Intratumoral Injection Therapy

An additional situation of some promise for radioimmunotherapy is the use of intracavitary therapy for tumors, such as ovary and colon, which stay confined to the peritoneal surface. Greater concentrations of antibody can be achieved in tumor after intracavitary injection than intravenously (93 ,94). In addition, the use of antibodies directly injected into primary brain tumors appears to show some promise as well (95), especially with the alpha emitter [211]At (see Alpha Therapy).

Intraperitoneal Therapy

A clinical trial performed by Stewart and colleagues (96) gives cause for some optimism regarding the possible use of radiolabeled monoclonal antibodies in microscopic disease when given by the intraperitoneal route as adjunctive therapy for ovarian cancer post surgery. Nine of 15 patients with stage I ovarian cancer and small tumors (<2 cm) had complete responses, and three others had positive peritoneal washings only. On the other hand, in patients with tumor masses larger than 2 cm (eight patients in this group), no objective responses to therapy occurred (97). Such studies lend credence to the concept that intraperitoneal therapy as a surgical adjunct may reduce the rate of recurrence in patients with intraperitoneal metastases. These studies have formed the basis for prospective clinical trials in Europe and the United States. In 52 patients who received adjuvant antibody therapy after cytoreductive surgery and chemotherapy, 21 showed no evidence of recurrence during the median follow-up of 35 months (98).

In a follow-up study, the same group studied radioimmunotherapy in an adjuvant setting after successful debulking surgery for ovarian cancer. Twenty-five patients received 25 mg of antihuman milk fat globulin antibody (HFMG1) labeled with ^{90}Y to a dose of 18 mCi per m^2. In comparison with case-matched controls, there are survival advantages and a Cox proportional hazards model predicts that 10-year survival will be 70% in comparison with only 32% for controls treated with chemotherapy alone (99).

Intralesional Administration

Intralesional Therapy in Brain Tumors

Surgically created resection cavities provide an opportunity for direct intracavitary therapy. ^{131}I-labeled 81C6 has been injected into a surgically created cavity in the tumor site of patients with glioblastoma multiforme. At the maximum tolerated dose of 100 mCi injected, large doses of radiation can be delivered to the cyst wall (1,180 Gy) at 1-cm (71 Gy) and 2-cm (39 Gy) depths, with only approximately 6 Gy to normal brain tissue (99).

Alpha Therapy

Zalutsky et al. are performing a phase 1 trial to determine the maximum tolerated dose, pharmacokinetics, and objective responses for [211]At-labeled human/mouse chimeric antitenascin monoclonal antibody 81C6 administered into surgically created resection cavities of recurrent malignant glioma. Twelve patients have received a single injection of 10 mg of monoclonal antibody labeled with escalating doses of [211]At, ranging from 2 to 10 mCi. For 2 mCi [211]At monoclonal antibody, calculated radiation doses for the tumor cavity interface were 472 Gy compared with less than 0.02 Gy for normal brain, liver, spleen, and bone marrow. This study demonstrates that it is feasible to produce clinical levels of [211]At, administer [211]At-labeled chimeric 81C6 monoclonal antibody with minimal toxicity, and achieve high tumor:normal organ dose ratios (100 ,101).

Summary

Part of "14.3 - Radioisotope Conjugates "

Radioimmunotherapy with radiolabeled monoclonal antibodies is increasingly effective for hematopoietic tumors with a number of investigators reporting persistent major responses. Radioimmunotherapy for solid tumors has been more difficult, and only an occasional major response has been reported; so far, these have not been persistent. Toxicity is predominantly hematopoietic with platelets being most sensitive to the effects of radiation. Even at ultra-high doses (up to 28 mCi per kg of ^{131}I), second organ toxicity has not been reached. Rational approaches to dose planning are becoming possible with improvements in dosimetry, based on quantitative single-photon emission computed tomography and positron electron tomography imaging. Therapeutic indices for tumor/marrow, the most radiosensitive organ, are in the range of 5–10 to 1. This is probably still too low for curative treatment of solid tumors, and further refinements, perhaps based on novel antibody formulations, are needed.

Several approaches are being investigated that may potentially result in an improvement in tumor response and a reduction in toxicity. These include enhancement of vascular permeability, regional administration, bifunctional antibodies, improved labeling chemistry, new radiolabels, and the use of mouse-human chimeric antibodies. In the future, further investigations of alternate radiolabels, the use of radiation dose–modifying agents, the identification of more reactive antigens, the use of antibody combinations, the alteration of routes of excretion of chelated antibodies, the investigation of human monoclonal antibodies, and biochemical modifications of antibodies to improve tumor deposition and reduce nonspecific targeting of normal tissues will be conducted. The number of clinical trials using radiolabeled antibodies to deliver radiation therapy is rapidly expanding. These studies should define the role of this modality in the cancer therapeutic armamentarium.

Introduction

Part of "15.1 - B-Cell Lymphomas "

Using monoclonal antibodies (MAb) to treat cancer has evolved through a long process of promise, hype, and now, finally, positive clinical trial results. Lymphoma has been an appealing target for immunotherapy in part due to the relative ease of acquiring tumor cells by biopsy and because of the extensive identification and characterization of B-lymphocyte antigen expression.

The goal of antibody therapy for the treatment of cancer is the selective destruction of tumor, while minimizing toxicity to normal host tissues. Two general approaches have been pursued. The first uses "naked" or unconjugated MAb against antigens on tumor cells to cause direct effects and to recruit the host's immune system to eliminate the MAb-coated tumor cells. The second approach uses MAb conjugated to toxins, drugs, or radioisotopes to concentrate these agents at sites of tumor, thereby improving their therapeutic index.

Elements critical to the success of MAb therapy include the target antigen, the MAb, and the type and characteristics of the tumor. In 1981, the first MAb-based treatments demonstrated antitumor activity and with the approval of rituximab (anti-CD20 MAb, Rituxan), the antibody-based treatment of B-cell non-Hodgkin's lymphoma (NHL) has entered clinical practice. Hopefully, the agents discussed here represent the tip of the iceberg as more specific cancer therapies continue to be refined and developed.

Important Antigen Characteristics for Antibody Therapy

Part of "15.1 - B-Cell Lymphomas "

From a large number of preclinical and clinical trials since the early 1980s, many of the characteristics of antigens critical for successful antibody-based immunotherapy have been elucidated (Table 15.1-1). Of primary importance is the tissue distribution and expression of the antigen. The ideal tumor antigen would only be expressed on malignant cells and especially not on vital normal host cells. The B-cell surface immunoglobulin (Ig) is formed by genetic recombination and somatic mutation during development of B cells and the protein sequence and structure is unique to each mature lymphocyte and malignant clone. This surface Ig is tumor specific (Ig-idiotype), and treatment with antiidiotype antibodies causes minimal toxicity (1,2). In contrast, CD52 is expressed on most B and T cells, and treatment with anti-CD52 antibodies can cause profound immunosuppression (3,4). Many of the antigens targeted for B-cell lymphoma immunotherapy are restricted to expression in the B-cell or lymphoid lineage (Table 15.1-2). Thus, an effective therapy against a pan B-cell antigen would also deplete normal B cells. If the antigen were not expressed on stem cells or progenitor cells, however, normal lymphocytes would be expected to repopulate after the elimination of the MAb from the patient. This has been observed with anti-CD20 therapy (5). In some cases, the antibody (e.g., Lym-1) is more avid for HLA-DR10 on malignant cells than on normal lymphocytes, which may limit toxicity (6). Nonspecific binding of antibody can also result in toxicity to normal host tissues, especially with radioimmunoconjugate or immunotoxin.

Table 15.1-1 Ideal Antigen Characteristics for Monoclonal Antibody Therapy

Antigen Characteristic	Type of Antibody Therapy		
	Unconjugated	Immunotoxin	Radioimmunoconjugate
Expression on normal host cells	Disadvantage	Disadvantage	Disadvantage
Present on all tumor cells	Necessary	Necessary	Important
Mutation or loss of antigen variants	Disadvantage	Disadvantage	Disadvantage
High-density cell surface expression	Important	Important	Important
Shed from cell surface or secreted	Disadvantage	Disadvantage	Disadvantage
Internalization upon binding antibody	Disadvantage	Necessary	Disadvantage for [131]I
Biologic function	Important	Less important	Less important

Table 15.1-2 Characteristics of Selected Antigens on B-Cell Neoplasms

Antigen	Normal Tissue Distribution	MAb-Targeted NHL Histology	Mutation	Internalization/Modulation	Biologic Function
Immunoglobulin (idiotype)	Mature B cells	Low, intermediate, and high grades	Yes	Yes	Antigen receptor
CD5	T cells, B cells	CLL, mantle cell	No	Yes	CD72 ligand
CD19	Immature and mature B cells	Low, intermediate, and high grades	No	Yes	Signal transduction complex
CD20	Mature B cells	Low, intermediate, and high grades	No	No	Calcium channel
CD21	B cells, dendritic cells, neutrophils	PTLD	No	?	EBV/C3d receptor
CD22	B cells, T cells	Low, intermediate, and high grades	No	Yes	Adhesion receptor
CD24	B cells, T cells, neutrophils, neural tissue, red cells	PTLD	?	?	Cell adhesion and signaling
CD37	Mature B cells	Low, intermediate, and high grades	?	Yes	Tetraspanin
CD38	T cells, B cells, NK cells, monocytes	Multiple myeloma, PTLD	?	Yes	Ectoenzyme
CD40	B cells, T cells, dendritic cells	Low, intermediate, and high grades	No	Yes	Costimulatory molecule receptor
CD52	B cells, T cells, monocytes, platelets	Low, intermediate, and high grades, CLL	Yes	No	?
HLA-DR	B cells, T cells	Low, intermediate, and high grades	Yes	No	Antigen presentation
HM1.24	Plasma cells	Multiple myeloma	?	?	?

CLL, chronic lymphocytic leukemia; MAb, monoclonal antibody; NK, natural killer; PTLD, posttransplant lymphoproliferative disorder.

A second critical issue is the degree of heterogeneity of antigen expression on the malignant cell. Unconjugated MAb need to bind to all of the tumor cells as they act by directing components of the immune system to the tumor or by inducing intracellular signals, or both. Toxin or drug-conjugated MAb also need to bind to every cell as they act by delivering the substance to the cell cytosol. Tumor cells not expressing the antigen at the cell surface would not be killed. In contrast, radioisotopes emit radiation or particles, or both, that can exert lethal damage over a distance. Thus, a theoretical advantage of radiolabeled antibodies is the ability to kill nearby antigen-negative cells by this "cross-fire" effect. A high antigen mutation rate or the loss of antigen expression may lead to the escape of epitope-negative clones under the selective pressure of targeted therapy. The more critical the biologic function of the antigen, the less likely antigen loss mutation should occur.

Additional factors include antigen density and disposition of the antigen in the cell membrane. In most studies, higher density of the target antigen led to a greater clinical effect. Modulation or internalization of the MAb/antigen complex from the cell surface is required for immunotoxin constructs but is detrimental to unconjugated MAb therapy. Endocytosis of radioimmunoconjugate often leads to cleavage and secretion of the radioisotope-labeled fragments. Antigen shed or secreted from the cell into the serum can bind MAb and block interactions with the tumor. In some cases, this problem may be circumvented by infusing large doses of antibody (2).

Increasing importance is being given to the biologic function of the target antigen and to the intracellular molecular events arising from the interaction of antibody with antigen. These events may be crucial to the success of unconjugated MAb-based therapy. Interaction of the MAb with antigen may exert direct antitumor effects by blocking a natural ligand-ligand receptor interaction [anti-interleukin-6 (IL-6), anti-CD25], mimicking a natural ligand (antiidiotype antibody simulating antigen) or interfering with the function of a molecule. These interactions may have direct antiproliferative or apoptotic effects and are dependent on the antibody, the antigen, and the biology of the tumor cell. As an example, clinical trials of antiidiotype MAb found that the isotype of murine MAb used (thus, the ability of antibody to recruit effector cells) did not correlate with clinical outcome (2,7,8). However, the ability of antiidiotype MAb to induce tyrosine phosphorylation in the patient's lymphoma cells *in vitro* correlated with the clinical antitumor effectiveness of the antibody (9). The interaction of some anti-CD20 antibodies with CD20 directly induces growth arrest and apoptosis in some lymphoma cell lines (10,11 and 12). The degree to which these direct antitumor effects from antibody-antigen interactions influence the clinical outcome is still largely unknown. It is likely that the more successful antibody-based therapies (especially that of unconjugated MAb) will capitalize on these effects.

Selected characteristics of the antigens on B-cell lymphomas that have been targeted with MAb therapies are listed in Table 15.1-2 . Some are widely expressed on most B-cell malignancies,

whereas others are more restricted to a specific developmental stage or B-cell lymphoma histology. Specific clinical trials are discussed in the following sections.

Clinical Trials of Unconjugated Monoclonal Antibodies for Therapy of B-Cell Lymphoma

Part of "15.1 - B-Cell Lymphomas "

The development of MAb technology led to a large number of exploratory preclinical and clinical trials. Leukemia and lymphoma were often targeted for antibody therapy because of ease of access of antibody to tumor *in vivo*. Numerous preclinical models helped define the important interactions between antibodies, antigens, and the host environment. However, successful eradication of tumor in preclinical models was not always predictive of a response in human trials. More recently, clinical studies using genetically engineered MAb, combinations of antibodies, or combinations of antibody and chemotherapy have demonstrated significant activity in patients with NHL. This has renewed enthusiasm for the development and use of unconjugated antibodies for cancer therapy.

The greatest success in unconjugated antibody therapy for lymphoma has been with CD20-targeted treatment of follicular lymphoma. Substantial antibody activity has also been seen in posttransplant lymphoproliferative disorders (PTLDs), antiidiotype therapy of follicular lymphoma, and CD52-targeted therapy for chronic lymphocytic leukemia (CLL). Unconjugated MAb against other antigens, such as CD19 and HLA-DR, have been less successful. Table 15.1-3 lists selected informative clinical trials of unconjugated antibody therapy for the treatment of NHL. Therapy directed against CD20, surface Ig, CD21, CD24, and CD52 are discussed in detail.

Table 15.1-3 Selected Clinical Trials Using Unconjugated Monoclonal Antibodies for Treatment of B-Cell Lymphoma

Target	Antibody	Disease	Dose	Patients (n)	Response	Problems	Studies
CD20	C2B8 (Rituximab) (Chimeric)	Relapsed low-grade NHL	375 mg/m^2 qwk × 4	204	50% CR + PR	Mild infusional toxicity, fever, rare CD20 escape, rare HACA	Maloney et al. (5), McLaughlin et al. (18)
CD20	C2B8 (Chimeric)	Relapsed and refractory intermediate-grade NHL	375-500 mg/m^2 qwk × 8	54	5 CR, 12 PR	Mild infusional toxicity	Coiffier et al. (22)
CD20	C2B8 (Chimeric)	Untreated low-grade NHL	375 mg/m^2 6 doses + CHOP 6 cycles	38	22 CR, 16 PR	Mild infusional toxicity, no additive toxicity to CHOP	Czuczman et al. (23)
CD20	1F5 (Murine)	Refractory low- and intermediate-grade NHL	5-800 mg/m^2 /d × 5-10 d	4	1 PR	Minimal toxicity	Press et al. (14)
Ig idiotype	Custom anti-idiotype (Murine)	Relapsed low-grade NHL	400-11,500 mg qod × 2-3 wk alone, with Chl, or with INF	34	18% CR, 50% PR	Mild infusional toxicity; Id negative escape	Meeker et al. (2), Brown et al. (8), Maloney et al. (7), Davis et al. (20)
CD21 + CD24	BL13 + ALB9 (Murine)	PTLD	0.2 mg/kg /d × 10 d	58	36 CR	Mild infusional toxicity, neutropenia in 46%, HAMA	Benkerrou et al. (38)
CD52	CAMPATH-1G (Rat)	NHL	25-50 mg/d × 10 d	13	1 CR, 3 PR	Moderate infusional toxicity, fever	Dyer et al. (39)
CD52	CAMPATH-1H (Humanized)	Relapsed and refractory NHL	30 mg t.i.w. × 12 wk	42	6 PR	Moderate infusional toxicity, immunosuppression	Lundin et al. (4)
CD52	CAMPATH-1H (Humanized)	CLL: No prior therapy	30 mg t.i.w. × 18 wk	9	3 CR, 5 PR	Moderate infusional toxicity, immunosuppression	Osterborg et al. (42)
CD52	CAMPATH-1H (Humanized)	CLL: Prior therapy	30 mg t.i.w. × 12 wk	29	1 CR, 11 PR	Moderate infusional toxicity, immunosuppression	Osterborg et al. (3)
CD5	T-101 (Murine)	CLL	1-140 mg b.i.w. × 4 wk	13	Transient	Mild infusional toxicity, fever, antigen modulation	Foon et al. (45)
CD5	T-101 (Murine)	CLL	Various	4	Transient	Mild infusional toxicity, fever, antigen modulation	Dillman et al. (44)
CD19	CLB-CD19 (Murine)	Progressive NHL	225-1,000 mg	6	1 PR	Minimal toxicity, antigen modulation	Hekman et al. (46)
CD19	CLB-CD19 (Murine)	Low-grade NHL	50 mg/m^2 b.i.d. × 12 wk + IL-2	7	1 PR	Mild toxicity due to IL-2, antigen modulation	Vlasveld et al. (47)
HLA-DR	LYM-1 (Murine)	Refractory low- and intermediate-grade NHL	58-465 mg qwk × 4	10	3 Minor	Mild infusional toxicity	Hu et al. (48)

Chl, chlorambucil; CHOP, cyclophosphamide, doxorubicin, vincristine, and prednisone; CLL, chronic lymphocytic leukemia; CR, complete response; HACA, human antichimeric antibody; HAMA, human antimouse antibody; Id, idiotype; IL-2, interleukin-2; INF, interferon; NHL, non-Hodgkin's lymphoma; PR, partial response; PTLD, posttransplant lymphoproliferative disorder.

Anti-CD20 Antibody Therapy

CD20 is a nearly ideal antigen for unconjugated antibody therapy. The antigen is expressed in high density on most malignant B cells, does not mutate or internalize, and is not shed from the cell surface (13). The binding of some anti-CD20 antibodies directly induces antiproliferative or apoptotic events in some lymphomas (10,11 and 12). An early clinical trial of immunotherapy for B-cell lymphoma using the murine anti-CD20 MAb 1F5 was conducted by Press and colleagues in 1986 (14). Four patients with refractory, low-, and intermediate-grade NHL were treated with a continuous infusion of 1F5 over 5–10 days in a dose-escalation study. Total dosages ranged from 52 to 2,380 mg anti-CD20 MAb 1F5. Higher doses of antibody were required to penetrate extravascular tumor and to saturate binding sites. Most adverse events were asymptomatic low-grade fevers, transient reduction in neutrophil and platelet counts, and clearance of normal circulating B cells. The MAb was rapidly cleared from the blood after discontinuation of the infusion and partial remissions were observed in the two patients receiving the highest dosages.

A human/mouse chimeric anti-CD20 antibody rituximab (IDEC-C2B8) was developed to enhance tumor-cell lysis via complement fixation and antibody-dependent, cell-mediated cytotoxicity; reduce immunogenicity; and improve pharmacokinetics (15). Human IgG1k-constant regions were molecularly grafted onto the murine variable regions from anti-CD20 MAb IDEC-2B8 using recombinant DNA techniques. A dose-escalation clinical trial of rituximab in 15 patients with relapsed low-grade B-cell lymphoma established the safety in administering 10 to 500 mg per m^2 of this MAb in a 5- to 6-hour intravenous infusion (16). The mean serum half-life was 4.4 days, which was longer than that seen with the murine MAb 1F5. Moreover, 2 weeks after treatment, antibody bound to tumor could still be detected in excised lymph nodes and in the serum of most patients treated with more than 100 mg per m^2.

A trial of rituximab given as four weekly infusions in 20 patients with relapsed low- or intermediate/high-grade lymphoma confirmed the safety of the chimeric MAb (17). Side effects were similar to those seen in the initial study and were mostly related to the initial infusion. Grade I and II fevers, chills, asthenia, and nausea were the most frequent side effects. Skin rash, pruritus, urticaria, arthralgia, rhinitis, and night sweats were reported in 10% of patients. Peripheral B cells were rapidly depleted but repopulated the peripheral blood in 6 to 9 months. Mean Ig levels and T-cell subset numbers remained unchanged, and significant bacterial, viral, or opportunistic infections were not observed. Hematologic events included transient thrombocytopenia and neutropenia in a minority of patients and did not appear to be due to lymphoma involvement of the marrow, but may have been from clearance of cells with antibody bound to Fc-receptors or to release of cytokines. Only one patient treated in the phase 1 trials developed a human anti-chimeric antibody response. The mild toxicities and ease of administration in an outpatient setting helped move rituximab into larger multiinstitutional trials.

Two hundred and three patients with relapsed low-grade and follicular NHL were treated with four weekly infusions of 375 mg per m^2 rituximab [37 patients in a phase 2 single institution trial (5) and 166 patients in a phase 2 multicenter trial (18)]. On an intent-to-treat analysis, 46% to 48% of patients had an antitumor response [complete response (CR) or partial response (PR)] to therapy. The response of follicular lymphomas was better (53% to 60% CR + PR) than the response of small lymphocytic lymphoma (SLL) (0% to 13% CR + PR). The reason for the lower response in SLL is not known but may be due to the lower density of CD20. Additionally, response correlated with increasing MAb levels in the serum and patients with SLL had increased clearance of MAb (19). Collectively, there were 13 complete remissions using strict criteria (all lesions less than 1 cm × 1 cm). In the smaller study, the median time to onset of tumor response was 50 days and maximal tumor response occurred 3 to 4 months after therapy (5). Median time to progression in responders in both trials was 10 to 13 months. Forty percent of patients whose low-grade lymphoma progressed after a response to rituximab had another response to retreatment with rituximab(20). Forty-three percent of patients with bulky (more than 10 cm) low-grade NHL responded to treatment with rituximab, although most of the remissions were partial (21).

The single agent activity of rituximab for follicular NHL has encouraged trials of rituximab in other lymphomas that express CD20. Coiffier reported on a multicenter phase 2 trial of 54 patients with diffuse large-cell and mantle-cell NHL (22). Patients received either eight weekly infusions of 375 mg per m^2 or one infusion of 375 mg per m^2 followed by seven weekly infusions of 500 mg per m^2. Eighty-three percent of patients had received earlier chemotherapy, including autologous bone marrow transplantation (ABMT) in nine patients. Previously untreated patients were older than 60 years of age. Five patients (9%) had a complete remission and 12 patients (22%) had a PR to therapy for an overall response in patients with either diffuse large-cell NHL or mantle-cell lymphoma of 35%. The majority of responses were observed in patients without bulky tumor (largest lesion smaller than 5 cm) and with disease that was responsive to earlier chemotherapy. The median time to progression in responding patients had not been reached at the time of publication but exceeded 8 months. In seven patients with progressive intermediate-grade NHL after high-dose chemotherapy with ABMT support, salvage therapy with rituximab resulted in one complete remission, five PRs, and one mixed response. This study demonstrates that there is single-agent activity of rituximab in aggressive NHL and provides rationale for sequential or combined trials with standard therapy.

In vitro data suggest that rituximab may act synergistically with some cytotoxic chemotherapeutics (11). Czuczman et al.

reported on the results of a clinical trial of rituximab given concurrently with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) chemotherapy (23). Thirty-eight patients with newly diagnosed or relapsed low-grade NHL were treated with six cycles of standard-dose CHOP and six cycles of rituximab. Two doses (375 mg per m^2) of rituximab were given before the first cycle of CHOP, one dose was given before the third and fifth cycles of CHOP, and two doses were given after the sixth cycle of CHOP. Thirty-five of 38 patients who began treatment completed the regimen. A CR occurred in 22 (58%) and a PR in 16 (42%) of the treated patients for an overall response rate of 100%. The mean time to response was similar to that seen in trials of rituximab alone, and median time to progression was more than 17 months. Toxicity was additive, and the more serious adverse events were attributable to CHOP. It is not known if responses to rituximab plus CHOP will be more durable than responses to chemotherapy alone, but the shape of the disease-free survival curve is encouraging, with 75% of patients remaining in remission with more than 30 months' median follow-up.

Multiple ongoing cooperative trials (SWOG 9800, ECOG 1496, and ECOG/CALGB 4494) are addressing the benefit of consolidation with rituximab after treatment with chemotherapy. Additionally, trials are taking advantage of the peripheral blood B-cell depletion observed with rituximab to "in vitro purge" peripheral blood stem cell collections before high-dose therapy and peripheral blood stem cell transplantation and evaluating rituximab posttransplant to eliminate minimal residual disease.

In general, therapy with rituximab has been well tolerated. Dose-limiting or cumulative toxicities have not been observed. However, infusion-related symptoms consisting of fevers, chills, and rigor are most commonly observed (17). Nausea, hypotension, and bronchospasm are occasionally seen and can be abated by temporary cessation of the antibody infusion along with administration of acetaminophen and diphenhydramine (16,17). Reinfusion of antibody at a reduced rate is usually tolerated. Side effects are often most pronounced during the initial infusion and are less problematic with subsequent doses. In some patients, more serious adverse events, including death, have been reported. In some cases, these may be associated with high numbers of circulating tumor cells, leading to severe bronchospasm, hypoxemia, biochemical evidence of rapid destruction of tumor, and thrombocytopenia (24). It is possible that initial infusions of lower doses of antibody may prevent this constellation of symptoms in patients with large, readily accessible tumor burdens (24).

Antiimmunoglobulin Idiotype Antibody Therapy

During B-cell development, Ig variable-region gene segments undergo recombination and somatic mutation, which results in an Ig sequence unique to each B cell. Thus, clonally derived mature B-cell lymphomas usually express unique Ig sequences. MAb against these unique sequences (antiidiotype) can be generated using hybridoma technology; however, this necessitates the development of a custom antibody for each patient. Treatment with antiidiotype MAb can achieve potent antitumor activity. In a series of trials at Stanford University, 34 patients were treated with infusions of murine antiidiotype antibodies either alone, with chlorambucil, or with interferon (1,2,7,8). Tumor responses were observed in 68% of patients (CR in six patients). Responses occurred in patients who had failed earlier chemotherapy; who had large tumor burdens; and who had disease in blood, bone marrow, lymph nodes, spleen, liver and/or extranodal sites. In vivo antitumor activity correlated with the ability of antiidiotype antibodies to induce cell signaling through tyrosine phosphorylation in vitro in pretreatment tumor cells (9). This suggested that direct effects of the interaction of antiidiotype antibody with cell-surface Ig were important for antitumor activity. The addition of chlorambucil (7) or interferon (8) did not significantly improve disease response.

Most PRs lasted less than 1 year; however, in an update of long-term remissions induced by antiidiotype antibodies, six of eight CRs persisted longer than 4 years (25). Of interest, analysis of five patients in clinical complete remission 3 to 8 years after MAb therapy detected molecular markers of the tumor in all cases, suggesting the induction of a tumor dormancy state (25). Relapse, in these clinical trials, was usually owing to the outgrowth of idiotype-negative variant cells that expressed mutated Ig that did not bind the treatment antibody (26). Low levels of variant cells, a product of somatic mutation of the Ig hypervariable regions, could be detected in the pretreatment tumor-cell population, and treatment with monoclonal antiidiotype antibody allowed the outgrowth of these variants (26). In some cases of poor antitumor response, tumors secreted high levels of idiotype into the serum that bound to infused antiidiotype antibody and presumably blocked antibody from binding to lymphoma cells (2). Infusions of antiidiotype antibodies were generally well tolerated, with mild fever, chills, and rigor observed during the initial infusion (2,7). These studies first demonstrated that MAb could lead to tumor regression in patients with relapsed B-cell NHL.

Due to the expense and difficulty in developing custom antiidiotype MAb for each patient with follicular lymphoma and the frequent selection of idiotype-variant tumor cells, however, subsequent trials have explored vaccination with the idiotype protein to induce a polyclonal, in vivo immune response directed at multiple epitopes on tumor Ig idiotype, thus limiting the risk of variant idiotype tumor-cell outgrowth. For these trials, Ig is isolated from follicular lymphoma and used to formulate a custom antitumor vaccine. Long-term results from the Stanford idiotype-vaccine trial investigating the use of tumor-specific idiotype vaccination after standard chemotherapy in patients with follicular NHL has been reported (27). Forty-one patients were immunized with tumor idiotype chemically coupled to keyhole limpet hemocyanin and mixed with an immunologic adjuvant. Evidence of humoral or cellular antiidiotype immune responses could be detected in 20 patients postimmunization. Of 32 patients in first complete remission after standard chemotherapy, significant prolongation of time to tumor progression (7.9 years versus 1.3 years) and median survival from time of last chemotherapy was observed in patients with detectable antiidiotype immune responses compared to those not making an idiotype-specific immune response. Twenty

patients had residual tumor at the time of immunization. Tumor regression occurred in two of five patients who mounted a detectable antiidiotype immune response, whereas no cases of tumor regression were observed in the 15 patients without a detectable response. Despite these promising results, a randomized trial is required to prove that the induction of a polyclonal antiidiotype response or an idiotype-specific T-cell response, or both, is responsible for the improved outcome.

Anti-CD21 and Anti-CD24 Antibody Therapy of Posttransplant Lymphoproliferative Disorders

The combined use of two MAb reactive to different cell-surface antigens for the treatment of B-cell lymphoma was first explored in PTLD. PTLD most often arises from Epstein-Barr virus–infected B lymphocytes and is associated with T-cell immunosuppression. PTLD may be an oligoclonal or a monoclonal process at the time of diagnosis, often arising in recipients of T-depleted allogeneic bone marrow or solid organ transplants on immunosuppressive therapy. PTLD occasionally remits after reduction of immunosuppressive therapy, but outcomes of treatment with chemotherapy are generally poor (28,29). CD21, the human complement receptor type 2, is also the receptor for Epstein-Barr virus and is expressed on mature B cells and follicular dendritic cells (30). CD24 is a glycosylphosphatidylinositol-linked, mucin-type molecule expressed on B cells, neutrophils, neural tissue, and numerous types of tumors (31).

Infusion of murine anti-CD21 and anti-CD24 MAb was used to treat two children with PTLD after T-cell depleted mismatched bone marrow transplants (32). Complete remissions were obtained in both cases, and an open, multicenter, prospective trial was initiated. An update of 58 patients with PTLD who did not respond to reduction in immunosuppressive therapy showed complete remissions in 36 of 59 treated cases (61%) (33). CR rates were similar between patients who had developed PTLD after bone marrow transplantation or solid organ transplant. The relapse rate for complete responders was 8% with a median follow-up of 61 months. Significant factors predicting a poor response to antibody therapy were greater than four involved sites of disease, central nervous system disease, onset greater than 1 year from transplant, and transplant performed for treatment of hematologic malignancy. Monoclonal PTLD was statistically less likely to respond (48% CR rate) than oligoclonal disease (80% CR rate); however, overall survival was not statistically different. Time to complete response from the initiation of therapy ranged from 5 days to 150 days, with a median of 15 days. The treatment consisted of infusions of 0.2 mg of antibody per kg of body weight over 4 to 6 hours per day for 10 days and was well tolerated. Mild fevers and chills occurred in 20% of patients, and transient neutropenia occurred in one-half of the patients, presumably due to the expression of CD24 on neutrophils (34). Circulating B cells were also depleted but began to repopulate peripheral blood within 15 days of the completion of antibody infusion. Episodes of infection were infrequent and occurred during periods of neutropenia. Human antimouse antibodies (HAMA) developed in 50% of the patients tested.

For unclear reasons, PTLD may be particularly sensitive to unconjugated MAb therapy. An anecdotal response of PTLD to the sequential administration of anti-CD37 and anti-CD38 has been described (35). Relatively little experience is available on the use of anti-CD20, although preliminary reports suggest significant activity (36). Multiple trials in PTLD are under way with rituximab.

Anti-CD52 (CAMPATH-1) Antibody Therapy

CD52 is a 21- to 28-kd glycosylphosphatidylinositol-linked glycoprotein that is expressed at high density on T cells, B cells, and most lymphoid malignancies and is the target for the CAMPATH-1 MAb (37). It is not shed from the cell surface and does not modulate on binding anti-CD52 antibodies (38,39). Antigen-negative normal T cells have been observed posttherapy (40), but antigen-negative escape by lymphoma has not been reported.

Initial studies used a rat IgM anti-CD52 (CAMPATH-1M) antibody that actively fixed complement but was rapidly cleared from serum. Depletion of circulating lymphoma cells was transient and may have been due to sequestration rather than lysis (39). An IgG2b-subclass anti-CD52 (CAMPATH-1G) was tested in 18 patients with lymphoid malignancies because of the *in vitro* ability of the antibody to fix complement and mediate antibody-dependent cellular cytotoxicity (39). During treatment with 25 to 50 mg of CAMPATH-1G per day for 10 days, normal and malignant lymphocytes were cleared from the circulation, and unlike trials using CAMPATH-1M, lymphocytopenias persisted after discontinuation of therapy. Responses in blood, marrow, and spleen were observed, but minimal effects on lymph nodes and extranodal masses occurred. Subsequent trials have used humanized anti-CD52 antibody (CAMPATH-1H) developed by molecularly splicing the rat hypervariable regions into the human-IgG1 Ig genes (41).

In a phase 2 multicenter study, 50 patients with relapsed or resistant low-grade NHL received 30 mg of CAMPATH-1H thrice weekly for up to 12 weeks (4). Forty-two of the 50 patients had B-cell lymphomas and in this group there were six PRs. The median time to progression in responders was 4 months. As seen with CAMPATH-1G, the overall response of disease in blood and bone marrow was higher than in spleen and lymph nodes.

CAMPATH-1H has increased activity for CLL and T-cell disorders (mycosis fungoides and T-cell prolymphocytic leukemia). In a report of nine previously untreated patients with CLL, three patients had a complete remission, five had a PR, one had progressive disease, and three patients had a CR of lymph-node-based disease (42). Response duration was greater than 20 months in four patients at the time of publication. A phase 2 trial of subcutaneous CAMPATH-1H for first-line therapy of CLL has been initiated. Therapy in patients with previously treated CLL has been less successful, possibly due to immune system dysfunction secondary to advanced disease or earlier chemotherapy, or both. In 29 previously treated CLL patients, intravenous administration of CAMPATH-1H induced a CR in one patient and PRs in 11 patients (3). Bone marrow, spleen, and lymph nodes were cleared of disease in 36%, 32%, and 7% of patients, respectively, with a median duration of response of 12 months.

These results have been accompanied by infusion-related toxicity and immunosuppression. Infusion-related adverse events include fevers, rigors, nausea, and rash and were observed in the majority of patients (3). Tachyphylaxis rapidly occurred, and dosages could be escalated from 3 to 30 mg without causing additional infusion-related side effects. Hypotension requiring temporary cessation of infusion was reported in 16% of patients. The side effects have been less common with subcutaneous administration and have consisted principally of fever and moderate local skin reactions (43). Hematologic toxicities were less severe and less frequent in patients with CLL than in patients with NHL (3,4). Profound T-cell depletion accompanied by complications, including viral reactivation and opportunistic infections, were observed (3,4). These were more frequent in heavily pretreated patients. Current trials of subcutaneous CAMPATH-1H include prophylactic treatment with acyclovir, trimethoprim/sulfamethoxazole, and fluconazole to prevent infections.

Other Unconjugated Antibody Therapy

Additional cell-surface antigens on B-cell lymphomas have been targeted but have proved to be poor candidates for unconjugated antibody therapy. CD5 is a 65-kd transmembrane protein found on T cells, CLL, and mantle-cell lymphoma. Infusion of an IgG2a-murine anti-CD5 antibody (T101) in patients with CLL resulted in only transient (24 to 48 hours) reductions in levels of circulating malignant cells (44,45). CD19 is a 90-kd transmembrane protein expressed during B-cell development and on most malignant B cells. Infusions of IgG2a murine anti-CD19 antibody (CLB-CD19) in patients with low- or intermediate-grade NHL has produced responses in only a small minority of patients (46,47). Both CD5 and CD19 internalize on binding antibody, and more recent trials have focused on immunotoxin conjugates. MAb have also been raised against a polymorphic variant of HLA-DR that is present on normal and malignant B cells. Infusions of IgG2a murine anti-HLA-DR antibody (Lym-1) in ten patients with refractory low- and intermediate-grade NHL failed to produce significant responses (48), but some trials using radiolabeled Lym-1 are more promising.

Multiple myeloma is a late B-cell stage malignancy that usually does not express CD19 or CD20. Clinical trials of rituximab are under way to target "putative" B cells that may be part of the malignant clone. Additional MAb under development include anti-HM1.24 (49) and anti-CD38 (50). Myeloma may in part be driven by IL-6 or an IL-6 like substance (51,52 and 53). Trials of chimeric anti-IL-6 antibody therapy in patients with multiple myeloma have substantially lowered serum levels of free, biologically active IL-6 and C-reactive protein and have inhibited myeloma-cell proliferation during therapy but have not demonstrated disease responses (54,55 and 56).

Clinical Trials of Toxin-Conjugated Monoclonal Antibodies for Therapy of B-Cell Lymphomas

Part of "15.1 - B-Cell Lymphomas "

Immunotoxin therapy takes advantage of selective binding of MAb to the target antigen to deliver potent toxins to the tumor cells. Toxins or drugs must typically reach the cytosol to have antitumor activity (inhibition of protein synthesis); therefore, useful cell surface antigens must internalize on binding antibody. Additionally, because toxins are lethal to any cell that internalizes them, the antigens should be expressed on few nonmalignant cells. Early clinical trials using immunotoxins for treatment of malignancy encountered multiple difficulties. The chemical links between toxins and antibodies were unstable in vivo, resulting in short immunotoxin half-life and poor delivery of toxin to tumor. Unmodified toxins bound to liver and endothelium, which rapidly decreased serum concentrations of the immunotoxins and contributed to toxicity in normal host tissues. Second-generation immunotoxins were developed with more stable toxin-antibody links that would still allow release of free toxin intracellularly. Additionally, toxins were modified to limit binding to liver and endothelium. Most trials of immunotoxin therapy of NHL have used either the deglycosylated ricin-A chain or a "blocked"-heterodimeric ricin to reduce the nonspecific binding of the B chain to galactose residues on normal cells. A theoretical advantage exists to using a heterodimeric ricin conjugate because the B chain facilitates translocation of the protein into the cytosol after endocytosis.

CD19 and CD22 have been most extensively used as targets for immunotoxin-directed therapy of B-cell lymphoma (Table 15.1-4). Expression of these antigens is limited to lymphocytes, and both CD19 and CD22 internalize on MAb binding (57,58). CD19 is a B-cell differentiation transmembrane protein and part of the antigen receptor complex, and CD22 is a transmembrane adhesion receptor expressed on normal B cells and many B-cell malignancies.

Table 15.1-4 Selected Clinical Trials Using Immunotoxins for Treatment of B-Cell Lymphoma

Target	Antibody	Toxin	Disease	Dose (MTD)	Patients (n)	Response	Problems	Studies
CD19	Anti-B4 (Murine)	Blocked ricin	Refractory B-ALL, B-CLL, NHL	1-60 µg/kg/d × 5 d (50 µg/kg/d)	25	1 CR, 2 PR	Elevated aminotransferase, fever, HAMA, HARA	Grossbard et al. (63)
CD19	Anti-B4 (Murine)	Blocked ricin	Refractory B-ALL, B-CLL, NHL	CI 10-70 µg/kg/d × 7 d (50 µg/kg/d)	34	2 CR, 3 PR	Elevated aminotransferase, fever, thrombocytopenia, HAMA, HARA	Grossbard et al. (64)
CD19	Anti-B4 (Murine)	Blocked ricin	NHL post ABMT	CI 20-50 µg/kg/d × 7d q28d × 2 (40 µg/kg/d)	12	11 CR (13-26 months post ABMT)	Elevated aminotransferase, thrombocytopenia, mild capillary leak syndrome, HAMA, HARA	Grossbard et al. (67)
CD19	HD37 (Murine)	dgA	Refractory low- and intermediate-grade NHL	Bolus 2-24 mg/m²/8d (16 mg/m²/8d)	23	1 CR, 1 PR	Vascular leak syndrome, aphasia, acrocyanosis HAMA, HARA	Stone et al. (66)
—	—	—	—	CI 9.6-19.2 mg/m²/8d (19.2 mg/m²/8d)	9	1 PR	Vascular leak syndrome, aphasia, acrocyanosis, HAMA, HARA	Stone et al. (66)
CD19	Anti-B4 (Murine)	Blocked ricin	AIDS-related NHL	CI 20 µg/kg/d × 7d 2 cycles + m-BACOD 8 cycles	44	13 CR, 12 PR	Elevated aminotransferase, fever, HAMA, HARA	Scadden et al. (72)
CD19	Anti-B4 (Murine)	Blocked ricin	Multiple myeloma	30-40 µg/kg LBW/d × 5-7 d	5	none	Elevated aminotransferase, fatigue, thrombocytopenia	Grossbard et al. (70)
CD22	Fab"-RFB4 (Murine)	dgA	Refractory NHL	25-120 mg/m²(75 mg/m²)	15	38% PR	Vascular leak syndrome, fever, myalgia	Vitetta et al. (60)
CD22	IgG-RFB4 (Murine)	dgA	Relapsed NHL	5-142 mg/m²(32 mg/m²)	26	1 CR, 5 PR	Vascular leak syndrome, myalgia, fever, aphasia	Amlot et al. (59)
CD22	IgG-RFB4 (Murine)	dgA	Relapsed NHL	9.6-28.8 mg/m²(19 mg/m²)	18	4 PR	Vascular leak syndrome, fever, myalgia	Sausville et al. (61)
CD22	Bispecific F(ab")₂(Murine)	Saporin	Relapsed or refractory low-grade NHL	1-3 mg saponin qwk × 3-6 wk	5	5 transient PR	Myalgia, malaise	French et al. (62)
IL-2R	IL-2 (Ligand)	DAB₃₈₉ (Diphtheria toxin)	NHL	3-27 mg/kg/d × 5 d q3-4 wk	17	1 CR, 2 PR	Fevers, asthenia, anorexia, anti-DT, anti-DAB₃₈₉IL-2	LeMaistre et al. (73)

ABMT, autologous bone marrow transplant; AIDS, acquired immunodeficiency syndrome; ALL, acute lymphocytic leukemia; CI, continuous infusion; CLL, chronic lymphocytic leukemia; CR, complete response; dgA, deglycosylated ricin-A chain; DT, diphtheria toxin; HAMA, human antimouse antibody; HARA, human antiricin antibody; IgG, immunoglobulin G; IL-2, interleukin-2; IL-2R, interleukin-2 receptor; LBW, lean body weight; m-BACOD, methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine; MTD, maximal tolerated dose; NHL, non-Hodgkin's lymphoma; PR, partial response.

Anti-CD22 Immunotoxin Therapy

CD22 has been targeted with F(ab")₂ fragments or intact murine IgG1 anti-CD22 antibody (RFB4) coupled to deglycosylated ricin-A chain (RFB4-dgA) in three separate trials (see Table 15.1-4). Forty-one patients with refractory or relapsed B-cell NHL received two to 12 doses of immunotoxin every 48 hours in dose-escalation studies (59,60). Immunotoxin was rapidly cleared from the serum [half-life 1.5 hours for F(ab")₂-RFB4 (60) and 7.8 hours for IgG-RFB4 (59)]. Thirty-eight percent of patients treated with the F(ab")₂ immunotoxin had a PR (60), and 25% of evaluable patients treated with the IgG immunotoxin responded (CR+PR) (59). In general, responses were rapid, and delayed tumor regression was not observed. The higher doses of immunotoxin were associated with fever, myalgia, and a vascular leak syndrome. Dose-limiting toxicity consisting of pulmonary edema, aphasia, and rhabdomyolysis was observed.

IgG-RFB4-dgA was given as an 8-day continuous infusion in an effort to increase the therapeutic index, because earlier results suggested that peak dosage rather than cumulative dosages contributed to toxicity. However, the maximum tolerated dose was similar to that obtained by bolus administration, and three of the four PRs occurred in patients receiving the highest dose level of immunotoxin (61). Toxicities were similar to those seen with bolus infusions. One-third of treated patients developed HAMA or human antiricin antibodies, or both.

A novel approach to targeting toxin to CD22 has been described. Two distinct bispecific antibodies against CD22 and the ribosome-inactivating toxin, saponin, were used in combination in five patients with relapsed low-grade B-cell NHL (62). Each antibody recognized different epitopes on CD22 and saponin, resulting in a high-avidity double-attachment of saponin to CD22. Patients received weekly infusions of immunotoxin, and substantial but incomplete tumor response was seen in all five patients. Responses, however, were transient. Disease progressed in each patient between 2 and 4 weeks after completion of therapy. The immunotoxin was well tolerated, with mild weakness, myalgias, and malaise reported. HAMA occurred in only one patient.

A critical disadvantage to the use of CD22 alone as a target is the marked heterogeneity of antigen expression on lymphoma cells (59). Tumor cells lacking CD22 either constitutively or during a portion of the cell cycle escape the tumoricidal effects of the immunotoxin. In one report, patients with tumors that expressed CD22 in less than 50% of the lymphoma cells had a lower likelihood of responding to anti-CD22 immunotoxin therapy (60). Anti-CD19 immunotoxins have been developed, in part, due to the more ubiquitous and homogeneous expression of CD19 on B-cell lymphoma.

Anti-CD19 Immunotoxin Therapy

Early clinical trials of anti-CD19 immunotoxin therapy determined the dose-limiting toxicities and maximum tolerated dose of blocked ricin conjugated to a murine IgG1 anti-CD19 MAb (anti-B4-bR) given in either bolus or continuous intravenous infusions in patients with relapsed or refractory B-cell lymphoma. Dose-limiting toxicity was reversible elevation of serum aminotransferase without impairment of hepatic synthetic function, and the maximum tolerated doses were 50 µg per kg per day for both routes of administration (63,64). Other common

adverse reactions included fevers, headache, malaise, and hypoalbuminemia, with occasional capillary leak syndrome. Marked thrombocytopenia occurred more frequently with continuous infusion of anti-B4-bR. HAMA and human antiricin antibodies occurred in the majority of patients between 12 and 92 days after initiation of therapy and increased clearance of MAb on rechallenge.

Collectively, results from 59 treated patients were reported with three CRs and five PRs (overall response rate, 14%) (63,64). Responding patients did not have bulky disease. Additional trials have been done with another immunotoxin consisting of deglycosylated ricin-A chain conjugated to murine IgG1 anti-CD19 antibody (HD37-dgA). In 40 patients with refractory NHL, two patients had CRs and two patients had PRs, although one CR was accompanied by fatal toxicities from HD37-dgA given at the highest dose (65,66). Similar serum concentrations of HD37-dgA and maximum tolerated doses were seen in patients receiving the drug via bolus or continuous infusion. The dose-limiting toxicities were vascular leak syndrome, aphasia, and rhabdomyolysis.

Because tumor response to immunotoxin therapy was observed more often in patients with lower burdens of lymphoma, clinical trials using immunotoxins as adjuvant treatment after chemotherapy have been performed. Anti-B4-bR was administered after ABMT in 12 patients with NHL in complete remission (67). The majority of patients had low-grade NHL. The maximum tolerated dose of a continuous infusion of the immunotoxin for 7 days was 20% lower than that seen in patients who had not undergone transplant, but the dose-limiting toxicities were similar. Based on this phase 2 trial, adjuvant posttransplant immunotoxin therapy was evaluated in a phase 3 multicenter trial. Patients in complete remission 2 to 4 months post-ABMT received two 7-day infusions of anti-B4-bR at 30 µg per kg per day. Seventy-five patients were randomized to observation and 82 were placed on immunotoxin therapy. Treatment with anti-B4-bR was well tolerated, but at interim analysis there was no statistically significant difference in disease-free survival between the treatment arms, although the trends in disease-free survival favored patients or the observation arm (68). This phase 3 trial has been closed due to the low likelihood of demonstrating benefit from the adjuvant immunotoxin therapy in this setting.

The response of NHL to a combination of anti-CD19 and anti-CD22 immunotoxins to overcome the problem of heterogeneous expression of B-cell antigens in lymphoma has been explored. A phase 1 trial of deglycosylated ricin-A chain linked to anti-CD19 mixed with deglycosylated ricin-A chain linked to anti-CD22 (Combotox) has been conducted and further trials using Combotox in states of minimal residual disease have been proposed (69). Published results of these trials, however, are not yet available.

The use of immunotoxin therapy has been investigated in a number of other areas. Anti-B4-bR has been infused into patients with multiple myeloma but too few patients have been treated to draw conclusions about rates of response (70). The use of anti-B4-bR to purge stem cells of lymphoma *in vitro* has also been explored (71).

Acquired immunodeficiency syndrome–related lymphomas have been treated with combinations of anti-B4-bR and chemotherapy. In one report, 26 of 44 patients received up to two 7-day infusions of anti-B4-bR along with up to eight cycles of methotrexate, bleomycin, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), and dexamethasone (m-BACOD) (72). Elevated serum levels of liver transaminases, thrombocytopenia, and infusion-related flu-like symptoms were seen. The overall tumor response for the 44 patients treated with chemotherapy was 57%. It is not known if the 26 patients who received immunotoxin benefited from this combined approach because they also received chemotherapy. Among the 26 patients, 15 had measurable disease at the time of immunotoxin therapy. Two patients with a PR after two cycles of chemotherapy had a CR to anti-B4-bR and additional cycles of m-BACOD.

Numerous combinations of antibodies and toxins are in development and show disease activity in preclinical models. An alternative approach to the use of antibody for the selective targeting of toxin to tumor is the use of cell surface receptor ligands. A trial of IL-2 conjugated to diphtheria toxin as treatment of IL-2 receptor–expressing malignancies was performed in 73 patients (73). NHL was only minimally responsive, whereas 37% of patients with cutaneous T-cell lymphoma responded.

Although powerful antitumor activity has been observed *in vitro*, a number of obstacles have become apparent for the clinical application of immunotoxins. The first is that even with modification, most immunotoxins have nonspecific interactions, resulting in excessive toxicity at the doses required for antitumor effect. Second, the toxins are highly immunogenic, which limits retreatment options. Third, some antigens are heterogeneously expressed on B-cell lymphomas, which limits the extent of tumor-cell kill on exposure to the immunotoxin. As better drug/toxin conjugates become available, including the use of novel BsAb, these agents alone or in combination with or after chemotherapy may yet succeed.

Clinical Trials of Radiolabeled Monoclonal Antibodies for Therapy of B-Cell Lymphoma

Part of "15.1 - B-Cell Lymphomas "

Radiolabeled MAb possess several properties that impart a theoretical advantage over other forms of immunotherapy for the treatment of NHL. These include the observation that lymphoma is usually sensitive to the ionizing effects of radiation. Beta particles emitted by commonly used radioisotopes [iodine-131 (^{131}I) and yttrium-90 (^{90}Y)] are tumoricidal over a distance greater than a cell diameter. Thus, internalization of the targeted antigen is not necessary, and antigen-negative cells may be killed by nearby bound radioimmunoconjugates. Unlike unconjugated antibodies, radioimmunoconjugates do not depend on immune effector systems or critical biologic events arising from the interaction of antibody with antigen. However, this increased antitumor activity occurs at the cost of dose-limiting toxicity. Because hematopoietic cells are sensitive to radiation, hematologic toxicity has been a significant problem and is dose limiting. Moreover, proper dosimetry determinations may require sophisticated imaging systems and nuclear medicine expertise. Last, treatment with radioimmunoconjugates may

require hospitalization for administration depending on state and local regulations.

Two general approaches to the treatment of NHL with radioimmunoconjugates have been pursued (Table 15.1-5). One approach has been to use a low dose of radioactive isotope administered at the maximum bone marrow tolerated dose. The other approach has been to use stem-cell transplantation to rescue patients from the hematologic toxicity of radiation and to treat with the maximum tolerated amount with respect to nonhematologic toxicity.

Table 15.1-5 Selected Clinical Trials Using Radioimmunoconjugates for Treatment of B-Cell Lymphoma

Target	Antibody	Disease	Isotope	Dose (mCi)	Patients (n)	Response	Problems	Studies
CD20	B1 (Murine)	Relapsed low- and intermediate-grade NHL	[131]I	34-161	28	14 CR, 8 PR	Minimal infusion toxicity, myelosuppression	Kaminski et al. (75), (76)
CD20	Y2B8 or B1 (Murine)	Relapsed low- and intermediate-grade NHL	[90]Y	14-53	18	6 CR, 7 PR	Myelosuppression requiring PBSC support in 2 patients, infection	Knox et al. (81)
CD20	B1 (Murine)	Relapsed NHL	[131]I	280-785	29	23 CR, 2 PR	With ABMT support, reversible cardiopulmonary toxicity	Press (95), Liu (96)
CD21	OKB7 (Murine)	Relapsed low- and intermediate-grade NHL	[131]I	90-200	18	1 PR, 13 mixed	Myelosuppression, HAMA	Czuczman (87)
CD22	IgG-LL2 or F(ab")$_2$-LL2 (Murine)	Refractory NHL	[131]I	15-343	21	2 CR, 2 PR	Myelosuppression, HAMA	Juweid et al. (97)
CD22	IgG-LL2 (Murine)	Refractory NHL	[131]I	90/m^2	3	2 PR	With ABMT support	Juweid et al. (97)
CD37	MB-1 (Murine)	Relapsed low- and intermediate-grade NHL	[131]I	234-628	6	6 CR	With ABMT support	Press et al. (92), (93)
CD37	MB-1 (Murine)	Relapsed low- and intermediate-grade NHL	[131]I	25-161	10	1 CR, 1 PR	Myelosuppression	Kaminski et al. (74)
HLA-DR	Lym-1 (Murine)	Relapsed diffuse large cell NHL	[131]I	37-384	25	3 CR, 10 PR	Mild infusion toxicity, HAMA	Lewis et al. (84)
HLA-DR	Lym-1 (Murine)	Refractory NHL	[131]I	52-290	21	7 CR, 4 PR	Myelosuppression, HAMA	Denardo et al. (85)
HLA-DR	Lym-1 (Murine)	Refractory CLL	[131]I	160-500	5	1 CR, 4 PR	Thrombocytopenia	Denardo et al. (86)
Ig idiotype	Anti-idiotype (Murine)	Relapsed low- and intermediate-grade NHL	[90]Y	10-54	9	2 CR, 1 PR	Myelosuppression, idiotype-negative escape	White et al. (91)

ABMT, autologous bone marrow transplant; CLL, chronic lymphocytic leukemia; CR, complete response; HAMA, human antimouse antibody; ^{131}I, iodine-131; Ig, immunoglobulin; NHL, non-Hodgkin's lymphoma; PBSC, peripheral blood stem cell; PR, partial response; ^{90}Y, yttrium-90.

Clinical Trials Using Nonmyeloablative Doses of Radioimmunoconjugates

Anti-CD37 Radioimmunotherapy

Kaminski and colleagues initially studied the effects of nonmyeloablative doses of ^{131}I-labeled murine-IgG1, anti-CD37 (MB-1) in patients with relapsed or refractory NHL (74). To limit hematologic toxicity, patients were required to have less than 25% marrow involvement with lymphoma. Eleven of 12 patients who received antibody labeled with trace amounts of isotope had radioimmunoconjugate uptake in areas of lymphoma. Uptake in tumor masses, however, was heterogeneous within patients, and doses of radiation to tumor were not much higher than doses delivered to normal organs. Ten patients subsequently received MB-1 labeled with a quantity of ^{131}I projected to deliver a whole-body radiation dose of 10 to 50 cGy. Most patients received a whole-body dose of 40 to 50 cGy. Thrombocytopenia and leukopenia were dose-limiting toxicities, and peripheral counts did not recover until 2 months posttherapy. Responses correlated with favorable imaging of tumor. One patient had a CR lasting 2 months, and one patient had a PR.

Anti-CD20 Radioimmunotherapy

The delivery of radiation to sites of tumor compared to normal organs was significantly improved by targeting CD20 with the murine IgG2a anti-B1 antibody and by pretreating patients with unlabeled (cold) antibody (75). The pretreatment with cold MAb blocked readily accessible CD20 in the blood, spleen, and marrow, allowing the radiolabeled MAb to penetrate lymph nodes and extranodal tumor masses. Infusion of 685 mg of cold anti-B1 before infusion of radioactive anti-B1 appeared optimal for targeting radioactivity to tumor (75,76). On average, tumors received 17 times the dose of radiation delivered to the whole body.

In a dose escalation study of ^{131}I-anti-B1, 34 patients with low- or intermediate-grade NHL received an initial trace radioisotope-labeled

dose (76). Three patients developed HAMA and did not receive further antibody treatment, and three patients had rapid progression of lymphoma before receiving treatment doses of [131]I. Twenty-eight patients were given an infusion of radiolabeled antibody calculated to deliver 25 to 85 cGy to the whole body. The maximum tolerated dose was 75 cGy due to myelosuppression. Hematologic toxicity in patients receiving whole-body doses of 75 cGy or less was mild to moderate unless the patient had undergone earlier bone marrow transplantation. Infusions of radiotherapeutic dosages of antibody were accompanied by fever and chills in 31% and 14% of the treatments, respectively. Fourteen patients (41%) achieved a CR and eight patients (24%) a PR. Complete remissions were seen at all of the whole-body dose levels studied. All of the low-grade, 60% of transformed, and 33% of *de novo* intermediate-grade NHL responded. The median duration of response was 1 year, and the median survival from study entry was longer than 4 years (77).

Preliminary results of a multicenter, phase 2 trial of radiolabeled anti-B1 (tositumomab) for therapy of refractory low-grade or transformed NHL have been reported (78). Sixty patients received 450 mg of unlabeled antibody followed by 5 mCi of ^{131}I conjugated to 35 mg of anti-B1 to calculate biodistribution. One to 2 weeks later, patients received cold antibody followed by tositumomab labeled with a quantity of ^{131}I calculated to deliver a whole-body radiation dose of 65 cGy or 75 cGy, depending on the pretreatment platelet count. A CR to therapy was seen in ten patients (17%), and PRs occurred in 30 patients (50%). The duration of remission after radioimmunotherapy was significantly longer than the preceding cycle of chemotherapy. In one report, 13 patients with NHL relapsing after an initial response to ^{131}I-tositumomab were retreated with ^{131}I-tositumomab (79). Eight patients (62%) responded with a median duration of response of 210 days, and three of six patients who had a CR to initial radioimmunotherapy had a CR to retreatment. One patient developed significant neutropenia and thrombocytopenia.

A phase 2 trial of ^{131}I-tositumomab in previously untreated patients with follicular lymphoma is ongoing. Preliminary results have been reported (80). The response rate in 21 evaluable patients was 100% with a 71% CR rate. Some patients in CR had no molecular evidence of lymphoma. Symptomatic HAMA developed in more than one-third of the patients.

Anti-CD20 antibodies labeled with ^{90}Y have also been evaluated in patients with NHL. Potential advantages include a greater path length of radiation from ^{90}Y compared to [131]I (5.3 mm versus 0.8 mm), decreased hazard of thyroid toxicity, and less exposure to staff due to the absence of gamma emissions. These advantages of ^{90}Y may result in more homogeneous doses of radiation delivered to tumor and allow for safer outpatient administration. In a phase 1/2 study, 18 patients with relapsed low- or intermediate-grade NHL were treated with 14 to 53 mCi of ^{90}Y-labeled anti-B1 or murine-IgG1 2B8 (81). Because ^{90}Y does not emit gamma radiation, biodistribution studies were performed with indium-111-labeled antibody before treatment. Patients received infusions of cold antibody before infusions of radioimmunoconjugates. Lymph node-based disease was poorly imaged in patients with splenomegaly. Fevers and rash were the most frequent nonhematologic toxicities. Thrombocytopenia and leukopenia occurred in most of the patients 3 to 6 weeks after treatment. Two of the four patients receiving 50 mCi of ^{90}Y met criteria for reinfusion of previously harvested, purged, and stored stem cells. CRs occurred in six patients (33%), and PRs were seen in seven patients. The median duration of response was 6 months. Patients without splenomegaly, bulky adenopathy, or large tumor burdens tended to have better responses. Current clinical trials are evaluating [90]Y-2B8 with rituximab, as the cold MAb and have demonstrated substantial activity in low-grade NHL (82). Another trial is exploring pretargeted radioimmunotherapy in NHL as a means to increase the therapeutic index of administered radioisotope. Rituximab conjugated to streptavidin was infused and allowed to penetrate tumor masses and lymph nodes. Circulating antibody was subsequently removed by a clearing agent and ^{90}Y conjugated to biotin was injected. In preliminary studies, the estimated tumor to marrow radiation dose was 75:1, suggesting that pretargeting antibody may allow delivery of significantly higher levels of radiation to tumor without myelosuppression (83).

Anti-HLA-DR Radioimmunotherapy

The murine IgG2a antibody Lym-1 recognizes an HLA-DR antigen on B-cell lymphomas and normal B-lymphocytes but has increased avidity for B-cell malignancies (6). Minimal activity was observed with weekly infusions of unconjugated Lym-1 (see Table 15.1-3). However, significant activity in aggressive B-cell NHL has been noted after treatment with ^{131}I or copper-67 radioconjugates of Lym-1 (84). One trial evaluated the effect of low doses of radiolabeled Lym-1 given in multiple infusions to simulate fractionated radiotherapy (84). Twenty-five patients with relapsed NHL received 20 to 60 mCi of ^{131}I-conjugated Lym-1 given every 2 to 6 weeks. Before infusions of radiolabeled antibody, patients were given 5 mg of cold Lym-1 to block nonspecific binding sites in the bloodstream. Three patients had a CR of disease and ten patients had PRs. Responses were observed only in patients who received cumulative doses of 180 mCi or more of [131]I. Median survival of responders was 18 months in contrast to a survival of 3 months in patients without a response. Infusion-related toxicities were mild.

A dose-escalation study was performed in 20 patients with relapsed NHL to determine the maximum tolerated amount of iodinated Lym-1 per infusion (85). One patient entered the study twice, thus 21 treatments were counted. Most of the patients had extranodal or bulky (>7 cm) disease, or both, but patients with more than 20% of marrow involved by lymphoma were excluded. Eleven patients received radiation therapy to sites of lymphoma. The dose of ^{131}I was escalated from 40 to 100 mCi per m^2 per infusion. Multiple infusions were given to 14 patients at 4-week intervals. Significant thrombocytopenia and neutropenia occurred in some patients at the higher doses, and 100 mCi was determined to be the maximum tolerated dose. Seven patients (33%) had a CR with a mean duration of 14 months. Four patients (19%) had PRs.

More low-grade and high-grade lymphomas responded than did intermediate-grade lymphomas (67%, 67%, and 42%, respectively). The median duration of survival in patients with responsive disease was 19.5 months compared to 1.9 months in patients without a response.

Approximately 40% of CLL cases demonstrate Lym-1 reactivity, but the percent of Lym-1–positive CLL cells in a patient can vary considerably (6,86). The effect of repeated infusions of low doses of iodinated Lym-1 on refractory CLL was studied in five patients (86). Patients received 30 to 60 mCi of ^{131}I-Lym-1 administered at 2- to 6-week intervals for a total dose of 160 to 500 mCi. One patient, who had a lower burden of disease, had a complete remission and survived more than 24 months after therapy. The four other patients had partially responding disease that relapsed quickly. Lymph-node based disease tended to respond better than circulating CLL cells. This may be related to the ability of radiation to kill nearby antigen-negative cells in lymph nodes, whereas circulating antigen-negative cells may be more likely to escape a radiation cross-fire effect.

Other Radioimmunoconjugates

A dose escalation trial of ^{131}I conjugated to murine-IgG2b anti-CD21 (OKB7) was conducted in 18 patients with relapsed or refractory low- or intermediate-grade NHL (87,88). Patients received doses of 30 or 50 mCi of ^{131}I conjugated to 25 mg of OKB7 given 2 to 3 days apart to a cumulative dose of 90 to 200 mCi. Myelosuppression was seen in four patients. HAMA developed in 12 of 16 assessable cases. One patient who received two courses of treatment of 90 mCi each achieved a PR after the second course. Most responses, however, were mixed and of short duration.

Exploratory trials of the anti-CD22 MAb LL2 labeled with low doses of ^{131}I have been performed in patients with refractory NHL (89). Six patients received infusions of murine IgG-LL2, 14 patients received murine F(ab")$_2$-LL2, and one patient received human-mouse chimeric LL2. Multiple infusions of antibody were given. The cumulative dose of ^{131}I administered ranged from 15 to 343 mCi. Lymphoma completely responded in two patients and partially responded in two patients. Duration of response was generally less than 6 months. Because CD22 internalizes after MAb binding, treatment with a radiometal-labeled (e.g., ^{90}Y) MAb may be preferable. Radiometals are trapped within the cell rather than being quickly excreted in the urine, as with ^{131}I (90).

Antiidiotype antibodies have been conjugated to ^{90}Y and infused into patients with relapsed follicular or diffuse, mixed small- and large-cell NHL (91). Patients also received large doses of unlabeled antibody before infusion of the ^{90}Y conjugate to block readily accessible Fc and nonspecific binding sites and to eliminate circulating idiotype protein. Two complete remissions and one PR were seen; however, the responses were not unequivocally due to effects of radiation because unconjugated antiidiotype antibodies also have antitumor activity (2). HAMA was seen in only one patient, but two of five assessable patients had progression of idiotype-negative tumors after therapy. The outgrowth of antigen-negative escape variants was previously shown to be a serious hindrance to successful antiidiotype therapy with unconjugated MAb (26).

Clinical Trials Using Myeloablative Doses of Radioimmunoconjugates

Anti-CD37 Radioimmunotherapy

Press and colleagues have explored the effects of high doses of radiolabeled MAb for the therapy of NHL (92). To overcome dose-limiting hematotoxicity, patients have been supported using ABMT. Initial trials used iodinated anti-CD37 antibodies (93). Biodistribution studies of MB-1 showed those patients with splenomegaly or large tumor burdens had poor localization of antibody to tumor compared to normal organs. Six patients with relapsed low- or intermediate-grade B-cell NHL were treated with therapeutic doses of radiolabeled MB-1. All six patients had low tumor burden; normal-sized spleens, or had undergone splenectomy; low amount of tumor in the marrow; and favorable biodistribution of antibody. Three patients, two patients, and one patient received an amount of ^{131}I calculated to deliver 10 Gy, 15 Gy, or 17 Gy or less, respectively, to the normal organ receiving the highest dose of radiation. Whole-body radiation dosages ranged from 100 cGy to approximately 300 cGy. Toxicities due to infusion of the antibody were mild nausea, urticaria, pruritus, and malaise. Myelosuppression occurred in all patients and was maximal 20 to 40 days after treatment. Hematopoiesis recovered spontaneously in three patients. Three patients were infused with previously harvested, purged, and cryopreserved autologous bone marrow because of neutropenia. All six patients had a complete remission of disease that lasted from 4 months to longer than 53 months.

Anti-CD20 Radioimmunotherapy

Press and colleagues found that the anti-CD20 antibody, anti-B1, was superior to MB-1 at targeting tumor more than normal tissue (93). Twelve patients with relapsed low- or intermediate-grade NHL were treated in a dose-escalation study with therapeutic doses of ^{131}I-labeled anti-B1 calculated to deliver 17 to 31 Gy of radiation to the organ receiving the highest dose of radiation in biodistribution studies. Eleven patients were supported with ABMT from 13 to 27 days after treatment. Mild nausea, fever, hyperbilirubinemia, and elevated levels of serum aminotransferase occurred frequently. Biochemical hypothyroidism and partial alopecia were also observed. Six cases of minor infection and three cases of serious infection occurred, but all resolved with antibiotic therapy. Life-threatening cardiopulmonary complications occurred in two patients who received a dose of 2,725 cGy or 3,075 cGy to the lungs. A CR of disease occurred in ten patients (83%), a PR was seen in one patient, and one patient had a minor response. Eight patients remain in continuous complete remission 46 to 95 months after therapy (94).

A phase 2 trial of myeloablative doses of ^{131}I-anti-B1 was performed to more closely define the maximum tolerated dose and efficacy in patients with relapsed low- and intermediate-grade B-cell NHL (95). Twenty-five patients were entered on study. Nineteen patients had favorable biodistribution of antibody

to the tumor. Three patients presented with large tumor burdens but achieved favorable biodistribution of antibody after receiving cytoreductive chemotherapy. One patient developed a HAMA response and did not receive a therapeutic dose of iodinated anti-B1. Four patients who were treated in the preceding phase 1 trial were included in the analysis of the phase 2 study results. Twenty-one patients were administered therapeutic infusions of anti-B1 labeled with a quantity of ^{131}I calculated to deliver 25 to 27 Gy to the normal organ receiving the highest dose of radiation (lung in 20 cases and kidney in one case). Frequent nonhematologic toxicities included nausea, mucositis, partial alopecia, elevated serum aminotransferase levels, and asymptomatic hypothyroidism. All of the patients developed severe myelosuppression and were reinfused with previously harvested, purged, and stored marrow (19 patients) or with previously mobilized and stored peripheral blood progenitor cells (two patients). Seven minor infections and three serious infections, one that was fatal, were reported. A dose of radiolabeled anti-B1 calculated to deliver 27 Gy to the lungs was confirmed to be the maximum tolerated dosage.

Nearly all of the treated patients had a major response, CRs were seen in 16 cases (76%), and two additional patients achieved a PR. Extended follow-up of 29 patients treated with myeloablative doses of anti-B1 has been published (96). Twenty-three CRs (79%) and two PRs to therapy were reported. Disease remained in unmaintained remission in 14 patients 27 to 87 months posttherapy. The estimated progression-free survival and overall survival at 4 years were 42% and 68%, respectively, with a median time to treatment failure of 37 months. The majority of these patients had follicular or transformed histology. To improve on these results, a phase 1/2 trial combining high doses of etoposide and cyclophosphamide with ^{131}I-anti-B1 was initiated. Approximately 80% of treated patients are in complete remission 1 to 34 months after therapy (94).

Anti-CD22 Radioimmunotherapy

High-dose radioimmunotherapy using anti-CD22 has also been studied. In a preliminary report of a phase 1 trial of high doses of ^{131}I conjugated to LL2, three patients received 90 mCi per m² (97). Two patients were assessable for response. One patient had a PR of 2 months and one patient had a PR of 8-months' duration. A full report of this trial has not been published. However, the modulation of the cell surface CD22 that occurs after MAb binding likely results in rapid cleavage of the ^{131}I and elimination in the urine. Further trials using the radio metals (such as ^{90}Y), which tend to be retained within the cell on modulation, are ongoing (90).

Conclusion

Part of "15.1 - B-Cell Lymphomas "

Immunotherapy, and specifically MAb therapy, has emerged as a viable option for the treatment of patients with B-cell lymphoma. Unconjugated MAb-based treatments, such as rituximab (anti-CD20), have demonstrated significant single-agent activity with manageable toxicity that allows use alone, combined with, or after current standard treatments with chemotherapy or radiotherapy. Although this antitumor activity is a benefit to patients, clinical trials are still required to determine if these combinations result in longer disease-free or overall survival. Additional unconjugated MAb, such as CAMPATH-1H, may also find a place in the treatment of small-lymphocytic or CLL histology.

Radiolabeled MAb have also demonstrated augmented antitumor activity, but with dose-limiting toxicity. It is likely that [131]I- or ^{90}Y-radiolabeled anti-CD20 MAb will soon be available for clinical use. The use of nonmyeloablative and myeloablative doses of these MAb with stem-cell support provide additional treatment options for patients with B-cell NHL. Toxin labeled MAb continues to show promise, but with significant obstacles yet to overcome. Again, clinical trial results are required to determine the optimal use of these new agents, their proper sequence, and proper combination with or after current treatments.

Overall, the future is bright, with these treatments entering expanded clinical trials and a myriad of new agents poised on the horizon. The concept attributed to Ehrlich (98) and made possible by the pioneering works of Kohler and Milstein (99) has finally begun to be realized through the antibody-based treatment of B-cell malignancies.

Introduction

Part of "15.2 - T-Cell Leukemia and Lymphoma "

The hybridoma technique of Köhler and Milstein rekindled interest in the use of antibodies in cancer patients (1). Monoclonal antibodies (MAb) have been put to a broad array of uses in the clinical care of patients with T-cell leukemia and lymphoma (2). They have been used in conjunction with flow microfluorometry to define the immunologic phenotype of abnormal cells, thus providing an approach for the classification of T-cell malignancies. Radioimmunoassays and enzyme-linked immunosorbent assay procedures have been used to monitor the serum levels of the released form of T-cell surface peptides such as those identified by anti-CD4, CD8, and CD25 [anti-interleukin-2 receptor (anti-IL-2R)]. In particular, the assessment of the serum level of the Tac peptide (CD25) has proven to be of value in the diagnosis of certain lymphoreticular malignancies, in determining prognosis, and tracking the efficacy of therapy of these lymphomas (3,4). An additional diagnostic use of MAb involves the *in vivo* administration of a MAb radionuclide conjugate in conjunction with radioimmunoimaging or immunoscintigraphy to define tumor-bearing sites (5,6,7 and 8). This approach has been used with a number of tumors, including cutaneous T-cell lymphoma (CTCL), to obtain valuable staging information without resorting to a surgical procedure.

MAb have also been used with therapeutic intent to modulate the host's immune response, to purge autologous bone marrow of neoplastic cells, and, after intravenous administration, for the immune elimination of the neoplastic cells *in vivo*. The purging of malignant or normal T cells from bone marrow represents an *in vitro* use of MAb (9,10,11,12,13 and 14). Antibodies, including anti-CD2, CD5, and CD7 in conjunction with complement, and antibodies conjugated to toxins or to magnetizable compounds have been used to purge malignant cells, including malignant T cells, from bone marrow before autologous transplantation. Furthermore, they have been used to purge normal T cells from marrow to prevent graft-versus-host disease (GVHD) in allogeneic transplantation. Finally, MAb directed against tumor-associated antigens have been used as antitumor agents *in vivo*. This use of MAb as direct antitumor agents is the focus of the remainder of the chapter. Initially, such MAb had only modest effects against tumor cells in clinical trials (15). However, as noted by Dickman, 11 antibodies have received U.S. Food and Drug Administration (FDA) approval (16). At the present time, FDA approval has been achieved for rituximab (Rituxan, anti-CD20), trastuzumab (Herceptin, anti-HER-2/*neu*), and daclizumab (Zenapax, anti-IL-2Rα, CD25), among others (17,18,19 and 20). A number of factors underlie the improved efficacy of MAb therapy for cancer. First, human or humanized antibodies have been developed that manifest reduced immunogenicity, have augmented effector functions, and have markedly improved pharmacokinetics with prolonged *in vivo* survival when compared to unmodified murine antibodies. A second critical advance is that more effective antigenic targets have been identified, including growth factor (GF) and death pathway receptors. In the case of GF-receptor cytokine deprivation, mediated apoptotic cell death of the leukemic cells can be induced by interdicting the interaction of the GF with its receptor. In particular, receptors for IL-2 and IL-7 have been targeted in monoclonal antibody therapy of T-cell leukemia and lymphoma (19,20,21,22 and 23). A third advance involves the arming of antibodies with toxins or radionuclides, thereby enhancing their effector functions.

Anti-T-Cell Leukemia and Lymphoma Effects of Monoclonal Antibodies

Part of "15.2 - T-Cell Leukemia and Lymphoma "

Several MAb have been used in the treatment of human T-cell leukemia and lymphoma, including anti-CD5 (T101, Leu-1), CAMPATH-1, CD4, CD7, IL-7R, CD3 anti-T-cell receptor idiotype, and CD25 (anti-Tac)–directed antibodies. The MAb that have been developed include unmodified MAb, humanized antibodies, toxin conjugates of these antibodies, as well as antibodies armed with α- or β-emitting radionuclides. Many of the early studies on the *in vivo* effects of murine MAb in patients with T-cell leukemia and lymphoma used anti-CD5 antibodies (e.g., anti-Leu-1, T101). Anti-CD5 antibodies recognize a 65-kd glycoprotein (designated *T65*) present on the surface of normal and malignant T cells and on chronic lymphocytic leukemia (CLL) cells (24). Miller and coworkers (25,26 and 27) treated seven patients with T-cell lymphoma with dosages of anti-Leu-1 antibody ranging from 250 μg to 100 mg. Antibody treatment usually caused a rapid fall in circulating T cells with a return to baseline levels within 24 to 48 hours, although five patients had tumor responses of 1.5 to 4.0 months. Subsequently, anti-CD5 antibodies, predominantly T101, have been used by a number of groups in therapeutic studies of patients with CTCL (28,29). It was shown that the T101 antibody binds to tumor cells of the bone marrow, lymph nodes, skin, and peripheral circulation if appropriate dosing schedules are used. Although in a significant proportion of cases there was a rapid decrease in circulating cell counts, there usually was a return to baseline levels within 24 to 48 hours. A number of factors appear to contribute to this very limited therapeutic value using anti-CD5 antibodies. Antigenic modulation in which the antigen disappears from the tumor-cell surface either by shedding or internalization without cell death has been demonstrated (26). This antibody is unable to initiate complement-mediated or antibody-dependent cell-mediated cytotoxicity (ADCC) with human cells *in vitro*. Furthermore, 50% to 100% of patients with CTCL receiving T101 in different series developed antibodies to mouse immunoglobulin (Ig) (30,31). Thus, although unmodified anti-CD5 antibodies were well tolerated when administered slowly, they did not provide a clinically meaningful therapeutic response in patients with T-cell leukemia or lymphoma.

Rosen and coworkers (8) used iodine-131 (^{131}I)–labeled T101 for therapy for five patients with CTCL using a therapeutic dose of 100.5 to 150.1 mCi of ^{131}I on 9.9 to 16.9 mg of antibody. Minor to partial responses (PRs) reflecting regression of the skin lesions and peripheral adenopathy lasting from 3 weeks to 3 months were observed. Acute toxicity included fever and pruritus and mild dyspnea in two instances. Myelosuppression was the limiting toxicity in patients receiving the higher doses of ^{131}I-T101. The majority of the patients receiving radiolabeled T-101 for radioimmunodetection or radioimmunotherapy developed human antimouse antibody responses.

In an alternative approach, an anti-CD5 antibody was armed with the A chain of the toxin ricin (32). In a phase 1 trial involving 14 patients with CTCL, the predominant toxicities included fever, chills, hypoalbuminemia, edema, and dyspnea. The patients often developed antibodies against the immunoconjugate. PRs lasting 3 to 8 months were documented in 4 of the 14 patients.

Dyer et al. (33) have used an alternative antibody (CAMPATH-1, CD52) *in vivo* in patients with lymphoid malignancies. The CAMPATH-1 antigen does not readily undergo modulation and is abundantly expressed on virtually all lymphoid cells and monocytes, but not on other cell types (34). These properties make it a potentially useful target for the treatment of lymphoid malignant disorders. The IgM (CAMPATH-1) is lytic with human complement and is widely used for depletion of T cells from bone marrow to prevent GVHD (35). The IgG2b (CAMPATH-1G) is potent for cell depletion *in vivo*, probably because it can both bind to human fragment (Fc) receptors and activate the complement system. Patients with lymphoid malignancies treated with CAMPATH-1G (25 to 50 mg per day for 10 days) manifested a profound reduction in lymphoid infiltration of blood and bone marrow and improvement of splenomegaly. However, treatment with this rat antibody is likely to be limited by human antiglobulin responses. Therefore, Hale and coworkers (36) used a genetically reshaped human IgG MAb (CAMPATH-1H) to treat two patients with non-Hodgkin's lymphoma. In both patients, lymphoma cells were cleared from the blood and bone marrow and splenomegaly resolved. No antiglobulin response was detected in either patient. Major responses were observed in 11 of 15 patients with T-prolymphocytic leukemia (T-PLL), 43% compared to 40% treated with deoxycoformycin. Complete remissions were observed with nine of the patients treated with CAMPATH-1. However, two responding patients developed severe bone marrow aplasia. Nevertheless, CAMPATH-1H is a potent lympholytic antibody that may have a place in the treatment of lymphoproliferative disorders (37).

The CD7 antigen expressed on more than 70% of normal T cells and on the malignant cells of T-cell acute lymphocytic leukemia (ALL) is an alternative therapeutic target. One limitation of this approach is that the CD7 antigen is not expressed by the mature malignant cells in most cases of CTCL or adult T-cell leukemia (ATL). The anti-CD7 antibody TH-69 was shown to be highly effective in the treatment of xenografted human T-cell ALL (38). Decreases in total lymphocyte and leukemic lymphocyte cells were observed in a phase 1 dose-escalation study in children with relapsed T-cell ALL (33). The Fc portion of the antibody was shown to be required for the action of TH-69, although no evidence of ADCC function was observed. In other systems, Clynes, Ravetch, and coworkers have demonstrated the requirement of host FcRI and III for select monoclonal antibody action (39). Mice deficient in FcRI and FcRIII associated with the deletion of their common gamma (γ_c) chain that were bearing a transplanted melanoma or HER-2–expressing tumor were not responsive to passive MAb therapy with an anti-melanoma MAb or with trastuzumab. In parallel studies, there was a 70% diminution in the action of rituximab in such $\gamma^{-/-}$ mice bearing transplanted B-cell tumors.

An anti-CD7-ricin-A chain immunoconjugate led to a significant depletion or elimination of leukemic T cells in two murine models of human T-cell leukemia (40,41). Similarly, a CD7-pokeweed toxin conjugate was effective in eliminating ALL cells in mice receiving this antibody, whereas all mice receiving

unconjugated antibody died (42). This agent elicited selective and potent cytotoxicity against primary clonogenic ALL cells of the T-cell lineage. In other studies, an anti-CD7-specific, scFv-ricin immunotoxin internalized into CD7-expressing human T-leukemic cells. Furthermore, scFv linked to ricin toxin-A chain inhibited protein synthesis in CD7-expressing Jurkat cells (43). The toxicity and immunogenicity of anti-CD7-dgA deglycosylated ricin-A chain coupled to a mouse monoclonal antihuman CD7 antibody was assessed in patients with T-cell lymphoma (44,45). The antibody toxin conjugate elicited modest antiricin and antimouse antibody responses. The dose-limiting toxicity was the vascular leak syndrome (45).

A chimeric (murine/human) anti-CD4 MAb was used in the treatment of seven patients with CTCL (46). No toxicity occurred. No coating by antibody of most CD4-expressing cells occurred in the blood, and there was no depletion of such circulating CD4-expressing cells. All patients had some clinical improvement, but responses were of short duration.

An IL-7 receptor-specific agent DAB_{389}-IL-7 involving the molecular linkage of IL-7 to a truncated form of diphtheria toxin was generated (23). It was selectively toxic to IL-7R-expressing cells. It therefore possesses potential as a therapeutic agent for IL-7-R-bearing hematologic malignancies, including T-cell leukemia and lymphoma.

One series of approaches directed toward the T-cell antigen receptor have been initiated. This approach may take advantage of a form of self-tolerance involving T cells that leads to apoptotic suicide of such cells (47,48 and 49). In this form of self-tolerance or activation-induced cell death, intense and persistent stimulus through the T-cell receptor leads to the induction of IL-2 and its receptor. The subsequent interaction of IL-2 with its receptor stimulates the entry of the cell into cycle. Restimulation of the T-cell receptor in such cycling cells leads to the production of Fas ligand by CD4 cells and of tumor necrosis factor-α by CD8 cells. T-cell death follows the interaction of these ligands with their specific receptors. Ashwell and coworkers (50) showed that the activation of murine T-cell hybridomas with antigen inhibits their growth *in vivo* with an irreversible block in cell cycle at the G_1/S interface observed. They demonstrated that administration of the appropriate antigen immediately after inoculation with the appropriate T-cell hybridoma abrogated tumor formation (50). Furthermore, they have found that antibodies directed against CD3 induced both IL-2 production and growth inhibition in a murine chemically induced T-cell lymphoma, EL-4, and a human T-cell leukemia (50). Additional studies have used antiidiotypic MAb to the T-cell antigen receptor. Previously, in elegant studies, Miller, Maecker, Levy, and their coworkers (51,52,53 and 54) used antiidiotype MAb in B-cell lymphomas with promising results. In the initial patient, there was an uninterrupted remission for the more than 4 years of observation. A PR was observed in approximately one-half of the remaining patients.

B-cell neoplasias, however, have certain disadvantages with this form of therapy. The idiotypic Ig molecules are shed into the circulation and may inhibit the infused MAb from reaching the tumor cells. An even greater problem is that during maturation, B cells utilize somatic hypermutation to increase their antigenic diversity. Thus, there is a virtually universal idiotypic heterogeneity within the B-cell tumor population, leaving B-tumor cells that escape the attack of the MAb (52,54). In this regard, the rearranged idiotypic T-cell receptor offers certain advantages as a target for MAb when compared with the idiotypic B-cell receptor. The T-cell receptor is not secreted to a significant degree. Additionally, T cells do not use somatic mutation to generate diversity during maturation. Furthermore, it has been suggested that antigen-like antiidiotypic antibodies could have a direct inhibitory effect on the growth of T-cell neoplasms (50). Janson and coworkers (55) prepared a murine antiidiotypic antibody (IgG2a) against the variable part of the T-cell receptor for antigen on a tumor cell of a patient with a CD3- and CD8-expressing T-cell CLL. The MAb did not stimulate the tumor cells to DNA synthesis. Three infusions of 1 to 10 mg of antiidiotypic MAb were given over a period of 4 weeks. During the observation period, an 80% reduction of the total leukemic cells was noted. Side effects of therapy were fever, chills, nausea, vomiting, diarrhea, tachycardia, and shortness of breath. Six hours after the third infusion, the patient died suddenly with clinical signs of cardiac dysfunction. Autopsy showed a myocardial infarction. In an alternative approach, antibodies directed to the CD3 component of the CD3 T-cell receptor complex have been used in one patient with T-cell leukemia who developed a PR (56). Furthermore, OKT-3 therapy of a patient with T-cell ALL led to a decrease in lymphoblasts and an increase in IL-2 responsiveness (57). Ricin-containing immunotoxins targeted to CD3 have been used to treat malignancies and GVHD (58). However, the nonselective T-cell depletion was associated with a high mortality rate from infections and failure of engraftment.

Interleukin-2 Receptor as a Target for Immunotherapy in Patients with T-Cell Leukemia and Lymphoma

Part of "15.2 - T-Cell Leukemia and Lymphoma "

As noted in the previous section, the earlier efforts to use MAb directed toward malignant T cells were relatively ineffective. One of the factors in this limited efficacy was that the antibodies used were not directed against a vital structure on the surface of the malignant T-cell such as a GF receptor required for tumor cell proliferation and survival. Our laboratory readdressed this issue using the IL-2 receptor alpha subunit, IL-2Rα, (CD25) identified by the anti-Tac MAb as a target for immune intervention (19,20,21 and 22,59,60,61 and 62). The remainder of the chapter discusses IL-2R-directed therapy as a model for the consideration of different approaches to the use of MAb in the treatment of leukemia and lymphoma. The scientific basis for this approach is that resting normal cells, including the normal cells of patients with leukemia, do not express IL-2Rα in contrast to select malignant T cells, including those of patients with human T-cell lymphoma or leukemia virus type I (HTLV-I)–associated ATL (21,61,62) and those with CTCL (63) that express this receptor. Furthermore, IL-2Rα is constitutively expressed by the malignant cells of hairy-cell B-cell leukemia and the Reed-Sternberg cells of Hodgkin's disease (64,65).

To exploit the differences in IL-2R expression between normal and leukemic cells, a number of IL-2R-directed approaches

have been introduced, including (a) unmodified murine antibodies (Mu-anti-Tac) directed toward IL-2Rα, (b) humanized versions of the anti-Tac MAb prepared by genetic engineering, as well as (c) the anti-Tac MAb armed with toxins or radionuclides. Finally, receptors (e.g., IL-2/IL-15Rß) shared by multiple cytokines (e.g., IL-2 and IL-15) as well as molecules in the signaling pathway (e.g., Jak3) used by diverse T-cell stimulatory interleukins (IL-2, IL-4, IL-7, IL-9, and IL-15) are being targeted for therapy of leukemia and lymphoma (20,61).

Interleukin-2 and Interleukin-2 Receptor System and its Signal Pathway

Part of "15.2 - T-Cell Leukemia and Lymphoma "

An analysis of the structure and function of the multisubunit IL-2R and the disorders in IL-2R expression in HTLV-I–associated ATL provide the scientific basis for rational IL-2R-directed therapy (61,66,67). Successful T cell-mediated immune responses require that these cells change from a resting to an activated state. The sequence of events involved in the activation of T cells begins when a foreign pathogen encounters the antigenic-specific receptor on the surface of resting T cells. This antigen-stimulated activation induces the synthesis of the 15-kd lymphokine IL-2(68,69). To exert its biologic effect, IL-2 must interact with specific high-affinity receptors. However, resting cells do not express high-affinity IL-2R, but they are rapidly expressed on T cells after activation with antigen or mitogen (59,66,67,70).

IL-2 is a glycoprotein with an apparent molecular mass of 15.5 kd that is made up of 133 amino acids (aa) in a short-chain four-helical bundle topology (66,67,68,69 and 70). Three forms of IL-2R can be distinguished based on their affinity for ligand, with IL-2–binding affinities of 10^{-11}mol/L, 10^{-9}mol/L, and 10^{-8}mol/L (67,70). Furthermore, there are three critical IL-2R subunits, IL-2Rα, IL-2Rß, and IL-2Rγ (59,71,72). IL-2Rα, identified by the anti-Tac MAb, is a densely glycosylated structure with an apparent molecular mass of 55 kd composed of 251 aa (59,60,66,70,73). Using cross-linking methodology with radiolabeled IL-2, Sharon and coworkers (71,74) defined a second 70- to 75-kd IL-2 binding protein, now termed *IL-2Rß*. Hatakeyama and coworkers (75) molecularly cloned the gene encoding IL-2Rß and demonstrated that the mature protein is composed of 525 aa. Takeshita and colleagues (76) identified a third IL-2R subunit, the 64-kda γ chain, that binds IL-2 and plays a pivotal role in binding IL-2, in facilitating IL-2 binding by IL-2Rß, and in receptor signaling. IL-2Rß and IL-2Rγ are members of the cytokine receptor superfamily. Shared features of these receptors include four conserved cysteine residues located in an extracellular domain and a Trp-Ser-X-Trp-Ser motif (WSXWS) located just outside of the membrane-spanning domain (77). Cytokines, such as IL-2, manifest considerable redundancy that is explained by sharing of common receptor subunits among members of the cytokine receptor family. Each of these cytokines has its own private receptor, but IL-2 also shares two of its receptor subunits. In particular, the ß chain (IL-2/15Rß) is shared by IL-2 and IL-15 and the $γ_c$ chain is shared by the five cytokines: IL-2, IL-4, IL-7, IL-9, and IL-15 that activate T cells (78,79,80 and 81). The IL-2Rα subunit associates with IL-2/15Rß and $γ_c$ subunits to form a high-affinity IL-2R complex (20,70,82).

The IL-2R in T cells and natural killer (NK) cells, like most cytokine receptors, does not possess intrinsic protein tyrosine kinase domains. However, receptor stimulation evokes rapid tyrosine phosphorylation of intracellular proteins, including the receptors themselves. The IL-2R binds Jak1 and Jak3, members of the Janus kinase (Jak) family of protein tyrosine kinases (83,84). Jak activation by IL-2 in turn leads to phosphorylation and nuclear translocation of STAT3 and STAT5, two members of the transcription factor family known as *signal transducers and activators of transcription* (STATS) (84,85).

Interleukin-2 Receptor Expression in Normal Individuals and in T-Cell Leukemia and Lymphoma

Part of "15.2 - T-Cell Leukemia and Lymphoma "

Resting T cells, B cells, large granular lymphocytes (LGLs), and monocytes do not express IL-2Rα; however, they can be induced to express this receptor (66,67). Most LGLs constitutively express only IL-2Rß and IL-2Rγ of the IL-2 system as well as IL-15Rα, the private receptor for IL-15 (86). Addition of IL-2 to LGL enhances NK activity and leads to the generation of lymphokine-activated killer (LAK) activity and IL-2Rα expression (87). In contrast to the lack of IL-2Rα expression in normal resting cells, IL-2Rα is expressed by abnormal cells in patients with certain leukemias and autoimmune diseases and is associated with allograft rejection (62,66). That is, some of the abnormal cells in these diseases express the Tac antigen on their surface. Furthermore, Nelson, Rubin, and coworkers (4) demonstrated that the serum concentration of the soluble form of IL-2Rα (sIL-2Rα) is elevated in patients with these disorders. In terms of neoplasia, certain T cell, B cell, monocytic, and even granulocytic leukemias express the Tac antigen (62,63,64 and 65). In particular, the malignant T cells of patients with HTLV-I–induced ATL constitutively express IL-2Rα (62). Furthermore, the malignant T cells of the skin and lymph nodes of patients with CTCL (mycosis fungoides and the Sézary syndrome) express the Tac antigen (63). Additionally, virtually all of the malignant cells of patients with hairy cell B-cell leukemia and a proportion of other B-cell lymphomas are also Tac positive (65). Finally, true histiocytic leukemia cells and the Reed-Sternberg cells of Hodgkin's disease also manifest IL-2Rα(64). In addition to these Tac-expressing leukemias and lymphomas, our laboratory group has shown that there are certain leukemias (e.g., ALL and LGL leukemia) that do not express IL-2Rα yet express the IL-2Rß subunit of the IL-2R (87). Autoimmune diseases may also be associated with disorders of IL-2Rα expression (88,89,90 and 91). A proportion of the mononuclear cells in the involved tissues express the Tac antigen, and the serum concentration of the soluble form of this receptor subunit is elevated. Such evidence of T-cell activation and disorders of IL-2Rα expression are present in more than 15 autoimmune diseases, including tropical spastic paraparesis/HTLV-I–associated myelopathy (TSP/HAM) (91). Finally, the Tac antigen is expressed by the T cells recognizing foreign transplantation antigens in individuals undergoing allograft rejection (20,66).

Our group focused its initial IL-2R immunotherapeutic studies on ATL, a distinct form of aggressive T-cell leukemia defined by Uchiyama and coworkers (92). ATL is an aggressive malignancy of lymphocytes displaying a multilobulated nucleus expressing a CD3$^+$, CD4$^-$, CD8$^-$, CD7$^-$, and CD25$^+$ phenotype that typically infiltrates the skin, lungs, and liver. The disease exhibits a striking clustering of cases in certain geographic regions, notably southwestern Japan, the Caribbean basin, northeastern South America, Central America, sub-Saharan Africa, and, to a lesser extent, the southeastern United States. The retrovirus HTLV-I is clearly associated with this disease and appears to play a major role in its pathogenesis (93,94,95 and 96). The majority of HTLV-I-infected individuals are asymptomatic carriers of the virus; however, an infected individual has approximately 0.1% per year risk of developing frank ATL. Although ATL has a wide range of clinical courses, in the majority of patients the principal clinical features include lymphadenopathy; hepatosplenomegaly; and skin, central nervous system, and pulmonary involvement. The occurrence of hypercalcemia is characteristic of ATL (97). Patients with acute ATL manifest a striking degree of immunosuppression and develop opportunistic infections such as *Pneumocystis pneumonia* and cryptococcal meningitis.

Interleukin-2 Receptor α as a Target for Therapy in Patients with Human T-Cell Lymphoma or Leukemia Virus Type I-Associated Adult T-Cell Leukemia

Part of "15.2 - T-Cell Leukemia and Lymphoma "

All populations of leukemic cells my colleagues and I have examined from patients with HTLV-I-associated ATL constitutively express high- and low-affinity IL-2R, including large numbers of the IL-2Rα (CD25) defined by the anti-Tac MAb (62). An analysis of HTLV-I and its protein products suggests a potential mechanism for the association between HTLV-I and constitutive IL-2Rα expression (94). The retrovirus HTLV-I encodes a 42-kd protein (termed tax) that plays an important role in the early phases of HTLV-I-induced malignancy by deregulating the expression of the cellular genes that encode IL-2 and IL-2Rα, thereby establishing an autocrine stimulation of proliferation that can be inhibited by anti-Tac *ex vivo*.

No conventional treatment program is successful in inducing long-term disease-free survival in ATL patients. A total of 854 patients with HTLV-I antibody-positive ATL newly diagnosed from 1983 to 1987 were analyzed for prognostic factors and survival after combination chemotherapy by Shimoyama and the Japanese Lymphoma Study Group (98). The median survival time and projected 2- and 4-year survival rates of all patients were 10 months, 28%, and 12%, respectively. However, the HTLV-I-induced ATL cells constitutively express the IL-2Rα chain identified by the anti-Tac MAb, whereas normal resting cells do not. This observation provided the scientific basis for IL-2R-directed immunotherapy with this MAb. IL-2R-directed immunotherapeutic agents could theoretically eliminate IL-2Rα-expressing leukemic cells or abnormally activated T cells involved in other disease states while retaining the Tac-nonexpressing normal T cells and their precursors that express the antigen receptors for T-cell-mediated immune responses. In initial studies, my colleagues and I administered unmodified murine anti-Tac to patients with ATL (21). Our goal was to inhibit the interaction of IL-2 with its GF receptors expressed on the malignant cells. Six of the 19 treated patients had a partial (four patients), or complete (two patients) remission, lasting from 1 month to more than 9 years after anti-Tac therapy (21). This was assessed by the demonstration of the elimination of measurable skin and lymph nodal disease, normalization of serum calcium levels, and routine hematologic and phenotypic analysis of circulating cells. Furthermore, elimination of clonal malignant cells was shown by molecular genetic analysis of HTLV-I proviral integration and T-cell antigen receptor gene rearrangement.

Humanized Antibodies to Interleukin-2 Receptor α

Part of "15.2 - T-Cell Leukemia and Lymphoma "

Although murine antibodies, such as murine anti-Tac, are of value in the therapy of human disease, their effectiveness is limited because rodent MAb have a short *in vivo* survival in humans, induce an immune response that neutralizes their therapeutic effect, and, as is the case with anti-Tac, are ineffective at recruiting host-effector functions. We addressed these issues by joining with Cary Queen in the development and evaluation of humanized anti-Tac [Hu-anti-Tac (daclizumab)] (99,100). The Hu-anti-Tac molecules retain the complementarity-determining regions from the murine antibody but have virtually all of the remainder of the molecule derived from human IgG$_1$κ. Hu-anti-Tac had improved pharmacokinetics when compared with the murine version. Hu-anti-Tac *in vivo* survival was longer (terminal half-life 103 hours vs. 38 hours in Cynomolgus monkeys and 20 days vs. 40 hours in humans). In addition, Hu-anti-Tac was markedly less immunogenic than murine anti-Tac when administered to monkeys undergoing heterotopic cardiac allografting or to patients with leukemia or lymphoma or those receiving renal allografts (101,102). Furthermore, in contrast to the parent murine anti-Tac, Hu-anti-Tac participated in ADCC with human mononuclear cells (100).

Trials Involving Hu-anti-Tac (Daclizumab) in Benign Conditions and Leukemia

Part of "15.2 - T-Cell Leukemia and Lymphoma "

On the basis of encouraging observations in preclinical trials and in phase 1 and 2 trials of Hu-anti-Tac, two double-blind (placebo-controlled) randomized trials involving 535 evaluated patients were conducted to determine the value of Hu-anti-Tac (daclizumab) in preventing renal allograft transplant rejection (19). In each trial, the patients received a standard immunosuppressive agent regimen (cyclosporin A and hydrocortisone in one study; cyclosporin A, hydrocortisone, and azathioprine in the other). The parallel treatment groups received either an intravenous placebo or a dose of 1.0 mg per kg of daclizumab before transplant and on four subsequent occasions separated by 2 weeks. No drug-specific adverse events or increased morbidity were observed. In particular, there was no increase in the incidence

of infections or of B-cell lymphoma in the group receiving daclizumab. Acute rejection episodes were reduced by 40% in patients treated with daclizumab (*p* <.001). Ninety-eight percent of the patients receiving triple immunotherapy and daclizumab retained their renal allograft for 6 months, whereas only 92% of the patients in the placebo control group retained their grafts (*p* <.02). On the basis of these phase 3 clinical trials, the FDA on December 10, 1997, approved daclizumab for use in humans (marketing clearance) to prevent acute kidney-transplant rejection (20). In addition to its use in the prevention of organ allograft rejection, daclizumab (Hu-anti-Tac) appears to be of value in the therapy of T-cell mediated autoimmune disorders such as T-cell mediated uveitis and TSP/HAM, a neurological disorder that results from HTLV-I infection leading to immune activation (103,104). In this disorder, as in ATL HTLV-I, encoded Tax transactivates the expression of IL-2 and the IL-2 receptor. Anti-Tac blocks the interaction of IL-2 with IL-2Rα. Finally, humanized anti-Tac therapy has been associated with remissions in patients with ATL, especially in patients with smoldering and chronic forms of the disease (T. Waldmann, *unpublished observation*).

Bifunctional Antibodies

Part of "15.2 - T-Cell Leukemia and Lymphoma "

Bispecific antibodies (BsAb) with two distinct binding activities have been generated to retarget cytotoxic NK cells or cytotoxic T-lymphocytes to tumor cells—that is, to induce cytotoxic cells to target and lyse cells they normally would not lyse (105,106). Such bifunctional antibodies have been prepared by chemical cross-linking, by disulfide exchange, or by the production of hybrid hybridomas. To be effective, the BsAb not only must be targeted to cytotoxic cells but also must activate these cells into functional effectors bypassing normal, major histocompatibility complex and antigen-specific restrictions. The most effective bispecific MAb used as their nontarget antigen specificity the CD3 peptide on cytotoxic T cells or the CD16 FcRIII receptor on NK cells. BsAb with specificity against tumor targets and against CD3- or CD16-effector cells were modestly effective in mediating tumor-cell killing *in vitro* and *in vivo*. For example, the murine anti-Tac MAb does not participate in ADCC with human mononuclear cells. In contrast, murine anti-Tac-CD3 and anti-Tac-CD16 bifunctional agents used in conjunction with peripheral blood mononuclear cells killed IL-2Rα–expressing targets (106). Thus, although problems associated with their manufacture remain to be resolved, BsAb show modest promise as therapeutic agents for ATL.

Monoclonal Antibody and Cytotoxic Agent Conjugates

Part of "15.2 - T-Cell Leukemia and Lymphoma "

During the progression of ATL, the malignant cells continue to express IL-2Rα but no longer produce or require IL-2 for their proliferation and survival. Nevertheless, the signaling pathway involving Jak1 and Jak3 and STAT5 remains activated (107). A number of factors underlie this IL-2–independent activation. HTLV-I Tax transactivates IL-15, which acts on the private IL-15Rα and on IL-2/15Rβ and γ_c shared with IL-2(108). Additionally, in IL-2–independent ATL cell lines there is a loss of the SH2-containing phosphatase (SHP-1), the phosphatase that normally inactivates Jak3 (109). Nevertheless, IL-2Rα is still expressed on the leukemic cells but not on the normal cells of the patients, thus providing a target for immunotherapy.

Interleukin-2 Receptor-Directed Immunotoxins

Part of "15.2 - T-Cell Leukemia and Lymphoma "

An additional IL-2R–directed approach to the therapy of ATL is based on the observation that ATL cells continue to express IL-2R during the late stages of the disease when they no longer require IL-2 and thus are no longer responsive to therapy with unmodified murine anti-Tac. In this approach, anti-Tac or IL-2 is used to deliver a toxin to IL-2R-expressing cells. In this strategy, one selects from nature a toxic protein and then modifies the toxin so that it no longer indiscriminately binds to and kills normal cells but instead targets and kills only cells expressing the receptor identified by the MAb or lymphokine. The majority of toxins targeted to cell surfaces by immunoconjugates act in the cytoplasm, where they inhibit protein synthesis. We have collaborated with Ira Pastan and Robert Kreitman and coworkers in the study of immunotoxins involving *Pseudomonas* exotoxin (PE) conjugated to agents that target the toxin to the IL-2R (110,111 and 112). PE is an enzyme that catalyzes adenosine diphosphate (ADP) ribosylation and inactivation of elongation factor II, a factor that is required for protein synthesis. A functional analysis by Hwang and coworkers (111) of deletion mutants of the PE structural gene demonstrated that domain I of the 66-kd PE molecule is responsible for cell recognition, domain II for translocation across membranes, and domain III for ADP ribosylation of elongation factor II, the step actually responsible for cell death. A PE molecule from which domain I had been deleted (PE40 or PE38) has full ADP-ribosylating activity but extremely low cell-killing activity when used without an associated targeting agent because of the deletion of the cell recognition domain. The PE40 was produced in *Escherichia coli*, purified, and conjugated to anti-Tac. The anti-Tac-PE conjugates inhibited the protein synthesis of Tac-expressing T-cell lines, but not that of lines not expressing IL-2Rα. However, immunotoxins made by chemically attaching a toxin to an intact antibody generate a protein that is heterogeneous with yields that are often poor. To circumvent this problem, IL-2-PE40, a chimeric protein composed of human IL-2 genetically fused to the amino terminus of the modified form of PE40, was constructed to provide an alternative (lymphokine-mediated) method of delivering PE40 to the surface of IL-2–expressing cells (112). IL-2-PE40 was produced by fusion of a complementary DNA encoding human IL-2 to the 5" end of a modified PE40 gene that lacks sequences encoding the cell recognition domain. The addition of IL-2-PE40 led to the inhibition of protein synthesis when added to a human T-cell line, HUT-102, expressing high-affinity IL-2R. IL-2-PE40 was effective in a series of rodent models; specifically, IL-2-PE40 inhibited the growth of murine T-cell lymphoma (113). Furthermore, by killing activated T cells, it prolonged the survival of cardiac

allografts in mice and prevented the development of adjuvant arthritis in rats (114). However, IL-2-PE40 was much less active against primate- and human-activated T cells than against mouse T cells, even though its binding to the IL-2R of the two species was similar.

Bracha and associates (115) performed parallel studies in which the portion of the diphtheria toxin gene that encodes the receptor-binding domain was genetically replaced with the complementary DNA encoding IL-2. Using this agent, they achieved prolongation of allograft survival and suppression of delayed hypersensitivity. Furthermore, the diphtheria toxin/IL-2 fusion protein inhibited protein synthesis by 60% to 80% in lymph node ATL cells, whereas protein synthesis in peripheral blood was inhibited by 20% to 57% in acute type and 3% to 13% in chronic ATL (116). Recombinant fusion toxins containing truncated diphtheria toxin, including DAB_{486}-IL-2 and, more recently, DAB_{389}-IL-2, have been tested in clinical trials (117,118,119 and 120). DAB_{389}-IL-2, which appears to require high-affinity IL-2 receptors for cytotoxicity, produced five complete responses (CRs) and eight PRs in 35 patients with CTCL, one CR and two PRs in 17 patients with NHL, and no responses in 21 patients with Hodgkin's disease (119,120). In a phase 3 trial in CTCL patients, seven CRs and 14 PRs were observed in 71 patients. The more frequent toxicities included transaminase elevations (62%), hypoalbuminemia (86%), hypotension (32%), and rashes (32%). DAB_{389}-IL-2 has been approved by the FDA for salvage treatment of CTCL (119 and 120).

CD25 has been targeted using a chemical conjugate for anti-CD25 MAb RFT5 with dgA (121 and 122). RFT5-dgA has been tested in a phase 1 trial in which 2 of 20 patients with Hodgkin's disease responded. More than 50% of the patients treated for at least two cycles made high levels of antibodies to the infused agent after the second cycle. Similarly, patients with hematologic malignancies treated with DAB_{389}-IL-2 had high rates of seroconversion detected by enzyme-linked immunosorbent assay (119,120,121 and 122).

To address the limited activity of IL-2-PE40 against human T cells, alternative molecules have been constructed in a search for a more active agent. This required the observation that active single-chain Fv fragments of antibodies can be produced in *E. coli* by attaching the light- and heavy-chain variable domains together with a peptide linker (123). Single-chain antibody toxin fusion proteins [anti-Tac(Fv)-PE40 and anti-Tac(Fv)-PE38] in which the variable regions of anti-Tac are joined in peptide linkage to PE40 or PE38 was constructed and expressed in *E. coli* (110). Anti-Tac(Fv)-PE38 was very cytotoxic to IL-2R–bearing human malignant T-cell lines but was not cytotoxic to receptor-negative cell lines. Furthermore, this toxin fusion protein inhibited proliferative responses induced by the mixed leukocyte reaction and by CD3 antibodies. Finally, anti-Tac(Fv)-PE38 was cytotoxic to freshly obtained ATL cells (124). This agent is more than 100-fold more active against freshly obtained ATL cells than IL-2-PE38. Thus, this drug has characteristics that suggest that it may be a useful IL-2R-directed therapeutic agent in patients with ATL (124). The anti-Tac(Fv)-PE derivative produced complete regression in mice of an IL-2R expressing human carcinoma (125). Therefore, in collaboration with Pastan and Kreitman, a phase 1 trial of the immunotoxin anti-Tac(Fv)-PE38 has been completed that evaluated the immunogenicity, toxicity, and efficacy of this oncotoxin in the treatment of patients with a wide variety of IL-2Rα-expressing leukemias and lymphomas, including hairy-cell leukemia (HCL) and ATL (126). Of the 35 patients treated, one HCL patient had a CR. Furthermore, there were seven PRs consisting of HCL (three), CLL (one), Hodgkin's disease (one), CTCL (one), and ATL (one). All five patients with HCL or CTCL and one of two patients with ATL responded.

Anti-Tac Armed with α- and β-Emitting Radionuclides

Part of "15.2 - T-Cell Leukemia and Lymphoma "

The action of toxins conjugated to MAb depends on their ability to be internalized by the cell and translocated to the cytoplasm. In fact, the toxin conjugates do not pass easily from the endosome to the cytosol. Furthermore, large protein toxins are immunogenic and thus provide only a narrow therapeutic window before the development of host antibodies directed toward the toxin. In the future, these problems should probably be resolved. To circumvent these limitations, however, radiolabeled MAb were developed as alternative immunoconjugates to deliver a cytotoxic agent to target cells. A number of advantages exist over other approaches in the use of radiolabeled MAb conjugates for therapy. One is that with the appropriate choice of radionuclide, radiolabeled MAb kill cells at distances of several cell diameters; therefore, a radiolabeled MAb binding to an antigen-expressing cell may kill adjacent antigen-nonexpressing cells, thereby overcoming the tumor-cell antigenic heterogeneity that presents a problem for most other MAb-mediated approaches. Furthermore, the radiolabeled antibody need not be internalized to kill the tumor cell. Nuclear chemistry has provided a selection of radioisotopes that could be linked to immunoproteins.

In studies performed in collaboration with Otto Gansow and Martin Brechbiel, we turned to α- and β-emitting radionuclides as cytotoxic agents that could be conjugated to anti-Tac (127,128 and 129). In initial studies, a series of linker agents was developed that did not compromise antibody specificity and did not permit premature release of the radionuclide *in vivo*. The choice of isotopes was based on the desire to have agents with a short distance of action that would act on the cell in question and on a small number of bystander cells without unwanted toxicity.

Radionuclides emitting α particles release high-energy emission (6 to 9 MeV) over a short distance (40 to 80 μm) and are efficient at killing individual target cells such as those found in patients with leukemia without significantly penetrating normal tissues. Suitable α-emitting radionuclides that are under investigation include ^{213}Bi, ^{212}Bi, ^{212}Pb, and ^{211}At. We have shown with *in vitro* studies that ^{212}Bi is well suited for immunotherapy (129). Activity levels of 0.5 μCi targeted by ^{212}Bi-labeled anti-Tac eliminated more than 98% of the proliferative capacity of HuT-102 cells, with only a modest effect on IL-2R–negative cells. In addition, an *in vivo* tumor model in nude mice was used to show that ^{212}Bi-labeled anti-Tac used at a dose that produced only modest toxicity was effective in preventing the

development of tumors expressing the Tac antigen (130). [211]At, with its longer physical half-life 7.2 hours versus 1 hour for [212]Bi and its almost pure α emission, appears to be even more suitable for therapy (128). Therefore, our group plans to initiate the clinical trials of [211]At-labeled anti-IL-2Rα MAb for the treatment of IL-2R-expressing leukemia and lymphoma.

The focus of the program involving IL-2R-directed MAb armed with radionuclides has been on the use of yttrium-90 (^{90}Y) linked to anti-Tac (22). We administered anti-Tac armed with ^{90}Y to 18 patients with ATL; initially, (the first nine patients) in a phase 1 dose-escalation trial and, subsequently, (the second group of nine patients) in a phase 2 trial involving a uniform 10-mCi dose of ^{90}Y-labeled anti-Tac. Patients undergoing a remission were permitted to receive up to eight additional doses (22). At the 5 to 15 μCi doses used, 9 of the 16 evaluable patients manifested PR (seven) or CR (two) induced by courses of ^{90}Y anti-Tac therapy. The duration of the seven PRs ranged from 1.6 to 22.4 months (mean, 9.2 months). Two additional patients developed a CR. The observations that support these conclusions concerning the favorable therapeutic responses include the demonstration of a reduction in size of all measurable lesions as assessed by physical examination, computed tomography scan, and γ-camera imaging studies after intravenous coadministration of indium-111 anti-Tac. Furthermore, the clinical responses in all patients with leukemia were associated with a reduction in the number of peripheral blood leukemic cells enumerated by fluorescence-activated cell-sorting analysis, by a decline in the serum IL-2Rα concentration, by a normalization of the Southern blot patterns of T-cell receptor ß gene arrangement, and by HTLV-I integration. The responses observed represent an improved efficacy in terms of length of remission compared with previous results with unmodified anti-Tac. Clinically meaningful (≥grade 3) toxicity was limited largely to the hematopoietic system.

Future Directions

Part of "15.2 - T-Cell Leukemia and Lymphoma "

Although IL-2Rα-directed therapy has met with considerable success, there are limitations in approaches directed solely to this receptor subunit. Antibodies to IL-2Rα do not inhibit IL-2-mediated activation of NK cells, which, in their resting state, do not express IL-2Rα but do express IL-2/IL-15Rß and γ_c (87). Furthermore, antibodies to IL-2Rα do not inhibit the action of IL-15 that utilizes its own private receptor (IL-15Rα) rather than IL-2Rα (131). Finally, anti-IL-2Rα antibodies alone do not provide the virtually complete immunosuppression of T-cell function that could be achieved if the actions of all the cytokines that stimulate T cells were inhibited. These limitations are relevant to leukemia therapy because certain leukemias, such as T-cell-type LGL leukemia, express IL-2/IL-15Rß and γ_c, but not IL-2Rα.

As noted earlier, there is a sharing of receptor subunits and signaling pathway elements between IL-2 and its receptor plus those of the other cytokines that stimulate T cells (79,80,81,82,83,84 and 85). A major corollary of this sharing of cytokine receptor subunits and signaling pathways among the cytokines is that therapy directed toward a shared cytokine receptor (e.g., IL-2/IL-15Rß or γ_c), or to a shared signal transduction element (e.g., Jak3) may yield more profound immunosuppression than can be achieved by an antibody directed toward a private receptor subunit such as IL-2Rα. Tinubu et al. (132) demonstrated that a humanized version of the Mikß1 antibody directed toward the IL-2/IL-15Rß that is shared by IL-2 and IL-15 prolongs renal allograft survival in Cynomolgus monkeys. Furthermore, we are evaluating the value of Mikß1 in the therapy of patients with T-cell-type LGL associated with granulocytopenia.

Many groups have initiated programs directed toward developing and evaluating inhibitors of Jak3 as agents for controlled immunosuppression. Jak3 is involved in the signaling of some cytokines, including IL-2 and IL-15 that use γ_c but is not essential for signaling by other GFs (83,84 and 85). Jak3 expression is largely limited to lymphocytes and hematopoietic cells. Jak3 deficiency in the autosomal form of severe combined immunodeficiency disease (Jak3-deficient SCID) in humans yields immunodeficiency but no disorders in nonimmunologic systems (133,134). In parallel, mice made Jak3 deficient by gene targeting manifested an absence of NK cells and abnormalities of T and B cells but, like the Jak3-deficient humans, do not have disorders in nonimmunologic systems (135). Taken together, these observations suggest that agents that inhibit Jak3 action may be of value as therapeutic agents in patients with T-cell leukemia or lymphoma. In conclusion, the emerging understanding of the IL-2/IL-15R system opens the possibility for more specific immune intervention and for the therapy of T-cell leukemia and lymphoma.

Summary

Part of "15.2 - T-Cell Leukemia and Lymphoma "

MAb are assuming an increasing role in diagnostic and therapeutic approaches to T-cell leukemias and lymphomas. An array of MAb, including CD3, CD4, CD5, CD7, CAMPATH-1, IL-7R, anti-T-cell antigen receptor, and CD25 (anti-Tac, anti-IL-2R) directed antibodies, have been evaluated as anti-T-cell leukemia agents. The anti-CD5 antibodies were generally well tolerated but were relatively ineffective. Factors in the low efficacy observed with the early use of MAb include the fact that murine MAb are immunogenic and that, in many cases, they were not cytocidal or cytostatic agents against human neoplastic cells. To circumvent the first of these problems, chimeric humanized forms of CAMPATH-1 that react with virtually all lymphoid cells and monocytes have been generated. Additionally, antiidiotypic antibodies directed toward the human T-cell receptor were evaluated as a therapeutic modality for human T-lymphoid malignancies. Furthermore, the IL-2R is proving to be an extraordinarily valuable target, because it is expressed by the T cells in individuals rejecting allografts and by the abnormal T cells in select patients with autoimmune disorders and with certain lymphoid malignancies, whereas it is not expressed by normal resting cells. To exploit this difference in IL-2R (Tac) expression, we have initiated therapeutic trials using unmodified murine anti-Tac, humanized anti-Tac, anti-Tac variable-region truncated toxin fusion proteins [anti-Tac(Fv)-PE38], and α- and ß-emitting radionuclide-armed anti-Tac. Humanized hyperchimeric anti-Tac molecules have been prepared by genetic engineering in which the molecule is entirely human IgG$_1$, except

for the small complementary determining regions that are retained from the mouse antibody. The humanized antibody manifests ADCC with human mononuclear cells that were absent in the parental mouse anti-Tac. Thirty percent to more than 50% of patients with HTLV-I-associated ATL developed a remission when treated with unmodified anti-Tac or with the antibody armed with the ß-emitting radionuclide ^{90}Y. Thus, the developing understanding of receptors for antigen and for lymphokines on the surface of malignant T-lymphocytes, together with the capacity to produce humanized forms of receptor-directed monoclonal antibodies and to arm these antibodies with toxins or radionuclides, provide a new strategy for the treatment of human T-cell leukemias and lymphomas.

Therapy of Systematic Metastatic Melanoma

Part of "15.3 - Melanoma "

A need exists to establish new and improved treatments for metastatic melanoma. Only a few agents have demonstrated antitumor activity against metastatic melanoma. In a review of phase 2 trials supported by the National Cancer Institute, only 2 of 30 tested drugs demonstrated a response rate greater than 10% (with 80% confidence limits) (1). The best single agents for treatment of melanoma are dacarbazine, nitrosoureas, cisplatin, interleukin-2 (IL-2), and interferon-α (2,3,4,5 and 6). Higher responses have been reported in preliminary evaluations using combinations of chemotherapeutic drugs with IL-2 and interferon-α (7), but these studies need to be confirmed.

Monoclonal antibodies (MAb) have been used alone (unconjugated) or conjugated to cytotoxic agents for the investigational treatment of melanoma. Two general applications of unconjugated MAb are being explored:

1. Activation of components of the immune system (e.g., complement, effector cells), including mediation of cytotoxicity against target tumor cells
2. Induction of active immunity (vaccination) through an idiotype-antiidiotype network

MAb conjugated to radionuclides, toxins, chemotherapeutic drugs, and other cytotoxic agents are also being pursued. Phase 1 studies in patients with melanoma have demonstrated that

mouse MAb can be safely administered to patients with cancer, and severe toxicity is uncommon. Objective responses have been observed. The major challenge is to develop more effective strategies for therapy.

Antigen Targets for Treatment of Melanoma

Part of "15.3 - Melanoma "

Several extensive reviews of melanoma antigens have been conducted, including a National Cancer Institute workshop that analyzed and compared MAb generated in different laboratories (8,9,10,11,12,13,14 and 15). Five antigen systems expressed by melanoma cells have been most thoroughly investigated as targets for therapy (Table 15.3-1):

Table 15.3-1 Cell Surface Antigens of Human Melanoma: Targets for Monoclonal Antibody Therapy

Antigen	Type of Molecule	Description
GD3	Glycolipid	Disialoganglioside
GD2	Glycolipid	Disialoganglioside
p97	Glycoprotein	95–97 kd; melanotransferrin (homology to transferrin)
gp75	Glycoprotein	TRP-1; 75-kd melanosomal glycoprotein (member of the tyrosinase gene family, homology to mouse *brown* locus gene product)
mCSP	Glycoprotein	240-kd core protein; fully processed protein >400 kd; mCSP

mCSP, melanoma chondroitin sulfated proteoglycan; TRP-1, tyrosinase-related peptide–1.

1. Melanotransferrin, also known as the *p97/gp95 antigen*
2. The melanoma chondroitin sulfated proteoglycan (mCSP), also known as the *high-molecular-weight melanoma-associated antigen*
3. The glycolipid antigens, GD2 and GD3
4. gp75, the most abundant glycoprotein in melanocytic cells

In all cases, the antigens are expressed on certain normal tissues, as well as melanoma. In general, however, the quantity of antigen expression by melanomas is considerably higher than normal cells, and this quantitative difference appears to be crucial for tumor targeting and selective antitumor effects.

Melanotransferrin (p97/gp95)

Melanotransferrin is a 95,000- to 97,000-d phosphorylated sialoglycoprotein that is identified by more than ten different MAb (16,17,18,19,20 and 21). At least five distinct epitopes on the antigen have been mapped (18). Using MAb against distinct epitopes on melano-transferrin, it has been possible to measure melanotransferrin expression on tumors and normal tissues (22,23,24 and 25). Small quantities of melanotransferrin are expressed on most normal adult tissues, particularly the uterus, bladder, muscle, colon, and liver. It appears that smooth muscle cells express the highest levels of melanotransferrin among adult tissues—as many as 8,000 molecules per cell. Certain fetal tissues have been found to have relatively high expression, particularly fetal colon. Most melanomas express much higher levels than normal tissues—50,000 to 500,000 molecules per cell. Thus, there is a 10- to 1,000-fold higher expression on tumor compared with normal cells.

Melanoma Chondroitin Sulfate Proteoglycan

A series of MAb recognize a high-molecular-weight complex (>500 kd), which has the properties of a proteoglycan (20,26,27,28,29,30,31,32,33,34 and 35). The melanoma proteoglycan is comprised of a 240- to 280-kd sialylated core protein with N-linked carbohydrate chains, to which are added high-molecular-weight chondroitin sulfate glycosaminoglycan side chains. The mCSP antigen (also known as *high-molecular-weight melanoma-associated antigen*) is expressed on most melanomas and nevi. Reactivity by MAb has not been detected with normal epidermal melanocytes, but cultured melanocytes express the mCSP antigen (8,20). Although the expression of mCSP appears to be relatively restricted in normal tissues, small blood vessels also express the antigen.

The gene coding for the core protein of mCSP has been cloned (36) and appears to be encoded or regulated by a locus on chromosome 15 (37). In serum-free medium, melanoma cells readily shed mCSP into the culture medium, and the molecule has the properties of a peripheral membrane component rather than an integral membrane protein. In serum-containing medium, however, the antigen is not shed. The mCSP antigen is expressed on microspikes at the cell surface of melanoma cells, a domain at the cell periphery that is involved in cell-cell interactions and contact of cell footpads to substrate (38). These findings suggest that mCSP helps mediate melanoma cell attachment to other cells and to substrates in tissues and could play a role in metastasis. Contact with substrate can induce mCSP expression in mCSP-negative somatic cell hybrids (37), suggesting that contact with tissue substrates are involved in regulation of mCSP. Binding of anti-mCSP MAb to melanoma cells *in vitro* leads to marked decrease in colony formation in soft agar, presumably through interference with cell-cell interactions (39).

Gangliosides GD2 and GD3

Gangliosides are glycolipid molecules composed of a sialylated oligosaccharide chain linked to a ceramide core consisting of fatty acids linked to sphingosine derivatives. The ceramide portion is inserted into the cell membrane. The diversity of gangliosides is determined largely by the composition of the oligosaccharide chains and the number and position of sialic acids. Melanoma cells are rich in gangliosides; the most prominent melanoma gangliosides are GM3 and GD3, followed by GD2 and GM2 (40,41 and 42). One notable feature of melanoma gangliosides is that the ceramide portion has a predominance of long-chain fatty acids (C22:0 and C24:0) compared with normal brain gangliosides (C18:0) (43). Several MAb that bind to melanoma have been found to react with the disialogangliosides GD2 (44,45 and 46) and GD3 (19,20,43,46,47). The fine specificity of these MAb is remarkable; MAb can distinguish GD3 from GD2, even though the two molecules only differ by a single sugar moiety (GalNAc). MAb against GD3 can also distinguish between the form of sialic acid residues linked to the oligosaccharide (*N*-acetyl versus *N*-glycolyl sialic acids) (48).

GD3 is expressed on some normal tissues, including subpopulations of neurons, adrenal medulla, melanocytes, and connective tissue in a variety of organs (20,47,49,50). It appears that the expression of GD3 in most normal tissues is considerably lower than on melanoma cells. Cultured normal melanocytes express only low levels of GD3, whereas melanoma cells express much higher levels (51). Transformation of cultured normal melanocytes by expression of the oncogene v-ras leads to a marked upregulation of GD3 with levels increasing by 10- to 1,000-fold (52). The tissue distribution of GD2 appears to be more restricted, but GD2 is also present in normal brain and other neuroectoderm-derived tissues. Like GD3, GD2 expression appears to be upregulated by transformation of melanocytes (13,53). Both GD2 and GD3 appear to be present in the serum of healthy individuals; a study in a small number of patients with metastatic melanoma has suggested that levels of GD2 and GD3 are elevated (54). Gangliosides and other glycosphingolipids have been presumed to play a role in cell-cell and cell-substrate recognition and in regulation of cell surface molecules, such as growth factor receptors. A potential role for GD2 and GD3 has been suggested by studies that demonstrate an association of GD2 and GD3 with cell surface receptors for vitronectin and fibronectin (55,56). These disialogangliosides appear to modulate the binding of these receptors to [Arg-Gly-Asp]-containing substrates, including vitronectin and fibronectin. This suggests that these gangliosides may play a critical role in the attachment of melanoma cells to tissue substrate.

Other gangliosides are potential targets for therapy of melanoma. MAb are available against GM2 (57), which appears to be more restricted on normal tissues but only is expressed on a subset of melanomas (58). Gangliosides can be modified by acetylation, and an O-acetylated variant of GD3 has been detected in human melanoma cells by MAb (59,60). 9-O-acetylated-GD3 is generally expressed at lower levels than GD3 but also may be present in fewer normal tissues.

gp75

Also known as *tyrosinase-related peptide-1*, gp75 is a member of the tyrosinase gene family and was initially defined by antibodies from a patient with melanoma (61). gp75 is the most abundant glycoprotein in melanocytic cells and is expressed by both pigmented melanomas and normal melanocytes. Preclinical animal experiments using a B16 lung metastasis model have shown that anti-gp75 immunotherapy, either passive immunotherapy infusing MAb against gp75 or active immunotherapy immunizing against gp75, results in an inhibition of lung metastases (62,63). Clinical trials are planned in which melanoma patients will be immunized against gp75 using the gene encoding gp75.

Therapeutic Uses of Unconjugated Monoclonal Antibody Against Melanoma Antigens

Part of "15.3 - Melanoma "

Mechanisms of Antimelanoma Effects

A subset of MAb is able to induce killing of target tumor cells. Two basic mechanisms have been identified: (a) antibody-dependent cellular cytotoxicity (ADCC) and (b) complement-mediated cytotoxicity. ADCC is mediated by the Fab portion of the antibody molecule binding to the target tumor cell and the Fc portion binding to a receptor (Fc receptor) on an immune effector cell. Two features appear to be important for effective mediation of ADCC: (a) the immunoglobulin isotype, with mouse immunoglobulin G3 (IgG3) and IgG2a and human IgG1 and IgG3 being most effective, and (b) characteristics of the antigen target, particularly density on the cell surface. Mouse IgG3 antibodies directed against ganglioside antigens GD3 and GD2 have been particularly effective for mediating tumor lysis *in vitro* in ADCC assays (64,65,66,67,68,69 and 70). The ganglioside GD3 is generally expressed at high density on melanoma, and although level of expression is related to susceptibility to lysis (46,70), other undetermined properties of GD3 may exist that are crucial for effective killing. Several cell types, each characterized by the expression of Fc receptor, have been found to mediate ADCC. Natural killer cells and monocytes can mediate ADCC both *in vitro* and *in vivo* (68,71,72 and 73). IL-2, an activator of natural killer cells, can increase ADCC mediated by a natural killer cell population both *in vitro* and *in vivo* (74,75). Granulocyte-macrophage colony-stimulating factor can also increase ADCC mediated by peripheral blood mononuclear cells (76).

Complement activation can potentially induce a variety of events, including increased capillary permeability, edema, chemotaxis, activation of leukocytes, and local tissue destruction. Target tumor cells can be lysed by complement activation and deposition at the cell surface, leading to formation of pores in the cell membrane. Again, mouse IgG3 MAb against GD3 and GD2 have been particularly effective in activating human complement leading to killing of target melanoma cells (77,78). Combinations of MAb directed against different determinants on the same molecule or against distinct molecules on the same cell have been found to induce substantially more cytotoxicity *in vitro* than either MAb alone (79,80). An important property of tumor cells may be their ability to resist or inactivate complement-mediated cytotoxicity. Factors produced by cells, including decay-accelerating factor and homologous restriction factor, can inactivate the complement cascade before formation of cytotoxic complement complexes, and melanoma cells have been found to produce some of these inhibitors (81,82).

Several antigens, mCSP and the gangliosides GD2 and GD3, are probably involved in cell adhesion, and MAb against these antigens may interfere with melanoma cell adhesion. For example, MAb against the ganglioside GD3 on melanoma cells can effectively block adherence to surfaces (49) and inhibit cell proliferation. Thus, MAb against GD3 might act directly on melanoma cells to inhibit cell attachment and proliferation.

Clinical Trials Using Unconjugated Monoclonal Antibodies

Phase 1 studies of unconjugated MAb (Table 15.3-2) have shown that the MAb can reach tumor sites after systemic administration. Most of the experience using unconjugated MAb in melanoma has focused on two antigens—GD2 and GD3 ganglioside. Toxicity has generally been mild to moderate, although maximum tolerated doses have been established for MAb against GD2 and GD3. For these MAb, dose-limiting toxicity is related to cross-reactivity with normal tissues expressing the antigen. Phase 1

clinical studies carried out at a variety of research centers suggest that treatment with MAb against gangliosides can induce major tumor regressions. Treatment with R24 (antiGD3), 3F8 (antiGD2), 14G2a (anti-GD2), and ME36.1 (antiGD2/GD3) MAb have induced partial and complete responses in patients with melanoma and neuroblastoma. Generally, in these studies, MAb have been administered systemically by an intravenous route, but regional therapy has been explored with limb perfusion (83) and intrathecal administration for meningeal disease (84) with evidence of antitumor effects. There appeared to be less human IgG antimouse antibody (HAMA) response in patients treated by regional perfusion compared with systemic treatment (83). In addition, studies by Irie and Morton have shown regression of cutaneous melanoma metastases after intralesional injection of a human IgM MAb against GD2 (85). Human MAb potentially offer distinct advantages—they may be less immunogenic than mouse MAb but have been difficult to produce in large quantities.

Table 15.3-2 Passive Immunotherapy Clinical Trials Using Unconjugated Monoclonal Antibody (MAb) Administered Intravenously to Patients with Melanoma

MAb	Antigen	MAb Doses Used	No. of Patients	Toxicity	HAMA (%)	Response	Reference
R24	GD3 ganglioside	8-1,200 mg/m²	103	Urticaria, nausea, diarrhea, malignant HTN, vascular leak syndrome, hypotension	96	2 CR, 8 PR	89,167,168,169,170 and 171
MG21	GD3 ganglioside	5-100 mg/m²	8	Urticaria, nausea	Most patients	1 PR	91 (and I. Hellstrom, personal communication)
14G2a	GD2 ganglioside	10-200 mg/m²	30 (23 melanoma)	Pain syndrome, neurotoxicity, SIADH, fever	93	2 PR in neuroblastoma	172,173
Chimeric 14.18	GD2 ganglioside	5-100 mg/m²	13	Pain syndrome, nausea	61	None	97
3F8	GD2 ganglioside	5-100 mg/m²	17 (9 melanoma)	Pain syndrome	60	2 PR	90,174
R24 + 3F8	GD3/GD2 gangliosides	1-10 mg/m²	14 (6 melanoma)	Pain syndrome	NR	None	95
ME 36.1	GD2/GD3 gangliosides	25-500 mg/m²	13	None	NR	1 CR >3 yr	175
9.227	mCSP	361-1,000 mg	21	Fever, nausea, serum sickness	25-37	None	86,87
96.5 + 48.7	mCSP/melanoTr	212 each mg	4	None	100	None	88

CR, complete response; HAMA, human antimouse antibody; HTN, hypertension; melanoTr, melanotransferrin; mCSP, melanoma chondroitin sulfate proteoglycan; NR, not reported; PR, partial response; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

A common feature of these trials is that the MAb used for treatment were immunologically active. The antiganglioside MAb efficiently mediated ADCC, complement-mediated cytotoxicity, or both. Several phase 1 trials in patients with melanoma using MAb that were less active in ADCC and complement killing have demonstrated no antitumor activity (86,87 and 88). These observations suggest an association between the *in vitro* immunologic effects of MAb and tumor responses observed in phase 1 trials. More studies, however, are needed to establish response rates, duration, and responsive sites for these MAb. Although direct cytotoxicity is an attractive mechanism for tumor killing, several clinical observations suggest that the antitumor effects of antiganglioside MAb are mediated by alternate or additional mechanisms: (a) tumor regressions often begin 4-10 weeks (and as late as 16 weeks) after starting treatment (89), and (b) tumor sites are characteristically infiltrated by T lymphocytes after R24 and 3F8 MAb treatment (89,90). An important finding in all of the studies discussed is that mouse MAb reaches tumor sites without evident localization to surrounding normal tissues (83,87,88 and 89,91). It is possible that the foreign mouse protein at the tumor site elicits a strong immune response, leading to tumor cell lysis (92) or triggering an active immune response against weak tumor antigens (93). This simple explanation is unlikely because other mouse MAb that also localize to tumor sites have not induced tumor responses. Alternatively, treatment with mouse MAb could immunize the patient against the target tumor antigen by eliciting an antiidiotype response (94).

It is possible that combinations of MAb may offer advantages over single MAb. Combinations, however, must be chosen rationally. A combination of MAb against GD3 (R24) and MAb against GD2 (either 3F8 or chimeric 14.18, a human mouse chimeric version of the anti-GD2 MAb 14G2a) have been assessed clinically in a small number of patients based on the following observations:

- The two MAb react with a higher proportion of tumor cells in melanoma biopsies than either MAb alone.
- R24 plus 3F8 mediate additive or synergistic complement-dependent cytotoxicity of melanoma targets *in vitro.*
- Both R24 and 3F8 have demonstrated major antitumor effects in phase 1 trials.

No tumor responses were observed in 14 patients (only six with melanoma) treated with a combination of R24 and 3F8 MAb (95).

In 20 evaluable patients treated with R24 and chimeric 14.18 in combination with IL-2, only one partial response was observed (96). These observations suggest that, despite *in vitro* analysis, antitumor effects of a combination of these MAb were not synergistic.

Among trials in which it was assessed, 60% to 100% of patients developed a human antimouse antibody (HAMA) response. In the setting of circulating HAMA, the pharmacokinetics of mouse MAb are significantly altered, resulting in rapid clearance of MAb and reduced tumor targeting. In an attempt to reduce the immunogenicity of MAb, mouse MAb have been "humanized" by either grafting the mouse variable domains onto a human IgG backbone (termed *human-mouse chimeric MAb*) or by grafting only the mouse complementarity-determining regions (termed *CDR-grafted MAb*). Because CDR-grafted MAb do not contain murine framework regions, these MAb may be less immunogenic than the chimeric MAb.

Thirteen patients were treated with chimeric 14.18 alone (97). Chimeric 14.18 had a half-life β of 181 hours, which is significantly longer than its murine counterpart 14G2a (42 hours). Chimeric 14.18, however, was immunogenic in patients because 61% of patients developed detectable antibodies against the MAb, although chimeric 14.18 was less immunogenic than the corresponding murine 14G2a. Because only a single dose of chimeric 14.18 was administered, it was not possible to determine whether this antichimeric 14.18 response affected the pharmacokinetics. When patients were treated with chimeric 14.18 and IL-2, only 10 of 24 (42%) patients developed an antichimeric antibody response (98). It is not clear whether this decrease in immunogenicity in the setting of concomitant IL-2 treatment is reproducible and whether it can improve the therapeutic effect of MAb treatment.

Therapeutic Uses of Unconjugated Monoclonal Antibody in Conjugation with Cytokines

Part of "15.3 - Melanoma "

Another strategy to enhance immune effects of MAb is the administration of cytokines in combination with MAb. Cytokines can augment ADCC mediated by MAb (74,76) and increase antitumor effects of MAb in animal models (75). It is also possible that cytokines can modulate the expression of cell surface antigens on melanoma cells (99), making the cell more susceptible to MAb-mediated killing. Treatment in animal models has demonstrated an increase in tumor targeting of an antimelanotransferrin MAb (measured as the percent of injected dose of MAb per g of tumor) in animals treated with interferon-α (100).

Clinical trials have been conducted in melanoma patients in which MAb were combined with a variety of cytokines (IL-2, granulocyte-macrophage colony-stimulating factor, macrophage colony-stimulating factor, tumor necrosis factor-α) to evaluate toxicity, *in vitro* cytotoxicity by mononuclear cells, and antitumor effects (Table 15.3-3). Combining MAb with cytokines introduces an additional level of complexity in which dose, schedule, and relative timing of the MAb and cytokine are undoubtedly critical factors. This is illustrated by the two trials combining R24 and IL-2(101,102). When R24 was administered before IL-2, only one partial response was observed in 20 patients (101). When R24 was infused 2 weeks after beginning IL-2 administration, however, 10 of 32 patients experienced a partial response (102).

Table 15.3-3 Passive Immunotherapy Clinical Trials Using Unconjugated Monoclonal Antibody (MAb) in Combination with Cytokines in Patients with Melanoma

MAb	Antigen	MAb Dose	Cytokine	No. of Patients	Response	Comments	Reference
R24	GD3	1-12 mg/m^2 qd, d 8-12	IL-2	20	1 PR, 2 MR	Increase LAK, ADCC, peripheral blood T cells	101
R24	GD3	5-100 mg/m^2	IL-2	32	10 PR	2 IL-2-related deaths	102
MG22	GD3	75 and 150 mg/m^2 /d, d 8-15	IL-2	7	None	Increased NK, LAK activity	176
XMMME-001	GD3	0.5 and 1 mg/kg /d, d 8-12	IL-2	9	1 MR	Increased LAK, possibly ADCC	177
Ch14.18	GD2	2-10 mg/m^2 /d	IL-2	24	1 CR, 1 PR	IL-2 decreased anti-id response to chimeric 14.18	98
Ch14.18 + R24	GD2, GD3	2-7.5 mg/m^2 /d; 1-10 mg/m^2 /d	IL-2	20	1 PR	Increased MAb-related toxicity	96
R24	GD3	8 mg/m^2 /d, d 1-5 and 8-12	IFN-α	8	2 MR	Decreased NK activity	178
Ch14.18	GD2	15-60 mg/m^2	GM-CSF	16	None	4/15 patients developed anti-ch14.18 antibodies	179
R24	GD3	10 and 50 mg/m^2 /d, d 8-15	GM-CSF	12	None	Enhanced ADCC	180
R24	GD3	1-50 mg/m^2 /d d 1-5	M-CSF	19	None	—	181
R24	GD3	10 mg/m^2, d 1,3	TNF-α	8	None	Tumor lysis syndrome in one patient, almost no viable tumor remaining	103
^{111}In-96.5	melanoTr	10 mg/m^2 qd × 5 d	IFN-α	5	Not stated	IFN-α altered MAb biodistribution	182

ADCC, antibody-dependent cellular cytotoxicity; GM-CSF, granulocyte-macrophage colony stimulating factor; IL-2, interleukin-2; IFN-α, interferon-α; LAK, lymphokine-activated killer cells; MR, minor response; NK, natural killer cells; PR, partial response; TNF-α, tumor necrosis factor-α; id, idiotype; melanoTr, melano-transferrin.

In an attempt to recruit neutrophils to mediate ADCC against tumors, a pilot trial was conducted in which melanoma patients were treated with R24, followed 6 hours later with tumor necrosis factor-α on days 1 and 3 (103). One of the

eight patients treated experienced a massive tumor lysis syndrome hours after treatment with almost complete lysis of bulky tumor in multiple visceral sites. The combination R24 and tumor necrosis factor–α certainly merits further investigation and suggests that this approach may provide a means to focus to power of the immune system against tumor sites.

Monoclonal Antibodies Conjugated to Toxins

Part of "15.3 - Melanoma "

A popular strategy has been delivery of cytotoxic agents to tumor sites by linkage to MAb. Although a wide variety of cytotoxic agents have been considered for conjugation, three classes have been studied most intensively in preclinical models: (a) cytotoxic drugs, (b) toxins, and (c) radionuclides. Vindesine, daunomycin, neocarzinostatin, and purothionin conjugated to MAb have shown antitumor effects in animal melanoma models (104,105,106 and 107). Critical issues remain for the use of immunoconjugates for therapy of solid tumors. Although tumor:normal tissue ratios of radionuclide are typically favorable in patients with solid tumors, the absolute amount of injected dose that localizes to tumor is usually low. Specificity and affinity of the MAb are probably crucial for tumor localization, but a number of other factors could greatly impact on targeting, including:

1. Tumor blood flow
2. Vascular permeability
3. Circulating antigen
4. Tumor size
5. Antigen expression and antigenic heterogeneity in the tumor
6. Tumor necrosis

Thus, in some animal models and under some conditions, control MAb can show the same tumor localization (or even better) compared with a specific MAb.

Toxins are among the most potent cytotoxic molecules in nature (108). They come from two sources: plants (e.g., ricin, abrin) and bacteria (e.g., *Pseudomonas* exotoxin A, diphtheria toxin). The most widely studied plant toxin is ricin, a natural product of beans from the plant *Ricinus communis*, which is an extremely potent inhibitor of protein synthesis. The molecule is composed of two chains, A and B, that are disulfide linked. The A chain is able to inhibit protein synthesis while the B chain mediates binding to the cell surface. Ricin and other immunotoxins have demonstrated antitumor activity against cultured melanoma cells and melanoma tumors growing in mice (109,110,111,112 and 113), but resistance to the toxic effect of immunotoxins can be striking (114,115). For cytotoxicity to be effective, the toxin must be delivered by the MAb into the cell, and the efficiency of delivery depends on the properties of the antigen target. Once inside the cell, the toxin must be able to translocate across a membrane into the cytosol, where it can inhibit protein synthesis. Resistance to the effect of immunotoxins could occur at any of these steps. An additional obstacle is that ricin is relatively immunogenic, and patients readily develop antiricin antibodies that interfere with tumor targeting of the immunotoxin. Despite these problems, immunotoxins remain an appealing strategy, particularly as understanding of the biologic properties of the MAb, antigen, and toxin increases.

Therapeutic Uses of Monoclonal Antibody Conjugated to Ricin

Immunotoxins constructed using ricin A chain conjugated to MAb against mCSP have been evaluated in clinical trials (116,117,118,119 and 120). Generally, mild toxicity (flulike symptoms and hepatic enzyme elevations) has been observed, allowing treatment to be administered in an outpatient setting in some cases (118). Antiricin antibodies were commonly observed (116,118,119,120 and 121). Treatment with cyclophosphamide alone or in combination with prednisone did not affect immunogenicity (119,120,122), but azathioprine plus prednisone seemed to decrease the immune response (121). Among the 64 reported patients, one complete response and three partial responses have been observed.

Monoclonal Antibodies Conjugated to Radionuclides

Part of "15.3 - Melanoma "

Radiolabeled MAb against melanotransferrin, GD3, mCSP, and other antigens have been shown to localize to human melanoma tumors growing as xenografts in rodents after systemic administration (49,123,124,125,126,127,128,129,130 and 131). The central nervous system appears to be a sanctuary because antibodies, which are large protein molecules, do not readily cross the blood-brain barrier. Treatment with high osmotic solution, however, can augment central nervous system uptake (132).

The diagnosis and therapy of melanoma with radiolabeled MAb has been reviewed (133). Important issues for clinical trials with radiolabeled MAb include:

1. Route of administration
2. MAb dose
3. Type and dose of radionuclide
4. Ability of MAb to react with antigen after labeling with radionuclide (immunoreactivity)
5. Biodistribution and pharmacokinetics of radiolabeled MAb
6. Ability of MAb to reach tumor (reported usually as percent of injected dose of MAb/gram of tumor)
7. The use of control MAb (because control MAb can often localize preferentially to tumor sites) (49)
8. Nonspecific uptake of MAb or isotope by organs, such as the liver
9. Stability of MAb-radionuclide complex *in vivo*

Each of these issues is important for diagnosis and therapy with radiolabeled MAb and, in many cases, diagnostic studies are used to gather information about therapeutic potential of MAb. Optimally, evaluation of radiolabeled MAb should also include dosimetry data derived from biopsies of tumor, bone marrow, and other tissues.

Clinical Studies Using Radiolabeled Monoclonal Antibody to Target Melanoma

Clinical trials using nontherapeutic doses of radionuclide for detection of melanoma lesions have investigated MAb labeled with indium-111, iodine-131, iodine-125, or technetium-99m. Blood or plasma half-lives after intravenous injection were relatively short for Fab fragments (ranging from 80 to 100 minutes) and longer for whole IgG molecules (20-100 hours). Up to 0.04% of the injected MAb could be detected per gram of tumor, but usually a much smaller proportion of the injected dose reached the tumor. Autoradiography of biopsied lesions has revealed that distribution of radiolabel within lesions can be uneven, in part because of antigenic heterogeneity, but primarily because of factors unrelated to antigen expression (134). Toxicity has been seen only rarely. Control MAb could often localize to melanoma lesions, although, in most cases, two to more than ten times lower concentrations than the test MAb. Antimelanoma MAb have not been found to target nonmelanoma tumors (135).

In imaging studies, sensitivity (number of tumor lesions detected/number of known lesions) range from 16% to 96%, although most studies demonstrated a sensitivity in the range of 43% to 96%. In anecdotal case, previously unsuspected sites of disease were detected (136,137) with the potential for altering therapy (138). Interest exists in the effect of unlabeled ("cold") MAb on the biodistribution and tumor targeting of radiolabeled MAb (129). In several studies, imaging of tumor sites was improved when high doses of cold MAb were injected (139,140,141,142 and 143). In addition to evaluation for systemic disease, radiolabeled MAb have been evaluated as agents to detect regional metastases by lymphoscintigraphy after injection subcutaneously (144). It is not possible to determine the diagnostic role of radiolabeled MAb in the evaluation of patients for metastatic melanoma, although it is clear that, in individual patients, radiolabeled MAb can detect unsuspected metastatic sites. Imaging with radiolabeled MAb has not proved superior to conventional imaging techniques in patients with melanoma. Further clinical trials to compare radiolabeled MAb imaging with physical examination and standard diagnostic procedures is necessary to assess the role of diagnostic imaging with radiolabeled MAb.

Therapeutic Uses of Radiolabeled Monoclonal Antibody in Melanoma

Clinical experience with radiolabeled MAb for therapy of melanoma is limited (Table 15.3-4). For radiolabeled MAb, bone marrow toxicity (thrombocytopenia, neutropenia) appears to be dose-limiting, although this may have to be reassessed with the availability of bone marrow transplant techniques and hematopoietic growth factors. One partial response has been observed in intraabdominal lymph nodes lasting 3 months after two doses of 181 and 193 mCi of MAb 48.7 (145).

Table 15.3-4 Therapy Trials Using Radiolabeled Monoclonal Antibody (MAb) in Melanoma Patients Administered Intravenously

MAb	Route of Administration	Antigen	MAb Dose	Isotope	Total Isotope Dose	No. of Patients	Toxicity	Response	Reference
96.5 Fab	i.v.	melanoTr	5-10 mg	[131]I	132-529 mCi	7	Hematologic, chills, fever, hypotension	None	183
96.5 Fab	i.v.	melanoTr	10 mg	[131]I	100-200 mCi	7	None	None	144
48.7 Fab	i.v.	mCSP	2-10 mg	[131]I	142-374 mCi	2	Hematologic	1 PR	145

[131]I, iodine-131; melanoTR, melanotransferrin; mCSP, melanoma chondroitin sulfated proteoglycan.

Regional Administration of Monoclonal Antibody

Part of "15.3 - Melanoma "

Several investigators have explored the possibility of administering MAb into isolated regions rather than injecting the MAb intravenously (Table 15.3-5). This was done to achieve high local concentrations of MAb (e.g., regional perfusion, intralesional injection) or to deliver MAb into regions where MAb would generally not have access (e.g., central nervous system). The largest experience is from Coit and colleagues, who used isolated limb perfusion in 12 patients to achieve high local concentrations of the anti-GD3 MAb R24 (83). Only one partial response was observed. Irie et al. reported that among eight patients injected intralesionally with a human anti-GD2 antibody, four partial responses occurred (85).

Table 15.3-5 Regional Administration of Monoclonal Antibody (MAb) in Patients with Melanoma

MAb	Route of Administration	Antigen	MAb Dose	No. of Patients	Response	Reference
R24	Regional limb perfusion	GD3	10-25-50 mg/m^2	12	1 PR	83
R24	i.t.	GD3	92/8 mg	2	1 CR (>6 yr)	170
Human L72	Intralesional	GD2	0.6-6.0 mg	8	4 PR	85
[131]I-Mel 14 F(ab")$_2$	i.t.	mCSP	7.7-10.2 mg (42-80 mCi)	7	Clearance of malignant cells from CSF; no objective tumor responses	184
454A12-ricin A chain	Intraventricular	Transferrin receptor	380 µg	1	None	185
[131]I-81C6	Intracavitary, brain	Tenascin	9.8 mg (40 mCi)	1	None	184

CR, complete response; CSF, cerebrospinal fluid; ^{131}I, iodine-131; mCSP, melanoma chondroitin sulfated proteoglycan; PR, partial response.

A small number of patients have received MAb administered directly into the central nervous system, either via the intrathecal route or injected directly into the ventricle or a surgically prepared cavity. Although this type of treatment can clear malignant cells from the cerebrospinal fluid as assessed by cytologic examination, no objective antitumor responses have occurred.

Antiidiotype Monoclonal Antibodies as Vaccines

Part of "15.3 - Melanoma "

The antigen-binding or complementarity-determining region of antibodies can be antigenic. Thus, an immune response can be directed against determinants within or near the antigen-binding site, and the term *idiotype* refers to the collection of these determinants. Idiotype determinants are uniquely expressed on antibodies directed against a single antigen or are shared by small families of related antibodies. Antibodies directed against idiotypic determinants are called *antiidiotypic antibodies*. Some antiidiotype MAb bind directly within the antigen-binding site, forming an image of the antigen. This subgroup of antiidiotype MAb can mimic the antigen and provide an alternative

source of "antigen" for immunization. Antiidiotype antibodies have been used to immunize against a wide spectrum of viral (146,147,148,149,150 and 151), bacterial (152,153,154 and 155), and parasitic (156,157) antigen agents, as well as against tumor antigens (158,159,160 and 161). Antiidiotype vaccines offer potential advantages over purified antigen:

- They are a reproducibly pure source of "antigen," particularly where antigen is either hard to purify or is potentially dangerous (e.g. viruses).
- Antiidiotype antibodies may be able to induce an immune response or break immunologic tolerance in circumstances in which immunization with antigen is poorly immunogenic.

Antiidiotype MAb have been produced that mimic melanotransferrin (161), mCSP (160,162), GD3 ganglioside (158), GD2 ganglioside (163,164 and 165), and GM3 ganglioside (166). Immunization of animals with these antiidiotype MAb induce immune responses against purified antigen or antigen-positive melanoma cells. These mouse anti-id MAb are the basis for a novel strategy for antimelanoma vaccines.

Clinical trials have been carried out in melanoma patients using antiidiotypic MAb that mimic mCSP, GD3 ganglioside, or GD2 ganglioside (Table 15.3-6). These patients have had either metastatic melanoma or were at high risk for recurrence after being rendered free of disease after complete surgical resection. Experimental end points have generally been safety, induction of antibody responses against antigen (mCSP, GD3, or GD2), and tumor shrinkage in patients with active disease.

Table 15.3-6 Selected Clinical Trials Using Antiidiotypic Monoclonal Antibody (MAb) Vaccines in Patients with Melanoma

Antiidiotypic Vaccine	Antigen	No. of Patients	Disease Status	Results	Reference
MF11-30 MAb	mCSP	25	Metastatic	6 minor responses	186
MF11-30 MAb	mCSP	37	Metastatic	Antimelanoma antibodies not detected; 1 CR	162
MK-23 MAb conjugated to KLH, BCG adjuvant	mCSP	25	Metastatic	14/23 developed antibodies to antigen-positive melanoma; 3 PRs	160
MELIMMUNE-1 + SAFm adjuvant	mCSP	34	NED	Antibodies to mCSP identified in a subset of patients	187
MELIMMUNE-2 + SAFm	mCSP	26	Metastatic	1 PR	188
BEC2 MAb (and BEC2 conjugated to KLH), BCG adjuvant	GD3 ganglioside	32	NED	7/32 developed anti-GD3 antibodies	189,190
1A7 + QS21 adjuvant	GD2 ganglioside	12	Metastatic	Purified serum contained anti-GD2 antibodies; 1 CR	165

BCG, bacille Calmette-Guérin; CR, complete response; KLH, keyhole limpet hemocyanin; mCSP, melanoma chondroitin sulfated proteoglycan; NED, no evidence of disease; SAFm, syntax adjuvant formulation.

Several general conclusions are suggested by these data. First, these vaccines have been safe and have resulted in only minor toxicity. Second, it is possible to induce antibodies against melanoma antigens using murine antiidiotypic MAb vaccines. Murine antiidiotypic MAb alone, however, are not adequately immunogenic; these vaccines must be formulated with potent immune adjuvants. The experience with antiidiotypic MAb mimicking mCSP further suggests that murine MAb do not elicit help from T lymphocytes and that these molecules need to be presented on an appropriate carrier molecule, although this has not been definitively determined. Third, only a minority of patients responded immunologically, and titers induced against the tumor antigens have been low. Despite this, objective tumor responses have been observed in occasional patients. Although this strategy of immunization is exciting and potentially powerful, it remains to be determined whether this form of vaccine can be optimized to induce consistently specific immune responses against tumor antigens and whether these immune responses will have beneficial therapeutic effects.

Future Directions

Part of "15.3 - Melanoma "

MAb with potent inflammatory effector functions can induce major tumor responses in patients with metastatic melanoma.

R24, an MAb against GD3 ganglioside, is active against metastatic melanoma, and the response rate with R24 is similar to the response rates observed with single agent chemotherapy drugs and interferon-α. Efforts to improve the inflammatory effects of MAb by combining them with cytokines have been unsuccessful. A major barrier, however, has been the immunogenicity of MAb. Most of the MAb used in melanoma trials have been of mouse origin and, as a result, induce human antimouse antibodies in the patients. This limits the ability to treat patients over a prolonged period. It was hoped that chimeric MAb might prove less immunogenic, but experiences with chimeric 14.18 demonstrate that the presence of murine framework regions can be immunogenic. Fully humanized MAb, or CDR-grafted recombinant MAb, although more technically difficult to produce, offer the possibility of significantly lower immunogenicity.

Recombinant CDR-grafted MAb can also be engineered as antibody fragments (e.g. Fab, Fv). Because of their much smaller size, these fragments may be superior to complete immunoglobulin at targeting melanoma tumors. These fragments may improve the delivery of radionuclides or toxins to tumors.

MAb tested to date have targeted differentiation antigens on the surface of melanoma cells. An alternative (or complementary) strategy is to target antigens on tumor vasculature. Initial trials in other tumor systems are under way, and future MAb trials in melanoma might exploit the fact that melanoma tumors are devoid of cellular stroma and depend entirely on neovascularization for tumor support.

Antiidiotypics MAb are being used as surrogate antigens for active immunotherapy trials in three melanoma antigen systems. It is clear that antiidiotypic MAb can induce antibody responses against defined antigens, and ongoing trials will explore methods to optimize the immunogenicity of these antiidiotypic MAb, such as novel adjuvants and alternative routes of administration. If specific immune responses can be generated reproducibly against melanoma antigens, randomized phase 3 trials will be required to determine whether these vaccines can impact on the natural history of the disease.

Future approaches may also exploit the constant regions of the immunoglobulin molecule. Many biologically active proteins have half-lives in the range of minutes, which significantly compromises their usefulness. The pharmacokinetics of such molecules may be improved by conjugation to an immunoglobulin structure. Such a recombinant molecule may provide prolonged serum half-lives for such agents.

Breast Cancer and Other Adenocarcinomas

Margaret von Mehren

Louis M. Weiner

Introduction

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

The primary impetus behind the development of therapeutic and diagnostic strategies using monoclonal antibodies (MAb) has been the specific targeting properties of these molecules. The development of hybridoma technology (1) ushered in a new era in antibody therapy. It allowed the production of significant amounts of MAb for evaluation as oncologic therapeutic agents. Since the early 1990s, the ability to alter antibody structures and binding capabilities through protein engineering has further allowed the development of effective cancer therapies. An increasing number of antibodies are available for both diagnostic purposes and for therapy. This chapter focuses on antibody-based therapeutic agents and strategies for the treatment of solid tumors, with a primary focus on breast cancer. The fundamentals of therapeutic antibody structures and their limitations are discussed. The diagnostic utility of antibodies in pathology and radiology are reviewed. Targets on adenocarcinomas and therapeutic antibodies are discussed.

Basics of Antibodies

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

The structures of antibody-based therapeutic agents have expanded with the development of recombinant engineering technology (Fig. 15.4-1). Most therapeutic antibodies are IgG molecules, which contain two heavy chains with covalent linkages to two smaller light chains (see Fig. 15.4-1). Within each of these chains are constant and variable domains. The specificity of the antibody-binding site is conferred by these variable domains, as is the strength (affinity) with which the antibody binds to its target. The advent of phage display library techniques has also allowed for rapid screening and production of useful antibodies (2). Additionally, site-directed mutagenesis techniques and chain-shuffling have allowed for the production of antibodies with greater binding capacity for a particular antigen, which may allow for greater retention of antibodies at tumor sites (3).
FIGURE 15.4-1. Schematic diagram of an immunoglobulin G (IgG) molecule. There are two heavy chains consisting of one variable chain (V_H) and three constant domains (C_H1–3) linked by three interchain disulfide bonds. Linked to the heavy variable and first constant domain is the light chain, which also contains a variable and constant chain. The antigen-binding site is contained within the variable chains.

Enzymatic digestion and recombinant engineering techniques have led to the production and testing of smaller antibody-based structures (4), which are better able to reach tumor targets, but also are cleared more rapidly via renal excretion (5) (Fig. 15.4-2). Enzymatic digestion of the Fc portion of the antibody molecule produces Fab or F(ab")$_2$ fragments (6,7). Recombinant technology has facilitated the production of single-chain Fv (scFv) fragments, which contain the variable domains of both the light and heavy chains, connected by a short amino acid link. A bivalent form of an scFv can be constructed by adding carboxy terminal cystine residues to scFv, followed by chemical conjugation of two scFv, yielding a covalently linked structure (scFv")$_2$. These smaller structures overcome some of the limitations of larger antibody structures, as discussed in the section Limitations to Antibodies, and therefore are ideal candidates for imaging. Other antibody fragments have also been developed, but have had limited clinical applications to date and therefore are not reviewed here.
FIGURE 15.4-2. Schematic representations of smaller antibody structures. Diagrams (A) and (B) represent structures that are produced by enzymatic digestion of an immunoglobulin G molecule, whereas structures (C) and (D) are derived by recombinant engineering. These structures have mono- (B and C) or bivalent (A and D) antigen-binding site(s). A bivalent binding site is produced in an (scFv")$_2$ by adding a cysteine-containing linker to the carboxy terminus of the V_L chain of an scFv to allow two scFv to bond via a disulfide bond.

The ability to alter protein structures allows for the production of antibodies with altered constant or variable domains, or with additional moieties. Initially, antibodies were derived by immunizing an animal, usually a mouse, with a human antigen, followed by the production of large quantities of antibodies by hybridomas obtained by the fusion of murine splenocytes with myeloma cell lines (1). The antigenicity of such murine antibodies limits some therapeutic applications in humans. The variable domains of an antibody can now be cloned into human constant domain regions, markedly decreasing the antigenicity of the antibody (8). This allows for repeated administration of these agents without inducing an immune response that rapidly clears the infused antibodies. Antibodies also can be modified by adding additional protein structures. For example, immunomodulatory compounds that can activate the immune system, such as superantigens (9), immunotoxin (10), or cytokines (11) have been produced as chemical conjugates or fusion proteins. Radioactive elements have long been conjugated to antibodies, allowing for targeted

radiation. Similar approaches to target chemotherapeutic agents have been attempted, particularly with enzymes to activate prodrugs (12), thus targeting the tumor site for drug activation. Another pretargeting strategy uses antitumor antibodies fused to streptavidin (13,14 and 15). Then a biotinylated compound such as a cytokine, drug, or radioactive compound can be selectively accumulated at antibody-pretargeted tumor sites due to the high-affinity interaction between streptavidin and biotin. This approach may limit the toxicity associated with cytokines, chemotherapeutic agents, and radiation.

Another advance has been the development of bispecific antibodies (BsAb), which consist of two antibodies with specificity for distinct antigens (16). These constructs have been synthesized by covalently linking two MAb (17) or MAbFv (18) by the production of hybrid hybridomas (19), or by engineering recombinant bispecific molecules (20). This allows for the targeting of two different tumor antigens found on tumor cells or the simultaneous engagement of a tumor-associated antigen and a cytotoxic trigger molecule on effector cells. The rationale for the first approach is the hypothesis that the binding of two different antigens on tumor cells enhances targeting selectivity or may interrupt normal cellular metabolism by interfering with the function of either or both ligands (21). The second approach allows for targeting of an immune effector cell directly to a tumor cell, enhancing the immune response against the tumor. The majority of BsAb are of the latter type. A third strategy has been to combine a tumor-targeting antibody and an antibody with specificity for a therapeutic

agent to specifically target the drug or radiotherapeutic compound at tumor. Many of these molecules still are undergoing preclinical testing, while others have reached clinical trials and are discussed later in this chapter.

Mechanisms of Tumor Killing by Antibodies

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

Antibodies may direct antitumor effects by inducing apoptosis (22), interfering with ligand-receptor interactions (23), or by preventing the expression of proteins that are critical to the neoplastic phenotype. Antibodies have been developed to target receptors whose ligands are growth factors, such as the epidermal growth factor receptor. The antibody thus inhibits natural ligands that stimulate cell growth of the cell from binding to targeted tumor cells. Alternatively, antibodies may induce an antiidiotype network (24), complement-mediated cytotoxicity (25), or antibody-dependent cellular cytotoxicity (ADCC) (26). An antiidiotypic network results from the recognition of the antibody, called *Ab1*, by the host immune system. The antigenic binding site within the variable regions of the antibody is seen as foreign. When an antibody, termed *Ab2*, is formed against this binding site, it recapitulates the three-dimensional structure of the antigen targeted by Ab1. This chain of events can keep occurring, thus perpetuating the immune response against the primary antigen (27,28). Some classes of immunoglobulins (Ig) can activate complement or natural killer (NK) cells. The first component of the complement cascade, C1, is capable of binding the Fc portion of IgM and IgG molecules. C1 activation triggers the classical complement cascade, leading to the recruitment of phagocytic cells and death of the antibody-bound cells. This process occurs more efficiently with IgM molecules, but can also occur if IgG molecules are clustered on the cell surface. Cells coated by IgG1 or IgG3 isotype antibodies can also activate effector cells via the binding of the terminal Fc portion of the antibody to Fc receptors, found on NK cells, neutrophils, mononuclear phagocytes, some T cells, and eosinophils. ADCC occurs with the release of cytoplasmic granules containing perforins and granzymes from these effector cells. Some BsAb have been developed to facilitate ADCC by targeting a tumor antigen and an Fc receptor on immune effector cells and are discussed in the section Bispecific Antibody Therapy .

Limitations to Antibodies

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

Initial clinical trials with MAb led to some striking examples of antitumor effects (29), but the majority has served to illustrate the obstacles to successful therapy (Table 15.4-1). Most of the MAb used in clinical trials have been derived from mice, and patients exposed to them have developed human antimouse antibody (HAMA) responses, thus limiting the number of treatments patients can receive (30). Some tumor antigens are shed or secreted. Antibodies targeting these antigens bind their target in the circulation, limiting the amount of unbound antibody available to bind to tumor (31). Barriers impede antibody distribution within tumors, such as (a) disordered vasculature, (b) increased hydrostatic pressure within tumors, and (c) heterogeneity of antigen distribution within tumors (32). Due to these barriers, the length of time for an IgG molecule to travel 1 mm and 1 cm in a tumor has been estimated to be 2 days and 7 to 8 months, respectively. Estimates for a smaller molecule, such as an Fab fragment, are 1 day or 2 months to travel 1 mm or 1 cm, respectively. If antibodies do reach their targets, there is little evidence that they efficiently mediate *in vivo* antibody-dependent cytotoxicity. For this to occur, sufficient numbers of effector cells, such as macrophages, NK cells, or cytotoxic T cells, must be present in the tumor (33). Finally, many tumors are known to secrete compounds that down-regulate the immune response (34,35), or have decreased effector cells as a consequence of hypoxia (36). Despite these impediments, preclinical and clinical data with improved antibody-based molecules continue to demonstrate an emerging role for antibody-based therapy as a component of the oncologic armamentarium.

Table 15.4-1 Obstacles to Effective Antibody Therapy

Immunogenicity of xenogeneic antibodies
Shedding of antigen into circulation
Disordered vasculature in tumors
Increased hydrostatic pressure in tumors
Heterogeneity of antigen on tumor surface
Limited numbers of effector cells at tumor
Immunosuppressive tumor microenvironment

Targets for Antibody Therapy

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

Any structure on the surface of a cancer cell can be a target for binding by an antibody. An optimal antigenic target for a therapeutic antibody is unique to tumor cells or is significantly overexpressed on tumor cells relative to normal cells. The antigen selected should not be shed into the circulation, because it binds to antibody before the therapeutic vehicle can reach tumor sites. The targeted protein should not be internalized when bound by the antibody if the antibodies are to mediate ADCC and complement-mediated cytotoxicity. However, an internalized antigen is desirable as a target for immunotoxins or radiolabeled antibodies. The following describes antigens found on adenocarcinomas, particularly on breast cancers.

HER-2/neu (c-erbB-2)

The *neu* proto-oncogene encodes for a receptor tyrosine kinase. It is part of the Heregulin (HER) family, consisting of epidermal growth factor receptor, HER-2/*neu*, HER-3 and HER-4 (37). HER-2/*neu* was discovered by detecting a murine humoral response to a 185-kd protein after inoculation of mice with rat tumors stimulated by *in utero* nitrosoethylurea injections (38). The human homologue was discovered due to its similarity to HER-2/*neu* (39,40 and 41). The protein receptor, when transfected into fibroblasts, transformed the phenotype of these cells (42,43). The endogenous ligand is unknown. However, HER-2/*neu* has been shown to mediate intracellular signals when dimerized

with HER-3 and HER-4, or when bound with heregulin (44,45). Unlike the normal cellular homologue, which is not oncogenic, HER-2/*neu* contains a point mutation in the transmembrane portion of the molecule (46,47). Inserting truncated forms of HER-2/*neu* or overexpressing protein in the cell results in a transformed phenotype (48). In human tissues, HER-2/*neu* is detected in secretory epithelial tissues and the basal layer of skin (49,50). HER-2/*neu* also is overexpressed in approximately 30% of adenocarcinomas (51,52,53,54 and 55) of the lung, gastrointestinal tract, breast, and ovary. It is also found in comedo, large cell, and ductal carcinoma *in situ* (56). HER-2/*neu* has become a target for antibody-based therapies because of its role in oncogenesis and its relative overexpression in particular tumor types compared with normal host tissues.

Epidermal Growth Factor Receptor

Epidermal growth factor receptor (EGFR) is a 170-kd transmembrane glycoprotein that is overexpressed in many carcinomas, including 40% of breast cancers and many human gliomas (57). This receptor has a number of ligands, including epidermal growth factor (EGF) and transforming growth factor (TGF). Overexpression of EGFR and its ligands has been found in breast carcinoma cell lines and human carcinomas, providing evidence for the existence of an autocrine growth loop (58,59 and 60).

The most common mutant form of the receptor, EGFRvIII, has a deletion of exons 2 to 7 resulting in a truncated extracellular domain. The variant receptor is not found on normal tissues, but has been found on gliomas (61), non–small-cell lung cancer (62), and ovarian and breast cancer (63). Transfection with this mutant form results in transformation of fibroblasts (64), likely due to the constitutive activation of the c-Jun N-terminal kinase pathway (65). Evidence also exists for increased activation of phosphatidylinositol 3-kinase, which when blocked results in the loss of anchorage-independent growth and morphologic reversion of transformed cells (66). This mutant form is associated with drug resistance due to decreased apoptosis (67). When this receptor is bound, it leads to receptor internalization (68).

Carcinoembryonic Antigen

Carcinoembryonic antigen (CEA) is an 18-kd glycoprotein present on endodermally derived neoplasms and in the digestive organs of the human fetus (69,70). CEA is a member of the immunoglobulin superfamily located on chromosome 19 and is thought to be involved with intercellular interactions (71). CEA is thought to be an adhesion molecule, and may allow tumor cells to attach to normal cells in the metastatic process (72). Targeting CEA therefore may be important in the prevention of metastases. CEA is reported to be expressed in 68% to 88% of breast adenocarcinomas (73), the majority of colorectal adenocarcinomas, and in lung and gastric adenocarcinomas.

Carbohydrate Targets

Carbohydrate and mucin molecules are found on cell surfaces. Lewis-Y (Le^y) is a carbohydrate antigen found on the surface of many carcinomas, including breast (74), lung (75,76), ovary (77), gastric (78), colorectal (79), and prostate. Its presence has been correlated with apoptosis in both normal and malignant cells (80). In colon cancer, its expression may correlate with lymph node metastasis (81). Mucin molecules, also termed *polymorphic epithelial mucins*, are found on most carcinoma cells and differ from those found on normal cell surfaces as a result of incomplete glycosylation (82). The carbohydrate side chains are shorter, thus exposing the core peptide and glycopeptide determinants (83). The core amino acid sequence of these mucins has a sequence of 20 amino acids that are repeated. Many antimucin antibodies recognize an immunodominant epitope within this repeated sequence (84,85). Patients with breast and pancreatic carcinoma have been reported to develop specific cytotoxic T-cell responses against the mucin core (86), suggesting that these carbohydrate antigens may be good targets for antiidiotypic antibody therapy. One mucin antigen, MUC-1, is shed into the serum of patients with breast and ovarian cancer (87) and may not be the ideal antibody target. Another glycoprotein, termed *gp72*, has been found on colorectal, gastric, and ovarian cancer (88). Several antibodies have also been developed against human milk-fat globules found on normal and malignant breast epithelium (89).

Ep-CAM (EGP-2 or GA 733-2)

A series of murine antibodies, identified by immunizing mice with cell lines from gastrointestinal cancers, have been found to recognize closely related tumor-associated epitopes. These antibodies detect a 38-kd surface glycoprotein variously referred to as *Ep-CAM, EGP-2,* or *GA733-2.* The normal distribution of Ep-CAM is on the basolateral surface of nonsquamous epithelium of the lower respiratory tract, lower gastrointestinal tract, tubules of the kidney, surface epithelium of the ovary, exocrine and endocrine pancreas, hair follicles, secretory tubules of sweat glands, bile ducts, and thymic epithelium. Ep-CAM expression also is associated with various cancers such as those derived from the colon, rectum, pancreas, lung, and breast. Although the antigen is abundantly expressed, it is not shed in the circulation (90). Ep-CAM has been shown to have homology to proteins involved with cell-to-cell, as well as cell-to-matrix interactions. Cells transfected with this gene demonstrate enhanced *in vitro* intercellular adhesion (91).

Transferrin Receptor

The transferrin receptor is comprised of two identical transmembrane subunits that are linked by disulfide bonds and is constitutively expressed on all cells. Its expression is controlled both by posttranscriptional iron response elements on messenger RNA and at the transcriptional level. When the receptor complexes with a ligand, it is rapidly internalized via endocytosis. The ligand is altered in the acidic pH of the endosome and becomes unbound in the endosome cytosol. The endosome is then recycled within minutes (92). The rapid internalization and regeneration on the cell surface makes this receptor ideal for targeting drugs, toxins, or radioisotopes conjugated to antibodies. Transferrin receptors are expressed on breast carcinoma cells (93).

In summary, these proteins and glycoproteins provide targets for antibody therapies. Some of these proteins are found on normal cells, but are overexpressed on tumor cells, such as EGFR and HER-2. They have been shown *in vitro* to transform cells. Some targets are utilized due to changes in the target associated with malignant cells only, as seen with the carbohydrate antigens. Others have been targeted because of rapid internalization of ligands bound to them, such as the transferrin receptor. This provides a means to deliver toxins or chemotherapeutic agents specifically into targeted cells.

Antibodies as Diagnostic Tools

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

The specific binding properties of antibodies has led to their extensive use in the diagnosis of cancers. They are mainstays in the pathologic diagnosis of malignancy, allowing for discrimination of histologically similar cancers. For example, CEA is expressed by most adenocarcinomas, not only by those of the gastrointestinal tract (94,95). D-14 MAb, directed against a specific epitope of CEA, has been shown to be specific for colon cancers, but not for ovarian adenocarcinomas (96). Cytokeratin-7 is used to distinguish ovarian cancers from colon cancers (97). Antibodies to detect estrogen (ER) and progesterone (PR) receptors are used to identify breast cancer primary lesions, although one or both receptors can be found on other cancers (98,99 and 100).

Immunochemistry has also been used to provide prognostic information about the cancer being evaluated. This is particularly true in breast cancers, in which routine evaluation for prognostic factors influences therapeutic decisions. ER and PR are evaluated to determine if the patient is eligible for hormonal therapy, but the presence of PR positivity also has prognostic value, as patients with hormone receptor-negative tumors have poorer outcomes (101,102). The presence of PR is the most reliable predictor of survival in endometrial carcinoma (103). Mutations in p53 result in a longer protein half-life that can be detected by immunohistochemistry. p53 Expression in breast cancer is associated with a poorer prognosis (104) and is inversely correlated with response to chemotherapy (105). Ki-67, a marker of cell proliferation, has prognostic relevance in breast (106) and non-small-cell lung cancers (107). Expression of Ki-67 in colon cancer is only associated with metastatic disease (108). High levels of HER-2/*neu* expression have also been correlated with a poorer prognosis in breast cancer (109,110), non-small cell lung cancer (111), and in FIGO III and IV ovarian cancer (112). In breast cancer patients, overexpression is associated with poor response to chemotherapy (113); it is also assessed to determine a patient's candidacy for treatment with trastuzumab (Herceptin), as will be discussed.

The use of antibodies in radiologic diagnostic procedures offers promise, but to date has not been shown to be significantly superior to other available modalities. Antibodies labeled with radioactive agents can be systemically administered to detect disease (114). The distribution of radiolabels can be measured using gamma counters, single-photon emission computed tomography, or radioactive probes (115). The foremost examples of this technology are the OncoScint CR/OV scan, used to detect CEA-expressing tumors, and Prosta-Scint, used to detect prostate-specific membrane antigen in men with adenocarcinoma of the prostate (116). Studies evaluating CEA and human milk fat globulin antibodies have been done in breast cancer patients at presentation as well as at disease recurrence (117,118 and 119). The antibodies detected lesions, including primary cancers smaller than 1 cm in size, but had 90% to 63% sensitivity in detecting lymph node metastases. The pancarcinoma antibody NR-LU-10 has also undergone evaluation for staging of small-cell lung cancer (120) and in a variety of adenocarcinomas (121). Compared with standard radiographic techniques, the technetium-99m-labeled antibody was able to detect 88% of known lesions, but missed some lesions smaller than 2 cm in size. The antibody can detect metastatic bone disease in patients with positive bone marrow biopsies (122).

Another approach used for diagnosis is pretargeted immunoscintigraphy utilizing a biotinylated antibody, followed by avidin and, subsequently, indium-111 (^{111}In)-labeled biotin. This approach has been evaluated in ovarian cancer (123), medullary thyroid cancer (124), pituitary adenomas (125), other endocrine tumors (126), and lung cancer (127). A higher rate of detection of endocrine tumors occurred using the pretargeted strategy compared with standard radiographic techniques.

More recently, radiolabeled antibodies have been applied to radioimmunoguided surgery (RIGS), improving the completeness of surgical resections by detecting occult disease because micrometastatic disease may be missed by radiographic studies or standard surgical exploration (128,129). An initial problem with this strategy has been the length of time required between the administration of the antibody until surgery was performed to allow background radioactivity to clear from the body. F(ab")$_2$ or Fab", which clear more rapidly from the circulation due to their smaller sizes, may address this problem. RIGS has been used primarily in patients with colorectal carcinoma, but has also been evaluated in breast and pancreatic carcinomas (130). Because cancers have variable antigen expression, a cocktail of radiolabeled antibodies may lead to increased sensitivity of RIGS (131). At the present time, no studies have compared these techniques to determine if one approach is superior to the others.

Monoclonal Antibody Therapy in Breast and Other Adenocarcinomas

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

Breast cancer has been the focus of considerable research, particularly since the early 1990s. New chemotherapeutic agents have clearly impacted on survival in the metastatic disease setting, with some suggestion of improved disease-free survival in the adjuvant setting as well. The strides in breast cancer therapy have not been limited to standard therapeutic agents. RhuMAb HER-2 antibody therapy has clearly resulted in responses in metastatic disease, as well as improved response and duration of disease-free progression when combined with chemotherapy. Antibody therapy in other adenocarcinomas has also been evaluated. Antibody 17-1A, which recognizes Ep-CAM, has been

extensively tested with studies, suggesting benefit in the adjuvant therapy of colon cancer.

HER-2/neu (c-erbB-2)

HER-2/*neu* (c-erbB-2), a member of the EGFR family, has been targeted for antibody therapy as it is overexpressed on approximately 25% of breast cancers. RhuMAb HER-2(132), also known as *trastuzumab* (Herceptin), is a humanized antibody derived from 4D5, a murine monoclonal antibody, which recognizes an epitope on the extracellular domain of HER-2/*neu*. In a phase 2 trial in women with metastatic breast cancer, there was an objective response rate of 11.6%, with responses seen in the liver, mediastinum, lymph nodes, and chest wall. Patients received ten or more treatments with the antibody, and none developed an antibody response against RhuMAb HER-2. In a second phase 2 study, 222 women with metastatic breast cancer were treated with 2 mg per kg of RhuMAb HER-2 weekly, with an objective response rate of 16% (133). The median response duration was 9.1 months, with a median overall survival of 13 months, both of which are superior to outcomes reported for second-line chemotherapy in metastatic disease. In each of these trials, approximately 30% of the patients had stable disease lasting more than 5 months. Intriguingly, preclinical studies have demonstrated decreased expression of vascular endothelial cell growth factor and vascular permeability factor with 4D5 therapy, suggesting that an antiangiogenesis mechanism may account for some of the clinical impact of this antibody (134). RhuMAb HER-2 continues to be evaluated clinically in diverse adenocarcinoma types.

The results of a large randomized phase 3 trial comparing cytotoxic chemotherapy alone or with RhuMAb HER-2 have been reported in abstract form (135). Patients receiving initial therapy for metastatic breast cancer were treated with doxorubicin or epirubicin and cyclophosphamide, or with paclitaxel if they had received an anthracycline in the adjuvant setting. Patients were randomized to receive this chemotherapy alone or in combination with weekly antibody therapy. Response rates for combination therapy with an anthracycline regimen increased from 43% to 52% with the addition of RhuMAb HER-2. Using paclitaxel, response rates increased from 16% to 42% with the addition of RhuMAb HER-2. Myocardial dysfunction was observed with increased frequency in patients receiving doxorubicin or epirubicin when RhuMAb HER 2 was added. Therefore, RhuMAb HER-2 is not recommended in combination with anthracyclines. Based on these clinical trial results, RhuMAb HER-2 has been approved by the U.S. Food and Drug Administration for the treatment of women with metastatic breast cancer with HER-2/*neu* overexpression given either alone or in combination with paclitaxel. RhuMAb HER-2 is being evaluated in combination with other chemotherapeutic drugs and in other adenocarcinomas that overexpress HER-2/*neu*.

Ep-CAM (EGP-2 and GA 733-2)

The 17-1A antibody, which recognizes Ep-CAM, has undergone extensive clinical testing, with some studies suggesting efficacy in colorectal carcinomas (Table 15.4-2). Initial trials used a murine antibody, with more recent trials using a human chimeric construct suppressing the development of HAMA responses. The chimeric antibody results in greater human peripheral mononuclear cell-mediated ADCC compared with the original murine MAb (136). Initial human studies with the chimeric antibody revealed a prolonged half-life compared with the murine antibody, no HAMA development, and radiolocalization to known sites of disease (137). Clinical trials have also incorporated cytokines because of *in vitro* data that suggest increased apoptosis when 17-1A is used in conjunction with interferon-γ (IFN-γ) (138). There is also *in vitro* evidence of increased ADCC with IFN-γ (139), granulocyte-macrophage colony-stimulating factor (GM-CSF) (140,141), the combination of GM-CSF and interleukin-2 (IL-2) (142), interleukin-4 (IL-4) (143), and interleukin-8 (IL-8) (144). The therapeutic use of this antibody has also been shown to induce potentially effective antiidiotypic antibodies (145,146 and 147); concomitant therapy

with GM-CSF increased the induction of the antiidiotypic response (148) as well as increased infiltration of macrophages, CD4[+] and CD8[+] T cells within tumors (149). Induction of T cells against antiidiotypic epitopes has also been evaluated by proliferation assays, IFN-γ production, and delayed-type hypersensitivity reactions (150). Five of ten patients with antiidiotypic antibodies were also found to have induction of EP-CAM antigen-specific T cells. T cells were isolated from these samples and four patients demonstrated a proliferative response when stimulated with an antiidiotypic antibody *in vitro.* These four patients were reported to have clinical responses as well, in contrast to the six patients without evidence of T cells against antiidiotypic epitopes.

Table 15.4-2 17-1A Clinical trials

Phase	Dose/Schedule	Disease	No. of Patients	Responses	References
1	25–200 mg i.v.	Met GI	4	1 MR	Sears (152)
1	15–1,000 mg i.v.	Met GI	20	3 CR	Sears (153)
1	200 mg i.v.[a]	Met GI	22	None	Verrill (154)
1	400 mg i.v.	Met GI	25	NR	Khazaeli (155)
1	400 mg i.v.	Met GI	20	NR	Lobuglio (156)
1	400 mg i.v. with FAM chemotherapy	Pancreas	16 (eight patients 17-1A only)	2 PR (chemotherapy and 17-1A)	Paul (157)
1	400 mg i.v.	Pancreas	25	4	Sindelar (158)
2	200–850 mg i.v.	Colorectal	20	1 CR	Sears (159)
2	500 mg i.v. t.i.w. × 8 wk	Pancreas	28	1 PR	Weiner (160)
2	GM-CSF d 1-10 with 400 mg i.v. d 3	Colorectal	20	2 CR	Ragnhammar (161)
2	IFN-γ d 1-15 i.v. with 400 mg i.v. d 5,7,9,12	Met colorectal	15	None	Saleh (162)
2	IFN-γ d 1-4 i.v. with 150 mg i.v. d 2-4	Colorectal	19	None	Weiner (163)
2	IFN-γ d 1-4 i.v. with 150 mg i.v. d 2-4	Pancreas	30	1 CR	Tempero (164)
3	500 mg i.v. × 1, then 100 mg i.v. q4wk × 4	Dukes' C colorectal	189	Improved DFS and OS	Reithmuller (165)

CR, complete response; DFS, disease-free survival; FAM, 5-fluorouracil, adriamycin, mitomycin; GI, gastrointestinal; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN-γ, interferon-γ; Met, metastastic; NR, not reported; OS, overall survival; PR, partial response.

[a]Antibody was mixed with leukopheresed mononuclear cells preinfusion.

Initial phase 1 studies with 17-1A yielded promising results. Several studies demonstrated responses in patients with metastatic cancers of the gastrointestinal tract with only one intravenous dose of antibody. One patient received an intrahepatic infusion of autologous mononuclear cells mixed with 17-1A with regression of hepatic metastases. Antibody therapy was well tolerated with mild nausea, vomiting, or diarrhea. Phase 2 studies in colon and pancreatic cancers were less encouraging. Repeat dose injections and combinations with cytokines to enhance effector cell number and activity did not result in significant response rates, although *in vitro* assays of patient effector cells revealed increased activity with cytokine therapy. Repeat dose schedules with higher doses were theorized to induce tolerance to the murine antibody; however, this maneuver had no significant impact on the induction of HAMA. Evidence did exist of induction of antiidiotypic antibodies, with some trials showing a correlation with response. The overall lack of efficacy seen in these studies may have resulted from the large tumor burden or the associated immunosuppression seen in these patients with metastatic disease.

The initial study evaluating 17-1A in the adjuvant setting suggested the possibility of efficacy. A phase 3 clinical trial of patients with lymph-node positive colorectal cancer randomized patients to observation or therapy with 17-1A. The surgical approach was standardized and agreed to by all participating surgeons. All patients were followed postoperatively in a similar manner, irrespective of treatment. One hundred and eighty-nine patients were randomized, with 166 patients evaluated for overall survival and disease-free survival. Therapy with 17-1A was well tolerated except for malaise, low-grade fevers and chills, and mild gastrointestinal discomfort. Four episodes of anaphylactic reactions were treated without sequelae. At 5 years of follow-up, the death rate was 36% in the 17-1A group in contrast to 51% in the observation group, and the calculated recurrence rate was 48.7% versus 66.5% (165). At 7 years the death rates were 43% (17-1A) and 63% (controls), and the calculated recurrence rates were 52% and 68%, respectively, demonstrating a continued benefit in patients who received 17-1A (151). Treatment with 17-1A was associated with a decreased incidence of metastatic disease, but did not alter the incidence of local failure. This shift in failure pattern was thought to represent the ability of 17-1A to eradicate isolated metastatic cancer cells, but not bulkier disease. Alternatively, altered vasculature due to surgery and scar tissue may have limited antibody diffusion to tumor cells at the primary site. Another factor potentially accounting for the apparent lack of efficacy of 17-1A on local control is that 11 patients in the observation group received pre- or postoperative radiation therapy alone or in combination with chemotherapy. This trial has been criticized because of the higher rates of recurrence and death in the control arm than would be anticipated. Irrespective of these criticisms, this study is intriguing in demonstrating an effect of antibody-based therapy in the adjuvant setting of colorectal cancer. Current clinical trials are designed to confirm these results in stage II colon cancers and to test the value of adding 17-1A to standard chemotherapy in patients with stage III disease. Therapy with antibodies alone is likely not to be effective in all patients due to the antigenic heterogeneity of cancer cells. Combining standard adjuvant therapy with 17-1A would introduce therapies that have different mechanisms of action, are cell-cycle dependent and independent, and allow for death of cancer cells irrespective of antigen expression patterns.

Epidermal Growth Factor Receptor

EGFR is overexpressed on many cancers. The receptor and its ligands EGF and tumor necrosis factor-α (TNF-α) act in an autocrine loop to stimulate the growth of breast cancer cells. *In vitro*, some anti-EGFR antibodies have been shown to inhibit the binding of the receptor ligands (166,167). Antibodies that block the binding of EGFR ligands limit receptor activation by tyrosine kinases and inhibit growth of normal fibroblasts (168) as well as tumor cells in culture (169). Also, combining anti-EGFR antibodies with cisplatin leads to a significant decrease in the concentration that inhibits 50% of cisplatin(170), and cures of established tumors are seen when anti-EGFR antibodies are combined with cisplatin(171) or doxorubicin(172). *In vitro* and *in vivo* studies have also suggested that anti-EGFR antibodies may lead to terminal differentiation of squamous cell carcinoma cells, with accumulation of cells in G0-G1 phases of the cell cycle and expression of cell surface markers such as involucrin and cytokeratin-10 (173).

The anti-EGFR antibody MAb 225 blocks *in vitro* phosphorylation of the EGFR and induces receptor internalization as occurs with binding of the natural ligand (174). However, receptor processing is slower with antibody engagement than with natural ligand engagement (175). Smaller bivalent F(ab")₂ and univalent Fab" forms of this antibody also inhibit growth and decrease receptor phosphorylation, although the bivalent form is superior to the monovalent form (176). Because the smaller fragments lead to tumor regressions, the efficacy of antibody therapy is not dependent on ADCC, as these smaller fragments lack the Fc portion of the antibody required for ADCC. Rather, the efficacy of this antibody is due to its ability to inhibit binding of the natural ligand, limit receptor phosphorylation and thus downstream signals, and induce receptor internalization.

The chimeric form of MAb225, C225, has been evaluated *in vitro* and *in vivo* in hormone-sensitive and hormone-refractory prostate cancer (177). EGF is a strong chemoattractant for prostate cancer. Blocking the EGFR receptor with C225 *in vitro* results in decreased migration of prostate cancer cells in a dose-dependent manner due to decreased phosphorylation of the EGFR (178). This antibody has also been shown to lead to cell cycle arrest and decreased proliferation of prostate cancer cells (179,180). The binding of C225 to the EGFR results in multiple

events, leading to a decrease in proliferation and possibly decreased metastatic potential in prostate cancer. It has also been shown to inhibit the expression of vascular endothelial cell growth factor and vascular permeability factor, both involved in the induction of angiogenesis (134).

C225 has been tested in phase 1 studies in recurrent head and neck cancer in combination with cisplatin. Four out of seven patients demonstrated responses, three of whom had failed prior cisplatin therapy (181). C225 is currently undergoing phase 1 testing in combination with paclitaxel in women with stage IV breast cancer. ICR62, a rat monoclonal IgG, has been shown *in vitro* to block binding of the ligands of EGFR, inhibit growth of tumor cell lines that overexpress EGFR, and to cause differentiation of malignant cells to a normal phenotype. This antibody was evaluated in a phase 1 trial of patients with squamous head and neck and lung cancer. Evidence existed of localization of antibody to tumor sites at dosages of 40 to 100 mg and development of antirat antibodies (182). Another anti-EGFR antibody, RG 83853, has been used to treat patients with non-small cell lung cancer and head and neck cancer in a phase 1 setting. In this study, patients received up to 600 mg per m^2 by continuous infusion over 5 days without significant toxicity (183). Saturation of at least 50% of the EGFR at dosages of 200 mg per m^2 or more occurred. EGFR-expressing tumor cells demonstrate increased sensitivity to chemotherapy (184) and to radiation therapy (185) in the presence of EGF. In two of five patients with pre- and posttherapy biopsies of tumor, there was evidence for increased tyrosine kinase activity of EGFR, which provided rationale for combined modality therapy.

Carbohydrate Antigens

Carbohydrate antigens classically are described as poor immunogens and have not been used extensively as immunologic targets. However, by demonstrating the immunogenicity of such antigens as Le^y and the carcinoma-associated mucin epitopes Tf (ß-D-Gal-(1-3)-α-GalNAc), Tn (*N*-acetyl-D-galactosamine-α-O-Ser/Thr), sialyl-Tn (dAcNeuα2-6(GalNAc-*O*-Ser/Thr), and MUC-1, these antigens have proved useful as targets for cancer therapy.

Lewis Antigens

Le^y antigen, which is expressed on 75% of breast adenocarcinomas, is recognized by ABL 364 (186). In a study treating breast cancer patients with bone metastases, patients were randomized to receive antibody therapy or albumin infusions. The number of metastatic cells selectively decreased in patients treated with the antibody and not albumin, especially those whose bone marrow samples contained a large percentage of malignant cells at baseline. Reduction in the number of malignant cells in patients with less bone marrow involvement was not demonstrable, likely due to a sampling error.

Le^x, also known as *CD15*, has been used as a target on granulocytes as well as breast cancer cells (187). FC-2.15, which recognizes Le^x, was used to treat 11 patients with advanced malignancies. One patient with metastatic breast cancer demonstrated a partial response (188). All patients demonstrated a transient neutropenia that developed within 1 hour of initiating the antibody infusion and resolved within 1 hour of ending the infusion. One patient's course was complicated by the development of *Pseudomonas* bacteremia.

Other Le^y and Le^x antibodies have been developed. B1, anti-Le^y and B3, which identifies Le^y, di-Le^x and tri-Le^x antigens, have been shown to have minimal reactivity with normal tissues (189). The antibodies BR64 and BR96 recognize Le^y, with limited reactivity to normal tissues except for the gastric mucosa, although BR64 also binds capillaries of the myocardium (190). These antibodies are internalized and therefore of interest as carriers of toxins; conjugates with doxorubicin and ricin have been evaluated and are described later.

MUC-1

Breast epithelial mucins are large, highly glycosylated molecules. Most antibodies derived against these mucins recognize the core structure MUC-1 (31). Five antibodies, Mc5, BrE-1, BrE-2, BrE-3, and Mc1, recognize an immunodominant 8-amino-acid sequence of the tandem repeat sequence of MUC-1. Immunohistochemistry assays of these antibodies demonstrate different distribution of antibody binding in both normal and malignant tissues, likely due to differences in glycosylation of mucin. These antibodies were developed for radioimmunotherapy and are described more fully in the section Radioimmunotherapy .

hCTMO1 recognizes the tetrameric epitope RPAP of MUC-1 (191). *In vitro* experiments have demonstrated that it is rapidly internalized, with a high degree of tumor-selective retention in *in vivo* tumor models. There is also evidence of tumor inhibition with an idarubicin conjugate, whereas idarubicin alone had no activity. To date, this antibody has only been tested as an imaging agent (192). ^{111}In-labeled antibody was evaluated in 31 patients with ovarian cancer with circulating MUC-1 (193). This study demonstrated persistent uptake of antibody 6 days after a single intravenous injection within tumor, with a greater percentage within tumor than in normal tissues or blood. Because this is a humanized antibody, a clearing step of unlabeled antibody has been given before the labeled antibody to allow for enhanced imaging (194). C595 is a murine IgG_3 that also recognizes RPAP. This antibody was used to immunize mice to develop an antiidiotypic antibody against the MUC-1 epitope RPAP, termed *MAb 911.* This antibody helps evaluate the potential for inducing tumor immunity to MUC-1 (195).

A number of mucins have been identified in pancreatic cancers (196), with the target of PAM4 found on malignant cells of the pancreas but not on the normal glandular tissue. Preclinical trials using a radiolabeled antibody have revealed growth delays even with large tumors (197). H23 recognizes MUC-1H23, which is overexpressed on 91% of human breast cancers but only 2% of normal breast tissue samples (198). The selectivity of this agent for malignant tissues is promising.

Other Mucin Antigens

Sialyl Tn tumor antigen is found on most adenocarcinomas, and a series of MAb have been found that recognize this antigen: B72.3, MAb B195.3R11, TKH2, B239.1, and CC49 (199).

This antigen recognized by B72.3 and CC49 is also known as *tumor-associated glycoprotein-72* (TAG-72) (200). Human milk fat globule has also served as an antibody target (201), with therapeutic trials using radiolabled antibodies as described in the section Radioimmunotherapy .

Transferrin Receptor

The transferrin receptor TfR is another receptor on cancer cells that binds a growth-stimulatory ligand. Iron has been shown to be necessary for growth of malignant cells. Cells deprived of iron undergo growth arrest and apoptosis (202). Therefore, targeting the TfR found on most carcinomas, sarcomas, as well as some lymphomas and leukemias could have broad therapeutic applicability. 42/6, a murine IgA antitransferrin antibody, does not induce clinical responses, but decreases serum TfRs and increases serum iron and transferrin, suggesting blockade of iron uptake (203). Therapy with 42/6 was complicated by the induction of antibody responses against the murine antibody. This approach warrants further evaluation using a chimeric antibody that is administerable for protracted lengths of time. This target has also been used in immunotoxin constructs (204).

Carcinoembryonic Antigen

Although adenocarcinomas commonly express CEA, this has not been a common target in antibody-based therapies. It has been evaluated as a diagnostic antibody for RIGS and nuclear medicine scans, as previously discussed. Antiidiotypic antibody therapy has been evaluated and is reviewed in the section Antibodies as Vaccines .

Bispecific Antibody Therapy

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

BsAb are constructed with two distinct binding sites. BsAb may be whole IgG molecules or constructed of smaller antibody fragments. Smaller BsAb are being constructed to optimize penetration into tumor tissues (205,206 and 207). The specificities of the two antibody-binding sites may be for distinct tumor-associated antigens. For example, BsAb with varied specificity for mucin, three different glycoproteins, transferrin receptor, and HER-2/*neu* were screened for direct tumor growth inhibition (208). Binding of the two different sites on tumor cells was hypothesized to alter normal cellular signaling pathways. Growth of the breast cancer cell line SKBR3 was best inhibited using a BsAb with specificities for HER-2/*neu* and the transferrin receptor. When combined with the iron chelator deferoxamine, enhanced growth inhibition is achieved with lower doses of antibody and deferoxamine than when either one is used alone. BsAb also have been made with specificity for tumor antigens and for therapeutic agents such as drugs, or radioactive elements.

Extensive work has been done in the construction, evaluation, and *in vivo* testing of BsAb that target tumor-associated antigens and effector cells. These antibodies have targeted either elements of the T-cell receptor complex or Fcγ receptors found on monocytes, macrophages, neutrophils, and NK cells. The receptors that are targeted may function as activation triggers for the effector cell on binding of the antibody. BsAb promote the conjugation of effector T cells, NK cells, or macrophages (MØ) to malignant cell targets. When T-cell receptors are bound, the T cell is activated, leading to the production of IFN-γ and TNF-α, which may be responsible for the bystander effect observed in animal models in which cytotoxicity is not restricted to cells bound by antibody. Binding of T-cell receptors by these antibodies triggers cytotoxicity irrespective of the antigen specificity of the T cell (209,210) and is not dependent on major histocompatibility complex expression, which is often downregulated on malignant cells (211). The addition of IL-2 further activates these T cells. However, combinations of antibodies targeting three receptors on T cells results in profound T-cell activation that cannot be further manipulated by IL-2. This property may allow BsAb-promoted T-cell activation *in vivo* at tumor sites without the added systemic toxicities of IL-2 therapy (212).

Many of the BsAb-targeting T-cell receptors have been developed for lymphomas and leukemias. Table 15.4-3 provides a list of those BsAbs in clinical trials for solid tumors. One example of a clinically tested BsAb for solid tumors is OC/TR, which recognizes CD3 and the folate-binding protein on ovarian cancer cells (213). Patients with residual disease at the time of second-look surgery received autologous T-lymphocytes labeled with the BsAb via intraperitoneal administration daily for up to 9 days over 2 weeks with IL-2. Some patients underwent exploratory surgery after two cycles of therapy. Clinical responses lasted up to 12 months in duration. The significance of the responses is difficult to interpret, as patients with negative second-look surgeries are known to have prolonged disease-free survival (214). Another example is BIS-1, which recognizes CD3 and EGP-2, which has been evaluated in patients with lung cancer manifesting as malignant ascites or pleural effusions (215). Patients received therapy with preactivated T lymphocytes with BIS-1 injected directly into the pleural or peritoneal space. Limited toxicity occurred, in contrast with significant toxicity seen with intravenous administration of a F(ab")$_2$ of BIS-1 given with subcutaneous IL-2.

Table 15.4-3 Bispecific Antibodies in Clinical Trials

Effector Cell Target	Tumor Target
CD64/FcγRI	
MDX-210	HER-2
MDX-H210	HER-2
MDX-447	EGFR
CD16/FcγRIII	
2B1	HER-2
CD3/T-cell receptor	
BIS-1	Ep-CAM
M26.1	EGFR
OC/TR	Folate-binding protein

EGFR, epidermal growth factor receptor; HER, Heregulin.

Two BsAb with specificity for FcγR have been characterized and are undergoing clinical trials. MDX-210 is the fusion of the F(ab")$_2$ of two murine MAb, which recognize FcγRI and the extracellular domain of HER-2/*neu* (216). The binding site on FcγRI is distinct from that for the Fc portion of immunoglobulins, allowing for binding to the Fc receptor *in vivo* even if it is

occupied by an Ig molecule, and for ADCC, phagocytosis, superoxide generation, and enzyme release. *In vitro* assays of PMNs and monocytes show an upregulation of FcγRI in response to granulocyte colony-stimulating factor (G-CSF) (217), and IFN-γ (218). The FcαRI receptor, CD89, has also been evaluated as a target for bispecific antibodies (219). The FcαRI receptor binds IgA and can lead to antibody-dependent cell cytotoxicity dependent on the presence of neutrophils, rather than complement. *In vitro*, BsAb targeting CD89 and either c-erbB-2 or *Candida albicans* have led to effective killing of cancer cells and phagocytosis of fungi in the presence of neutrophils. The toxic effects were enhanced in the presence of G-CSF.

In a phase 1 trial, patients with advanced breast and ovarian cancer overexpressing HER-2/*neu* were given one dose of MDX-210 antibody (216). Most patients developed fever and mild hypotension. One-third of patients were noted to have increases in transaminases for 48 to 72 hours after therapy. Transient monocytopenia was seen with increased TNF-α levels 1 to 3 hours after the initial infusion, followed by IL-6 and G-CSF increases. Biopsies demonstrated mononuclear cell infiltrates and antibody localization 48 hours after infusion. Ten patients were evaluated for clinical responses. One patient with breast cancer experienced a tumor flare and erythema after injection and a subsequent decrease in the size of subcutaneous metastases and axillary adenopathy; no change was seen in lymphangitic lung disease. Another patient with ovarian cancer had a 50% reduction in cervical lymph nodes, but progression of intraabdominal disease was suggested by the development of intestinal obstruction. In a separate phase 1 study, MDX-210 combined with G-CSF was well tolerated, with evidence *in vitro* of enhanced cytotoxicity in the presence of neutrophils and antibody (220). MDX-H210, a humanized form of the antibody, is currently in phase 2 trials in combination with GM-CSF for patients with renal cell carcinoma, prostate cancer, and colorectal cancer. An early report of these studies described responses in renal cell and prostate cancer (221). This antibody has also been evaluated with IFN-α with evidence of immunologic and clinical activity (222). MDX-447 combines anti-FcRI and anti-EGFR specificities. In 36 patients with renal cell, head and neck, bladder, ovarian, prostate, or skin cancer, nine patients treated with MDX-447 had stabilization of their disease for 3 to 6 months (220).

Preclinical data have demonstrated the ability of BsAb that bind tumor and FcγRIII to redirect lysis by large granular lymphocytes in the presence of competing human immunoglobulin (223,224). We have evaluated 2B1, which recognizes HER-2/*neu* and FcγRIII (225). In a phase 1 study, patients with HER-2/*neu* overexpressing tumors were treated with six infusions of antibody over 8 days (226). Immune activation was demonstrated by increases in circulating TNF-α, IL-6, IL-8, and, to a lesser extent, GM-CSF and INF-α. This group of patients developed antibody responses against the intracellular domain of HER-2/*neu* (227). These results suggest that BsAb-promoted cytolysis leads to processing of HER-2/*neu* via FcγRIII, leading to antigen presentation and immunization *in vivo* against HER-2/*neu*.

BsAb can also target a tumor-associated antigen and a chemotherapeutic agent (228,229,230 and 231) or radionuclide (232). An anti-TAG-72 antibody has been combined with an antimethotrexate antibody, with *in vitro* data demonstrating targeting to and cytotoxicity of antigen-positive cells. In preclinical murine models, a bispecific targeting CEA and the vinca alkaloids vinblastine and vindesine demonstrate accumulation of drug at tumor sites, changes in drug biodistribution, and evidence of chemotherapeutic effect in tumor pathology. Similarly, a BsAb recognizing CEA and boron-10 can selectively concentrate boron in CEA-expressing tumors *in vivo.* Another construct targeting EGFR and doxorubicin also demonstrates altered biodistribution of the chemotherapeutic agent; of particular interest is evidence for decreased uptake in the myocardium compared with control animals not receiving the BsAb. This approach has not been tested in human clinical trials.

BsAb are also being evaluated in the preclinical setting in vaccine strategies (233). Tumor cells exposed to cytokines to upregulate major histocompatibility receptors and adhesion molecules were incubated with a BsAb that binds tumor and CD28, a costimulatory molecule on T cells. CD28, when bound, reverses T-cell anergy. When used as a vaccine *in vivo*, cytotoxic T-cell responses were induced, with cures of established tumors and inhibition of tumor rechallenges.

Radioimmunotherapy

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

Antibodies can also be used to deliver radioactive compounds to cells, leading to tumor cell death (234,235). Some preclinical studies suggest radioimmunotherapy can also decrease vascular permeability (236). Approaches using standard- and high-dose radiation therapy requiring bone marrow or stem cell transplant support have been evaluated with some efficacy. Antibodies, however, have limited capacity to penetrate into tumor tissues (32) and may therefore have limited therapeutic efficacy in large, bulky, solid tumors. Also, because tumor antigens are often found on normal host tissues, toxicity to normal organs has not been eliminated. Antibodies are cleared via the kidney or alternatively via the reticuloendothelial system, putting these organs at risk for injury from radiation. Last, the radionuclides distribute systemically, and therefore all tissues are exposed to radiation, particularly the bone marrow, which is quite sensitive to the effects of radiation. Some studies have used radiolabeled antibodies given by intraperitoneal injection in the setting of malignant ascites. However, this approach does not limit systemic absorption or toxicities (237,238,239 and 240). The following is an overview of antibodies targeting solid tumors that have been tested in clinical trials.

DeNardo and colleagues have developed a humanized antiadenocarcinoma antibody, chimeric L6 (ChL6) (241). It has been chelated with various radioisotopes, including Iodine-131 (¹³¹I), and evaluated clinically (242,243). In chemotherapy-refractory metastatic breast cancer patients, ChL6 radioimmunotherapy has a 50% response rate; however, due to myelosuppression, doses of radiation could not be escalated above 60 to 70 mCi per m², More recent studies have escalated doses to 150 mCi per m², followed by autologous stem-cell transplantation. The clinical course of only three patients has been reported. These patients were given 200 mg of unconjugated antibody before ¹³¹I-ChL6

treatment to block binding by normal vascular endothelium and Lugol's solution to block the uptake of radioactive iodine by the thyroid. One patient was able to receive three cycles of therapy with the addition of cyclosporin to inhibit the formation of HAMA, with an improvement in her performance status, a decline in her tumor markers, and 9-months' relief of bone pain. In a subsequent study, patients received up to four doses monthly of ^{131}I at doses of 20 to 70 µCi per m^2. Four of ten patients had partial responses lasting up to 5 months with an overall survival of 2.3 to 9.0 months (244). Further preclinical work is being done with a chimeric antibody conjugated to yttrium-90 (^{90}Y). This radiolabeled antibody and paclitaxel in a murine model have synergistic activity using human breast cancer xenografts (245).

The pancarcinoma antibody NR-LU-10 has been extensively evaluated for radioimmunotherapy. To limit normal host toxicity, radiolabeled NR-LU-10 was mixed with a collagen-based gel and injected intratumorally in a murine model, with improved tumor retention (246). Clinical trials have been done with rhenium-186 (^{186}Re)–labeled NR-LU-10 in ovarian cancer patients treated by intraperitoneal injection (238,239 and 240). Initial studies designed to estimate radiation doses to normal organs revealed dose-limiting hematologic toxicity at calculated bone marrow doses greater than 100 rad. A subsequent study treated patients with 25 to 150 mCi of ^{186}Re-NR-LU-10. Two patients at the highest dose experienced myelosuppression. Other clinically significant toxicities were fever and rash, but no significant gastrointestinal toxicity was found. Seven patients with minimal residual disease underwent repeat surgical exploration after therapy. Four of these patients had a decrease in residual disease. Another phase 1 study treated 15 refractory metastatic epithelial carcinoma patients with ^{186}Re-NR-LU-10 (247). Dose-limiting myelosuppression occurred at 120 mCi per m^2. This antibody has undergone clinical testing using a streptavidin-biotin pretargeting approach.

Mucin is an attractive target for radioimmunotherapy. Preclinical studies have demonstrated efficacy of ^{131}Iodine-Mc5 with no significant loss of MUC-1 expression in residual malignant tissue (248). ^{67}Copper-labeled MAb C595, another anti-MUC-1 antibody, is able to target transitional cell carcinoma and is being developed for intravesicular administration (249). BrE-3 has been investigated in the clinical setting (250). The initial phase 1 study done with the murine antibody conjugated to ^{90}Y demonstrated tolerable toxicity with doses of 6.25 to 9.25 MCi per m^2; however five of six treated patients developed HAMA after one dose of antibody (251). In a second phase 1 study escalating doses of 90Y-BrE-3 were used to treat heavily pretreated metastatic breast cancer patients. ^{90}Y conjugated to the antibody via MX-DPTA dissociates from the antibody and becomes incorporated into bone, resulting in a higher radiation dose to the bone marrow tissue than to other tissues. To minimize hematologic toxicity, patients were reinfused with autologous stem cells or bone marrow and treated with G-CSF after 1.5 mg per m^2 BrE-3 labeled with 15 MCi per m^2 or 20 MCi per m^2 ^{90}Y. Patients at both dose levels developed grade 4 thrombocytopenia, whereas grade 4 neutropenia was only seen at the higher dose level. Four patients had partial responses, with responses in lymph nodes, skin, and bone marrow. Another patient experienced transient palliation of bone disease, but no objective response. Further dose escalation is planned with this compound. A humanized construct of this antibody has been developed and evaluated as an imaging agent for advanced breast cancer (252). This study demonstrated a longer biologic half-life than the murine construct. The decreased antigenicity of the antibody allows repeated administration in therapeutic trials, allowing for dose fractionation mimicking conventional radiation therapy. However, the longer half-life may increase the nonspecific deposition of radioactivity.

Methods of decreasing toxicity from nonspecific radiation are being developed. Preclinical studies suggest combining IFN-α with radioimmunotherapy may decrease bone marrow toxicity (253). Antibodies directed against the chelating agent used to conjugate the radionuclide to an antitumor antibody decrease the radiation dose to blood and normal tissues, with a relative increase in radiation delivery to tumor (254). A similar approach has been used to clear biotinylated, radiolabeled antibodies. Unbound biotinylated antibodies can be cleared rapidly from the circulation by streptavidin, which has a high affinity for biotin (255). Pretargeting offers another approach to limit nonspecific delivery of radiation. In this strategy, an antiantibody conjugated to streptavidin is systemically administered. After unbound antibody has cleared from normal organ reservoirs, a biotinylated radioactive element is subsequently administered. This radionuclide thus selectively binds to the tumorbound streptavidin. This approach need not be limited to radiotherapy, and indeed there are preclinical data using this approach to target cytokines to tumor sites (256). This approach has been tested in various disease settings. The biotinylated antibody Mov18 was injected intraperitoneally to 15 patients with known intraabdominal ovarian cancer (257). ^{111}In-streptavidin was given 3 to 5 days later followed by laparotomy 1 to 8 days later. Radioactivity in resected malignant and normal tissues demonstrated favorable ratios of radioactivity in tumor compared with normal organs. Using a murine NR-LU-10 antibody-streptavidin conjugate, biotinylated ^{90}Y was tested in the phase 2 setting in colon cancer and prostate cancer. Although there was some clinical activity in these patients, diarrhea was dose limiting due to expression in the gastrointestinal tract of the Le^y antigen recognized by NR-LU-10 (258).

Another approach to radioimmunotherapy is to combine it with other forms of therapy. Monoclonal antibody ^{125}Iodine-A33, specific for an epithelial antigen found in 90% of colorectal cancers (259), has demonstrated preliminary evidence of increased activity when combined with chemotherapy without added bowel or bone marrow toxicity at a dose of 350 mCi per m^2 (260). Some patients who achieved CEA response or stable disease were subsequently treated with carmustine, vincristine, 5-fluorouracil, and streptozocin, with 50% responding; a phase 1 study using the unlabeled antibody weekly with chemotherapy is being conducted to define the interaction between radioimmunotherapy and chemotherapy.

Immunotoxins

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

An immunotoxin (IT) is an engineered drug that consists of a targeting monoclonal antibody linked to a protein toxin (261). ITs

were originally constructed using chemical cross-linking agents that couple the toxin to the antibody, resulting in a large protein structure with a molecular mass of 175 kd or more. More recently, IT have been cloned and expressed in bacterial expression systems as single-chain IT-fusion proteins linking the variable region of the antibody to the toxin (262), allowing for enhanced tumor penetration. The antibody component binds to the target on the malignant cell, is internalized, and the toxin or drug incapacitates the cell. Multiple compounds have been developed targeting various antigens linked to several different toxins.

The toxins used most commonly have been ricin, diphtheria toxin (DT), and *Pseudomonas* exotoxin (PE). Ricin and DT contain two chains, A and B. In ricin, the A chain is responsible for the toxic effects via *N*-glycosidase activity, which inactivates the 60S ribosomal subunit (263). The A chain of DT and domain 3 of PE have adenosine diphosphate ribosylation activity, which inactivates ribosomal elongation factor-2 and inhibits protein translation (264,265). The B chains and domains 1 and 2 of PE are required for intact toxin binding to the cell surface and translocation to the correct cytoplasmic compartment. Recombinant ITs engineered with specific intracellular translocation sequences can target the appropriate intracellular compartment where the toxin is active (266,267,268 and 269). This strategy has not always been successful due to poor internalization of the IT or inappropriate intracellular translocation of the toxin. Variations on this basic theme substitute chemotherapy agents or cytokines for the toxic moiety (270). More recently, two novel ribosome-inactivating proteins, ocymoidine and pyramidatine, have been evaluated. The ITs have activity both *in vitro* and *in vivo* (271).

Preclinical data and human clinical trials have identified challenges to the successful clinical use of ITs. Selecting an epitope on the antigen of interest closer to the cell surface appears to aid in improved internalization (272,273 and 274). Some ITs also have been found to have limited *in vivo* stability due to rapid clearance by the liver. Strategies have been developed to limit the recognition of the glycosylated proteins by the reticuloendothelial system (261,275,276), reduction of the proteins by glutathione (277), and complex formation with α_2-macroglobulin (278). Treatment with IT has been associated with unanticipated toxicities (279,280,281 and 282). The development of humoral responses directed against the toxin has limited the ability to administer repeated doses of drug. Common toxicities include fever, anorexia, malaise, arthralgias, and myalgias. A vascular leak syndrome characterized by weight gain, edema, dyspnea, and hypoalbuminemia has been seen in numerous studies with varying agents. The syndrome is hypothesized to be due to endothelial damage secondary to high concentrations of toxin (283); others have demonstrated binding of the immunotoxin to Fc receptors on monocytes releasing vasoactive compounds (282). Also observed were neurologic toxicities, including sensorimotor neuropathies associated with axonal loss and demyelination (281). Cases of rhabdomyolysis and acrocyanosis, manifested as reversible distal digital skin necrosis, have also been reported (284).

One IT that has been developed is based on BR96 (285), a murine IgG3 monoclonal antibody, which recognizes the Le^y antigen. It is rapidly internalized into lysosomes and endosomes by tumor cells and mediates antibody- and complement-dependent cytotoxicity, growth inhibition, and cell death. When this IT binds to cells bearing the Le^y antigen, protein synthesis is inhibited in a manner dependent on the number of Le^y surface receptors (286). Initial screens of the antibody revealed that it bound to a myriad of neoplasms and to a limited number of normal tissues, including the esophagus, stomach, intestines, and acinar cells of the pancreas. This normal tissue-binding pattern accounts for the gastrointestinal toxicity observed with this agent. BR96 has been conjugated to PE40 (287) (BR96 scFv-PE40) and to doxorubicin (BR96 IgG-DOX) (288). Preclinical studies of BR96 scFv-PE40 in murine and rat xenograft models using the human breast carcinoma cell line H3396 (289) and MCF-7 (290) demonstrated elimination of tumors in a dose- and schedule-dependent manner. Large tumors were cured when treated with 0.625 mg per kg intravenously every 4 days for a total of five doses. Preclinical toxicology studies revealed hepatotoxicity and vascular leak syndrome, which could be abrogated by premedicating with steroids (291).

The intracellular target of the toxin can also be targeted. Early IT with PE were found to be inactive when the antibody moiety was ligated to the carboxy terminus of PE. Analysis revealed that the amino acids, REDLK, at the end of the molecule are critical for the cytotoxicity of the molecule. These critical amino acids were changed to a similar sequence, KDEL, known to retain proteins in the lumen of the endoplasmic reticulum where protein synthesis occurs. Constructs combining an scFv directed against the IL-2 receptor and PE, PE-KDEL, or PE-(KDEL)$_3$ were compared. The KDEL modification enhanced *in vitro* cytotoxicity and *in vivo* antitumor effects by two- to threefold as compared with unmodified toxins (292).

More recently, ribonucleases (RNases) have been evaluated as candidate toxins (293,294). RNase from eosinophils (295,296), and pancreatic tissue (297) has been found to be cytotoxic to mammalian cells and to prolong survival in animal tumor models. Rybak and colleagues initially have evaluated bovine pancreatic ribonuclease A, and more recently angiogenin, a human protein with homology to pancreatic RNase. Angiogenin has been linked to an antitransferrin antibody (CH2.5-Ang). CH2.5-Ang supernatants selectively inhibit protein synthesis of cells from the leukemia cell line K562 by 50% after a 24-hour incubation. Adding excess parental antibody to the supernatant could block this toxicity. These observations suggest CH2.5-Ang is effective only when it is internalized into cells. Angiogenin is an attractive toxin to use as it is of human origin and should not be as immunogenic as catalytic toxins derived from prokaryotes.

Preclinical studies suggest limited toxicity when ITs are given intrathecally. LMB-7 is an IT constructed from a scFv that recognizes Le^y antigen linked to a component of the PE. Preclinical studies using a rat model demonstrated efficacy of intrathecal therapy with LMB-7 (298). After intrathecal seeding of A431 tumor, animals were treated with 10 mg of LMB-7 intrathecally on days 3, 5, and 7. Untreated animals died in 10 days. Twelve of 20 treated animals lived for more than 170 days. Nine of these animals demonstrated no histologic evidence of tumor at autopsy. An ongoing phase 1 clinical trial is determining the

maximum tolerated dose of the LMB-7 for carcinomatous meningitis in patients with B3 expressing tumors.

Cytokine Therapy with Antibody Therapy

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

Cytokines can expand or mitigate an immune response. The ability of certain cytokines to increase numbers of effector cells and activate these cells makes them ideal candidates to combine with antibody therapy. Increasing the number of activated cells at tumor sites may promote *in situ* ADCC. Commonly used cytokines include GM-CSF, due to its ability to activate macrophages and monocytes, and IL-2, due to its role in activating NK cells. IL-2 therapy has been shown to enhance ADCC (299,300). GM-CSF has also been examined in this context (301). Cytokine therapy can also increase the expression of some tumor antigens. Increased expression of some tumor antigens has been observed with IFNs (302,303); this provided the rationale for combining antibodies targeting CEA and TAG-72 with IFN-α and IFN-γ (304). TNF-α up regulates EGFR and in conjunction with an anti-EGFR antibody in a phase 1/2 clinical trial of patients with unresectable pancreatic cancer demonstrated enhanced growth inhibition, with increased doses of antibody and one complete remission lasting for 3 years (305). Cytokine therapy also upregulates major histocompatibility receptors, leading to enhanced cell surface antigen presentation (306,307).

MoAb L6, the original murine antibody from which ChL6 was developed, has been used to treat patients in conjunction with IL-2(308). Sixteen patients were accrued to cohorts with escalating doses of IL-2, 2.0 to 4.5×10^6 U per day, given days 15 to 18, 22 to 25, and 29 to 32. All patients received 200 mg per m² of antibody on days 1 to 7. A patient with breast cancer had a mixed response with improvement in subcutaneous nodules, but developed a malignant pleural effusion. A colon cancer patient had a partial response lasting 12 weeks.

As described earlier, the antibody 17-1A has also been tested clinically with several cytokines. Three clinical trials in advanced colorectal cancer and pancreatic cancer were undertaken combining the antibody with IFN-γ because of *in vitro* data suggesting increased ADCC and apoptosis with combination therapy (138). The combination was not clinically effective (162,163). When 17-1A was combined with GM-CSF, clinical responses as well as increased induction of antiidiotypic antibodies were reported in one trial (309).

To increase antigen expression, IFN-α has been combined with the radiolabeled TAG-72 antibody CC49 (310). Patients were randomized to receive 3×10^6 U IFN-α subcutaneously daily for 14 days, or no interferon followed by ^{131}I-labeled CC49. Patients receiving the IFN were found to have significant increases in their TAG-72 antigen expression by tumors and improved localization of CC49 MAb. In a phase 3 breast cancer study, IFN-α increased the tumor uptake of radiolabeled CC49 and prolonged the circulation time of the radiolabeled antibody compared with patients receiving no cytokine therapy (311).

Another approach is the creation of fusion proteins containing an antibody linked to a cytokine. IFN-α has been conjugated to the humanized BrE-3 and Mc5. In murine models, there was enhanced efficacy of the conjugated antibody compared with IFN-α alone, or an irrelevant IgG conjugated with IFN-α. Upregulation of antigen recognized by BrE-3 was also observed (312).

Monoclonal Antibody Therapy in Conjunction with Chemotherapy

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

Combination therapy with MAb and chemotherapy has been approached in various ways. One strategy to minimize toxicity from chemotherapy has been to exploit the specificity of antibodies to target an enzyme to tumor, followed by the administration of a chemotherapeutic prodrug. The drug is then converted to its active form only at tumor sites. The enzymes used have been endogenous alkaline phosphatase and β-glucuronidase, as well as the bacterial enzymes β-lactamase and carboxypeptidase G2 (CPG2). The prodrugs for etoposide, mitomycin-c, and phenol mustards are substrates for alkaline phosphatase. β-Glucuronidase converts the prodrug of doxorubicin to its pharmacologically active form. Doxorubicin, mustard, and vinca alkaloid prodrugs can be converted by β-lactamase. CPG2 only activates the mustard-alkaloid prodrug. These bacterially derived enzymes are antigenic and thus may have limited therapeutic utility. β-Lactamase-conjugated Fab specific for CEA and TAG-72 target breast and ovarian cancer lines and activate the prodrug of doxorubicin, with *in vivo* efficacy in preclinical models (313). The tumor growth suppression seen with the antibody and prodrug was equal to using free doxorubicin; however, the maximum tolerated dose of doxorubicin increased using the prodrug strategy due to decreased systemic-free drug. Similarly, the use of a BsAb with specificities for a tumor antigen and a chemotherapeutic agent can lead to specific tumor retention of drug, as described in the section Bispecific Antibody Therapy .

Conjugation of chemotherapeutic agents to antibodies has been tested preclinically (314) and clinically (BR96-DOX). Initial phase 1 studies identified a dose-limiting toxicity of hematemesis secondary to an exudative gastritis (315), which could be ameliorated by premedicating with corticosteroids, 5-hydroxy-tryptoamine-3 antagonists, and infusing the antibody over 24 hours (316). The maximally tolerated dose was 700 mg per m², delivering 21 mg per m² of doxorubicin every 3 weeks. Two partial responses were observed in breast and gastric cancer. A randomized phase 2 study compared BR96-DOX, 21 mg per m² doxorubicin to single agent doxorubicin 60 mg per m², with patients crossing over to the alternate arm with disease progression or stable disease after four cycles (317). The toxicities of the immunoconjugate were gastrointestinal with limited hematologic toxicity, suggesting specific targeting of drug due to Le^y in the gut. The response rates were 7% for the immunoconjugate and 44% for doxorubicin. The decreased activity of the immunoconjugate may be due to the large antigen pool in the gastrointestinal tract limiting targeted delivery of antibody to tumor sites. Other constructs targeting HER-2/*neu* are under development (318).

Another means to combine drug and antibody therapy is to use agents that act intracellularly on overexpressed receptors on malignant cells. One such approach combined the anti-EGFR antibody C225 with inhibitors of type 1 cyclic adenosine monophosphate-dependent protein kinase (PKAI), 8-chloro-cAMP (319).

PKAI overexpression has been demonstrated after transformation with TGF-α (320). Its overexpression has also been correlated with poor prognosis in breast cancers. *In vivo* models of combined therapy revealed prolonged survival of tumor-bearing animals with evidence of decreased production of autocrine growth factors by the malignant cells. The decrease in autocrine factors resulted in decreased tumor growth and a decrease in angiogenesis. There was no evidence of toxicity due to the antibody or PKAI. C225 was also combined with an antisense oligonucleotide that targets the expression of the regulator subunit of PKAI (321). Combined treatment of EGFR-expressing renal cell lines leads to loss of colony formation *in vitro* as well as growth inhibition and apoptosis. Tumor xenografts regressed with combination therapy. This exciting new therapeutic concept is an area for continuing drug development.

Last, the combined use of standard chemotherapy and antibody therapy is being increasingly explored, particularly in view of the effectiveness of RhuMAb HER-2 and paclitaxel therapy. Based on preclinical data in animal models, a phase 2 study has been completed in metastatic breast cancer, which overexpresses HER-2/*neu* combining RhuMAb HER-2 with cisplatin chemotherapy (322). Patients received an intravenous loading dose of 250 mg of antibody followed by 100 mg intravenously each week for 9 weeks. Treatment was combined with intravenous cisplatin 75 mg per m^2 days 1, 29, and 57. There were nine partial responses in 37 assessable patients with median response duration of 5.3 months. Another nine patients exhibited minor responses or stable disease. There were no unanticipated toxicities and pharmacokinetic studies revealed no change in antibody clearance with cisplatin. At the present time, the mechanisms underlying the efficacy of combination therapy are not understood at a cellular level. Studies are ongoing evaluating RhuMAb HER-2 with paclitaxel or docetaxel (Taxotere) in women with metastatic breast cancer and gemcitabine in patients with pancreatic cancer. RhuMAb HER-2 is also being combined with carboplatin and paclitaxel in patients with newly diagnosed metastatic breast cancer. If increased efficacy is seen with platinum-based combination therapy, other HER-2/*neu* overexpressing tumors, such as non-small cell or ovarian cancer, may benefit from this therapeutic approach. Similar encouraging results have been observed using the antiepidermal growth factor antibody C225 with cisplatin in head and neck cancer. *In vitro* studies continue to evaluate other antibody and chemotherapy combinations (323).

Antibodies as Vaccines

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

Based on the idiotypic network put forth by Lindenmann and Jerne, various investigators have created antiidiotypic antibodies to serve as vaccines (324,325,326,327 and 328). One such vaccine was derived by immunizing goats with the MAb 17-1A (325). Thirty patients with advanced colorectal cancer were immunized intradermally with 0.5 to 4.0 mg of the antibody weeks 0, 1, 2, and 5 with 11 patients subsequently receiving a booster dose between 1.5 to 11 months thereafter. All patients developed an antiidiotypic cascade of antibodies. Six patients had partial responses and seven patients had stable disease. Response was not correlated with the dose of vaccine the patient received. However, only four of the patients with response or stabilization of their disease solely received vaccine. All others had received concurrent chemotherapy, making it unclear whether the clinical responses were due to vaccine, chemotherapy, or combination therapy.

An antiidiotypic antibody, created using an antibody directed against gp72 (324), has been used to treat patients with advanced colorectal cancer (329) and rectal cancer patients in an adjuvant setting (330). The antibody 105AD7 was produced by fusion of plasma cells from patients treated with an anti-gp72 antibody 791T/36 with EL41, a mouse/human heterohybrid. The 105AD7 hybridoma was found to produce a human IgG1 that bound to the binding site of the 791T/36 antibody. In 13 patients with metastatic colorectal cancer treated with the vaccine, survival was 12 months as compared to 4 months for patients in a contemporary control cohort; the significance of this increase in survival is unknown as this was not a prospectively randomized study. *In vitro* immunologic correlates demonstrated evidence of cellular responses as indicated by lymphocyte proliferation to gp72-expressing tumor cells and IL-2 production. In the adjuvant setting, six patients were vaccinated preoperatively. Three of these six patients subsequently demonstrated increased killing of autologous tumor cells by peripheral lymphocytes and by lymphocytes from draining lymph nodes; the killing observed by peripheral lymphocytes was increased as compared with baseline blood samples suggesting an immunologic impact of the vaccination. Evidence also existed of increased nonspecific killing of autologous tumor cells by NK cells.

Foon and his colleagues have evaluated an antiidiotypic vaccine strategy for CEA-expressing tumors. The antiidiotypic antibody 3H1 was derived from a murine antibody that targets a highly restricted epitope of CEA, which is not found on normal adult tissues or hematopoietic cells. Patients with advanced colorectal cancer treated with 3H1 injections developed both humoral and cellular responses against CEA (331). This response was not abrogated by concurrent chemotherapy (332). A phase 2 randomized study is ongoing evaluating 3H1 plus GM-CSF, or alum-precipitated 3H1 antibody with GM-CSF in patients with stage II or stage III colorectal cancer. This is the first trial evaluating an antibody as a vaccine in the adjuvant setting. Antiidiotypic antibodies against gp72 have also been developed (333), and 105AD7 has been tested in patients with advanced colorectal cancer (334). Patients were found to have a cellular, but not a humoral response to the immunization. Compared with contemporaneous controls, vaccinated patients survived a median of 12 months compared with nontreated patients who survived 4 months. In a follow-up study, the immunologic responses and progression-free survival were superior in patients who received a 100-μg versus 200-μg dose of vaccine (335).

Another antigen evaluated for immunization is the human milk-fat globule in women with breast cancer. Preclinical studies of 11D10, an antiidiotypic antibody derived against BrE-1, have been performed in cynomolgus monkeys (336). Immunization of the animals led to the production of both a cellular and humoral response. This vaccine strategy has been used in a

limited number of breast cancer patients, both in the adjuvant and metastatic setting with evidence of cellular and humoral responses in both patient populations (337). Objective responses have not been observed in the metastatic setting.

The impact of antiidiotypic vaccines remains to be clarified. Most of the vaccines use nonhuman antibodies for the vaccine, which may help stimulate an immune response against the antibody. However, as has been seen with intravenously administered antibodies, multiple administrations of the antiidiotype vaccine may be limited by the immune response against the constant regions of the antibody (e.g., HAMA response). Also, although *in vitro* data supporting the induction immune responses have been demonstrated, there is not clear evidence for the induction of clinically meaningful responses. Clinical trials with various antibodies have demonstrated antiidiotypic cascades after therapy (338). There are also examples of antibodies with specificity for the tumor antigen that are being used as vaccines (339,340). The infused antibody may allow for *in vivo* immunization, and the induction of these antiidiotypic antibodies may serve to amplify the antigenic stimulus to the immune system. Ovarian and breast cancer patients receiving high-dose chemotherapy followed by stem-cell transplantation were immunized with Theratope STn-KLH, an antibody directed against the MUC-I epitope. Eleven of 26 patients developed STn specific T-cell responses (341). It remains to be determined if such responses are components of therapeutic responses.

New Approaches

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

Antibody therapy has been evaluated with chemotherapy and cytokines for many years. Various toxins added on to the antibody, such as radioactive elements, toxins, or cytokines, have also been evaluated. However, antibodies have been evaluated as potential enhancers of external beam radiation therapy only since the 1990s. One report of the anti-EGFR antibody C225 with radiation therapy in head and neck cancer has demonstrated the safety of the combination and superior outcomes compared to the published response rates for radiation therapy alone in patients with locally advanced head and neck cancer (342).

Gene therapy strategies have evaluated constructs that transcribe antibody or antibody fragments, also termed *intrabodies.* The delivery and production of an antibody within a cell can bind to oncogenic proteins and downregulate their expression. For example, HER-2/*neu* has been targeted in this fashion (343,344). Transfection with the gene for an anti-HER-2/*neu* scFv construct containing the endoplasmic reticulum-directed leader sequence led to decreased cell surface expression of the protein, loss of anchorage-independent growth in agar, and death of transfected malignant cells. This was not observed when the HER-2/*neu* overexpressing cells were transfected with a scFv gene that localized to the cytosol, demonstrating the importance of binding the protein before it reaches the cell surface. This same approach in HER-2/*neu* expressing prostate (345), breast (346), and lung (347) cancer cell lines led to cell death. The mechanism of this cell death was shown to be apoptosis (348). In an ovarian cancer *in vivo* model, malignant ascites was treated with intraperitoneal injections of adenovirus complexed to the scFv plasmid DNA. The malignant cells were subsequently shown to have minimal cell surface expression of HER-2/*neu.* Thirty percent of animals treated with the scFv plasmid and cisplatin survived, whereas none survived when either was given as a single agent (349). This approach is intriguing, but like many gene therapy approaches is limited by the difficulty of delivering the gene into enough cells of interest.

Single chain fragments may provide a means to target genes to malignant cells by systemic administration. The sequence for a high-affinity scFv specific for CEA has been incorporated into the envelope protein of a retrovirus that contains the herpes simplex thymidine kinase (TK) gene (350). TK is a "suicide" gene, as cells that contain it die when exposed to ganciclovir. This approach allows for targeted delivery of the suicide gene to CEA-expressing cancer cells, specifically due to the binding of the scFv to cell surface CEA. *In vitro* there is evidence for efficient targeting and production of the kinase in CEA expressing cells.

New delivery systems are being evaluated for toxic therapies that incorporate antibodies. One example is the addition of antibodies to a lipid-encapsulated drug to specifically target the drug to the disease site. Another is the use of a gel in the delivery of a radioactive antibody for the treatment of liver metastases (351). Such an approach in a mouse model enhanced radioactive tumor retention, limited host toxicity, and allowed for the delivery of a higher dose to tumor site with improved therapeutic outcome.

Conclusions

Part of "15.4 - Breast Cancer and Other Adenocarcinomas "

We are in an era of tremendous growth and development in the field of antibody-based therapeutics. Clinical trials have documented the efficacy of some antibodies in the metastatic disease setting as single agents or in combination with chemotherapy. Our challenge is to continue to understand the mechanisms by which these antibodies achieve therapeutic efficacy and to use this information to seek new therapeutic targets and agents. Novel targets, such as receptors and proteins associated with drug resistance, may allow for killing of cells that are insensitive to the normal oncologic drug armamentarium (352). The increased ability to engineer antibody-based proteins assures an abundant supply of new therapeutic agents. These agents likely have the ability to target therapeutic agents such as cytotoxic drugs or radioactive compounds. Alternatively, cytokines that modify the tumor microenvironment can be targeted to the tumor, increasing immune responses at tumor sites. Strategies to optimize a particular type of immune response can be developed and used in conjunction with vaccines, allowing for the development of cellular antitumor responses. With the demonstration of clinical responses in the metastatic setting, the evaluation of effective antibodies in the settings of smaller bulk disease, such as in the posttransplant period or in the adjuvant disease setting, is anticipated with great interest.

Epidermal Growth Factor Receptor

Part of "15.5 - Monoclonal Antibodies Directed Against Growth Factor Receptors "

Since the 1980s, monoclonal antibodies (MAb) have attracted considerable interest as potential agents in the treatment of human cancer. Potential uses of MAb in the therapy of cancer include activating the immune and inflammatory systems or carrying cytotoxic agents to specific target sites. An alternative approach is to use MAb to block or interfere with the physiologic function of a receptor; in this case, the antigen is a molecule with known biologic activity that acts in signal transduction when activated by a particular ligand.

Human tumors express high levels of growth factors and their receptors, and many types of malignant cells appear to exhibit autocrine- or paracrine-stimulated growth. MAb directed at growth factor receptors provide a selective strategy to interfere with receptor function and hence inhibit tumor growth. Because most studies have been conducted with MAb directed against the erbB tyrosine kinase receptors (also known as *type I receptor tyrosine kinases*), this review focuses on these receptors as targets for antibody therapy.

The erbB receptor family is comprised of four homolog receptors: erbB1 (also known as *epidermal growth factor receptor* [EGF-R] or *HER1*), erbB2 (also known as *HER2/neu/p185HER2*), erbB3 (HER3), and erbB4 (HER4). These receptors are composed of an extracellular binding domain, a transmembrane lipophilic segment, and an intracellular protein

tyrosine kinase domain with a regulatory carboxyl terminal segment (Fig. 15.5-1) (1). erbB3, however, is different from the other members in that it has a deficient tyrosine kinase domain (2).
FIGURE 15.5-1. A: The erbB receptors are composed of an extracellular binding domain, a transmembrane lipophilic segment, and an intracellular protein tyrosine kinase domain with a regulatory carboxyl terminal segment. Monomeric receptors are inactive. B: Dimerization triggers receptor activation. In addition to ligand binding, mechanisms that promote the formation of dimers include receptor overexpression and transactivation (heterodimerization) (136). After receptor dimerization, activation of the intrinsic protein tyrosine kinase and tyrosine autophosphorylation occurs. These events lead to activation of a cascade of biochemical and physiologic responses that are involved in the mitogenic signal transduction of cells.

The rationale to target erbB receptors with MAb is compelling: These receptors are frequently overexpressed in human tumors; their overexpression typically confers a more aggressive clinical behavior; and MAb directed at these receptors inhibit tumor growth in laboratory model systems. Although an alternative approach would be to target the growth factors, the targeting of the receptors is preferred because of the multiplicity of ligands for a given receptor and the lack of known ligands for some of the family members.

Monoclonal Antibodies Against the Epidermal Growth Factor Receptor

Research with MAb against the EGF-R is presented in some detail as an example of the approach that can be taken in the exploration of receptor blockade as therapy for cancer.

Epidermal Growth Factor Receptor and Its Ligands

At least six different ligands, known as *EGF-like ligands*, activate the EGF-R (also known as *erbB1* or *HER1*) (3). These ligands include EGF, transforming growth factor-α (TGF-α), amphiregulin, heparin-binding EGF, betacellulin, and epiregulin. Some of the EGF-like ligands elicit differential biologic responses *in vitro*, suggesting that they may have unique physiologic roles (2,3 and 4).

The EGF-R with which these ligands interact is a 170-kd glycoprotein in the plasma membrane (see Fig. 15.5-1) (5). After binding of ligand, EGF-Rs form homodimers, an event believed to activate the intrinsic tyrosine kinase, resulting in transautophosphorylation of tyrosine residues, primarily in the carboxy terminal segments (5). Phosphorylation on serine and threonine residues is mediated by secondary activation of protein kinase C or other kinases (5). In addition to the formation of erbB1/erbB1 homodimers, EGF-like ligands can also induce erbB1/erbB2 heterodimers, and erbB1/erbB3 and erbB1/erbB4 heterodimers can also be occasionally detected (2,3,6).

Epidermal Growth Factor Receptor and Human Malignancy

Many types of epithelial malignancies display increased EGF-Rs on their cell surface membranes. Examples include cancer of the breast, lung, glioblastoma, head and neck, and bladder (7). Gene amplification is not a commonly reported finding in these tumors with the exception of the glioblastomas. Furthermore, in the case of glioblastomas, mutant EGF-Rs have been described. Increased EGF-R expression correlates with a poorer clinical outcome in malignancies of the bladder, breast, and lung (7). The level of increased expression can reach an order of magnitude or greater. Increased receptor content is often associated with increased production of TGF-α by the same tumor cells (8). This establishes conditions conducive to receptor activation by an autocrine stimulatory pathway.

Laboratory Studies with Antiepidermal Growth Factor Receptor Monoclonal Antibodies

The concept of EGF-R blockade by specific MAb as a novel form of cancer therapy was founded in the overexpression of EGF-R on tumor cells relative to normal cells and in potential qualitative differences in the response to disrupted receptor function in cancer cells versus normal cells. This concept was tested using a panel of MAb against the EGF-R. Two MAb, 225 immunoglobulin G1 (IgG1) and 528 immunoglobulin G2a (IgG2a), were found to bind to the receptor with affinity comparable with the natural ligand ($K_d = 2$ nM), compete with EGF binding, and block activation of receptor tyrosine kinase by EGF or TGF-α (9,10 and 11). It is likely that these MAb do not react with the actual EGF binding site, but near enough it to prevent EGF from binding because they react with a human-specific sequence and do not recognize EGF-R on rodent cells. MAb 225 produces antibody-mediated receptor dimerization, resulting in receptor downregulation, and this effect appears to be important for its growth inhibitory capacity (12). MAb 225 and 528 can block EGF- and TGF-α-induced stimulation of growth rate of a variety of human cells that express EGF-R and ligand (9,10,13,14). The interruption of the EGF-R ligand autocrine pathway by MAb 225 affects cell cycle progression, resulting in a G1 phase arrest that is accompanied by elevated levels of p27KIP1 inhibitor of cyclin-dependent kinases (15,16). In cells in which the EGF-R ligands act as survival factors rather than growth-promoting factors, such as in colon adenocarcinoma DiFi cells, these antibodies cause an irreversible G1 arrest followed by apoptosis (17).

In vivo effects of these MAb were assayed against tumor xenografts with A431 vulvar squamous carcinoma cells or MDA-MD-468 breast carcinoma cells, which express extremely high levels of EGF-Rs (18). Administration of 225 or 528 MAb

intraperitoneally, beginning concurrent with tumor cell implantation subcutaneously, caused a dose-dependent inhibition of tumor growth. The response to MAb treatment of well established (˜ 0.5 cm diameter) xenografts varied with the cell line, but generally tumors were not eliminated. Based on antitumor activity, murine MAb 225 was selected for clinical development. A chimeric human:murine version of MAb 225 (C225) was produced to obviate the immune response produced in humans by repetitive exposure to murine MAb 225 (19). The chimeric antibody C225 binds to the EGF-R with higher affinity (kd = 0.39 nM) than the murine MAb and is capable of inducing complete regressions of well-established xenografts of tumors overexpressing the EGF-R. An interesting finding is that C225 has greater antitumor efficacy *in vivo* than in cell culture inhibitory studies. As possible mechanisms for this enhanced *in vivo* antitumor effect, C225 has been shown to downregulate vascular endothelial growth factor production and suppress angiogenesis (20). In addition, C225 may elicit an immune or inflammatory response mediated by the Fc portion of the MAb.

Other laboratories have produced anti-EGF-R MAb with inhibitory activity against cells bearing EGF-Rs. 425 is an IgG2a MAb that inhibits the proliferation of A431 cells and colorectal SW948 adenocarcinoma cells in culture and in xenografts (21). Iodine-131–labeled F(ab")2 fragments of this MAb detected xenografts that overexpress the EGF-R (22). MAb 108 against the high-affinity EGF-R inhibited human oral epidermoid carcinoma cell growth in culture and in xenografts (23).

Laboratory Studies of Chemotherapeutic Agents in Combination with Antiepidermal Growth Factor Receptor Monoclonal Antibodies

Part of "15.5 - Monoclonal Antibodies Directed Against Growth Factor Receptors "

A 1988 study reported synergistic cytotoxicity against human tumor xenografts when anti-EGF-R MAb 108 was combined with cisplatinum therapy against K562 squamous carcinoma cells (23). These observations stimulated us to explore the hypothesis that chemotherapy and growth factor blockade may work through common mechanisms to increase tumor cell kill, especially in the case of well-established xenografts, which are generally not completely eliminated by treatment with the anti-EGF-R MAb. Subsequent studies confirmed and extended the initial observation. In cultures of A431 or MDA-468 cells, doxorubicin in combination with MAb 528 or 225 (but not with control antibody) produced an additive inhibition of growth. In mice bearing well-established A431 tumor xenografts, doxorubicin alone, or MAb 528 (or 225) did not eliminate the tumors. In contrast, the combination of doxorubicin and MAb 528 resulted in a major antitumor effect with cure in all of the animals (24). In MDA-468 xenografts, the combined treatment with MAb 528 and doxorubicin also resulted in a major antitumor activity.

Further studies have been conducted against A431 cell xenografts with the chemotherapeutic agent cisplatin in combination with MAb 528 or 225. The results of these experiments show again a marked synergistic effect with disappearance of well-established tumor xenografts, whereas the administration of cisplatin or MAb alone were not inhibitory (25). MAb 225 also enhances the antitumor activity of the paclitaxel in the MDA-468 breast cancer xenograft model (7).

What are the mechanisms underlying the enhancement of the activity of different classes of chemotherapeutic agents when given in combination with anti-EGF-R MAb? We favor an interpretation of our findings that implicates checkpoint regulation of the cell cycle as the activator of cell death (14). When cells are functioning properly, deprivation from the signaling pathways activated by essential growth factors activate the G_1 checkpoint, known as the *restriction point*, and the cells arrest in G1. Likewise, cells damaged by chemotherapy arrest typically in G2-M to repair alterations in DNA, tubulin, or other molecules. Malignant cells appear to be able to disobey checkpoints in some situations without jeopardizing cell survival. This was seen when MAb 225 was added to most tumor cell cultures, which resulted in incomplete G1 arrest. In contrast, cultures of nontransformed cells were completely arrested in G1 phase. We hypothesize that when tumor cells simultaneously disobey two checkpoint signals (activated by MAb 225 and chemotherapy), this becomes intolerable and results in cell death. Another way of conceptualizing this is to consider that in the face of chemotherapeutic damage, which signals the cell to pause for repair, the requirement for a growth factor for cell cycle traversal is converted to requirement of the growth factor for cell survival. Thus, malignant epithelial cells damaged by chemotherapy now act like DiFi cells, and when deprived of EGF-R kinase activity, they can no longer survive. Ample precedent exists for growth factors acting as survival factors in hematopoietic cell lines, in cultures of nerve cells, and in epithelial cells driven to proliferate by constitutive expression of myc (26,27). A corollary to this hypothesis is the prediction that nonmalignant epithelial cells, which obey the checkpoint signals, may be less susceptible to cytotoxicity from this combination therapy.

A newer approach to enhance the activity of anti-EGF-R MAb is the combination with inhibitors of related growth factor receptors, such as erbB2 (28), or with inhibitors that act on downstream signaling molecules, such as farnesyltransferase inhibitors (29), or with combined blockade of EGF-R and protein kinase A (30). Furthermore, anti-EGF-R antibodies may augment the activity of radiation therapy, as suggested by the observation that MAb 225 blocks the ability of the ligand EGF to enhance growth and radioresistance of breast cancer cells (31) and can potentiate the radiosensitivity of cultured cells (32,33).

Clinical Trials with Antiepidermal Growth Factor Receptor Monoclonal Antibodies

In an initial phase 1 single-dose study, indium-111–labeled murine MAb 225 was found to be safe, and satisfactory tumor localization was achieved (34). All patients produced human antimouse antibodies, however, which would have precluded the administration of multiple doses of antibody. To obviate the immune response, the chimeric human:murine version of MAb 225 (C225) was produced (19). An initial series of phase 1 trials with C225 have been recently completed in a total of 52 patients

with advanced, EGF-R-overexpressing tumors (35,36 and 37). In the first study, patients received a single intravenous dose of C225 at dose levels of 5, 20, 50, and 100 mg per m^2. In the second study, four weekly doses of 5, 20, 50, and 100 mg per m^2 were examined. In the third study of this series, cisplatin was added at a dose of 100 mg per m^2 on day 1 (cisplatin was later decreased to a dose of 60 mg per m^2), and weekly C225 was continued at the dose levels of 5, 20, 50, 100, 200, or 400 mg per m^2. A critical issue in these trials was to define the optimal dose and schedule at which complete and sustained receptor saturation was achieved. In cell culture, murine MAb 225 levels at 20 times the receptor-binding affinity resulted in receptor saturation and maximal inhibition of growth (9,10). In nude mouse models, saturating MAb 225 levels in the serum produced optimal antitumor activity against the xenografts (18). These observations served to define initially the optimal biologic dose of C225 as the lowest dose that would continuously maintain serum concentrations of the antibody above 30 nM. Although this criterion was met in these trials with the 100 mg per m^2 weekly dose, consideration was given to the idea that the concentration of the antibody required for EGF-R saturation in preclinical models might not directly correlate with what is required in humans. Indeed, EGF-R is widely expressed in normal tissues, providing additional competing antibody-binding sites that would have to be completely saturated in addition to the tumor cells as well. Hence, it was specifically hypothesized that the systemic clearance of C225 would depend on the antibody binding to EGF-Rs in a large number of tissues (38). If this were the case, then complete saturation of EGF-R binding should be accompanied by saturation of the antibody systemic clearance. A dose-dependent antibody clearance within the 20 to 100 mg per m^2 dose range was observed, however, indicating that the process was not yet saturated (Fig. 15.5-2A). Therefore, further escalation of the dose of C225 was conducted in a study that combined cisplatin and antibody. In that study, no apparent effect of cisplatin on C225 clearance was observed. Furthermore, at the 200 and 400 mg per m^2 dose levels, complete saturation of drug clearance was achieved (see Fig. 15.5-2A), and this dose range was selected for phase 1 trials (35,36 and 37). Mean circulating C225 levels were sustained above 200 nM beyond the initial dose for patients treated with multiple doses at 200 and 400 mg per m^2 (Fig. 15.5-2B).
FIGURE 15.5-2. A: C225 clearance in relationship to the different dose levels. Data from the three phase 1 studies have been pooled and the average value obtained is presented in the graph. Clearance decreased with increasing C225 doses until reaching the 200 mg per m^2 dose level. Clearance values derived from study CP02-9503 indicated that little, if any, difference in drug clearance occurred between the 200 and 400 mg per m^2 dose levels (p = .179, t-test). B: Mean serum levels of circulating C225 in study CP02-9503 in dose levels 200 and 400 mg per m^2 shown on a semilogarithmic plot scale. Mean serum levels of C225 were sustained above approximately 200 nM throughout treatments at dose levels 200 and 400 mg per m^2. (doxo, doxorubicin; TAX, paclitaxel.) [From Baselga J, Pfister D, Cooper MR, et al. Phase I studies of antiepidermal growth factor receptor chimeric antibody C225 alone and in combination with cisplatin. *J Clin Oncol* 2000 (in press), with permission.]

The difference between the optimal biologic dose projected from preclinical models and the higher C225 dose required to achieve saturation of drug clearance in patients could not have been predicted from studies with human xenografts in nude mice because of the lack of MAb 225 or C225 binding to the murine receptor. This observation emphasizes the need of developing reliable biologic markers in trials that evaluate agents that act on the EGF-R (39,40 and 41). The pharmacokinetic findings with C225 are in agreement with a prior phase 1 single-dose clinical trial with a different murine anti-EGF-R MAb, RG 83852, in patients with non-small-cell lung cancer or head and neck tumors (39). In that study, dose-dependent pharmacokinetics were observed with higher antibody doses that resulted in reduced plasma clearance, suggesting saturation of extravascular clearance mechanisms at higher antibody doses. In addition, tumor EGF-R saturation assessed in biopsied tumor samples by immunohistochemistry and EGF-R tyrosine kinase assays showed receptor saturation of equal to or more than 50% at doses equal to or more than 200 mg per m^2(39). Overall, the results from these studies support the hypothesis that saturation of antibody binding to the EGF-R in humans occur only when complete saturation of drug clearance (i.e., zero order kinetics) is achieved.

C225 was well tolerated in these phase 1 trials, and the dose schedule that saturates the body clearance mechanisms was achieved before reaching the maximal tolerated dose (35,36 and 37). Although these trials were not designed to analyze clinical response, C225 given as a single agent did induce frequent stabilization of tumors. This was observed at all the C225 dose levels, although patients at higher dose levels had a higher tumor stabilization rate. Tumor regressions were demonstrated in two patients with head and neck tumors treated with C225 at doses of 200 mg per m^2 and 400 mg per m^2 in combination with cisplatin(36,37). A series of phase 2 studies of C225 given alone or in combination with several chemotherapeutic agents in head and neck cancer, prostate, renal cell, and breast cancer are ongoing. The most extensive studies with C225 have been on patients with advanced head and neck cancer. A phase 1/2 trial involving 15 patients with surgically unresectable disease combining radiation with MAb C225 treatment demonstrated a complete response in 13 patients and partial responses in the remaining two patients (42). The expected complete response rate was less than 50%. Based on these promising results, a randomized phase 3 trial comparing radiation with and without C225 is under way. A phase 2 trial of cisplatin plus C225 is ongoing. The results for six evaluable patients include three partial responses and one complete response. Two responders had previously failed regimens that included cisplatin(43). A phase 3 trial of cisplatin with or without C225 is planned.

In another phase 1 trial, the rat anti-EGF-R MAb ICR62 was evaluated in 20 patients with head and neck or lung cancer (44). This antibody effectively blocks the binding of EGF, TGF-α, and heparin-binding EGF to the EGF-R; inhibits the growth *in vitro* of tumor cell lines that overexpress the EGF-R; and eradicates such tumors when grown as xenografts in athymic mice. Groups of three patients were treated with 2.5 mg, 10 mg, 20 mg, or 40 mg of ICR62, and a further eight patients received 100 mg. In that trial, no serious toxicity was observed. Antibody ICR62 could be detected in the sera of patients treated with 40 mg or 100 mg of ICR62. Four patients showed human antirat antibodies. In four patients receiving doses of ICR62 at 40 mg or more, biopsies were obtained from metastatic lesions and showed the localization of MAb ICR62 to the membranes of tumor cells; this appeared to be more prominent at the higher dose of 100 mg (44).

Low-molecular-weight inhibitors of EGF-R also have been produced. These generally act intracellularly by blocking the activation of the tyrosine kinase portion of the receptor molecule (45). A number of these kinase inhibitors have been reported in preclinical studies, demonstrating efficacy in blocking the activation of the EGF-R kinase and inhibiting the growth of xenografts (46,47 and 48). Phase 1 trials of these receptor kinase inhibitors have been initiated.

Monoclonal Antibodies Against the HER2 Receptor

*Part of "*15.5 - Monoclonal Antibodies Directed Against Growth Factor Receptors "

HER2 Receptor

The HER2 receptor (also known as *neu, erbB-2*, and *p185* [HER2] *receptor*), is a 185-kd tyrosine kinase receptor that belongs to the erbB receptor family and has partial homology to the EGF-R (49,50 and 51). The two other members of the erbB receptor family are erbB3 (HER3) and erbB4 (HER4).

Unlike the EGF-R (erbB1), a ligand for HER2 (erbB2) has not been identified. In spite of sequence homology between HER2 and the EGF-R, EGF-like ligands bind to the EGF-R but not to HER2 (3). A second class of ligands of erbB receptors, collectively termed *neuregulins* (also known as *neu differentiation factors* or *heregulins*), bind directly to erbB3 and erbB4, but not to HER2 or to the EGF-R (52). HER2, however, is the preferred heterodimerization partner within the family (53). HER2 is frequently transactivated by EGF-like ligands (see the section on Epidermal Growth Factor Receptor and Its Ligand), resulting from the formation of erbB1/HER2 heterodimers (2,3). In an analogous way, neuregulins can induce the formation of HER2/erbB3 and HER2/erbB4 heterodimers (54,55,56 and 57). This heterodimerization between HER2 and the other receptors of the family allows the participation of HER2 in signal transduction, even in the absence of a cognate ligand. The heterodimers between HER2 and the other members of the family (erbB1, erbB3, and erbB4) show relatively high ligand affinity and potent signaling activity and are synergistic for cell transformation (6,53,58,59 and 60). In one report, a transmembrane protein that contains two EGF-like domains, ASGP2, has been shown to interact with the extracellular domain of HER2 and potentiate signaling through the erbB receptor network (61).

HER2 has been shown to be overexpressed, most commonly by gene amplification, in an array of human carcinomas including, but not limited to, breast, ovarian, gastric, colon, and non-small-cell lung carcinoma (62). The most comprehensive studies have been conducted in breast cancer showing that HER2 is overexpressed in 25% to 30% of human breast cancers and predicts for a worse prognosis in patients with primary disease (63,64). In addition, several other lines of evidence support a direct role for HER2 in the pathogenesis and clinical aggressiveness of HER2 overexpressing tumors: The introduction of HER2 into nonneoplastic cells causes their malignant transformation (65,66); transgenic mice expressing HER2 develop mammary tumors (67), and MAb directed at the HER2 receptor inhibit the growth of tumors and transformed cells that express high levels of this receptor (62,68,69,70 and 71).

A distinct feature of the HER2 receptor when compared with other members of the erbB family is that the extracellular portion of the receptor can be cleaved and released into the media. This process is regulated and (72) of unknown importance, although high levels of extracellular HER2 in the serum of patients with breast cancer has been associated with a more aggressive clinical behavior and decreased sensitivity to conventional anticancer agents.

Laboratory Studies with Anti-HER2 Monoclonal Antibodies

Several groups have produced antibodies directed against the rat neu receptor (68,69) and the HER2 receptor on human cells (73,74,75,76,77 and 78). Genentech produced a series of murine MAb that inhibit the proliferation of monolayer cultures of breast and ovarian tumor cells overexpressing HER2 (70,73,79). In their extensive studies, a clear relationship between the level of HER2

proto-oncogene expression and sensitivity to the growth inhibitory effects of the antibodies were observed. One of the most potent growth inhibitory anti-HER2 MAb, 4D5, which is directed against the extracellular domain of HER2, was selected for further clinical development (72,73,79). As discussed previously, murine antibodies are limited clinically because they are immunogenic. To attempt to circumvent the antiglobulin response, a "humanized" antibody was constructed. The resulting recombinant humanized anti-erbB2 MAb, trastuzumab (Herceptin), has a higher binding affinity for erbB2 (K_d = 0.1 nM) than the murine 4D5 and has a marked growth inhibitory effect against cultured breast cancer cells overexpressing erbB2 (80). Furthermore, trastuzumab is much more efficient in supporting antibody-dependent cellular cytotoxicity against human tumor cell lines in the presence of human peripheral mononuclear cells, which can increase its antitumor activity (55,80,81).

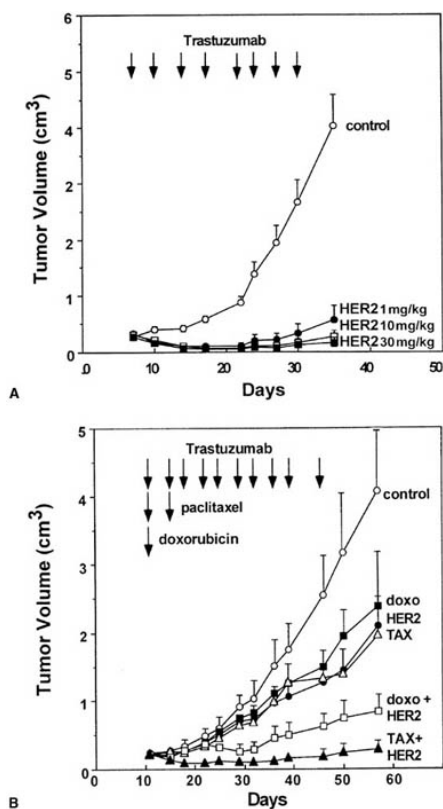
In the first report using trastuzumab against human tumor xenografts, a single dose of antibody-inhibited tumor growth by 50% (82). Subsequently, we confirmed the *in vivo* antitumor activity of trastuzumab against human breast cancer BT-474 xenografts that overexpress erbB2 (83). Repeated administrations of the antibody given at doses equal to or greater than 1 mg per kg resulted in strong growth suppression and eradication of tumors in a significant proportion of animals. In our animal model, doses of 1 mg per kg given twice a week resulted in maximal inhibition of growth (Fig. 15.5-3A). This dose level is similar to the one being administered in the clinical trials in patients with advanced breast cancer (2 mg per kg × weekly).


FIGURE 15.5-3. A: Activity of anti-erbB2 monoclonal antibody trastuzumab against well-established BT-474 tumor xenografts in athymic mice (80). Trastuzumab was given intraperitoneally twice a week for 4 weeks at doses of 1 mg per kg, 10 mg per kg, and 30 mg per kg. The control group was treated with a nonspecific rhu monoclonal antibody IgG at a dose of 30 mg per kg. Trastuzumab at doses equal to or greater than 1 mg per kg markedly suppressed the growth of BT-474 xenografts. B: Antitumor activity of trastuzumab in combination with paclitaxel or doxorubicin against well-established BT-474 tumor xenografts in athymic mice (137). The control group was treated with the control rhu monoclonal antibody IgG at a dose of 0.3 mg per kg twice weekly intraperitoneally. Trastuzumab was given intraperitoneally twice a week for 5 weeks at a dose of 0.3 mg per kg. Paclitaxel was given intravenously at a dose of 10 mg per kg on days 1 and 4. Doxorubicin was administered intraperitoneally at a dose of 10 mg per kg of body weight on day 1. Doxorubicin or paclitaxel, given each in combination with the control antibody, resulted in a modest antitumor activity. Trastuzumab also resulted in a modest inhibition of growth. The combined treatment with trastuzumab plus paclitaxel or doxorubicin resulted in a marked enhancement of the antitumor effects compared with either chemotherapeutic agent alone. Greater inhibition of tumor growth occurred in the group of animals treated with paclitaxel and trastuzumab. Results are given as mean tumor volume + SE. Arrows show days on which treatment was administered. (doxo, doxorubicin; HER2, trastuzumab; Tax, paclitaxel.)

In contrast with anti-EGF-R, MAb that mainly act by preventing ligand binding, the mechanism of action of antibodies directed against HER2, is not well understood. In fact, unlike MAb C225, binding of trastuzumab to its receptor activates the HER2 tyrosine kinase, resulting in autophosphorylation (84). Several possible mechanisms exist, however, by which anti-HER2 MAb could exert their tumor-inhibitory effects. Treatment of cancer cells overexpressing HER2 with MAb 4D5, trastuzumab, and other growth-inhibitory antibodies results in a marked downregulation of HER2 expression (79,84,85). Antibody-induced downregulation of erbB2 has been shown to induce reversion of the transformed phenotype in HER2-transformed cells (68). A relationship between receptor degradation and antitumor effects of anti-erbB2 MAb is supported by a study using a large battery of anti-HER2 antibodies (78). In that study, stimulation of erbB2 receptor phosphorylation was

found to be uncoupled from the growth inhibitory effects of the antibodies (78). Another property of trastuzumab is its partial ability to disrupt the formation of erbB2/erbB3 and erbB2/erbB4 heterodimers, but a relationship between this effect and growth inhibition is not established (78,86). Possible additional *in vivo* mechanisms of action involve the observation that trastuzumab is a potent inducer of antibody-dependent cellular cytotoxicity (81) and has antiangiogenic activity with downregulation of vascular endothelial growth factor and other angiogenic factors (20). In addition to MAb, a variety of research approaches exist to target erbB2-overexpressing cells, including immunoconjugates, vaccines, tyrosine kinase inhibitors, antisense, and transcriptional downregulators.

Laboratory Studies of Chemotherapeutic Agents in Combination with Anti-HER2 Monoclonal Antibodies

As in the case of anti-EGF-R MAb, a way to optimize the efficacy of anti-HER2 MAb is to administer them in combination with chemotherapy. Hancock et al. showed that an anti-HER2 antibody, TAb 250, markedly enhanced the antitumor effects of cisplatin(74). Using the same antibody, Arteaga has shown enhanced etoposide-induced cytotoxicity against human breast carcinoma cells and postulated that erbB2 antibodies may alter the sensitivity of topoisomerase II toward etoposide(87). Studies by Slamon with MAb 4D5 or trastuzumab and chemotherapeutic agents have demonstrated that 4D5 promotes sensitivity to cisplatin in cisplatin-resistant ovarian carcinoma cell lines (88,89). Searching for mechanisms, it has been shown that anti-HER2 MAb interfere with repair of DNA damage owing to cisplatin, which could promote drug cytotoxicity against target cells (88,90).

Because paclitaxel and doxorubicin are two of the most active chemotherapeutic agents for the treatment of breast cancer (91), we hypothesized that finding enhanced antitumor activity of these drugs when combined with anti-HER2 MAb would have distinct clinical implications (83). Hence, a series of experiments with trastuzumab in combination with paclitaxel or doxorubicin was conducted. In cultured cells overexpressing HER2, an additive cytotoxic effect was observed with cotreatment combining trastuzumab plus paclitaxel. In our BT-474 tumor xenograft mouse model, doses of trastuzumab that modestly inhibit growth of well-established tumors effectively enhance the tumoricidal effects of paclitaxel and results in a striking rate of tumor eradication (Fig. 15.5-3B).

Trastuzumab enhanced the antitumor effects of doxorubicin as well, albeit to a lesser degree than was observed with paclitaxel (see Fig. 15.5-3B). Animals treated with trastuzumab alone or with trastuzumab plus chemotherapy had a significantly higher complete tumor regression rate than control animals. The highest complete tumor eradication rate was observed in those animals treated with trastuzumab plus paclitaxel(83). In addition to our data, a number of studies have shown that therapies leading to HER2 receptor downregulation or inhibition of its phosphorylation may enhance sensitivity to a variety of chemotherapeutic agents (92,93 and 94).

The simplest explanation for the enhanced activity of paclitaxel and trastuzumab is that it is the result of the summation of effects of two anticancer drugs that act on different targets; trastuzumab acts on the HER2 receptor signaling pathway and paclitaxel acts on tubulin. The magnitude of the enhanced antitumor activity with the combination, however, may be well beyond a simple summation of effects (83). It has been shown that overexpression of HER2 activates the cyclin-dependent kinase inhibitor p21, which inhibits p34^{cdc2} kinase. p34^{cdc2} kinase activation is required for paclitaxel-induced apoptosis, and overexpression of HER2 blocks paclitaxel-induced apoptosis by inhibiting p34^{cdc2} activation (95). This finding provides a mechanistic link between erbB2 overexpression and paclitaxel sensitivity. Therefore, it is possible that trastuzumab, by downregulating HER2, may prevent or inhibit p21 activation and, as a result, increase paclitaxel-induced apoptosis because of the presence of activated p34^{cdc2} kinase.

Clinical Trials with Anti-HER2 Monoclonal Antibodies

The first phase 2 study of multiple-dose intravenous administration of trastuzumab was conducted in patients with metastatic breast carcinoma overexpressing HER2 (96). The study included 46 patients that in general had extensive metastatic disease and had received prior chemotherapy. Based on prior phase 1 clinical trials, patients received a loading dose of 250 mg trastuzumab on day 0 and, beginning on day 7, 100 mg weekly for a total of 10 doses. More than 90% of the examined population had trastuzumab trough serum levels above the targeted 10 μg per mL level. Suboptimal serum concentrations, however, were found in those patients with high circulating levels of tumor-shed HER2 extracellular domain. Antibodies against trastuzumab were not detected in any patients. Trastuzumab was remarkably well tolerated. Out of a total of 768 administrations of trastuzumab, only 11 events occurred that were considered to be related to the use of the antibody. Among 43 evaluable patients, five had tumor responses (one complete remission and four partial remissions) for an overall response rate of 11.6% (Table 15.5-1). No responses were seen in patients with high serum levels of shed HER2 extracellular domain. Because elevated levels of shed HER2 ectodomain were associated with lack of response to trastuzumab and the shedding event is a regulated process, the results of laboratory studies examining a combined therapeutic approach with inhibitors of HER2 shedding and trastuzumab deserve consideration (72). Another important observation of this trial was that 37% of patients achieved minimal responses or stable disease (96). The median time to progression in patients with minor or stable disease was 5.1 months. The unusually long durations of minimal responses and stable disease seen in this trial suggested that stable disease may be an authentic reflection of the biologic action of the drug. This trial provided the first clinical evidence that anti-growth factor receptor-directed strategies were useful in the treatment of human cancer (96).

Table 15.5-1 Trastuzumab Activity: Single-Agent Breast Cancer Studies

	Proof of Concept Phase 2 (%)	Pivotal Phase 2 (%)	Current Phase 2 (%)
No. of patients (intent-to-treat)	46	222	112
Prior CT regimens metastatic disease (median)	Yes (3)	Yes (2)	No
Complete response	1	8	6
Partial response	4	26	20
Response rate	11	14	23
95% CI	4-24	11-21	15-31
Median duration of response (mo)	6.6	9.1	8.0
Median survival (mo)	14	13	N/A
Reference	93	94	95

CI, confidence interval; CT, chemotherapy; N/A, not available.
Note: First-line therapy trial (patients without prior chemotherapy).

In a follow-up pivotal study (97), 222 women with HER2+ metastatic breast cancer and two prior chemotherapy regimens were enrolled in an open label, phase 2 trial of trastuzumab

(loading dose, 4 mg per kg and weekly dose, 2 mg per kg). The overall response rate as determined by an independent Response Evaluation Committee was 14% (95% confidence interval, 10% to 20%) with a 2% complete response rate and a 12% partial response rate. Response Evaluation Committee–determined median duration of response was 8.5 months and estimated median survival is 13 months. Cardiac dysfunction was observed in ten patients, six of them symptomatic, including one death due to a ventricular arrhythmia; all had prior anthracycline chemotherapy or had a cardiac history.

A more recent study has analyzed the activity of trastuzumab in patients with metastatic breast cancer overexpressing HER2 as first-line therapy of breast cancer (98). A total of 114 women have been entered in this study. Patients were randomized to receive the conventional trastuzumab dose (loading dose, 4 mg per kg and weekly dose, 2 mg per kg) or a higher dose regimen (loading dose, 8 mg per kg and weekly dose, 4 mg per kg). Mean age in this study was 57 years, 26% had a metastatic-free interval of less than 12 months, and 86% had visceral disease. Of 112 evaluable patients, six complete remissions and 20 partial remissions have been observed for an overall response rate of 23% (95% confidence interval, 15% to 31%). The response rate in the group of patients with the higher level of HER2 overexpression (3+) (n = 85) was 31%. No differences existed in response between the two dose levels, and the median duration of response was 8 months.

In summary, trastuzumab is active as a single agent in women with HER2+ metastatic breast cancer and induces durable objective tumor responses as first-line therapy in previously treated patients. We conclude that trastuzumab is safe and effective for the therapy of patients with HER2+ metastatic breast cancer.

Clinical Trials with Anti-HER2 Monoclonal Antibodies and Chemotherapy

Based on the preclinical synergism, a phase 2 study of antibody and cisplatin was conducted in parallel to the first single-agent phase 2 trial (99). The study included patients with extensively pretreated advanced breast cancer with HER2 overexpression and disease progression during standard chemotherapy. The dose and schedule of trastuzumab administration was identical as in the single-agent phase 2 trial, and cisplatin (75 mg per m^2) was given every 4 weeks. Of 37 patients assessable for response, nine (24.3%) achieved a partial response, nine (24.3%) achieved a minor response or stable disease, and disease progression occurred in 19 (51.3%). The median response duration was 5.3 months (range, 1.6–18). No evidence exists that trastuzumab enhanced the toxicity of cisplatin. Mean pharmacokinetic parameters of trastuzumab were unaltered by coadministration of cisplatin. The presence of high serum levels of HER2 extracellular domain, however, was inversely related with the serum half-life of trastuzumab. The 24% response rate observed with the combination is greater than the reported response rate with cisplatin alone in patients who were previously treated for their metastatic disease (0% to 7%) and further supports the laboratory data showing marked enhancement of the antitumor effects of cisplatin when combined with trastuzumab.

The mentioned preclinical data showing marked antitumor effects when anthracyclines, and especially taxol, were combined with trastuzumab led to the design of a phase 3 multicenter clinical trial of chemotherapy (doxorubicin based or paclitaxel based) plus trastuzumab versus chemotherapy alone in patients with advanced breast cancers overexpressing HER2 (100). A total of 469 female patients with no prior chemotherapy for their metastatic breast cancer were included in the trial. The patients received doxorubicin-cyclophosphamide (AC) (n = 281) or paclitaxel (n = 188) as first chemotherapeutic regimen if they had not received prior adjuvant doxorubicin or paclitaxel if previously exposed to doxorubicin. The schedules of chemotherapy were: AC, doxorubicin (60 mg per m^2) (or epirubicin, 75 mg per m^2) plus cyclophosphamide (600 mg per m^2) or paclitaxel (175 mg per m^2) in a 3-hour infusion. All chemotherapeutic agents were given every 3 weeks for six cycles. One-half of the patients (stratified by the chemotherapeutic regimens) were randomized to additionally receive trastuzumab (4 mg per kg loading, then 2 mg per kg intravenously weekly). An independent Review Evaluation Committee-determined time to disease progression and response rates show a significant augmentation of the chemotherapy effect by trastuzumab without increase in overall severe adverse events. A syndrome of myocardial dysfunction similar to that observed with anthracyclines was reported more commonly with AC plus trastuzumab (16%, grade 3/4) than with AC alone (3%), paclitaxel alone (1%), or paclitaxel plus trastuzumab (2%). The benefits of adding trastuzumab to the chemotherapeutic regimens used are summarized in Table 15.5-2 . Trastuzumab significantly increased time to progression and response rate and duration. The time to disease progression was 4.6 months with chemotherapy alone and increased to 7.6 months with combined therapy (p = .001). The increase in time to disease progression was particularly positive in the paclitaxel plus trastuzumab arm when compared with trastuzumab alone. The overall response rate was 32% with chemotherapy alone and 49% with combined therapy (p = .0002). The augmentation of response rate was more pronounced in the paclitaxel arm than in the AC arm (see Table 15.5-2). Of interest, the 1-year survival was 78% in patients treated with trastuzumab

and chemotherapy versus 67% in patients treated with chemotherapy alone (p = .008) (97).

Table 15.5-2 Trastuzumab in Combination with Chemotherapy

	No. Patients	Median TTP (Mo) (p Value)		Response Rate (%) (p Value)		Median DR (Mo) (p Value)	
H + AC	143	8.1	(.0003)	52	(.1038)	9.1	(.0025)
AC	138	6.1		43		6.5	
H + P	92	6.9	(.0001)	42	(<.0001)	11.0	(.0001)
P	96	3.0		16		4.4	
H + CT	235	7.6	(.0001)	49	(.0002)	9.3	(.0001)
CT	234	4.6		32		5.9	

AC, doxorubicin + cyclophosphamide; CT, chemotherapy; DR, duration of response; H, Herceptin; P, paclitaxel; TTP, time to progression.

The results of these clinical trials have shown that trastuzumab is effective for the treatment of patients with HER2+ metastatic breast cancer. To further establish the role of trastuzumab in the therapy of patients with breast cancer, a series of clinical trials are under way or are in the planning process. The areas that appear to be of major interest for further development of trastuzumab are:

1. Studies of trastuzumab in combination with other active agents and regimens
2. Combination studies with hormonal therapy
3. New schedules with taxanes (± platinum)
4. Adjuvant and neoadjuvant studies

In addition, because HER2 is also overexpressed in other common malignancies, such as colon and non–small-cell lung cancer, studies are also being planned with trastuzumab alone or with conventional chemotherapeutic agents.

Novel Antibody-Based Strategies Directed Against ErbB Receptors

Part of "15.5 - Monoclonal Antibodies Directed Against Growth Factor Receptors "

In addition to antibodies that are directed against the extracellular domains of EGF-R or HER-2, recombinant antibody technology has been proved as a useful tool in designing and producing novel antibody-based molecules (101). These novel antibody-based molecules include intracellular antibodies, bispecific antibodies, and antireceptor antibody fusion molecules. Another therapeutic strategy involving antigrowth factor receptor MAb is the use of the receptor-mediated endocytosis pathway for gene delivery. Some of these antigrowth factor receptor strategies are entering clinical trials.

Intracellular Antibody

The intracellular antibody strategy is based on the delivery of a single-chain antibody construct containing the variable domains of heavy and light chains of the antibody (scFv) into target cells via a vehicle such as recombinant virus (102). When functionally expressed in target cells, the scFv antibody can bind to the targeted molecules and prevent their transit and delivery through the endoplasmic reticulum. This results in the functional inactivation of the targeted molecules and, therefore, can be applied to selectively "knock out" some specific oncoproteins, potentially creating a new form of anticancer therapy. Research has been carried out on scFv antibodies directed against EGF-Rs and HER-2. Expression in the endoplasmic reticulum of the anti-HER-2 scFv antibody resulted in a profound downregulation of cell surface HER-2. This was accompanied by marked inhibition of proliferation in HER-2–overexpressing cell lines, and even killing of targeted tumors cells via apoptosis in some cases (102). Anti-HER-2 scFv can also reverse the phenotype of NIH3T3 cells transformed by HER-2 (103). Similar experiments with intracellular expression of an scFv antibody derived from anti-EGF-R MAb R1 also led to growth inhibition of cells expressing EGF-Rs (104).

Bispecific Antibody

Considerable progress has been made in the production of bispecific MAb (BsMAb) with dual specificity for cancer-associated antigens and for cells and molecules that can trigger cytotoxicity, such as leukocyte surface receptors or chemotherapeutic drugs. BsMAb have been produced by chemically cross-linking two individual F(ab") fragments by fusion of two parental hybridomas into a hybrid-hybridoma and screening for BsMAb expression or trough molecular construction of BsMAb fusion antibody using recombinant antibody technology (105).

Several BsMAb that bind to HER-2 or EGF-Rs have been made, and targeted lysis of tumor cells by BsMAb has been achieved. Some studies used BsMAb directed to the EGF-R coupled with reactivity to CD3 or doxorubicin; other studies used BsMAb directed to HER-2 coupled with reactivity to CD3, CD64 (FcγRI), CD43 (FcγRII), or CD16 (FcγRIII) (101). The results of these studies indicate that the BsMAb can significantly enhance the specific cytotoxicities of T cells, natural killer cells, or polymorphonuclear leukocyte cells on targeted tumor cell lines. 2B1, a hybrid-hybridoma BsMAb consisting of MAb 520C9 to HER-2 and MAb 3G8 to CD16 and MDX210, another BsMAb consisting of chemically cross-linked F(ab") fragments of MAb 520C9 to HER-2 and MAb H22 to CD64, have undergone phase 1 evaluation. No untoward toxicities were observed (106,107). As an alternative approach, the natural ligands for receptors may also be used for construction and expression of such fusion proteins (108).

Antireceptor Antibody Fusion Molecules

Genetically engineered fusion proteins coupling MAb with cytokines or toxins provide an approach that combines the specific targeting ability of antibodies with the multifunctional cytotoxicities of cytokines or toxins. This approach can be achieved via the fusion of genes encoding toxins or cytokines to the genes encoding for MAb with expression in a bacterial vector (109). With advances in recombinant DNA technology, scFv antibodies have been used as recognition domains. This novel form of fusion protein is superior to the conventional chemical conjugates of MAb with toxins, in that antibody single-chain fusion proteins are much smaller than the original conjugate and have superior properties in their penetration into large tumors. Also, the fusion proteins are easier to produce and purify and are more stable and consistent in activity. Research on the activity of antibody-cytokine or antibody-toxin fusion proteins has been carried out in cancer cells overexpressing EGF-Rs or HER2. These include anti-EGF-R MAb fusion proteins containing interleukin-2 (IL-2) (110) or lymphotoxin (111) and anti-HER2 receptor MAb fusion proteins containing B7-2 (CD80) (112).

The recombinant immune toxins scFv(225)-ETA and scFv(FRP5)-ETA contain a single-chain antibody against the EGF-R (225) or HER2 (FRP5), respectively, in fusion with a truncated gene encoding for the exotoxin (ETA) of *Pseudomonas aeruginosa* (109). The scFv(225)-ETA has been shown to specifically inhibit the growth of cultured cells expressing high levels of EGF-Rs, and scFv(FRP5)-ETA inhibited the growth of cultured cells, as well as xenografted tumor cells expressing HER2 (113). Another experimental capacity of these immunotoxins is the ability to purge, *ex vivo*, hematopoietic progenitor cells contaminated with mammary carcinoma cells because CD34[+] hematopoietic progenitor cells do not express EGF-Rs or HER2 (114). Because some tumor cells express EGF-Rs and HER2 and the two receptors may synergize in cellular transformation, a bivalent scFv2(FRP5/225)-ETA fusion protein (a fusion containing HER2–specific and EGF-R–specific MAb domains fused to ETA) or, alternatively, a bivalent scFv2(FRP5)-TGF-α-ETA (a fusion immunotoxin containing HER2–specific MAb domain and TGF-α fused to ETA), were also constructed and expressed (115,116). In these studies, they were found to be more potent than the corresponding monovalent toxins in killing human tumor cells coexpressing HER2 and EGF-R *in vitro* and in xenografts.

Monoclonal Antibodies Against Other Receptors

Part of "15.5 - Monoclonal Antibodies Directed Against Growth Factor Receptors "

Monoclonal Antibodies Against the Receptor for Transferrin

The transferrin receptor is displayed on the cell surface when cells proliferate, and transferrin appears to be an essential ingredient of the culture medium for cells grown under serum-free conditions (117). In many cases, evidence exists that the transferrin receptor is expressed in higher numbers on tumor cells than in normal tissues (118). These properties suggest that the transferrin receptor may be a fruitful target for novel forms of anticancer therapies.

Antitransferrin receptor antibodies have shown antitumor activity in experimental murine and human xenograft models (119,120). 42/6 is a murine IgA monoclonal antihuman transferrin receptor MAb previously shown to have *in vitro* antitumor activity (119,121). 42/6, given as a 24-hour infusion, has been tested in an initial phase 1 clinical trial in patients with refractory malignancies (122). This represented the first clinical trial with an IgA mouse MAb, and antibody concentrations capable of inhibiting malignant cell growth were obtained without toxicity.

As with anti-erbB MAb, preclinical evidence exists that supports an enhanced antitumor activity when combined with other anticancer agents. Antitransferrin MAb enhance the antitumor effects of cyclophosphamide (Trowbridge, *unpublished observations*), desferroxamine (123), anti–IL-6 antibodies (124), and retinoid acid (125).

Monoclonal Antibodies Against the Interleukin-2 Receptor

The IL-2 receptor is a multisubunit complex containing two ligand-binding sites, IL-2 receptor α (p55 or Tac protein) and IL-2 receptor ß (p75). In addition 22-, 35-, 75- (non–IL-2 binding), and 95- to 105-kd peptides, as well as class I major histocompatibility complex, intercellular adhesion molecule-I, and two tyrosine kinases are associated with the two IL-2–binding polypeptides (126). The distinct mature T-cell form of acute leukemia, termed *adult T-cell leukemia* (ATL), is a malignant proliferation of T cells that express IL-2 receptors, including the Tac peptide. Receptor expression is activated by the tax protein of human T leukemia virus-1, the primary etiologic agent in ATL. An early clinical trial evaluated the efficacy of anti-Tac MAb in patients with ATL. None of the 16 patients demonstrated any toxicity, one patient had a mixed response and another patient had a partial response, and four developed complete remissions lasting from 1 to more than 8 months (126,127 and 128). In one of these cases studied in great detail, there was a decline to normal in the number of Tac-expressing cells, paralleled by an elimination of circulating malignant cells characterized as cells bearing human T leukemia virus-1 integrated into their DNA and cells with a clonal T-cell receptor rearrangement. A bispecific humanized anti-IL receptor αß has also been produced and may be more efficacious than anti-Tac or MAb, or both, directed at IL-2 receptor α and ß, respectively (129).

To limit the immunogenicity, humanized anti-Tac MAb have been produced (130). In addition, to enhance their effector function, anti-Tac antibodies have been armed with immunotoxins or with α- and ß-emitting radionuclides. Anti–IL-2 receptor antibodies linked to a deglycosylated ricin-A toxin have shown promising activity in patients with refractory Hodgkin's lymphoma (131). In a clinical trial with 90Y-anti-Tac, 11 of 17 patients with ATL underwent a remission (132).

A new class of receptor-active cytotoxic fusion protein, DAB$_{389}$IL-2, composed of the binding domain of diphtheria toxin and the receptor-binding domain of IL-2, has also been

shown to be active in cutaneous T-cell lymphoma and in other non-Hodgkin's lymphomas (133). Five complete and eight partial remissions occurred in 35 patients with cutaneous T-cell lymphoma and one complete remission and two partial remissions out of 17 patients with non-Hodgkin's lymphomas. The median time to response was 2 months, and the duration of response was 2 to 39+ months. No responses were documented in patients with Hodgkin's disease. A randomized trial assessed the safety and efficacy of DAB$_{389}$IL-2 at two dose levels (134). Based on these studies, DAB$_{389}$IL-2 has undergone accelerated Food and Drug Administration approval for treatment of patients with persistent or recurrent cutaneous T-cell lymphoma that express the IL-2 receptor.

Antibodies Against Interleukin-6 Receptor

IL-6, also known as *B-cell stimulatory factor-2*, was originally described as a *T-cell product*, which enhances immunoglobulin synthesis by B cells. It has been shown that IL-6 stimulates the growth of multiple myeloma (135) and hematopoietic stem cells (136). Studies with anti-IL-6 antibody have demonstrated growth inhibition of freshly isolated human myeloma cells in culture (135). Because these cells produce IL-6 and express its receptor, these studies provide direct evidence that an autocrine growth regulatory pathway is active in the oncogenesis of human myelomas.

In patients with advanced multiple myeloma, an excess of production of IL-6 occurs *in vivo,* and elevated serum levels are associated with plasmablastic proliferative activity and short survival. These data provided the rationale to perform a clinical trial with a murine anti-IL-6 MAb to neutralize the activity of this putatively deleterious factor in these patients (137). Ten patients with extramedullary involvement were treated with anti-IL-6 MAb. Among seven patients receiving the anti-IL-6 MAb for more than 1 week, three had objective antiproliferative effects marked by a significant reduction of the myeloma cell labeling index within the bone marrow. One of these three patients achieved a 30% regression of tumor mass. None of the patients studied, however, achieved remission or improved outcome as judged by standard clinical criteria. Of major interest, objective antiproliferative effects were associated with complete inhibition of C-reactive protein synthesis and low daily IL-6 production *in vivo.* On the other hand, the lack of effect in four patients was associated with a higher IL-6 production and inability of the MAb to neutralize it. The generation of human antibodies to Fc fragment of the murine anti-IL-6 MAb observed in one patient was associated with dramatic progression (137).

Because the production of human antibodies against the MAb may limit their clinical applicability, a murine antibody, PM 1 MAb, which binds to the human IL-6 receptor and inhibits IL-6, has been humanized (138). The humanized PM1 MAb is equivalent to the murine PM1 MAb in terms of antigen binding and growth inhibition against multiple myeloma cells. This or other humanized anti-IL-6 receptor-humanized MAb could be useful agents in the treatment of patients with myeloma.

Summary

Part of "15.5 - Monoclonal Antibodies Directed Against Growth Factor Receptors "

A large body of preclinical evidence exists that demonstrates that targeting the EGF-R (erbB1) or HER2 (erbB2) by MAb is a successful approach to suppress malignant growth in *in vitro* and *in vivo* model systems. Furthermore, extensive studies have shown that these compounds markedly enhance the cytotoxicity of common chemotherapeutic agents. The clinical trials that build on these laboratory studies have confirmed the activity of antigrowth factor receptor MAb as anticancer agents and their ability to augment the benefits of standard chemotherapy.

The success of this hypothesis-based development of novel anticancer drugs is best represented by the approval of the anti-HER2 MAb trastuzumab for use as a single agent or in combination with paclitaxel for the treatment of patients with metastatic breast cancer whose tumors overexpress HER2 and who have received one or more chemotherapy regimens for their metastatic disease. The anti-EGF-R MAb C225 is also being evaluated in phase 3 trials given in combination with radiotherapy or chemotherapeutic drugs. Hence, after almost two decades of intensive research in the field, the original hypothesis that targeting of receptors for growth factors may become a useful strategy in the treatment of cancer has proved to be right (9,18). In the years to come, it is anticipated that we will further define the indications and optimal regimens of these new antireceptor strategies.

Principles and Practice of Cancer Vaccines

16
Cancer Vaccines: Cancer Antigens

16.1

Shared Tumor-Specific Antigens

Thierry Boon

Benoît J. Van den Eynde

Discovery of the *MAGE* Genes

Part of "16.1 - Shared Tumor-Specific Antigens "

The elucidation of antigens recognized by T lymphocytes on human tumor cells began with an analysis of metastatic melanoma. This is because the *in vitro* culture of metastatic melanoma has a much higher rate of success (approximately 50%) than that of nonmetastatic melanoma and other tumor types. A clonal cell line named MZ2-MEL was obtained from a melanoma patient with visceral metastasis. Lethally irradiated MZ2-MEL cells were used to stimulate autologous (from the same patient) peripheral blood lymphocytes in the presence of a small amount of interleukin-2 (20 U per mL).

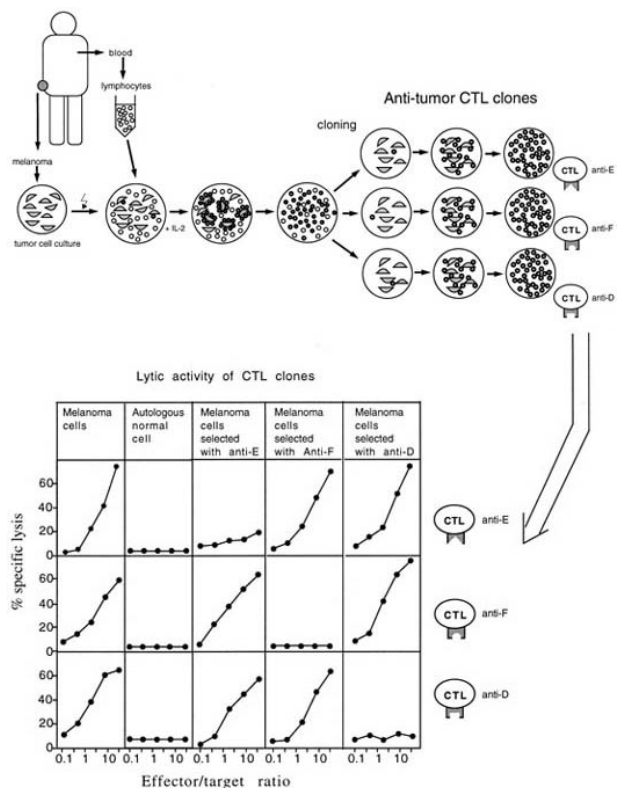
The responder cells were restimulated weekly with irradiated melanoma cells. The lymphocytes of these autologous mixed lymphocyte tumor cell cultures were tested for their ability to lyse the MZ2-MEL cells in chromium-release assays (1). Significant and specific lytic activity was observed after 3 weeks. The responder lymphocyte populations were restimulated in limiting dilution conditions (one to 20 cells per well) so as to obtain cytolytic T lymphocyte (CTL) clones (i.e., long-term cultures of CTL derived from a single CTL). More than 50 CD8+ CTL clones directed against the MZ2-MEL cells were obtained in the course of several experiments. Most of these clones showed a high level of lytic activity on the autologous melanoma cells (e.g., 20% of lysis at a 1:1 effector to target ratio) (Fig. 16.1-1). Moreover, their specificity was remarkably strict: they did not lyse K562, which are natural killer target cells, nor did they lyse autologous Epstein-Barr virus–transformed B (EBV-B) cells or fibroblasts. (Note: For a proper understanding of the difficulty of the field, it is worth mentioning that even the "best" CTL clones [i.e., those that multiply five/fold or more during a stimulation cycle of 7 days] and that show specific lysis, often lose their proliferative or lytic activity for reasons which, to this day, are not understood. Hence, the considerable importance of preparing many frozen stocks for each clone as soon as possible. Even so, the difficulty in sharing CTL clones between laboratories has remained a significant impediment to progress.)


FIGURE 16.1-1. Schematic drawing of the mixed lymphocyte tumor culture (MLTC) used to obtain anti-tumor cytolytic T lymphocyte (CTL) clones (A), and lytic activity of three CTL clones tested against autologous melanoma cells, normal control cells (fibroblasts), and melanoma cells selected *in vitro* for resistance to each of the three CTL clones (B). These antigen-loss variants are resistant to one CTL clone but still sensitive to the two others, indicating that the three CTL clones recognize three distinct antigens. Lysis was assessed by measuring the release of 51chromium from target cells after 4 hours of incubation with the lymphocytes at the indicated effector to target ratios. (IL-2, interleukin-2.) (From Van den Eynde B, Hainaut M, Hérin A, et al. Presence on a human melanoma of multiple antigens recognized by autologous CTL. *Int J Cancer* 1989;44:634-640, with permission.)

The CTL clones directed against the MZ2-MEL cells were used to select resistant tumor cell variants *in vitro* (2). Approximately 10 million MZ2-MEL cells were mixed with a number of CTL of a given clone. In many instances, a few surviving melanoma cells were observed after a few days. These cells were allowed to multiply before being submitted to another selection step with the same CTL clone. Thus, resistant melanoma cells were obtained. These were named *antigen-loss variants* under the presumption that their survival was due to their having lost the expression of the gene coding for the antigen recognized by the CTL. This presumption was based on previous findings from mouse tumor antigens and was confirmed later, when the genes coding for the antigens were identified. However, such *in vitro* selection procedures could also produce "presentation-loss variants" (i.e., cells that have lost the presenting HLA molecule or a component of the antigen-processing pathway). An important observation was that each antigen-loss variant obtained with one anti-MZ2-MEL CTL clone had usually kept its sensitivity to lysis by most of the other CTL clones directed against the same tumor (see Fig. 16.1-1). This led to the conclusion that the MZ2-MEL tumor carried not one but several (more than five) antigens that were recognized by autologous CTL. This observation, which has been extended to several other tumors, may have quite an important bearing on the prospects of immunotherapy; first, because immunization against several antigens borne by the same tumor may provide a more effective attack of the tumor cells by the CTL, and second, because the occurrence of antigen-loss variants leading to tumor escape ought to be much reduced under these circumstances.

We and our colleagues then set out to identify the gene coding for the antigen recognized by one of the anti-MZ2-MEL CTL clones (3). Our approach was to prepare a library of cosmids each carrying approximately 50 kilobases (kb) of DNA of the tumor cell line. This library was then transfected into an antigen-loss variant selected with the CTL clone. This CTL clone had been shown to produce tumor necrosis factor (TNF) only when presented with its target antigen: Pools of approximately

30 transfectants were mixed with the CTL, and the TNF released in the supernatant was measured. A few positive microcultures were obtained. Duplicates of the microcultures were then subcloned so that the antigen-bearing transfectant cells could be identified (4).

Thanks to a most useful property of the cosmids, it was possible to retrieve from the transfectant the cosmid that carried the gene responsible for the expression of the antigen. This led to the identification of a gene that was named *MAGE*, which contains three exons and codes for a protein of 309 amino acids (3). Previous work on mouse tumors had demonstrated that there are two main genetic mechanisms producing tumor-specific antigens. The first is the acquisition of point mutations by genes with ubiquitous expression (5). The mutation produces an amino-acid change enabling a peptide that is usually 9 or 10 amino acids long to bind to a class I major histocompatibility complex molecule, whereas the normal peptide cannot bind. In other cases the amino-acid change confers a new epitope to a peptide that was already capable of binding to a major histocompatibility complex molecule but was not recognized by T lymphocytes because of central or peripheral natural tolerance. The second major mechanism that generates tumor-specific antigens is the activation in the tumor cell of a gene that is silent in normal cells (6). This produces a tumor-specific protein, which can be degraded into tumor-specific antigenic peptides (Fig. 16.1-2).
FIGURE 16.1-2. Main mechanisms of expression of tumor antigens. The peptide recognized by cytolytic T lymphocyte (CTL) on tumor cells can result either from a mutation (1) in a gene that is also expressed in normal cells or from the activation of a gene (2) that is normally silent. In the first mechanism, the nonmutated peptide may either be incapable of binding to the major histocompatibility complex (MHC) molecule, in which case the mutation is said to create an aggretope, or the nonmutated peptide may bind to the MHC but fail to be recognized by the immune system because of natural tolerance, in which case the mutation is said to create an epitope.

The sequence of the *MAGE* gene (now called *MAGE-A1*) located in the MZ2-MEL tumor proved to be identical to that of the gene located in normal cells of the same patient. But the *MAGE-A1* gene was expressed in the MZ2-MEL tumor cell line and also in a frozen tumor sample, indicating that it was not an artefact of cell culture. The expression of the *MAGE* gene was then tested by reverse transcriptase–polymerase chain reaction on a large set of samples of normal tissues: no expression whatsoever was observed except in testis, where expression seemed to

be of similar intensity as in the tumor (Fig. 16.1-3). The *MAGE-A1* gene was expressed in a large proportion of the melanoma samples. Remarkably, it was also expressed in many other types of tumor, such as bladder carcinoma, head and neck carcinoma, and lung carcinoma. For other types of tumor, such as renal carcinoma, colon carcinoma, and leukemia, expression was either infrequent or absent.

FIGURE 16.1-3. Expression of gene *MAGE-A1* in normal tissues. The expression of *MAGE-A1* was measured by reverse transcriptase-polymerase chain reaction (RT-PCR) using specific primers on RNA extracted from the indicated tissues. (+, positive; -, negative.)

To identify the antigenic peptide recognized by the CTL clone used for the cloning of *MAGE-A1*, various regions of the coding sequence were transfected into target cells. When a small region was thus selected, a set of overlapping nonameric peptides encoded by the gene were tested for their ability to sensitize target cells to lysis by the CTL. This led to the identification of peptide EADPTGHSY, which is presented by the HLA-A1 molecule (7).

The only normal cells that express MAGE-A1 are male germ-line cells (8). As these cells do not express HLA class I molecules, they cannot present MAGE antigens (9). Therefore, these antigens appear to be strictly tumor-specific. And because they are shared by many tumors of various histologic types, they are referred to as *shared tumor-specific antigens.*

Recent Approaches

Part of "16.1 - Shared Tumor-Specific Antigens "

Although successful for the identification of the first *MAGE* gene, the aforementioned approach was time consuming and difficult to repeat for the identification of other tumor antigens. Therefore, using MAGE-A1 as a model, we and our colleagues (10 ,11) searched for alternative transfection approaches. We observed that the well-known COS cells, which are monkey cells transfected with the SV40 large T antigen, strongly stimulated the anti-MAGE-A1 CTL when they were first transfected with both the MAGE-A1 and the HLA-A1 complementary DNAs (cDNAs). This showed that COS cells were capable of processing peptides encoded by transfected genes and of presenting them on transfected HLA. This opened the way for a cloning strategy based on cDNA libraries, which are substantially smaller than genomic cosmid libraries. Additionally, the COS can be transfected transiently rather than stably, thereby allowing the transfected cells to be tested as soon as 1 or 2 days after the transfection (10). The library is divided into 1,000 to 2,000 pools of 100 cDNAs each. DNA is extracted from each pool and transfected together with DNA from the gene encoding the HLA-presenting molecule. The CTL are then added to the transfected cells, and the TNF production is measured after an overnight incubation. When a positive cDNA pool is identified, it can be subcloned to identify the positive cDNA clone. The first antigen thus identified was tyrosinase, which is a melanocyte differentiation antigen (11). Many other antigens were subsequently identified by this approach, including two other antigens of melanoma MZ2-MEL, which are encoded by two new genes that were named BAGE and GAGE. Like the *MAGE* genes, these genes are

totally silent in normal tissues except testis, but are expressed in many tumors (see below) (12 ,13). Despite their identical expression profile, these genes do not show any sequence homology to the *MAGE* genes, but rather belong to distinct gene families. The peptides were identified and presented by two HLA-C molecules, namely HLA-Cw16 and HLA-Cw6.

Once it became clear that the expression profiles of the *MAGE, BAGE*, and *GAGE* genes were so remarkably similar, it was reasonable to start looking for other genes that had the same expression pattern. The cDNA subtraction technique based on polymerase chain reaction, and known as *representative differential analysis*, was used to search for genes expressed in tumors but not in normal tissues (14 ,15). By applying this approach to several tumors, previously identified *MAGE* genes were retrieved several times, indicating that the number of gene families with *MAGE*-type expression is probably not very large (16). But a few new genes were discovered, including *MAGE-C1*, a new member of the *MAGE* family, and *LAGE-1*, which are also expressed only in testis and in tumors (17 ,18).

A completely different approach, which was used by Pfreundschuh and colleagues, relies on the use of the sera of cancer patients to screen expression libraries (19 ,20). It is called *SEREX* (for *se*rological analysis of *r*ecombinant *ex*pression libraries with autologous serum). A cDNA library prepared in bacteriophage lambda is expressed in bacteria, transferred on filters, and screened directly with the serum of the patient (20). Quite unexpectedly, the first antigens found to be recognized by the patient's sera included intracellular proteins such as MAGE and tyrosinase, which had originally been identified as T-cell antigens. Apparently, these proteins are shed in the course of the necrosis of some cancer cells, thereby becoming immunogenic for B cells and CD4 T cells. The first new tumor-specific gene found by SEREX was *SSX-2* (21). *SSX-2* has a MAGE-type expression profile [i.e., it is silent in normal tissues except testis and is activated in a high proportion of tumors (50% of melanomas)]. Two other MAGE-type genes were then found by SEREX, namely *NY-ESO*-1 and *SCP1* (22 ,23). *NY-ESO-1*, which is closely related to *LAGE-1*, was subsequently found to encode peptides that are recognized by antimelanoma CTL, indicating that it can stimulate both an antibody response and a CTL response in cancer patients (24). It is likely that other antigens discovered by SEREX will also prove to encode T-cell epitopes.

MAGE-Type Gene Families

Part of "16.1 - Shared Tumor-Specific Antigens "

After the identification of gene *MAGE-A1*, it became clear that it belonged to a multigenic family. Other members of the family were then identified using *MAGE-A1* as a probe to screen recombinant libraries. A first group of 12 *MAGE-A* genes was identified, all located in a cluster at the end of the long arm of chromosome X (Fig. 16.1-4 , Table 16.1-1) (25). Like *MAGE-A1*, the other

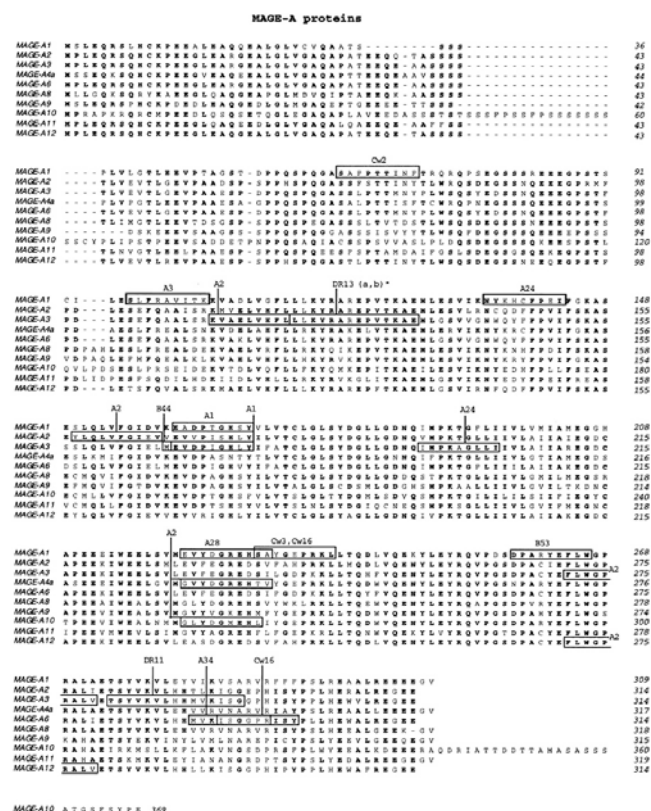
MAGE-A genes have their entire coding sequence located in the last exon, which shows 64% to 85% identity with that of *MAGE-A1*. Because of the presence of a premature termination codon, the predicted MAGE-A5 protein is much shorter than the others. *MAGE-A7* is never expressed and appears to correspond to a pseudogene. Figure 16.1-5 shows an alignment of the remaining predicted protein sequences, which have 57% to 77% identity with MAGE-A1. At least seven of the MAGE-A genes code for T-cell epitopes that are presented by various HLA molecules.
FIGURE 16.1-4. Localization of MAGE-type genes on chromosome X.


FIGURE 16.1-5. Alignment of the predicted MAGE-A protein sequences. The antigenic peptides recognized by T lymphocytes are indicated with boxes, and the presenting HLA molecules are mentioned. *DR13 (a,b): Two DR13 peptides were found: AELVHFLLLKYRAR and LLKYRAREPVTKAE.

Table 16.1-1 MAGE-Type Genes

Family Name	Number of Members	Chromosomal Location	Method of Identification	References

CTL, cytolytic T lymphocyte; RDA, representative differential analysis; SEREX, serological analysis of recombinant expression libraries with autologous serum.

Another cluster of MAGE genes was then identified by chance in the course of sequencing cosmids covering the Xp21.3 region, which is on the other arm of chromosome X (see Fig. 16.1-4) (26). This cluster contains four homologous genes, which were given the MAGE-B title (27) (see Table 16.1-1). Their coding region shows 45% to 63% identity with the MAGE-A genes (14% to 47% at the amino acid level). Remarkably, despite this homology, the MAGE-B genes were not detected by hybridization with probes derived from MAGE-A genes. As opposed to the MAGE-A proteins, which are acidic [isoelectric point (pI), 4.0 to 4.6] the MAGE-B proteins have a pI of 9.0 to 10.7 due to a higher content of basic residues.

Last, two additional MAGE genes were isolated by the representative differential analysis approach and located on a third cluster on chromosome Xq26, which was named MAGE-C (28). The 5" end of the coding region of MAGE-C1 is composed almost exclusively of numerous short repetitive sequences. As a result, the predicted MAGE-C1 protein is much longer than the other MAGE proteins (1,142 amino acids). After this repetitive region, the C-terminal segment of the MAGE-C1 protein is 44% to 55% or 39% to 44% identical to the corresponding parts of the MAGE-A and B proteins, respectively.

The function of the MAGE proteins is not known. Their sequences show significant homology to a mouse protein, necdin, which is expressed in the nuclei of postmitotic neurons and may control cell growth during brain development (29). Mouse genes homologous to human MAGE-A and MAGE-B genes have been isolated. Some of them are expressed in blastocysts and embryonal stem cells, suggesting a function of the MAGE proteins in embryonic development (30). The analysis of MAGE knockout mice, which are currently being prepared, could shed some light on the function of MAGE.

The GAGE gene family is also clustered on chromosome X at position Xp11.2-p11.4. In addition to the six members initially described (13), two new GAGE genes have been uncovered (31). Each of these eight genes encodes at least one T-cell epitope that is presented either by HLA-Cw6 or HLA-A29. A ninth GAGE gene isolated from a prostate carcinoma line was initially named PAGE-1(32). It shows several insertions and deletions compared to the GAGE sequences, some of which can be explained by splicing differences (31). Given the high homology to the other GAGE genes, this PAGE-1 gene clearly belongs to the same gene family and should be renamed GAGE-9. On the other hand, a related but distant family of genes was retrieved from the analysis of sequence databases, and these genes were also called PAGE-1, -2, and -3(33). As opposed to the GAGE genes, the latter PAGE-1 gene is expressed in normal somatic tissues of the reproductive tract, including prostate and uterus. The antigenic peptides recognized by GAGE-specific CTL are absent from the PAGE-1 protein sequence. PAGE-1 was mapped on chromosome X at the same locus as the GAGE family (33).

The proteins encoded by genes LAGE-1 and NY-ESO-1 share 84% identity (18). This homology and the location of both genes on the same locus on chromosome Xq28 clearly indicate that they belong to a single gene family (18 ,22). Two major transcripts of LAGE-1 result from alternative splicing and code for two proteins that differ at their carboxy-terminus (18).

The first members of the SSX gene family were initially identified as the fusion partners on chromosome X of the t(X;18) chromosomal translocation that is present in the majority of human synovial sarcomas (34). The fusion partner on chromosome 18 is SYT, a gene coding for a putative transcription factor. As a result of the translocation, a hybrid transcript SYT-SSX1 or SYT-SSX2 is produced, which codes for a chimeric protein. Gene SSX2 was picked up by the SEREX approach, indicating that it can induce antibody responses in melanoma patients (21 ,35). A study of the expression of SSX2 then showed that it is activated in 50% of melanomas and in a few other tumor types (21). Unlike synovial sarcoma, this activation does not involve chromosomal translocation.

The only MAGE-type genes that are not located on chromosome X are BAGE and SCP1 (see Table 16.1-1). The exact chromosomal localization of the BAGE family, which contains at least two different genes, is not known. SCP1 has been mapped to chromosome 1. It codes for the major component of the synaptonemal complex, which is formed between homologous chromosomes during the prophase of the first meiotic division (36). This gene is expressed exclusively in sperm cells during this meiotic prophase. It was retrieved from a testis cDNA library by SEREX using serum from a female patient with renal cancer (23). This gene is activated in several tumor types, mainly glioma (40%) and breast cancer (27%).

Although not qualifying sensu stricto as a MAGE-type gene because of its expression in the retina, the RAGE gene is silent in all the other tissues tested, including the testis. It has been mapped to chromosome 14 (B. J. Van den Eynde, unpublished results). Different transcripts can be generated by alternative splicing, and RAGE-1 has been found to encode a T-cell epitope recognized by CTL directed against renal cell carcinoma. It is expressed in 14% of sarcomas but only 2% of renal carcinomas (37).

Expression of MAGE-Type Genes

Part of "16.1 - Shared Tumor-Specific Antigens "

The common feature of the MAGE-type genes is their pattern of expression: they are silent in normal tissues except in testis and expressed in a variety of tumors. Table 16.1-2 shows the frequency of expression of the MAGE-type genes known to encode T-cell epitopes, measured by reverse transcriptase-polymerase chain reaction in a large collection of tumor samples of different histologic types. Expression is frequently observed in melanomas and in carcinomas of the lung, head and neck, bladder, and esophagus. Expression is absent or infrequent in renal carcinoma and leukemia. This picture is consistent for all the MAGE-type genes, even those from different families. Also consistently observed is a higher frequency of expression in metastatic versus primary melanoma, and in infiltrating versus superficial bladder carcinoma. This coordinated expression suggests that a common mechanism controls the activation of MAGE-type genes. Transfection studies of the MAGE-A1 promoter have shown that it can exert transcriptional activity in cells that do not express the gene, suggesting that the transcription factors capable of activating MAGE-A1 are ubiquitous (38). Transcriptional control of MAGE genes therefore does not involve specific transcription factors. Indeed, it was found later to rely on the methylation of the promoter. The MAGE-A1 promoter contains binding sites for transcription factors of the Ets family, which are essential for its activity (38). These sites contain CpG dinucleotides, which are methylated in cells that do not express the gene, thereby preventing the binding of the Ets factor (39). Treatment of tumor cells or fibroblasts with the demethylating agent 5"-aza-2"-deoxycytidine activates gene MAGE-A1 (40). This is also true for most MAGE-type genes. A global demethylation of the genome is often observed in tumor cells and is correlated with tumor progression. It is also correlated with MAGE-A1 expression, which therefore appears to be a random consequence of this genome-wide demethylation (39). This provides an explanation for the higher frequency of MAGE expression in advanced cancers. It also explains the expression of MAGE-type genes in male germ cells, which also have reduced levels of methylated DNA (41).

Table 16.1-2 Expression in Tumor Samples of MAGE-Type Genes Encoding T-Cell Antigens

Among the *MAGE* genes not listed in Table 16.1-2 , *MAGE-B2* is expressed in 45% of non-small-cell lung cancers and in 22% of melanomas, whereas *MAGE-C1* is expressed in 46% of melanomas and 18% of bladder cancers (17 ,27).

Other Mechanisms Producing Shared Tumor-Specific Antigens

Part of "16.1 - Shared Tumor-Specific Antigens "

Two antigens that have been characterized on human melanoma also represent specific shared antigens, but their presence on tumor cells results from different genetic mechanisms. The first one is due to the activation of a cryptic promoter located in an intron of the gene coding for *N-* acetylglucosaminyltransferase V, an enzyme involved in protein glycosylation (42). An abnormal transcript is produced, containing the 5"-end of this intron and the following exon. This transcript is totally absent from normal cells but is present in approximately 50% of melanomas. The peptide recognized by the CTL is encoded by the intronic part of this transcript and is therefore strictly tumor specific. The reason why this cryptic promoter is active in melanoma and not in normal cells is unknown. The second antigen results from an incomplete splicing of the transcript of *TRP2*, a gene encoding a melanocytic protein (43). Again, the peptide recognized by the CTL is encoded by the retained intronic sequence. This incompletely spliced form of the message was not found in normal melanocytes, but was observed in approximately 50% of melanomas.

Antigenic Peptides

Part of "16.1 - Shared Tumor-Specific Antigens "

Antigenic Peptides Identified with Cytolytic T Lymphocytes

The complete characterization of the CTL-defined tumor antigens required the identification of the antigenic peptides actually presented to the T cells by the HLA molecules. This was achieved on the basis of the sequence of the genes that had been found to sensitize transfected cells to the CTL. A number of truncated genes were produced and tested in transfection experiments to delineate the region encoding the peptide. The predicted protein sequence of the relevant region was then searched for peptides bearing anchor residues for the presenting HLA molecule based on the published consensus binding motifs (44). Synthetic peptides were then used to pulse target cells, which were then tested for recognition by the CTL. A comprehensive list of the peptides currently identified is provided in Table 16.1-3 .

Table 16.1-3 Shared Tumor-Specific Antigens

Antigenic Peptides Identified by Reverse Immunology

It seemed certain that genes like *MAGE-A1*, which was identified with a CTL clone restricted by HLA-A1, were also coding for many other antigenic peptides that could bind to various HLA class I molecules and be recognized by other CTL clones. This prediction was borne out when a CTL directed against a MAGE-A1 antigen presented by HLA-Cw16 was isolated by autologous stimulation with MZ2-MEL cells (45). Clearly, many antigenic peptides encoded by MAGE-type genes and binding to various HLA molecules remained to be defined. In addition, a wealth of MAGE-type gene sequences were obtained by DNA hybridization with probes of known MAGE-type genes, by enrichment for genes that are specifically expressed in tumors, and by the SEREX method. For all these new genes, the

encoded epitopes remained to be discovered. Therefore, an effort was made to identify a number of these antigenic peptides by a reverse approach—that is, starting from the gene sequence rather than from an antitumor CTL clone.

A first approach was based on the results of Rammensee and others who demonstrated that the peptides binding to the product of a given HLA allele have consensus residues (i.e., preferred residues located at the anchoring points of the peptide in the groove of the HLA molecule) (44). The putative protein sequence encoded by a gene was screened for the presence of peptides bearing the consensus residues. The binding affinity of these peptides for the HLA molecule was then evaluated directly. The good binders were then mixed *in vitro* with blood lymphocytes from noncancerous donors to stimulate the putative CTL precursors present in these populations. This approach was applied with success to the identification of a MAGE-A3.A2 and a MAGE-A3.B44 epitope (46 ,47). However, it has many drawbacks. First, the search is limited to peptides corresponding to consensus motifs and such motifs are not available for all the HLA alleles. Moreover, some effective peptides proved to be different from the consensus peptides. Secondly, in a number of cases it proved difficult to obtain CTL directed against the peptide or, more seriously, when CTL that recognized cells pulsed with the peptide were obtained, they very often proved incapable of lysing cells that expressed the relevant gene and HLA allele, presumably because the peptide was not processed. As a result, the number of infertile attempts to identify peptides has vastly outnumbered the successful attempts. Moreover, for the MAGE-A3.A2 antigenic peptide, it became clear that, even though some tumor cells expressing MAGE-A3 and HLA-A2 are well lysed by the CTL clone, most such tumor cells are not. This suggested that only those cells expressing high levels of MAGE-A3 and HLA-A2 could be recognized, presumably because the MAGE-A3.A2 peptide is poorly processed. One reason for this poor processing appears to be the presence of internal cleavage sites for the proteasome within the MAGE-A3.A2 peptide (48).

These difficulties led us to try a different approach involving T-lymphocyte stimulation by dendritic cells infected with an ALVAC virus containing the MAGE-A1 sequence. After repeated stimulation with dendritic cells, CTL and CTL clones of noncancerous donors were obtained against five new MAGE-A1 epitopes (49). It seems likely that this method will be applicable generally. All the peptides thus identified appear to be well processed, as one would expect, because they must be processed by the presenting dendritic cells.

Because of the availability of highly purified MAGE-A3 protein produced in *Escherichia coli*, it has been possible to pulse dendritic cells with the protein and use these cells to stimulate CD4+ T lymphocytes of noncancerous donors. T-cell clones that recognize EBV-B cells pulsed with MAGE-A3 protein were obtained (50). Using sets of overlapping MAGE-A3 peptides, peptide MAGE-A3$_{121-134}$ was found to be recognized by the CD4+ clone on the DR13 molecule. Two other CD4 T-cell clones directed against this region of the MAGE-A3 protein were obtained from two other individuals. It should be noted that many CD4+ T-cell clones obtained in these stimulations turned out to recognize contaminants in the MAGE-A3 protein preparation. MAGE-A3 protein prepared with a baculovirus construct ought to be very useful to screen out these T-cell clones conveniently. CD4+ T cells stimulated with the *E. coli* protein could be tested against the baculovirus protein, which ought to contain a completely different set of impurities. Immunization of patients against class II–presented tumor-specific antigens as well as class I–presented antigens may be of crucial importance for the obtention of T cells that can be stimulated and amplified on the tumor site.

Therapeutic Immunization

Part of "16.1 - Shared Tumor-Specific Antigens "

Eligible Patients

The proportion of metastatic melanoma patients who carry a known MAGE-type antigen is high (see Table 16.1-2). Less high but nevertheless considerable figures apply to other types of tumors, such as lung cancer, head and neck, and bladder cancer. It now appears quite certain that relatively large proteins, such as the *MAGE* proteins, contain at least one peptide that can be presented by any given HLA allele. It is therefore reasonable to embark on clinical trials of immunization with proteins or recombinant viruses carrying entire MAGE-type gene sequences without limiting the eligible patients to those who express an HLA allele corresponding to a known HLA-peptide combination for this gene.

For immunization trials involving peptides, the situation is quite different. Here the eligible patients are only those whose tumor expresses the relevant MAGE-type gene and also carry the appropriate HLA allele. With the exception of HLA-A2, an allele present in approximately 50% of the white population, this considerably restricts the number of eligible patients.

Modes of Immunization

Even though the extrapolation of animal observations to the human situation is not always straightforward, the careful study of a preclinical model may help to define general guidelines allowing a more rational design of human trials. The best model system for the human shared tumor-specific antigens is the antigen encoded by mouse gene *P1A.* This gene was cloned by the cosmid approach mentioned in the section Discovery of the *MAGE* Genes as the gene responsible for the expression of the antigen recognized by CTL directed against mouse tumor P815 (6). Like the MAGE-type genes, this gene is silent in normal tissues except in testis and is expressed in several mouse tumors, including mastocytomas, lymphomas, and sarcomas. A peptide derived from the P1A protein is presented to CTL by class I molecule H-2 L^d. When mice are injected with 1 million living cells transfected with P1A and with B7.1, they reject those cells, develop a strong CTL response against P1A, and are protected against a challenge injection of P1A-positive tumor cells P815 (51). Given the expression of P1A in testis, we have looked for autoimmune reactions in male mice immunized against P1A. We did not observe any sign of inflammation in their testes, nor did we record any reduction in their fertility (52). This is presumably related to the immune privilege of the testes, combined to the fact that P1A-positive testis cells are spermatogonia,

which do not express class I molecules. Because MAGE-type genes also appear to be expressed in class I-negative male germ cells, this observation suggests that human beings can also be immunized safely against shared tumor-specific antigens. We also used this preclinical model to test different modes of immunization that are acceptable for human use and to compare the CTL responses induced. Three protocols appeared to give good responses in most animals. One is the injection of peptide with a QS21-based adjuvant and with interleukin-12 (IL-12) locally (53). A second is the injection of mononuclear cells pulsed with the peptide and injected with IL-12 (54), and a third is the injection of a recombinant adenovirus containing a P1A minigene, followed by boost injections of peptide plus adjuvant (55 and G. Warnier, *personal communication*, 1997).

Clinical Trials

A trial involving immunization of metastatic melanoma patients with a MAGE-A3 peptide binding to HLA-A1 has been completed (56). The patients had measurable disease, and the severity of the disease ranged from regional cutaneous (in transit) to visceral metastases. Patients with brain metastasis were excluded. The immunization schedule involved three monthly subcutaneous and intradermal injections of 100 μg or 300 μg of peptide without adjuvant. No significant difference was observed in the results obtained with either of the two doses of peptide. The locations of the injections were distant from the tumor sites.

Of the 39 patients who entered the treatment, 14 were removed after one or two injections because of disease progression. No significant toxicity was observed in any patient. Tumor regressions were observed in 7 out of the 25 patients who completed the treatment. Among the 17 patients who had no visceral metastases, six displayed tumor regressions. Two of these regressions were complete and long lasting (more than 4 and 2 years, respectively). Among the eight patients with visceral metastases, one showed complete regression of several lung metastases and of a mediastinal lymph node. This patient relapsed 6 months later and died approximately 2 years after that.

No convincing evidence for an anti-MAGE-A3 CTL response could be obtained even in those patients who showed tumor regression. The response was analyzed only in the blood. It may well be that CTL responses were obtained but that the CTL were confined to the tumor sites or lymph nodes.

In some instances, the onset of regression was not observed until a few months after the third injection. In most instances, the regressions that became complete took several months to reach this stage. This pattern of response would fit well with the notion that only a weak anti-MAGE CTL response was produced. Remarkably, patients with a partial or complete response could relapse at new sites in the absence of relapse at the sites that had regressed. This was particularly striking for the patient with lung metastases who cleared five lung metastases and relapsed in cutaneous sites, in lymph nodes, and in adrenals, but never in the lung. Thus, it appears that the immune response could clear up a tumor site completely without affecting small metastases present at that time. MAGE-A3 expression was retained in those tumor sites that did not regress in the course of mixed responses or that relapsed after complete responses. Thus, neither the lack of a complete response nor the event of a relapse can be assigned solely to the selection of antigen-loss variants. We were not able to evaluate the antigen-presentation capability of these tumors, and it may well be that, as widely reported in the literature (57 ,58), many of them had a defect in the HLA molecule, ß-2 microglobulin, transporter associated with antigen processing, or another component of the antigen-presentation machinery.

Finally, it seems that persistence in the injections may be an important component in obtaining regressions and preventing relapse. One of the patients recorded as nonregressing in this trial later received a large number of injections of MAGE-A3.A1 and MAGE-A1.A1 peptides. After several months of this treatment, most of approximately 50 cutaneous and subcutaneous metastases started to regress. At that point, two large cutaneous metastases were irradiated. A few months later, all of the metastases had disappeared.

Another trial involved the injection of advanced melanoma patients with autologous dendritic cells pulsed with MAGE-A3- and MAGE-A1–encoded peptides presented by HLA-A1. No significant toxicity was observed. A partial tumor response was observed in one of the six patients who received the treatment (56). Strong delayed-type hypersensitivity responses against the peptide-pulsed dendritic cells were observed in the responding patient and in one of the nonresponding patients.

Whereas the clinical trials reported here provide some hope that effective therapeutic vaccination may be achievable, they represent only a first step in a long series of trials aimed at finding effective ways of triggering T-cell responses and of monitoring them. It is particularly important to assess to what extent the failures can be attributed to defects in the antigen presentation of the tumor cells.

Introduction

Part of "16.2 - Differentiation Antigens "

Studies carried out in the 1980s demonstrated that tumor-infiltrating lymphocytes (TILs) could recognize tumors in a class I major histocompatibility complex (MHC)-restricted manner. These extensive experiments carried out using TIL derived from melanoma patients indicated that human T cells could recognize widely shared tumor antigens. Additionally, *in vitro* stimulation of peripheral blood mononuclear cells (PBMCs) with autologous as well as allogeneic MHC-matched tumor cell lines was found to result in the generation of tumor-reactive T cells. Further studies demonstrated that these T cells could, in many cases, recognize MHC-matched normal melanocyte-cultured cell lines, but not a variety of syngeneic or allogenic MHC-matched normal cell lines. These findings indicated that melanocyte differentiation gene products were recognized by some melanoma-reactive T cells. The subsequent cloning of the genes that encode these products directly demonstrated that T cells

recognized melanocyte differentiation antigens in a conventional class I and class II restricted manner.

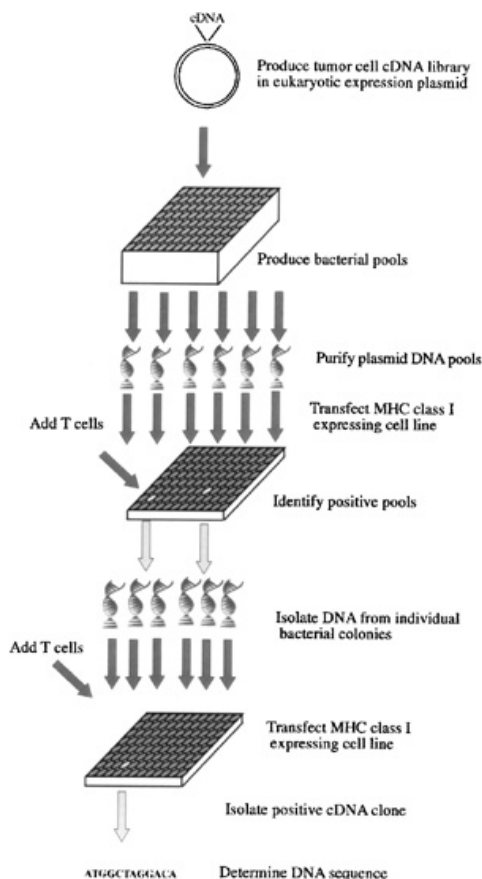
The majority of tumor antigens have been identified using a genetic approach. After the generation of a complementary DNA (cDNA) library from tumor-cell messenger RNA (mRNA) in a eukaryotic expression vector, pools of cDNA containing between 50 and 200 individual cDNA clones have been produced and cotransfected with a construct encoding the appropriate class I MHC gene into highly transfectable cell lines (Fig. 16.2-1). In a variation of this method, cDNA library pools have been transfected into cells that stably express the appropriate class I product. Cells transfected with the cDNA pools were then assayed for their ability to stimulate cytokine release from tumor-reactive T cells, and single clones were identified by subcloning from a positive pool.


FIGURE 16.2-1. Genetic approach to the identification of tumor antigens. (cDNA, complementary DNA; MHC, major histocompatibility complex.)

The peptide epitopes derived from these antigens have primarily been identified through the use of HLA peptide-binding motifs. These motifs have been derived by comparing MHC-binding peptides that have been identified in a variety of antigens and by sequencing peptides that have been eluted from class I MHC molecules. The results of this analysis indicate that peptides that bind to a particular HLA allele contain a limited number of amino acids at particular positions that are termed *anchor residues.* These residues interact with amino acids in the MHC-binding pocket, providing the free energy for this interaction. Consensus sequences have been identified for a large number of class I molecules (1), allowing the generation of algorithms that can be used to predict potential class I MHC-binding peptides (2).

Another method that has been used to identify tumor antigens involves the elution of peptides from tumor-cell surface MHC molecules. Peptides are then fractionated using reversed phase high-performance liquid chromatography columns and are used to sensitize target cells for T-cell recognition (Fig. 16.2-2). After further fractionation of positive pools, individual peptides found in positive subpools that have been sequenced using a triple-quadrupole mass spectrometer have then been synthesized and tested for their ability to sensitize targets for recognition by specific T cells. The antigen from which the positive peptide is derived is then identified through the use of database searches.
FIGURE 16.2-2. Biochemical approach to the identification of tumor antigens. (HPLC, high-performance liquid chromatography; MHC, major histocompatibility complex.)

Using these methods, a variety of melanocyte differentiation antigens have been isolated (Table 16.2-1). A number of homologues of these genes have now also been identified in the mouse, and therapeutic protocols have been established using some of these antigens in mouse model systems, providing a basis for future human clinical trials. Ongoing clinical trials are evaluating the efficacy of specific tumor antigen immunization using peptides that have been identified from these antigens, either administered singly or as mixtures of peptides in adjuvant. Recombinant viral constructs encoding these antigens, including vaccinia, fowlpox, and adenovirus, have been administered to cancer patients. Some studies have demonstrated that modified peptides that possess optimal anchor residues resulting in increased binding to MHC class I alleles are also more immunogenic. These studies, which are beginning to provide some insight into the nature of antitumor immune responses, should hopefully lead to the development of effective cancer vaccines that are capable of mediating tumor regression in the majority of cancer patients.

MART-1

Part of "16.2 - Differentiation Antigens "

The observation that normal, cultured melanocytes were recognized by melanoma-reactive T cells suggested that tissue-specific antigens might serve as the targets of tumor-reactive T cells (3). The first member of this family to be isolated, termed *MART-1* (4) or *Melan-A* (5), was identified after the screening of a cDNA library with HLA-A2-restricted TILs or cytolytic T-lymphocyte (CTL) clones, respectively. High levels of expression of the MART-1 gene product were found in retinal tissues, which have been shown to contain melanocytes, and in normal skin melanocytes. This gene, which encodes 108 amino acid proteins of unknown function, contains a hydrophobic region between amino acids 27 and 47 and may represent a melanosomal membrane protein (6).

Identification of the T-cell epitopes from the MART-1 protein was initially carried out by synthesizing 23 peptides that were identified in this protein through the use of the HLA-A2-binding motif. The HLA-A2-expressing mutant cell line T2, which possesses a defect in antigen processing that facilitates the exogenous loading of high levels of peptides, was then pulsed individually with these peptides (7). In this study, ten out of ten MART-1-reactive TILs and the MART-1-reactive T-cell clone A42 reacted with target cells that had been pulsed with a single nonamer peptide, AAGIGILTV (MART-1:27-35), as well as decamer peptides that contain one additional amino acid at the amino (EAAGIGILTV) (MART-1:26-35) and carboxy (AAGIGILTVI) (MART-1:27-36) terminus of the MART-1:27-35 peptide. The A42 clone appeared to recognize targets pulsed at a minimum, with 1 nm of the MART-1:27-35 peptide, whereas 100 nm of the MART-1:26-35 peptide was required to sensitize targets for recognition by this T-cell clone. In contrast, TILs recognized targets pulsed with 1 nm of either the MART-1:27-35 or the MART-1:26-35 peptides to a similar degree. This appears to represent a dominant T-cell epitope in HLA-A2 expressing in melanoma patients. In another study, 22 out of 30 HLA-A2-restricted TILs were found to recognize this peptide (8). Although it has been reported that HLA-A2-restricted, MART-1-reactive T cells recognize a partially overlapping peptide [ILTVILGVL (9)], the majority of MART-1-reactive T cells do not appear to react with this peptide [(10) and Y. Kawakami, personal communication, 1995]. Melanoma-reactive T cells have also been found to recognize two MART-1 peptides, AEEAAGIGILT and AEEAAGIGIL, that partially overlap with the HLA-A2 peptide in the context of HLA-B45 (11).

A study has been carried out to examine the response of T cells generated from tumor-infiltrated lymph nodes (TILN) by stimulation with interleukin-2 (IL-2) to the MART-1:26-35 and MART-1:27-35 peptides, as well as several variants of these peptides (10). In contrast to previous results (7), targets pulsed

with the MART-1:26-35 peptide were recognized at a five- to tenfold lower concentration than those pulsed with the MART-1:27-35 peptide. Several variants containing substitutions at positions 1, 2, or 3 of the MART-1:26-35 peptide with enhanced binding to HLA-A2 were also examined for their ability to be recognized by MART-1–reactive T cells. A variant containing a substitution of leucine for alanine at position 2 of the MART-1:26-35 peptide was recognized at a ten- to 1,000-fold lower concentration than the native peptide by T-cell clones as well as TILN, whereas more variable recognition of the other variants was observed. This peptide could also induce *in vitro* responses from the PBMC of melanoma patients more efficiently than the unmodified parental peptide. In another study, a peptide containing a substitution of alanine for the glutamic acid residue at position 1 of the MART-1:26-35 peptide was found to possess a higher affinity for HLA-A2, and was recognized more efficiently by eight out of ten MART-1–reactive CTL clones than was the unmodified peptide (12). This result was consistent with previous observations, indicating that the presence of a charged amino acid may be detrimental to the binding of peptides to HLA-A2 (13). In addition, a peptide containing a substitution of leucine for alanine at position 1 of the MART-1:27-35 nonamer peptide was significantly more efficient at generating tumor-reactive T cells *in vitro* than the parental MART-1:27-35 peptide (14).

Additional experiments to explore the immunogenicity of MART-1 peptide variants have been carried out in HLA-A2 transgenic mice (15). The mouse homologue of MART-1 is nearly identical to the human sequence, containing only a single substitution of isoleucine for threonine at position 34 of the human peptide. In agreement with the results of *in vitro* sensitizations that were carried out with human PBMC (12), the MART1:26-35 peptides containing substitutions of leucine for alanine at position 2 were significantly more immunogenic in HLA-A2 transgenic mice than the native MART-1 peptide. Moreover, the T cells generated with the modified peptide appeared to recognize melanoma cells expressing the naturally processed MART-1 epitope. These results provide additional support for the use of modified MART-1 peptides in clinical vaccine trials.

Responses to MART-1 appear to be immunodominant in HLA-A2 individuals, and responses can readily be elicited in HLA-A2+ normal, as well as melanoma patients. One possible explanation for these findings is that the MART-1 peptide represents an epitope mimic. In one study, evidence was obtained indicating that MART-1–reactive T cells reacted with peptides derived from a variety of sources, including viral proteins (16). Thus, T cells reactive with exogenous antigens, such as viral epitopes, may cross-react with the MART-1 epitope, thereby leading to the relatively high precursor frequency of T cells reactive with this epitope. Evidence has also been obtained suggesting that some self-antigens may serve as partial agonists or antagonists of MART-1–reactive T cells and thus may limit antitumor responses of these T cells (17).

Some data have indicated that T cells reactive with MART-1 may be present in individuals with vitiligo, an autoimmune disease that results from the destruction of normal skin melanocytes (18). In this study, T cells isolated from vitiligo patients were examined for their ability to recognize the MART-1 antigen using a class I MHC tetramer bound to the modified MART-1:26-35 peptide containing a substitution of leucine for alanine at position 2. The PBMC isolated from seven out of nine vitiligo patients appeared to contain between 0.1% and 0.5% of CD8+ T cells reactive with this peptide, whereas five out of six normal controls contained less than 0.05% MART-1–reactive CD8+ T cells. Many of the MART-1–reactive T cells obtained from vitiligo patients also expressed high levels of the skin-homing receptor cutaneous lymphocyte-associated antigen (CLA), a form of the P-selectin-binding glycoprotein 1 (19). A relatively high frequency of MART-1–reactive T cells was observed in one of the six normal HLA-A2+ individuals, but these cells did not appear to express CLA. These results suggest that expression of accessory molecules, such as the CLA homing receptor, may play a role in the maintenance of tolerance to normal tissue antigens.

gp100

Part of "16.2 - Differentiation Antigens "

The gene encoding a second melanocyte differentiation antigen, termed *Pmel17* or *gp100*, was initially isolated from melanocytes (20). Expression of this gene appeared to be correlated with melanin content, and subsequent studies demonstrated that gp100 is a melanosomal matrix protein that is directly involved with the synthesis of melanin (21). A number of monoclonal antibodies that are diagnostic for melanoma also have been shown to react

with gp100 (22). Screening a cDNA-expression library with a melanoma-reactive CTL also resulted in the isolation of a gene that was nearly identical to the previous gp100 isolates (23). Differential splicing and sequence polymorphisms appear to account for the differences between these sequences.

Identification of the T epitopes in gp100 was carried out by synthesizing 169 peptides from this protein that conformed to the HLA-A2 binding motif. The screening of candidate peptides from gp100 with four TILs resulted in the initial identification of three nonomer peptides, gp100:154-162, 209-217, and 280-288; and two decamer peptides, gp100:457-466 and 476-485 as peptide epitopes (24). Approximately 20% of HLA-A2-restricted, melanoma-reactive TILs reacted with each of the three peptide epitopes gp100:154-162, 209-217, and 280-288 (8) (Table 16.2-2). There appeared to be a significant correlation between the ability of TILs to recognize gp100 and patient responses to adoptive immunotherapy, whereas there was no significant correlation between MART-1 responses and patient responses to therapy. These observations indicate that gp100 may represent a significant tumor rejection antigen.

Table 16.2-2 Responses of HLA-A2 Restricted Tumor-Infiltrating Lymphocytes (TILs) to Epitopes from MART-1 and gp100

++, >500 pg/mL; +, 100-500 pg/mL; -, <100 pg/mL of interferon-γ secretion by TILs after stimulation with T2 cells that had been pulsed with the indicated peptides.

From Kawakami Y, Dang N, Wang X, et al. Recognition of shared melanoma antigens in association with major HLA-A alleles by tumor infiltrating lymphocytes from 123 patients with melanoma. *J Immunother (in press)*, with permission.

The gp100:280-288 peptide was also identified by testing HLA-A2-binding peptides that had been isolated from melanoma cells and fractionated by high-performance liquid chromatography. These peptides were tested for their ability to sensitize target cells for recognition by melanoma-reactive CTL lines that had been derived by stimulation of PBMC with autologous melanoma cells (25). Five out of the five lines that were tested in this study reacted with the gp100:280-288 peptide. It is not clear why, in contrast to the results obtained with TILs, responses to this epitope appeared to be so dominant. It is, however, possible that the source of cells plays a role in influencing the specificity of T cells.

Attempts were then made to enhance the immunogenicity of peptides from gp100 by substituting optimal for nonoptimal anchor residues. When the threonine at position 2 of the gp100:209-217 peptide was replaced with either a leucine or methionine residue, the HLA-A2-binding affinity was increased by a factor of 52 and nine, respectively (26). Tumor-reactive T cells could be elicited more reliably and after fewer *in vitro* stimulations when the modified peptide-containing methionine at position 2 (gp100:209-217 2M) was used than when the native gp100:209-217 peptide was used. Clinical trials involving immunization with the gp100:209-217 2M peptide in Freund's incomplete adjuvant have demonstrated that this peptide is more immunogenic than the native peptide (27). In addition, patient response rate appeared to be increased when the modified peptide was administered in conjunction with IL-2.

Melanoma-reactive T cells have been shown to recognize additional gp100 epitopes. One peptide, gp100:619-627, has been found to be recognized by an HLA-A2-restricted CTL clone, but not bulk melanoma reactive HLA-A2-restricted TIL lines (28). This epitope contains the optimal anchor residues at positions 2 and 9, and this peptide has been shown to bind to HLA-A2 with a higher affinity than previously described gp100 epitopes (29). A second gp100 epitope, gp100:639-647, contains two cysteine residues, one at position 7 and one at the C-terminal anchor position (28). To explore the nature of the naturally processed epitopes, peptides were synthesized in which the cysteine residues were replaced with α-aminobutyric acid, an amino acid that contains a side chain similar in size to the cysteine side chain that cannot form disulfide bonds. Replacement of the cysteines at either position, individually, or at both positions with α-aminobutyric acid appeared to significantly enhance T-cell recognition, thus indicating that the formation of disulfide bonds, either with a second cysteine residue or another sulfhydryl compound, may inhibit binding of the peptide to class I. Although interactions with amino acids in the HLA-A2-binding pocket may prevent modification of cysteine residue side chains in this peptide, it is possible that cysteine residues present in the natural epitope may contain unknown modifications that interfere with disulfide bond formation.

The antigenic epitope recognized by an HLA-A24-restricted CTL clone has been found to be encoded by sequences within an intron of gp100 (30). The screening of a melanoma cDNA library with this T-cell clone resulted in the isolation of an insert that had retained a sequence corresponding to the fourth intron of the gp100 gene. Translation of this product in the normal gp100 open-reading frame resulted in the addition of 35 amino acids not found in the normal gp100 protein, which were followed by a stop codon, resulting in premature termination of translation. The T-cell epitope was

encoded entirely within the intron region and conformed to the HLA-A24 consensus-binding motif. This appears to represent an aberrant transcript that is expressed at relatively low levels in melanomas. Expression of this product does not appear to be related to cellular transformation, however, because T cells that recognized this epitope also responded to an HLA-A24-expressing melanocyte cell line.

An epitope of gp100 that is recognized in the context of HLA-Cw8 has been identified (31). An octamer peptide, gp100:71–78, appeared to represent the optimal epitope, although significant recognition of nonamer and decamer peptides containing either one or two additional amino acids at the amino-terminal end of the octamer were also well recognized. This represented a predominant specificity in melanoma patient 15,392, because the majority of clones obtained from tumor-invaded lymph node cells that were isolated from this patient appeared to recognize this epitope. Additionally, this epitope appeared to be capable of rapidly generating tumor-reactive T cells using PBMC from this patient, although responses of additional HLA-Cw8–expressing patients were not examined in this report.

Tyrosinase

Part of "16.2 - Differentiation Antigens "

Tyrosinase represents a critical enzyme involved in the first steps of melanin synthesis. The gene encoding this product was first isolated in 1987 (32). Subsequently, two HLA-A2-restricted, melanoma-reactive T-cell clones were shown to recognize tyrosinase transfectants (33). These T-cell clones were found to recognize two distinct epitopes of tyrosinase, one beginning with the amino-terminal methionine of the tyrosinase signal sequence (MLLAVLYCL, tyr:1–9) and a second beginning with amino acid residue 368 (YMNGTMSQV, tyr:368–376) (34). The processed tyr:368–376 peptide that is expressed in association with HLA-A2 has been shown to be posttranslationally modified, containing a substitution of an aspartic acid for an asparagine residue at the third position (35). This modification, which was found at an asparagine residue that is part of an *N*-linked glycosylation site, may result from the activity of a mammalian enzyme that is responsible for the removal of *N*-linked oligosaccharide side chains from glycopeptides (36).

Additional studies have demonstrated T-cell recognition of tyrosinase in the context of the HLA-A24 (37 ,38), HLA-B44 (39), and HLA-A1 (40) class I restriction elements. Five out of six HLA-A1–restricted CTL lines isolated from melanoma patients appeared to recognize the tyrosinase nonamer KCDICTDEY and the overlapping dodecamer DAEKCDICTDEY (40). Modified peptides containing a substitution of either serine or alanine for cysteine at position 2 of the nonamer, as well as peptides containing these substitutions at the corresponding residue in the dodecamer, were recognized at concentrations that were 100- to 1,000-fold lower than the unmodified peptide. These results are similar to those found with the gp100:639–647 epitope, as discussed in the gp100 section. The status of the downstream cysteine residue was less clear, however, because some peptides containing modifications at this position were less stimulatory than the parental peptide.

A CD4+ melanoma-reactive TIL has been shown to recognize the nonmutated tyrosinase gene product after screening transfectants expressing candidate melanoma antigens (41) and two peptide epitopes of tyrosinase that are recognized in the context of HLA-DRB1*0401 have been identified (42). Although it is not clear what role class II–restricted T cells play in tumor regression, cytokine production in the tumor microenvironment by CD4+ cells may be involved in the activation of tumor-reactive CD8+ T cells. Some studies suggest that CD4+ T cells play an important role in activating antigen-presenting cells to facilitate efficient stimulation of naïve CD8+ T cells (43 ,44 and 45). The recruitment of inflammatory cells, such as neutrophils, by tumor-reactive CD4+ T cells may also play a role in tumor rejection (46).

TRP-1

Part of "16.2 - Differentiation Antigens "

The gp75 protein, which is recognized by immunoglobulin G antibodies in the serum of a patient with melanoma (47), represents one of the most abundant intracellular glycoproteins in melanocyte-lineage cells. The gene encoding gp75, *TRP-1*, was initially shown to represent the human homologue of the mouse brown-locus gene, a mouse-coat color gene (48). More recently, the gp75 protein has been found to possess DHI-2-carboxylic acid oxidase activity, demonstrating that this represents an enzyme involved in the synthesis of melanin (49).

Melanoma-reactive T cells have been shown to recognize an epitope of gp75 in the context of HLA-A31 (50). The gp75 epitope recognized by HLA-A31–restricted melanoma-reactive T cells was not encoded by the normal TRP-1 open reading frame (ORF). An alternative ORF consisting of only 24 amino acids and beginning at an AUG codon that is downstream from the normal TRP-1–initiation codon was found to encode the T-cell epitope recognized by this T cell (51). The amino terminus of the alternative ORF appeared to correspond with the amino terminus of the optimal T-cell epitope. This epitope also conformed to the HLA-A31 consensus motif that consists of a hydrophobic residue at position 2 and a positively charged residue at the carboxy terminus of the peptide.

A number of examples of T-cell epitopes that are encoded by alternative ORF have been described. A peptide derived from an alternative ORF of *NY-ESO-1*, a gene that encodes a cancer testis antigen, has been shown to be recognized by tumor-reactive T cells (52). Additionally, T-cell epitopes encoded by alternative ORF of a normal self-protein (53) and as a retroviral gene product (54) have been identified. These observations indicate that the translation of alternative ORF represents a general mechanism for generating T-cell epitopes.

Attempts have also been made to determine whether T-cell epitopes from TRP-1 and TRP-2 (described in the following section) that are recognized in the context of HLA-A31 are also recognized in the context of additional class I alleles. Both the TRP-1 and TRP-2 peptides were found to bind to HLA-A3, -A11, -A31, -A33, and -A68. T cells recognized the TRP-2 peptide in the context of HLA-A31 and -A33 (55). These HLA types appear to possess similar binding motifs and fit into what has been termed the *HLA-A3–like supertype*(56). Future studies

should reveal whether it is possible to elicit response to these peptides in patients that express additional members of the HLA-A3 class I supertype.

Studies carried out in the B16 mouse melanoma tumor model have demonstrated that protective immunity can be generated by immunization with a vaccinia virus construct encoding mouse TRP-1 (57). The induction of protective immunity was found to be dependent on class II-restricted, but not class I-restricted, T cells. This protection may have resulted from the generation of antibodies directed against the TRP-1 protein. Alternatively, CD4+ T cells may recognize B16 antigens that are processed and presented by host antigen-presenting cells, resulting in the activation of nonspecific cells that mediate tumor destruction. In addition, immunization with this viral recombinant was found to induce vitiligo. A correlation between the development of vitiligo and responses to adoptive immunotherapy has been previously noted (58). This observation provides further evidence that responses directed against melanocyte differentiation antigens may be involved with tumor regression.

TRP-2

Part of "16.2 - Differentiation Antigens "

The TRP-2 gene product is approximately 40% identical at the amino acid level to *TRP-1,* and represents another melanosomal enzyme involved in the synthesis of melanin (59,60). The *TRP-2* gene was also found to encode an antigen that was recognized in the context of HLA-A31 (61). The T-cell epitope was encoded by the normal ORF of *TRP-2* and conformed to the consensus HLA-A31–binding motif. Results of one study also demonstrate T-cell recognition of a TRP-2 epitope in the context of HLA-Cw8 (31).

In an attempt to identify HLA-A2–restricted TRP-2 epitopes, peptides from this protein that fit the HLA-A2–binding motif were initially tested for binding to this class I molecule using a standard competitive inhibition assay (62). Twenty-one peptides were identified that inhibited the binding of a standard peptide at a concentration of 2 µM or below. These peptides were then used to carry out *in vitro* stimulations of peripheral blood lymphocytes from HLA-A2 melanoma patients. One of the peptides that was tested, SVYDFFVWL (TRP2:180–188), elicited CTL from patient peripheral blood lymphocytes that recognized T2 cells pulsed with this peptide as well as HLA-A2+ and TRP-2+ melanomas. The sequence of the human and corresponding mouse peptides are identical, and this peptide has been shown to represent an immunodominant epitope that is recognized by T cells reactive with the murine melanoma B16 in the context of H-2K^b (63,64). Adoptive transfer of CTL lines generated by stimulation with this peptide was shown to be effective at mediating the regression of established B16 lung metastases. In this model system, CTL lines that were generated using low concentrations of this peptide (10^{-9}M) were more efficient than CTL generated using a relatively high concentration (10^{-5}M) of peptide. Therapeutic strategies can therefore be evaluated in a mouse model system using the identical epitope recognized by human tumor-reactive T cells.

Melanoma-reactive T cells have also been shown to recognize an epitope that is encoded by a retained intron sequence from the *TRP-2* gene (65). The screening of an autologous melanoma cDNA library using an HLA-A68 restricted, melanoma-reactive T-cell clone resulted in the isolation of a partial cDNA clone containing the second intron of the *TRP-2* gene as well as a portion of the fourth intron of this gene. Extension of the normal *TRP-2* ORF through the region of the second intron resulted in the generation of a truncated protein of 227 amino acids, 39 of which are encoded by the intron sequence. The T-cell epitope was encoded entirely within the region derived from the second intron. Transcripts containing the second intron were either undetectable or were expressed at low levels in melanocytes, whereas this transcript was readily detected in melanomas that expressed TRP-2, as assessed by reverse transcriptase-polymerase chain reaction. As expected, T cells specific for the intron TRP-2 epitope failed to recognize melanocytes expressing HLA-A68. Previously, T cells that recognized a gp100 epitope encoded within the fourth intron of gp100 in the context of HLA-A24 had been found to react with melanoma cells and with normal melanocytes expressing this class I allele (30). Consistent with this observation, comparable levels of a gp100 gene transcript containing the fourth intron of this gene were found in melanocytes and melanomas (65). These findings indicate that epitopes derived from introns can represent both tumor-specific as well as normal-differentiation antigens and raise the question of whether these types of antigens differ in terms of their ability to generate therapeutic antitumor responses.

Some studies have also been carried out to evaluate the melanocortin-1 receptor (MC1R) as a candidate melanoma antigen (66). This protein, which is a member of a family of G-protein–coupled receptors that bind melanocyte-stimulating hormone, appears to be primarily expressed in cells of the melanocyte lineage. Peptides from MC1R that fit the HLA-A2–binding motif were synthesized and tested for their ability to bind to purified HLA-A2. When the 12 peptides with the highest affinities were tested for their ability to elicit CTL, three peptides were found to elicit peptide-specific T cells in the majority of normal donors tested. The CTL lines generated with each of the three peptides also appeared to recognize 8 out of 13 HLA-A2+, MC1R+ melanomas, and expression of the MC1R molecule correlated with recognition by specific T cells. These CTL lines failed to recognize melanomas that expressed only the HLA-A2 or MC1R molecules. This molecule thus represents another potential target for immunotherapy.

Clinical Observations

Part of "16.2 - Differentiation Antigens "

Several observations suggest that melanocyte-differentiation antigens may represent important tumor-regression antigens. Although TILs that induced tumor regression after adoptive transfer into autologous patients has been shown to recognize gp100 and MART-1, clinical responses to TIL therapy were significantly correlated with recognition of gp100 but not MART-1 in HLA-A2 patients (Table 16.2-3) (8). Vitiligo has also been observed in approximately 30% of the melanoma patients who responded to IL-2–based therapy in the Surgery Branch, National Cancer Institute, but was never seen in renal cancer patients after therapy (58). The destruction of normal skin melanocytes, which leads to the development of vitiligo, presumably results from the stimulation of T cells that recognize shared melanocyte-differentiation antigens, such as gp100, in these patients. The fact that clinical responses appear to correlate with the development of vitiligo suggests that immune responses to melanocyte-lineage antigens may play some role in the *in vivo* regression of tumors seen after treatment with immunotherapy.

From Kawakami Y, Dang N, Wang X, et al. Recognition of shared melanoma antigens in association with major HLA-A alleles by tumor infiltrating lymphocytes from 123 patients with melanoma. *J Immunother (in press)*, with permission.

Clinical trials are being carried out to evaluate the effect of immunization with specific peptides from these antigens and recombinant viral constructs encoding tumor antigens in combination with a variety of cytokines. The efficacy of immunization with modified peptides and the adoptive transfer of tumor-reactive T-cell clones are also being evaluated in patient clinical trials. The development of assays that facilitate the monitoring of patient responses represents an important aspect of these trials. Limiting dilution assays (67,68) and measurements of the ability of T cells to generate immune responses after *in vitro* stimulation have been used to monitor patient responses. The enzyme-linked immunospot assay has also been used to directly enumerate tumor-reactive T cells (69).

Complexes of class I MHC tetramers bound to specific peptides have been used for determining the frequency of peptide-specific T cells, in bulk populations of T cells, and for the direct isolation of antigen-reactive cells (70,71). The precursor frequency of T cells reactive with the MART-1:26-35 peptide has been estimated to be between 1 in 50 and 1 in 500 in tumor-infiltrated lymph nodes, whereas the frequency of T cells reactive with a peptide epitope from tyrosinase was below the limit of detection (<0.05%) (72). Another approach to monitoring involves the identification of T-cell receptors' subfamilies or clonotypes that are expressed by tumor-reactive T cells (73,74). Analysis of the expression of specific T-cell receptors in tumor sites and peripheral blood should allow monitoring of lymphocyte trafficking after immunization or adoptive transfer.

A number of peptides from MART-1, gp100, and tyrosinase are being evaluated in clinical trials. In one trial, the MART-1 peptide and two HLA-A2 binding tyrosinase peptides were administered intradermally in a soluble form to melanoma patients (75). Delayed-type hypersensitivity responses directed against the tyrosinase signal peptides were observed in some patients, but significant tumor regressions were not observed in this trial. The ability to induce tumor-reactive T cells after *in vitro* stimulation of PBMC with peptides appeared to be modestly enhanced after the immunization of HLA-A2 patients with the MART-1 and gp100:209-217 peptides in Freund's incomplete adjuvant (76,77). Significant clinical responses, however, were only observed in small numbers of patients in these trials.

The modified gp100:209-217 2M peptide has been used to immunize HLA-A2 melanoma patients in one phase 1 clinical trial (27). The responses of PBMC from 10 out of 11 immunized patients after one *in vitro* stimulation with the gp100:209-217 2M peptide were significantly enhanced by this immunization protocol. The precursor frequency of T cells reactive with the gp100:209-217 peptide was estimated to be between 1 in 3,000 and 1 in 6,000 in immunized patients, whereas the preimmunization frequency of peptide-reactive T cells was estimated to be less than 1 in 30,000. Analysis of the responses of an additional 19 patients that were immunized with the gp100:209-217 2M peptide, along with high-dose IL-2, indicated that only 3 out of the 19 patients treated with this regimen developed enhanced-peptide reactivity. Although none of the patients that had received the gp100:209-217 2M peptide alone in adjuvant demonstrated a clinical response, 8 of the 19 patients treated with the gp100:209-217 2M peptide plus IL-2 demonstrated objective cancer regressions. This represents a higher response rate than was seen in previous clinical trials carried out with IL-2 alone, which ranged between 15% and 20%.

It is not clear why decreased peptide reactivity was observed in patients that were treated with the combination of the gp100:209-217 2M plus IL-2. Patients that had been initially immunized with peptide plus IL-2 responded when subsequent immunizations were carried out with peptide alone, indicating that the IL-2 did not lead to a general inability to detect memory

T cells. The diminished responses did not simply result from enhanced migration of T cells from the peripheral blood to lymph nodes or other tissues following the administration of IL-2, because patients that had first been immunized with peptide alone appeared to develop reactivity after immunization with the peptide plus IL-2.

Clinical trials have also been carried out with recombinant viral vaccines that encode melanoma antigens. Only a small number of patients that had been immunized with adenoviral or vaccinia, constructs encoding gp100, and MART-1 demonstrated clinical responses. *In vitro* responses to these antigens were not enhanced in immunized patients. One possible explanation for these findings is the observation that high titers of neutralizing antibodies directed against these viruses, presumably resulting from smallpox vaccination and environmental exposure to adenovirus, may have had a negative impact on these responses (78).

These studies have provided the basis for a number of ongoing as well as future clinical trials. One clinical trial that has been initiated in the Surgery Branch of the National Cancer Institute involves the immunization of melanoma patients with peptides derived from MART-1, tyrosinase, and gp100 in an attempt to prevent the recurrence of tumors that have lost the expression of one of these antigens. Recombinant viral constructs have now been generated that encode gp100 epitopes that have been modified to enhance their immunogenicity, as described above, either in the context of full-length genes or as minigenes. Another strategy that is now being evaluated in clinical trials is the adoptive transfer of highly reactive, melanoma-specific T-cell clones. The identification of additional shared antigens recognized by CD4[+] tumor-reactive T cells may also lead to the development of peptide and protein vaccines that can be utilized as immunogens either alone or in combination with class I antigens. Hopefully, some of these approaches, used either alone or in combination, may lead to the development of cancer vaccines that result in long-term cures in the majority of patients.

Introduction

Part of "16.3 - Viral Antigens "

Viruses are recognized as a major etiologic factor in human cancer. Estimates of the frequency of virus-induced cancer worldwide as a proportion of all cancers are in the order of 15% to 20% (1 ,2). The tumor viruses involved in human cancers are Epstein-Barr virus (EBV), human T-cell lymphotropic virus type I (HTLV-I), human herpesvirus type 8 (HHV-8), hepatitis B and C viruses (HBV and HCV, respectively) and human papillomavirus (HPV) types 16 and 18 (and other less prevalent oncogenic-HPV types). The pathways by which these tumor viruses induce cancer are often long and characterized by premalignant stages. Malignant transformation by these viruses involves the expression of at least some viral genes in the premalignant lesions and in the ultimate cancers, providing target antigens for the immune system.

Immunocompromised individuals, such as transplant patients and human immunodeficiency virus 1 (HIV-1)-infected subjects display an increased risk to most types of virus-induced cancer (3 ,4). This indicates that the host immune response plays an important role in the prevention of virus-induced cancers. To persistently infect human cells and induce

transformation, some viruses interfere with cell-cycle control or prevent or delay apoptosis, whereas others have coevolved with the host's immune system and developed ways to slow down host defenses or even hide themselves from it.

To treat or prevent the outgrowth of these virus-associated tumors by immunotherapy (e.g., by adoptive cell therapy or by prophylactic or therapeutic vaccination) one has to consider the following four questions:

1. Which cells are primarily infected?
2. Which antigens are expressed during different stages of viral infection or tumorigenesis?
3. Which types of immune response play a role in the normal defense against these viruses?
4. How does the virus or the arising tumor evade the immune response?

This chapter globally describes the human tumor viruses, the immune response against them, and the evasive actions of these viruses. HPV is dealt with in somewhat more detail as an example of a human tumor virus. We describe the kinetics of HPV infection and pinpoint the HPV-derived specific antigens that might be suitable targets for immunoprophylaxis and T-cell immunotherapy at different disease stages.

Immunity Against Tumor Viruses and Their Subsequent Evasive Actions

Part of "16.3 - Viral Antigens "

The viral life cycle, the host immune response to the virus, and other host factors together determine the natural outcome of infection with oncogenic viruses. Ideally, the increased knowledge of the natural history of infection with these viruses, the viral antigens that are expressed at each stage of disease, and the immune response against them should allow the development of prophylactic vaccines providing long-lasting immunity or therapeutic vaccines to treat minimal residual disease. We broadly review the human tumor viruses and then focus on vaccination against HPV-16 as a detailed example for the other tumor viruses.

Epstein-Barr Virus

More than 95% of the world's population are infected with EBV. Primary infection occurs through the throat where the virus replicates in the epithelial cells and infects circulating B cells. Productive infection by EBV involves the expression of more than 80 virus lytic-cycle genes and formation of infectious virus particles in the epithelium of the throat. EBV infection of the epithelium is characterized by lack of an inflammatory response, which can, in part, be explained by the production of the viral homologue of human interleukin-10 (IL-10) (5) that inhibits full deployment of a type 1 T-cell response and decreases the magnitude of CD8 cytolytic T lymphocyte (CTL) responses generated by limiting the production of IL-2 and interferon-γ (IFN-γ). When EBV is transmitted to B cells, the virus enters a latent stage in which a limited set of latency-associated genes is expressed.

After infection, the virus persists for the lifetime of the infected individual, and it rarely causes disease in the immunocompetent host. Detailed studies on the immune response to EBV have firmly established that EBV-infected B-cell growth is under control of CTL-recognizing peptide epitopes in the latent proteins Epstein Barr (virus) nuclear antigen 2-6 (EBNA2-6), latent membrane protein-1, and latent membrane protein-2a (6,7 and 8). Furthermore, CD4+ T-helper (Th) cells specific for the major envelope protein gp340 as well as EBNA2-specific CD4+ major histocompatibility complex (MHC) class-II-restricted CTL have been described (9). EBV-infected cells evade the immune response by controlling the expression of latency-associated genes (10) and thus the available targets for T-cell recognition.

In immunocompromised individuals, expression of all nuclear- and late-membrane proteins is found in EBV-infected B cells (Table 16.3-1). Due to the loss of immunologic control of viral infection, these patients are often faced with immunoblastic lymphoma. However, the broad expression of EBV proteins makes it possible to treat, for example, immunodeficient patients after bone-marrow transplantation with adoptive transfer of donor-derived virus-specific T cells (10,11). In contrast, EBV-associated Hodgkin's lymphoma (HL), nasopharyngeal carcinoma, and Burkitt's lymphoma (BL) are found in patients with an intact immune system. The first two cancers express a restricted number of antigens (see Table 16.3-1). It is difficult to explain how HL and nasopharyngeal carcinoma escape from immunosurveillance, but downregulation of surface HLA class I, as noted in HL, might facilitate escape from virus-specific CTL (10). Furthermore, local inhibitory factors might play a role (12). BL cells are poorly immunogenic, the likely result of exclusive EBNA-1 protein expression. This protein is needed to maintain the virus episome in dividing cells (13). *In vivo*, the EBNA-1 protein does not elicit CTL responses. EBNA-1 consists of an N-terminal part that is followed by a polymorphic Gly-Ala co-repeat unit and a conserved C-terminal region. This Gly-Ala repeat-unit blocks processing of the protein by the proteasome and thus presentation of EBNA-1 peptides at the cell surface and subsequent recognition of the peptides by CTL (14). Recognition of EBNA-1–derived peptides potentially generated by proteolytic enzymes other than the proteasome is further impaired by defects that have been found in the transporter-associated proteins (TAPs) (15) or allele-specific downregulation of HLA-class-I molecules (16). In addition, the cell surface of BL cells expresses no adhesion molecules (17).

Table 16.3-1 Antigen Expression and Immunity against Tumor-Associated Viruses

Virus	Disease	Antigen Expression	T-Cell Reactivity/Immune Evasion
EBV	Burkitt"s lymphoma	EBNA-1	No gly-ala repeat at N-terminus of protein prohibits antigen processing by proteasome.
			Lack of costimulatory molecules at surface infected cells.
			TAP defects inhibit transport of peptides to ER and subsequent expression at cell surface.
			HLA class I downregulation.
	Hodgkin"s lymphoma	EBNA-1	CTL activity toward LMP1 and LMP2a and LMP2b.
	Nasopharyngeal carcinoma	LMP-1, LMP-2a, LMP-2b	Possible escape due to local expression of inhibitory factors and/or HLA class I downregulation.
	T-cell lymphoma		
	Immunoblastic lymphoma in immunocompromised individuals	EBNA-1, 2, 3	All proteins (except EBNA-1) provide target epitopes for CTL.
		EBNA leader protein	
		LMP1, LMP2a, LMP2b	
HTLV-1	Adult T-cell leukemia	Gag, envelope, reverse-transcriptase, integrase, protease, tax, rex	CTL activity against envelope, gag and tax has been found.
			Other proteins probably provide T-cell epitopes as is noted for HIV-1.
			Latent infection and mutation of T-cell epitopes provide temporary escape.
			TGF-ß production by ATL inhibits induction of CTL response.
			Infection of CD4$^+$ T cells results in loss of T-helper cell function.
HHV-8	Kaposi"s sarcoma	HHV-8 shows sequence similarity to two other oncogenic γ-herpes viruses:	No T-cell antigens have been identified yet.
	Primary effusion lymphoma	Herpesvirus of Saimiri and EBV; similarly early and late antigens will probably be expressed.	The mechanisms of how HHV-8 infected cells evade host immune responses are not yet known.
HBV	Hepatocellular carcinoma in HBsAg positive patients	Pre-S, HBsAg, HBeAg, HBcAg, HBxAg, polymerase	CTL have been found against epitopes in the surface, core, and polymerase antigens.
			T-helper cells strongly reacted against the core antigens (HBe and HBc) in patients with acute hepatitis.
	Hepatocellular carcinoma in HBsAg-negative patients	HBxAg	Deletion or mutation of T-cell epitopes weakens the response, allowing *HBV* virus- or HBV-containing tumors to persist.
		(HBeAg and HBcAg are deleted in numerous tumors)	
HCV	Hepatocellular carcinoma	Core, envelope 1, and envelope 2, nonstructural proteins: NS2, NS3, NS4, and NS5	CTL and T-helper cells react to all proteins.
HPV	Cervical intraepithelial neoplasia	E1, E2, E4, E5, E6, E7, L1, and L2	CTLs have been found to react against E2 and E7.
			T-helper cells have been found against E7.
			Tumor escape by HLA class I and/or TAP downregulation.
	Cervical carcinoma	E6 and E7	Possible escape by E7-mediated impairment of IFN-γ response.

ATL, adult T-cell leukemia; CTL, cytolytic T lymphocyte; EBNA, Epstein Barr (virus) nuclear antigen; EBV, Epstein-Barr virus; ER, endoplasmic reticulum; HBcAg, hepatitis B core antigen; HBeAg, hepatitis B early antigen; HBsAg, hepatitis B surface antigen; HBxAg, hepatitis B X antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HHV, human herpesvirus; HIV-1, human immunodeficiency virus 1; HPV, human papillomavirus; HTLV-1, human T-cell lymphoma/leukemia virus type 1; IFN, interferon; LMP, latent membrane protein; pre-S, pre-surface; TAP, transporter-associated protein; TGF-ß, transforming growth factor-ß.

The EBV-derived protein expression in immunoblastic lymphoma, HL, and nasopharyngeal carcinoma leads to the conclusion that these diseases might be treated by the use of EBV-specific, CD8$^+$ or CD4$^+$ T cells, or both, directed at the available antigens. Treatment of disease might be achieved by adoptive transfer of T cells or therapeutic vaccination aimed at the activation of EBV-specific T cells. T-cell based immunotherapy for the treatment of BL seems not feasible.

Human T-Cell Lymphotropic Virus Type I

HTLV-I is a retrovirus and the etiologic agent of adult T-cell leukemia (ATL), a condition in which the CD4$^+$ T cells are mainly affected (18). Breast-feeding, sexual intercourse, blood transfusions, and needle sharing transmit HTLV vertically and horizontally. In addition to genes common to all retroviruses, the HTLV genome carries a region that is related to the T-cell immortalizing phenotype of the virus and codes for two transacting regulatory proteins, tax and rex (19,20) (see Table 16.3-1).

HTLV-I-specific CTL directed against env, gag, and tax have been observed in 57% of asymptomatic HTLV-I carriers (21), and these CTL appear to control viral replication (22,23). At an early stage of viral gene expression, tax and rex proteins are predominantly produced (24). Therefore, these antigens are attractive targets for the immune system (25) and may be used as target antigens for prophylactic vaccination.

Besides HTLV-I-specific T-cell responses, HTLV-I-neutralizing antibodies that inhibit cell fusion have been reported (26).

ATL develops in a small proportion of HTLV-I-infected people (1 per 1,000) (27). HTLV tax induces the expression of IL-2 and IL-2 receptor genes in infected T cells, therefore providing an autocrine loop for T-cell proliferation (28,29). During progression, ATL cells no longer produce IL-2, but they continue to express the IL-2 receptor. Widespread infection of CD4⁺ T cells might result in a loss of T-cell help during the CTL-mediated response and form a plausible reason for the escape of HTLV-I from the immune system and the subsequent development of ATL. Furthermore, HTLV-I-induced immunosuppression is indicated by the fact that most ATL patients are susceptible to various opportunistic infections by bacteria, fungi, protozoa, and viruses (18), which are normally under control of T-cell mediated immunity. HTLV-I infection of CD4⁺ T cells impairs T-cell function by decreasing the surface expression of the T-cell receptor/CD3 complex and diminishing helper function (30). Indeed, only 18% of ATL patients show an HTLV-I-specific CTL response (21), suggesting that the capacity to induce HTLV-I-specific CTL is decreased. The positive and negative regulation by tax and rex regulatory molecules result in transient expression of HTLV-I and allows a temporal escape from the immune system (24). HTLV tax transactivates various cellular molecules, including transforming growth factor-ß (TGF-ß) and IL-6 (31,32), and ATL cells constitutively produce IL-10 (33). Although both IL-6 and IL-10 might decrease the inflammatory response, TGF-ß might inhibit the induction of a T-cell response. TGF-ßs are highly immunosuppressive, and they inhibit the proliferation and effector functions of T cells, B cells, natural killer cells, and macrophages (34).

Conventional therapy by combination chemotherapy or treatment of ATL patients with radioactively labeled anti-IL-2 receptor antibodies results in partial or complete remissions in approximately 50% of treated patients (35). Alternative therapies for the treatment of ATL patients, such as the adoptive transfer of CD8⁺ HTLV-I tax-specific CTL, seems more attractive but only when the negative effects of tumor-produced cytokines are circumvented (36). Immunotherapy of established disease, therefore, appears a tough task. Prophylaxis of tumors by vaccination against HTLV-I (e.g., by induction of neutralizing antibodies against intact envelope components) in endemic regions seems more attractive.

Human Herpesvirus Type 8

In 1994, HHV-8 has been identified as an etiologic agent in Kaposi's sarcoma (KS) and primary effusion lymphomas (37,38). HHV-8 is sexually transmitted and may infect 10% of the general population. In HIV and acquired immunodeficiency syndrome patients, a higher fraction of the population is affected (39,40).

Antibodies directed against HHV-8 are detected in HIV patients and in some blood donors (41,42). The presence of antibodies to HHV-8 in HIV-1-infected patients is a predictor for the development of KS, showing that antibodies do not mediate full protection against HHV-8. Although no cell-mediated T-cell responses against HHV-8 have been described at present, several studies indicate a prominent role for the T-cell mediated control of HHV-8. Detection of HHV-8 in peripheral blood mononuclear cells increases with immunosuppression, as shown by the correlation with a reduced number of CD4⁺ T cells (43). Furthermore, HHV-8 produces the chemokine homologue vMIP-II that displaces the CC chemokines MIP-1α and monocyte chemotactic protein 1 from their receptors (44,45). Chemokines are potent leukocyte chemoattractants that are involved in the recruitment of immune cells to sites of inflammation and infection. Production of viral homologues by HHV-8 prevents a local inflammatory response and thus protects the virus from immune-mediated clearance. It is not known how HHV-8 transforms cells into tumor cells, but some of the open reading frames (ORFs) of HHV-8 encode homologues that are important for transformation such as ORF72, the D-type cyclin homologue (46), and ORF16, a bcl-2 homologue (47,48). Additionally, the HHV-8 K2 gene encodes a functional IL-6 homologue. Human IL-6 inhibits apoptosis in myeloma cell lines (49) and viral IL-6 might play the same role. Furthermore, the HHV-8 K9 gene encodes a homologue of the viral interferon regulatory factor (vIRF). vIRF inhibits IFN-ß inducibility of p21^waf1/cip1 and thus indirectly prevents p53-induced cell cycle arrest (50). The oncogenic potential of vIRF is demonstrated by the fact that expression of vIRF fully transforms NIH3T3 cells (50). The ORF of HHV-8 K13 shows a significant homology to the ORFs present in three other γ-herpesviruses encoding viral inhibitors that interfere with apoptosis signaled through death receptors (51). These inhibitors, called *vFLIP*, inhibit the recruitment and activation of the ICE-like protease FLICE by FAS/CD95 and might protect HHV-8-infected cells against apoptosis, leading to a higher virus production and persistence of HHV-8. At present, it is not known which antigens are expressed at which stage of disease, but based on the sequence similarity of HHV-8 to two other oncogenic γ-herpesviruses, herpesvirus of Saimiri and EBV, early and late antigens are probably expressed (see Table 16.3-1).

Hepatitis B Virus

HBV is a noncytopathic, enveloped virus with a circular double-stranded DNA genome. HBV causes acute and chronic necroinflammatory liver disease. Approximately 5% of the world's population is infected by HBV. More than 95% of adults acutely infected with HBV are able to clear all viral antigens and develop antiviral antibodies (52,53). During the acute phase of the disease, the T-cell response to HBV in these patients is vigorous, polyclonal, and multispecific (53). Sterilizing immunity, however, frequently fails to occur, as traces of HBV surface antigen and activated HBV-specific CTL can be detected in HBV surface-antigen-negative patients that have recovered years ago (54). The antibody response to HBV probably prevents viral spread, whereas the CTLs control HBV replication (53,55). Some HLA class-II alleles are associated with clearance of HBV infection (56), and patients that clear HBV show a concomitant HBV-specific CD4⁺ T-cell response that is absent in patients who do not (57). In addition to killing of infected hepatocytes, CTLs downregulate the expression and replication of HBV in surrounding liver tissue (58). Cytokines secreted by CTLs, such as IFN-γ and tumor necrosis factor α

(TNF-α), play an important role. TNF-α mediates the accelerated degradation of cytoplasmic HBV messenger RNA (mRNA) and IFN-γ plays a role in the upregulation of MHC class I expression, proteasomal cleavage of antigens, and expression of a variety of cellular antiviral proteins. Furthermore, IFN-γ is a powerful activator of macrophages. Activated hepatic macrophages have been shown to persistently abolish HBV gene expression and replication from the hepatocytes, possibly by the secretion of TNF-α and IFN-α/ß (59).

The dominant cause of viral persistence seems to be a weak antiviral response to the viral antigens. Indeed, a relatively narrow and weak T-cell response is correlated with high viral load in patients with chronic hepatitis (53,57). Viral evasion by mutations in CTL or Th epitopes can contribute to viral persistence, as might the infection of immunologically privileged sites. Obviously, vaccination-induced upgrading of the natural T-cell response against the envelope, nucleocapsid, and polymerase antigens (60) into a vigorous HBV-specific immune response may result in control of HBV infection and prevent the development of hepatocellular carcinoma (HCC).

HCC is a common complication of chronic HBV infection. Most HCC tumors contain clonally integrated HBV DNA. Indeed the HBV-X gene product and preS2/S can transactivate cellular genes that are involved in cellular growth control and inhibit p53 gene function (61,62,63 and 64). Like other retroviruses, HBV integration can only take place in dividing cells, and an active immune response, resulting in an enhanced hepatocellular turnover, has been implicated as mediator of hepatocarcinogenesis in chronic HBV infection (65). No evidence of a rise in hepatocellular cancer incidence was found in HIV-1 seropositive subjects, which suggests that the development of HCC might be dependent on a chronic and weak immune response to HBV (4).

Numerous tumors contain viral RNAs encoding the HBV-X, -S, and -C genes, whereas in other tumors these genes are disrupted and only HBV-X is expressed (66). CTLs recognizing surface and core antigens that are encoded by HBV-S and HBV-C have been found, suggesting that tumors expressing these antigens might be treated by immunotherapy (see Table 16.3-1). Considering the decreased immune status of tumor-bearing patients (2,67) and the routes tumor cells follow to resist T-cell immunity (36,68,69), adoptive transfer of *in vitro*-expanded HBV-specific T cells might be feasible, provided that the primary tumor has been resected. CTLs directed at the transactivating gene X have not been reported, suggesting that treatment of tumors expressing only HBV-X may be much harder. Prevention of HBV infection and incidence of HCC might decrease by prophylactic vaccination with HBV antigens, as was shown by vaccination-induced reduction of HBV-related HCC in children (70,71).

Hepatitis C Virus

HCV is a small, enveloped RNA virus that encodes a single polyprotein of approximately 3,000 amino acids. At the 5" end, a highly conserved region encoding the core protein is located, which is followed by five less-conserved nonstructural regions and a hyper-variable region encoding the envelope. *In vivo* replication of HCV takes place predominantly in the liver. Most patients with acute infection are asymptomatic, nevertheless 50% to 70% of the infected individuals progress to chronic liver disease (72). Viremia may be lifelong, although clearance of HCV-RNA may occur transiently. In 20% of these patients, symptomatic cirrhosis develops after one or more decades, which then might slowly evolve to hepatocellular cancer (73).

The immune response necessary to elicit protective immunity against HCV is presently unknown. Humoral responses to multiple HCV antigens are present, but the antibody titer of the response does not correlate with course of disease. Moreover, high-titer antibodies have been associated with disease transmission and persistent viremia (74,75). In addition to antibodies, lymphocytes are observed within the hepatic parenchyma of individuals infected with HCV. Both HCV-specific CD4+ and CD8+ T cells exist, and these responses appear to be directed at many HCV epitopes (76,77,78,79,80 and 81). All HCV-derived proteins are a target for CD4+ Th cells, but CD4+ T cells specific for HCV core are associated with a benign course of infection (81). In view of the HIV-like high RNA replication rates and poor proofreading ability of HCV, which leads to frequent transcription errors, a Th response directed at the conserved core protein might be better able to maintain the humoral and CTL response. Furthermore, current data on HCV suggest that in the case of HBV, HCV infection of immunologically privileged sites or weakening of T-cell–mediated immune responses might allow the virus to persist. Continuous priming of the CTL response by persistent virus, long after clinical recovery, might wear out the T-cell response. Moreover, HCV proteins containing epitopes that elicit neutralizing antibodies mutate frequently and appear to permit the virus to escape.

A role for T cells in the pathogenesis of liver injury is indicated by the fact that HCV-specific CTL produces cytokines, including IFN-γ, TNF-α, granulocyte-macrophage colony-stimulating factor, IL-8, and IL-10 in an antigen- and class I-restricted manner (80). The release of these proinflammatory cytokines by CTL on recognition of their cognate target may contribute to the pathogenesis of liver injury. Direct liver damage of noninfected hepatocytes might also occur by molecular mimicry between an HCV-derived CTL epitope and a cytochrome p450-derived peptide (82) and it can be envisaged that this type of CTL epitope might also play a role in HBV infection and the development of HCC. The nature of HCV replication makes it unlikely that HCV integrates in the host genome, and HCV-positive tumors, therefore, express all HCV proteins (see Table 16.3-1). If protection from HCV infection turns out to be T-cell mediated, the conserved antigens of HCV are attractive immunotherapeutic targets to treat HCV-associated HCC.

Human Papillomavirus Type 16

Part of "16.3 - Viral Antigens "

HPVs of the high-risk types (e.g., HPV-16, -18, -31, -33, and -45) are responsible for cancer. The HPV genomes can be divided into three regions: a long control region (LCR) and an early (E) and a late (L) region. The L genes encode structural proteins, the E region codes mainly for regulatory proteins engaged in genome persistence, DNA replication, and activation of the lytic cycle (83). Virus gene expression is controlled by viral- and cellular-derived transcription factors such as Brn3a (84) or the epithelial factor Epoc1/Skn-1a (85) that regulates papillomavirus

transcription in a differentiation-dependent fashion in the suprabasal cells of the cervical epithelium. The E1 and E2 genes regulate viral replication. Furthermore, E2 and E5 regulate transcription. The E2 protein controls the expression of the E6- and E7-oncoproteins by binding to sites close to the TATA box within their common promoter (86). E5 enhances the transcription of the immediate early genes (87,88). The E5 protein of HPV shows only weak transforming activity in NIH3T3 cells by *in vitro* transfection experiments. Indeed, the E5 ORF is frequently deleted in cervical cancers (89). The early genes E6 and E7 interfere with cell cycle control. The E6 protein of the high-risk HPV types specifically binds to p53 and targets its rapid degradation through the ubiquitin pathway (90). p53 Is involved in initiation of apoptosis, and loss of this protein results in the prevention of apoptosis. HPV-16 viruses, with an E6 protein that displays variation in areas likely to be important for protein-protein interaction with p53, reportedly are more prevalent in invasive cervical carcinoma than are prototype viruses (91). The E7 protein of high-risk types binds to pRB, which normally prevents cells from entering the cell cycle by inactivating E2F, a protein needed for cell cycle entry (92). E7 expression results in the failure of infected cells to withdraw from the cell cycle and differentiate. In addition, HPV-16 E7 can bind to another identified cellular partner, the human homologue hTID56 of the *Drosophila* tumor-suppressor protein TID56 (93). The combined actions of E6 and E7 create an environment conducive to viral replication. Finally, E4 expression correlates exactly with the start of viral DNA replication (94) suggesting a role for the E4 protein in DNA replication, but the exact role of E4 remains unclear.

Kinetics of Human Papillomavirus Infection and Development of Human Papillomavirus-Induced Cervical Carcinoma

Papillomaviruses infect basal keratinocytes, and the differentiation of these cells allows HPV to replicate and assemble new virions. These new viruses are released when the superficial cells flake off (95). After infection of the basal epithelial cells, the immediate HPV early genes E1, E2, E5, E6, and E7 are expressed. As the infected basal cell migrates through the differentiating layers of the epidermis, HPV late gene expression is initiated. Expression of the nonstructural early protein E4 precedes the expression of the L1 and L2 capsid proteins for one or two cell layers (94). In the most superficial epithelial layers, L1 and L2 are expressed. Here, the new HPV virions are assembled and released.

Low-risk HPV types (e.g., HPV-6 and -11) cause benign warts, whereas the high-risk types are responsible for cancer in more than 99% of cases. In some cases, HPV of the high-risk types persist and the viral genome is linearized and integrated. Malignant transformation occurs when the E2 region is disrupted. Loss of E2-protein expression leads to elevated expression of the E6 and E7 oncoproteins and in abortion of the productive infection cycle. Prolonged and elevated expression of the E6 and E7 oncoproteins is tightly associated with HPV-induced dysplasia and transformation into cervical carcinoma (83). This sets the stage for a transformation process involving progression from precursor lesions, termed *cervical intraepithelial neoplasia* (CIN), and potentially evolving to monoclonal cervical carcinoma. Indeed, in a high proportion of CIN III lesions, and in all tumors, the E2 gene was disrupted although no detectable E2 transcripts were found (96,97). The precursor lesions (CIN I to III) are classified on the basis of a progressive increase in cellular atypia and tissue architecture. CIN I lesions spontaneously regress in 60% of cases and are mostly associated with infection of low-risk HPV types 6 and 11. Approximately 10% of CIN I lesions progress to CIN II or CIN III (severe dysplasia and carcinoma *in situ*). With progression to high-grade CIN, the chance of spontaneous regression diminishes, but the chance of developing cervical carcinoma and the incidence of high-risk HPV types increases (98,99,100 and 101). A strong relationship was found between persistence of oncogenic HPV types and progression of premalignant cervical lesions. In contrast, the absence of progression was often found to be associated with HPV clearance or fluctuation. HPV-16 can be found in 30% to 70% of CIN III lesions, the majority of which progress to cervical carcinoma in the absence of treatment (83,102).

Immunity to Human Papillomavirus

In most women, infection with genital HPV is a transient phenomenon. Natural HPV infection at the genitomucosal surfaces is poorly immunogenic. Premalignant HPV infections are restricted to the epithelium, limiting contact with immune-effector cells and antigen-presenting cells (APCs). Moreover, HPV is a nonlytic virus that exploits the normal differentiation of the keratinocytes for viral replication and production. Viral particles are shed from the upper layers of the epithelium and, as a consequence, HPV infection produces little or no local inflammation. Involvement of the immune system in the defense against HPV infection was suggested by (a) an increased incidence of HPV-induced epithelial lesions in immunosuppressed patients (3); (b) association of particular HLA alleles with increased susceptibility to, or protection from, HPV infection and cervical neoplasia (103,104); (c) seemingly spontaneous regressions of CIN lesions and clearance of concomitant HPV infections (105); and (d) downregulation of MHC class I or TAPs, or both, in the majority of cervical cancers (106).

More direct proof of natural HPV-directed immunity has accumulated since the mid-1990s. The existence of natural HPV-16 E7-specific CTL immunity, and homing of these CTLs to the site of premalignant and malignant lesions, has been shown in the blood, lymph nodes, or tumor material of patients with HPV-16 or -18 DNA–positive lesions (107,108,109,110 and 111). In a nonintervention follow-up study, HPV-16 E7-specific CTLs, as well as Th cells, were found only in the blood of patients with a persistent HPV infection or with progressive cervical lesions (112,113). This agrees with the idea that the cells of the basal layer that are most likely to contact immune cells express only a limited repertoire of viral gene products. Antigen expression is probably too low to induce a protective immune response, and T cells are only triggered on viral persistence and progression of HPV-infected lesions when the expression of the E6 and E7 protein is increased and the normal epithelial organization is disrupted and thus accessible for antigen-presenting cells.

In addition to T-cell responses, antibodies to the early genes E2, E4, E6, and E7 have been described (114,115,116 and 117). These antibodies do not appear to have any antiviral effect once HPV infection has been established but merely reflect progression of disease. E2- and E4-specific antibodies have been found at the time of replication, whereas E6- and E7-specific antibodies were found in tumor-bearing patients when E1 and E2 expression is disrupted and the antigen burden of the E6 and E7 oncoproteins is increased. Furthermore, HPV capsid-specific antibodies of the immunoglobulin G (IgG) class have been found. These antibodies seem to be insufficient in mediating a protective response because the presence of capsid-specific IgG antibodies is associated with and predictive for persistent HPV-16 infection and the development of high-grade CIN (118).

A Th type 1 cytokine profile of the HPV-specific immune response seems in favor of the host. IgG2 (Th type 1) reactivity against HPV-16 E7 in CIN patients is associated with viral clearance, whereas an increase in HPV-16 E7-specific IgG1 antibodies (Th type 2) is found in cervical cancer patients, indicating a possible shift from a Th type 1 to Th type 2 response (119). Indeed, IL-2 production by peripheral blood lymphocytes in response to stimulation with soluble antigen was reported to be reduced in HPV-infected individuals with high-grade lesions or carcinoma (120,121). In contrast, production of IL-4 and IL-10 was found to be elevated in HPV-infected patients with high-grade disease (121). Moreover, high expression of the Th type 1 cytokine IFN-γ correlated with good prognosis in cervical cancer, whereas an abnormally elevated concentration of the Th type 2 cytokine IL-6 was associated with poor prognosis (122).

Persistence of oncogenic HPV types might be achieved by multiple pathways. Lack of a local inflammatory response and low antigen expression of viral antigens in the basal layer of the epithelium can be just enough to avoid induction of protective immunity. Whether the viral genome is involved in downregulation of APC function, particularly of Langerhans' cells in the skin, remains unclear at present. HPV-16 E7 seems to impair the IFN-γ response of infected cells (123). Furthermore, high-risk HPV harbor glucocorticoid responsive elements within the LCR (124), and exposure of infected cells to glucocorticoids could have multiple effects. Glucocorticoids were found to substantially enhance immortalization of HPV-16 but not of HPV-11–infected cells *in vitro* (125). Exposure of transgenic mice expressing HPV-16 oncogenes under the human keratin-14 promotor to estrogen, which enhances the action of glucocorticoids, is known to induce cancer in these transgenic mice (126). Alternatively, hydrocortisone and progesterone were found to downregulate human HLA class I molecule expression at the surface of HPV-positive cells (127) leading to reduced presentation of peptide antigen to T cells. Downregulation of HLA class-I molecules or TAP expression has also been noted in cervical carcinoma cells (106).

Antigens Accessible for Prophylactic Vaccination Against Human Papillomavirus-16

Approximately 50% of young, sexually active women are infected at one time or another with HPV types that have the potential to progress to malignancy (128). An early termination of viral infection might not only protect the host from subsequent reinfection of newly assembled virus or the potential formation of premalignant lesions, but may also limit the spread of the virus in the population and thus the incidence of HPV infection. Prophylactic vaccination aimed at the suppression of HPV infection at the port of entry, thus, is preferred. Generation of local antibody responses against the capsid antigens L1 and L2 could block the interaction between the infectious virion and its cellular receptor and prevent infection of the cervical epithelium. Moreover, these antibodies might facilitate the degradation of virions through antibody-mediated uptake by macrophages. It is, however, not formally proven that such antibodies are capable of preventing virus transmission by flaked-off virus-infected epithelial cells. L1-specific antibodies of the IgG class were found in the majority of patients with persistent infections and histologically confirmed high-grade lesions, suggesting that these antibodies are insufficient for the control of established HPV infections (118). More relevant than L1- or L2-specific IgG antibodies might be mucosal IgA responses with the capacity to neutralize virions. Cervical mucous antibodies of the IgA type that reacted with HPV-16 capsid proteins were found particularly in patients who displayed low-grade lesions (CIN I) (129).

In addition to mucosal L1- or L2-specific antibodies of the IgG and IgA type, a cell-mediated immune response against the early gene products E1, E2, E5, E6, and E7 might protect against HPV-16. The L1, L2, and E4 proteins are unlikely to be suitable CTL targets, as these proteins are expressed in the late phase of infection when the cells are already dying as part of their differentiation program. Furthermore, the manifestation of E6 and E7 proteins is low as a result of E2 expression. The E1 and E2 proteins constitute a replication complex necessary for the maintenance of the episomal genome and thus should be expressed in all cells that contain episomal HPV. Therefore, the E1 and E2 proteins are attractive targets for CTL as well as for supportive Th type 1 responses (see Table 16.3-1). Prophylactic vaccines must include L1, L2, and, preferably, E2 antigens of multiple oncogenic HPV types to make an impact in the reduction of cancer and high-grade cervical lesions. Luckily, each of the types of HPV is highly conserved globally, and the viral genomes are not ostensibly prone to mutation. Phase 1, phase 2, and phase 3 efficacy trials of prophylactic vaccination with virus-like particles composed of HPV-16/18 L1 with or without L2 and other viral proteins are currently under way and should answer the question whether reduction of viral burden or disease, or both, induced by these high-risk HPV types is feasible.

Antigens Accessible for Therapeutic Treatment of Human Papillomavirus-16 Positive Lesions

Constitutive expression of E6 and E7 is needed for maintenance of the transformed state of cervical carcinoma cells. The E6 and E7 proteins thus form attractive targets for the treatment of disease characterized by the presence of transformed cells. E7-specific CTLs have been found in high-grade lesions, and the frequency of these CTLs was higher in tumors and tumor-draining lymph nodes than in the blood of these patients (107). This

shows that HPV-specific CTLs can home to the sites of disease. However, this also indicates that these CTLs are not sufficiently effective to accomplish tumor regression. Furthermore, HPV-16 E7-specific Th responses, as well as E7-specific CTLs, seem to develop as a consequence of increased viral antigen burden resulting from tumor growth, and, therefore, their induction is probably too late to have any effect on established tumor (112,113). Active immune intervention aiming at E6 and E7 in premalignant or minimal residual disease after cancer surgery may provide adequate and effective immunity. Therapeutic treatment should result in the elimination of residual cancer, the regression of existing lesions, or prevention of progression from low-grade into high-grade disease. Two approaches can be followed: therapeutic vaccination or adoptive immunotherapy, or both.

Many animal studies have shown that vaccination with various formulations of E7-derived peptides, E7 protein, dendritic cells pulsed with peptide or protein, virus-like particle–containing E7, or recombinant viruses expressing E7 protein, elicit E7-specific CD8+ CTL capable of protecting animals from a tumor challenge (130,131,132,133 and 134). Moreover, therapeutic intravenous vaccination with dendritic cells, pulsed with either an E7-derived CTL epitope or with unfractionated acid-eluted peptides from an HPV-16+ tumor, resulted in tumor regression and long-term immunity (135,136). Of note, the time span allowed between onset of tumors and start of treatment for therapy to be effective was limited in these murine tumor models relative to the situation found in cervical cancer patients. Instead of therapeutic vaccination, adoptive transfer of antigen-specific Th cells and CTL might be a practical way to control advanced disease. Indeed, established virus-induced or p53-overexpressing tumors of considerable size can be eradicated in murine models when treated with adoptively transferred CTL (137,138) or injection of E7-specific CTL directly into an HPV-16+ tumor (139). In humans, CTL were shown to control persistent viral infection or exert antitumor reactivity as illustrated by the therapeutic activity of *ex vivo* expanded autologous cytomegalovirus or EBV-specific T cells in bone marrow transplant patients (11,140), or the infusion of expanded tumor-infiltrating lymphocytes in patients with malignant melanoma (141).

We are currently not aware of any trials that conduct the adoptive transfer of HPV-specific T cells in patients with HPV-induced tumors. Possibly this is due to the fact that good protocols needed for the expansion of HPV-specific memory T cells are still lacking. Additionally, the restricted repertoire of viral gene products in basal cells, the limited contact of immune cells with HPV-infected epithelium, and downregulation of epithelial APC function probably impede vigorous priming of HPV-specific T cells. This is confirmed by the fact that the majority of T-cell responses were found in patients in later stages of disease when antigen burden is high and the structure of cervical epithelium is altered (112,113).

Instead of expanding existing HPV-specific T cells *ex vivo*, priming of autologous naïve T cells to react to HPV may be considered. Priming of CTLs able to react against HPV-16–positive tumor cells is feasible (142,143), but *in vitro* induction of antigen-specific CTLs is quite laborious and, except for melanoma antigens, the success rate and reproducibility are low. *In vitro* generation of antigen-specific Th cells seems more successful and reproducible (144). Previously, it was shown in an animal model that murine leukemia virus-specific Th cells were needed for the induction of CTL-mediated protection against challenge with the aggressive virus-induced RMA tumor (145). Dissection of the cellular interactions involved in the generation of effective CTL responses revealed that Th cells and CTLs must recognize antigen on the same APC (146,147). Recognition of APCs by Th cells induces APC maturation through CD40L-CD40 cognate interactions (148,149 and 150). This is associated with IL-12 production by the APC, with upregulation of MHC class I and class II molecules, and costimulatory molecules that convert the APC into a CTL-priming state. Thus, in essence, adoptive transfer of HPV-specific Th cells, which can recognize their antigen captured by local APC, results in maturation of the APC and potentiates priming of HPV-specific CTL. Furthermore, antigen-specific Th cells are able to activate macrophages and eosinophils that produce both superoxide and nitric oxide, resulting in MHC-independent antitumor activity (151). We have identified E7-derived peptides that were able to prime and expand HLA-DR–restricted E7-specific Th cells from the blood of healthy blood donors in a time span of 3 to 4 weeks (S. H. van der Burg, *in preparation*). Such T cells, if prepared under good manufacturing practice conditions, could be used for immunotherapy by adoptive transfer, possibly resulting in a more efficient local activation of effector cells. In general, the importance of exploiting the full therapeutic potential of tumor-specific CD4+ Th cells, orchestrating several effector functions that can cooperate in an effective antitumor response, should be stressed here (152).

Stage of Patients and Efficacy of Therapeutic Treatment

The stage of disease might have a profound outcome on the efficacy of treatment. Late-stage cancer patients display impaired immunity as shown by loss of CTL responses to influenza or diminished proliferative Th responses against *Mycobacterium tuberculosis* or tetanus toxin (153). Furthermore, cervical tumor cells tend to lose MHC class I expression or downregulate peptide transport into the endoplasmic reticulum, or both, resulting in loss of recognition by the immune system. Several groups have vaccinated HPV-16-infected late-stage cervical carcinoma patients with E7-derived CTL epitopes and Th peptide formulations, E6 and/or E7 proteins, or recombinant vaccinia virus expressing E6 and E7. Only a few of the patients reacted to the vaccine and displayed E7-specific CTL responses (110,153,154) or Th peptide-specific responses (153,155). In general, these vaccines were shown to be safe, but due to the small groups and, more important, the impaired immunity of late-stage cancer patients, it was difficult to evaluate the full potential of these vaccines.

Based on these experiences, new trials should include patients with less advanced stages of disease, and HPV-specific Th epitopes should be included in these vaccines. Therapeutic vaccination or adoptive transfer of HPV-specific T cells in addition to the standard treatment of HPV-16-infected patients with severe dysplasia or noninvasive tumor might shed a light on a potential beneficial effect of HPV-specific CTL and Th cells in the elimination or control of residual disease.

Cost-Effectiveness of Treatment Modalities

Apart from the feasibility of prophylactic vaccination, one should remember that of the 30% to 50% of the sexually active population that is infected with HPV, only a small percentage (less than 1%) progress to full-blown invasive cancer. This can be compared to other viruses such as EBV and HBV (155). Thus, cancer induction by these viruses is an accident of an otherwise uneventful virus-host relationship. Furthermore, the generation of long-term high-titer neutralizing antibodies at the mucosal surfaces may be hard to achieve and may not be enough to fully control disease. Additionally, substantial numbers of HPV-specific Th cells and CTLs should be maintained over prolonged periods. Both probably require regular boosts and antibody, and HPV-specific T-cell levels need to be high for many years. It requires many years of patience to observe a reduction of cervical carcinoma after vaccination, but prophylactic vaccination inducing both humoral and cellular immunity might limit the spread of virus in populations at risk.

Assuming that T cells play an important role in the control of HPV infections, immunotherapy of people with severe dysplasia or noninvasive carcinoma as adjuvant therapy to the standard treatment limits the number of individuals that should be treated (less than 1% of infected subjects). Adoptive transfer of HPV-specific T cells enhances the costs due to the necessity for cytokines and specialized personnel for T- and dendritic-cell culturing and antigen preparation, which are needed to obtain clinical-grade HPV-specific T cells at sufficient numbers (if possible).

Therapeutic vaccination might lower the costs dramatically if no cell culture is needed. Ideally prophylactic and therapeutic vaccines are identical and may be composed of recombinant proteins or viruses (vaccinia or adenovirus) expressing HPV antigens. Because this kind of active immunotherapy depends heavily on an intact immune system, it is only possible in immunocompetent patients.

Introduction

Part of "16.4 - Oncogenes and Mutations "

Two of the important criteria for a good tumor antigen are (a) unique expression in the tumor cell that allows the immune system to distinguish cancer cells from normal cells and (b) essentialness of the function of the protein for malignant transformation, preventing the tumor from escaping the immune response by suppressing expression of the antigen without losing its malignant phenotype. Mutations that occur in oncogenes and tumor suppressor genes often fulfill both of these criteria, because the mutation is unique to the tumor and also results in a function that contributes to the malignant phenotype. For these reasons, mutant oncogene and tumor suppressor gene products, such as mutant ras or mutant p53, have been widely studied as potential tumor antigens against which to target immunotherapeutic vaccines. Of a similar nature, but not a mutation in the strict sense, are the fusion proteins created by chromosomal translocations. These are formed when a chromosomal translocation juxtaposes the 5" portion of one gene with the 3" portion of another to create a new gene and a novel gene product not present in normal cells. Several of these, such as those that occur in several leukemias and sarcomas (see Novel Fusion Proteins Created by Chromosomal Translocations), result in novel transcription factors that cause aberrant transcription of genes that lead to the malignant phenotype. Thus, they meet the criterion that they are causal and hence essential for the malignant transformation. Furthermore, the junction or breakpoint at which the two sequences join may create a neoantigenic determinant that is not present in either of the parent proteins from which the fusion was derived. Any epitope that spans this breakpoint junction is unique to the tumor. Thus, these fusion proteins meet the same criteria as missense mutations in oncogenes and in effect create novel oncogenes. All of these types of tumor-unique antigens are discussed in this chapter. Also discussed are certain oncoprotein/receptors that are overexpressed in the tumor, albeit not unique to the tumor, such as HER-2/*neu.* These may serve as tumor markers, because, if the level of expression in normal cells is too low to be detected by the immune system, only the tumor cells that overexpress these proteins may be detected.

One key aspect of most of these oncogene product or mutant protein potential tumor antigens, other than receptors or receptor-like proteins such as HER-2/*neu*, is that they are not cell-surface proteins and thus are not accessible to antibodies. Indeed, many of these are predominantly nuclear proteins. Such internal proteins were not originally considered candidate tumor antigens because of the inaccessibility to antibodies. However, the key discovery from basic immunology, that the T-cell immune system is designed to detect internal proteins that are not necessarily ever expressed intact on the cell surface (1,2), has opened the door to exploiting these unique tumor markers as potential vaccine targets. In particular, class I major histocompatibility complex (MHC)–encoded molecules such as HLA-A, -B, and -C in humans or H-2K, D, or L in mice, appear to have evolved to provide surveillance of all proteins synthesized in a cell and displaying fragments of these for recognition by CD8[.] T lymphocytes, such as cytotoxic T lymphocytes (CTLs). A portion of all protein molecules made in the cell is degraded by proteasomes in the cytosol and short peptide fragments of these proteins are actively transported from the

cytosol to the endoplasmic reticulum by a heterodimer complex called the *transporter of antigenic peptides.* In the endoplasmic reticulum, these peptides bind to newly synthesized class I MHC molecules that then carry them out to the cell surface and display them within their peptide-binding groove, for recognition by CD8+ T cells. The T-cell receptors are specific for the complex of a particular peptide bound to a particular MHC molecule, accounting for the phenomenon of genetic restriction of T cells that has played so critical a role in immunology that its discovery led to the award of a Nobel prize (3). T cells with receptors that could recognize fragments of normal cell proteins presented by the host's own MHC molecules are most often deleted in the thymus, by a process called *negative selection*, or are tolerized by other mechanisms of peripheral self-tolerance. Thus, the T cells would be expected to react primarily to any protein that is not present in normal cells, such as viral proteins made in virally infected cells or mutant or otherwise abnormal proteins expressed in tumor cells. The surveillance provided by the class-I MHC molecule thus declares these abnormal cells to the immune system and facilitates their elimination.

If these unique tumor antigen markers exist and can be presented by MHC molecules, why are not all tumors harboring them deleted by the immune system before they reach a clinical stage? The answer probably lies in the fact that most tumor cells are not effective antigen-presenting cells (APCs), lacking the critical costimulatory molecules, such as CD80 and CD86, or intercellular adhesion molecule-1 (ICAM-1) and leukocyte function-associated antigen-3 (LFA-3), that contribute to activating T cells. Thus, they may never initiate an immune response and so avoid detection. These accessory molecules are needed only for the afferent limb of the immune response and its induction, however, not for the efferent limb or effector phase. Thus, if a vaccine that allows the relevant tumor antigens to be presented on professional APCs, such as dendritic cells (4,5), which express these accessory or costimulatory molecules at high levels, can induce CTLs specific for the tumor antigens presented on the patient's class I MHC molecules, these CTLs should be able to recognize the tumor cells and destroy them. Only the expression of the antigen presented by the MHC molecules is necessary for the tumor cells to function as targets of the CTLs. Therefore, lack of immunogenicity of the tumor does not imply that it is not amenable to specific immunotherapy.

A review of the progress in developing these mutant proteins, fusion proteins, and other oncogene products as tumor antigen targets of vaccines for the immunotherapy of cancer, both in animal models and in human clinical trials, is covered in this chapter. The potential tumor antigens discussed are listed in Table 16.4-1 . Other reviews of tumor antigens, including some in these categories, have been published (6,7).

Table 16.4-1 Potential Tumor-Specific Antigens Discussed

Tumor Antigen	Major Histocompatibility Complex Class	Tumor Type
Mutant Proteins		
ras	I and II	Wide variety of tumors
p53	I	Wide variety of tumors
p16	I	Wide variety of tumors
ß-Catenin	I	Melanoma
Triosephosphate isomerase	II	Melanoma
CDC 27	II	Melanoma
Fusion proteins

EWS-FLI-1	I (and II?)	Sarcoma
PAX-3-FKHR	I (and II?)	Sarcoma
EWS-ATF1	I (and II?)	Sarcoma
EWS-WT1	I (and II?)	Sarcoma
SSX-SYT	I (and II?)	Sarcoma
Overexpressed oncoproteins		
HER-2/*neu*	I	Variety of tumors

Mutant ras

Part of "16.4 - Oncogenes and Mutations "

Mutant ras protein constitutes a potentially valuable tumor antigen because ras mutations are present in approximately 15% of cancers, including, for example, approximately 90% of adenocarcinoma of the pancreas and almost 50% of colorectal adenocarcinomas, approximately 30% of lung adenocarcinomas, and approximately 50% of thyroid tumors as well as 30% of myeloid leukemias (8), but are not present in normal cells. Furthermore, they fulfill the second criterion mentioned in the first paragraph of this chapter, in that they contribute directly to malignant transformation, and thus their expression cannot be suppressed to escape immune detection without loss of the malignant state. ras Is a key molecule in the signal transduction pathway for cell activation. Another advantage of ras mutations is that the vast majority occurs at one of three codons, 12, 13, and 61, and thus they are limited in variety. For example, in one large study of colorectal cancer (9), 80.8% of the Ki-ras mutations occurred at codon 12, which is a glycine in the wild-type protein. Most of the remainder were codon-13 mutations. Of the codon-12 mutations, Asp was the most common (30.6% of codon-12 mutations), followed by Val (23.4%). Other common

but less frequent codon-12 mutations were to cysteine, alanine, and serine. Of the codon 13 mutations, the vast majority was from Gly to Asp. Thus, a few mutant sequences might provide a vaccine for a large number of different cancers. Meta-analysis of a number of epidemiologic studies indicates that mutations in ras may have an adverse impact on prognosis in colorectal cancer (9). In this study, ras 12-Val stood out as the only mutation that by itself conveyed an increased risk of recurrence and death ($p = 0.007$ and 0.004, respectively). Thus, mutant ras-bearing tumors may be important targets also because they are present in more aggressive cancers.

Animal Models of Mutant ras

To obtain proof of principle that mutant ras could serve as a tumor antigen for immunotherapy of cancer, several groups developed mouse models. Both CD4+ and CD8+ T-cell responses were obtained.

CD4+ T Cells

Peace et al. (10) from the group of Cheever pioneered the use of ras as a tumor antigen in murine models (7). First to be detected were CD4+ T-cells from C57BL/6 (H-2b) mice specific for the codon-12 Arg mutation presented by the class II MHC molecule I-Ab. T cells raised by immunization with a synthetic peptide spanning residues 5 to 16 responded not only to the immunizing peptide but also to the intact mutant ras p21 protein. Additionally, C3H/HeN (H-2k) mice immunized with peptide spanning residues 54 to 66, containing the Leu mutation at codon 61, responded to this mutant peptide. In both cases, the wild-type peptide was not recognized, indicating that the T cells could distinguish the single point mutation from the wild-type sequence, an essential requirement if a vaccine is to be tumor specific. Furthermore, immunization with the intact 61 Leu mutant p21 ras protein was able to elicit CD4+ T cells from C3H/HeN mice specific for the 61 Leu-containing synthetic peptide (11), indicating that the flanking sequences in the native mutant protein did not interfere with immunogenicity of the epitope.

Abrams et al. (12) were able to raise CD4+ T cells from BALB/c mice immunized with a peptide spanning residues 5 to 17 and containing the codon-12 Val mutation. These cells were phenotyped as Th1 by their cytokine production [including interleukin-2 (IL-2), interferon-γ (IFN-γ), and tumor necrosis factor] and by their ability to lyse target cells in a class II MHC–restricted fashion. The restriction element was mapped using monoclonal antibodies and transfected L cells to the hybrid molecule containing the Abβ chain and the Eα chain. Importantly, these T cells, CD4+ not CD8+, could lyse A20 B lymphoma cells transfected with the mutant K-ras oncogene with the 12 Val mutation. Abrams et al. (13) then went on to identify an overlapping epitope in the same mutant sequence presented by the H-2Kd class-I molecule. These CD8+ CTLs recognized the ras 4-12 peptide containing the 12-Val mutation, but not the corresponding wild-type peptide. They also lysed the A20 lymphoma transduced with the corresponding mutant ras oncogene. Thus, the same mutant peptide can serve to induce both CD4+ and CD8+ CTLs specific for closely overlapping epitopes in mutant ras, which might function together to reject tumor cells. Furthermore, Th1 cells specific for this site might provide help for the induction or maintenance of the CD8+ CTLs.

CD8+ T Cells

Murine CD8+ CTLs specific for mutant ras peptides were first described by Skipper and Stauss (14). C57BL/10 mice immunized with recombinant vaccinia viruses expressing either N-ras with the mutation of Gln to Lys at codon 61 or wild-type N-ras produced CTLs that recognized the same segment 60 to 67 of ras but did not cross-react, so that the ones immunized with the mutant sequence recognized only that and not the wild-type and vice versa. They also recognized targets expressing the whole mutant or wild-type ras, respectively, expressed either by transfection or infection with recombinant vaccinia virus. However, they did not lyse normal cells expressing the normal endogenous levels of ras. These were just the characteristics that one would like to obtain for immunotherapy (i.e., specificity for the mutation and ability to lyse cells expressing mutant ras but not normal cells). Peace et al. (15) carried out binding assays for overlapping ras peptides spanning the Gln to Leu mutation at codon 61 to determine which bound with highest affinity to the murine class I MHC molecule H-2Kb, and identified the nonamer 59 to 67 as the best binder. They used this for induction of a primary in vitro CTL response from naive C57BL/6 spleen cells, and raised a CTL line that they showed recognized this peptide presented by H-2Kb, as well as a B6-fibroblast line transformed by transfection with the c-Ha-ras 61-Leu gene. These CTLs were specific for the mutation, as they did not recognize untransfected fibroblasts or cells incubated with the wild-type sequence peptide. Thus, CTLs could be raised that were mutation-specific and killed tumor cells expressing the mutant ras gene. To test whether soluble ras protein could elicit CTLs that could protect an animal from a tumor expressing the ras mutation, Fenton et al. (16) immunized BALB/c mice with 5-µg soluble recombinant-ras protein expressing the 12-Arg mutation intraperitoneally and were able to elicit mutation-specific CD8+ CTLs as well as protection in nine of ten mice against challenge with tumor cells expressing the Arg-12 mutation. The protected animals were disease free for more than 6 months after tumor challenge. The protection was specific in that no protection was observed after challenge with tumor cells expressing the Val-12 mutation instead of Arg 12, and no protection against the Arg-12 tumors was seen after immunization with the wild-type ras protein. Thus, ras mutation-specific CTLs could be induced that protected mice in vivo against a tumor expressing the corresponding mutation in ras. These results are promising for the immunotherapy of human tumors expressing mutant ras.

Human T-Cell Responses to Mutant ras Epitopes

Human CD4+ T Cells

Jung and Schluesener (17) first identified human CD4+ T cells specific for mutant ras by in vitro stimulation of peripheral blood mononuclear cells (PBMCs) from normal healthy blood donors

with a mutant peptide corresponding to residues 5 to 16 of ras containing the mutation of Gly to Val at codon 12. These were found to be restricted by the class II MHC molecule HLA-DR1. Importantly, they did not respond to the corresponding wild-type ras peptide with Gly 12. Gedde-Dahl et al. (18) similarly were able to induce human primary *in vitro* T-cell responses to mutant ras peptides corresponding to residues 1 to 25, including T-cell lines specific for ras-12-Arg and ras-12-Lys restricted by HLA-DR and ones specific for ras-12-Val restricted by HLA-DQ. Gedde-Dahl et al. (19) also identified HLA-DQ8–restricted memory T cells from a patient with follicular thyroid carcinoma specific for the ras-61 Gln to Leu mutation that did not cross-react with the corresponding wild-type ras. Inability to detect this ras mutation in tumor biopsies was puzzling, but taken to suggest the possibility that tumor cells expressing this mutation had arisen and been cleared by the immune system, as this response was not seen in healthy, nontumor-bearing patients. Since these 1992 studies, this group of Thorsby and Gaudernack has continued to be perhaps the most productive in pursuing the induction of human T cells against mutant ras for the therapy of cancer. Gedde-Dahl et al. (20) went on to show that overlapping epitopes spanning the ras-61-Leu mutation were presented by HLA-DQ8 and by HLA-DQ4 to several T-cell clones with different T-cell receptors from this same patient, suggesting some promiscuity of presentation. Similarly, in a study by Fossum et al. (21), the same group went on to show that the segment spanning residues 9 to 16 of the mutant ras with codon 12 Arg was a promiscuous epitope presented by at least three distinct human class II HLA molecules, HLA-DR2, -DQ7, and -DP3. This result suggested that a broad segment of the HLA-diverse population might be able to respond to mutant-ras peptides. Fossum et al. (22,23) also found that HLA-DQ7 presented two overlapping epitope peptides containing the ras-13-Asp mutation to independent T-cell clones with distinct T-cell receptors from a colon cancer patient. In an analysis of 251 colon cancer patients, 26 of whom had ras-13-Asp mutations, they did not find a decreased frequency of HLA-DQ7 among those with ras-13-Asp mutations, as might have been expected if this HLA allele were protective, but fewer ras-13-Asp-expressing tumors were classified in advanced Dukes' stages when DQ7 was present (p <0.025, among 26 patients studied), suggesting a modifying effect of this HLA molecule. Cheever's group (24) also examined pancreatic and colon cancer patients for the presence of CD4+ T-cell proliferative responses to mutant ras-12-Asp, the most common of the ras mutations, and found responses in 7 of 16 (44%) of the pancreatic cancer patients, and 2 of 25 (8%) of the colon cancer patients, but not in any of 11 normal individuals, suggesting natural immune responses to mutant ras can be generated by the tumor. It should also be noted that Chicz et al. (25) identified a ras peptide naturally processed and able to be eluted from HLA-DR8 molecules, indicating that endogenous ras can be processed and presented by class II MHC molecules in human cells. Cheever's group also demonstrated serum antibodies to mutant ras-12-Asp p21 protein in 51 of 160 colon cancer patients (32%), compared to 1 of 40 (2.5%) normal individuals, consistent with the induction of antibodies to ras by the presence of the tumor (26). Most of the antibodies were directed to the unmutated portions of the molecule, especially the carboxyl terminus, although some was directed to the mutant epitope. Thus, the breaking of tolerance to ras by the presence of the tumor could be due to level of expression, increased apoptosis of tumor cells and resulting antigen presentation, or the induction of T-helper cells specific for the mutant epitope, providing help for autoimmune B cells.

Based on these promising studies, Gjertsen et al. (27,28) carried out a human clinical trial of vaccine immunotherapy in pancreatic cancer patients. They immunized five patients with pancreatic cancer and ras mutations (three patients with 12 Asp, one each with 12 Val and 12 Arg) with 1 to 4 ×10⁹ leukapheresed, autologous PBMCs pulsed overnight with 25 μmol of the ras 5 to 21 peptide corresponding to the mutation with Val, Arg, or Asp at codon 12 in their tumor. None of the patients had T-cell proliferative responses to the peptide before vaccination, and two developed transient responses after immunization, one specific for ras-12-Val uniquely and the other responsive to ras-12-Asp (but cross-reactive with wild-type ras-12-Gly). No adverse effects of the vaccination were detected, even in the patient who developed T cells cross-reactive with wild-type ras. No complete or partial tumor response was seen to the therapy, but the two responding patients survived longer (9 and 12 months) than the nonresponding patients (3.5, 4.5, and 5 months, respectively). Whether this intriguing observation in the small group of patients reflects a result of the therapy, a greater ability of healthier patients to mount an immune response, or a mere coincidence cannot be determined.

Human CD8+ T-Cell Responses

In the case of CD8+ T-cell responses primarily measured as CTLs, Fossum et al. (23) first described CD8+ T cells isolated from the blood of a colon cancer patient specific for mutant ras-13-Asp. Importantly, these cells were shown to kill a human tumor cell line, HCT116, which expresses the ras-13-Asp mutation and shares both HLA-A2 and -B12 with the patient (29), if the tumor cells were treated with IFN-γ. The lytic activity could be blocked by anti-CD8 and by anti-HLA-B12, mapping the restriction element, and proving for the first time that a human tumor cell could process and present endogenous mutant p21-ras in association with a human class I MHC molecule on the tumor cell (29).

Elsas et al. (30) identified a peptide containing the ras-61-Leu mutation as the C-terminal anchor residue that bound to HLA-A2.1 and were able to raise primary *in vitro* CTL responses to this peptide in PBMCs of normal healthy HLA-A2.1–positive individuals by stimulation with T2 cells deficient in the transporter of antigenic peptides that were loaded homogeneously with the mutant ras peptide bound to HLA-A2.1. The wild-type peptide, with Gln at the C-terminus, which is not a functional anchor residue, bound much more weakly to HLA-A2.1 than the mutant peptide and was not recognized by the CTLs. However, the CTLs in this case did not lyse melanoma cells transfected with the mutant ras gene, perhaps because their avidity was too low. Similarly, Juretic et al. (31) were able to raise *in vitro* CTLs against ras-61-Leu peptides presented by HLA-A2.1 from PBMCs of healthy individuals, but none of these killed tumor cells expressing the specific mutation.

On the other hand, Gjertsen et al. (32) were able to raise CD8[+] CTLs (as well as CD4[+] T cells) specific for ras-12-Val from a pancreatic cancer patient whom they immunized with a mutant ras-17-mer peptide containing this mutation. In this case, they were able to raise an autologous pancreatic tumor cell line and show that these tumor cells were killed by the ras-12-Val–specific CD8[+] CTLs (as well as by the CD4[+] CTLs) from the patient. Using tumor cell lines matched for either HLA-B35 or for the ras-12-Val mutation, or both, they showed that the CTLs were specific for the mutant peptide endogenously presented by HLA-B35 on the tumor cells. Thus, mutant ras in these pancreatic tumors is endogenously processed and presented to autologous CTLs by the tumor's class I MHC molecules. The most common human class I MHC molecule is HLA-A2.1, present in almost one-half of most populations. Smith et al. (33) found that the ras peptides spanning residues 5 to 14 contained an HLA-A2.1–binding sequence motif and, using a binding assay with T2 cells described by Nijman et al. (34), they found that most of the ras-12 and ras-13 mutant peptides bound to HLA-A2.1 with higher affinity than the wild-type ras-12-Gly, 13-Gly peptide (Fig. 16.4-1). This preferential binding may favor generation of responses specific for the mutant sequence in the tumor that do not cross-react with the wild-type sequence present in normal cells. The mutations were also found to have some effect on the processing of the peptides by extracellular serum or cell-surface proteases, making the 10-mers more effective in some cases and longer (17-mer) peptides more effective in other cases (33) (see Fig. 16.4-1). In a phase 1 trial just being completed, we immunized cancer patients with autologous PBMCs pulsed with synthetic 17-mer peptides, with the mutation in the center, containing all possible nonapeptides spanning the mutation present in the patient's tumor. We were able to raise mutant ras-specific CTLs against ras-13-Asp, ras-12-val, and ras-12-Cys, especially in patients bearing HLA-A2.1, but did not have tumor specimens to test the ability of the CTLs to lyse tumors (Carbone et al., manuscript in preparation). In a phase 1 phase 2 trial, Khleif et al. (35) and Abrams et al. (36) immunized patients with mutant ras-13-mer peptides containing codon-12 Asp, Cys, or Val mutations. They were able to raise both class II, HLA-DQ–restricted CD4[+] T cells and class-I HLA-A2.1–restricted CD8[+] T cells specific for the ras-12-Val mutant peptide from one patient, as well as a CD4[+] T-cell line specific for ras-12-Cys, and a CD8[+] T-cell line specific for ras-12-Asp from other patients. In this case also, the CD8[+] CTLs specific for ras-12-Val

could lyse a nonautologous SW480 colon carcinoma cell line expressing both HLA-A2.1 and the mutant ras-12-Val if the tumor cells were treated with IFN-γ. Thus, at least three independent studies demonstrate that human CD8⁺ CTLs from cancer patients, in two of the cases immunized with mutant ras peptides, can kill human tumor cells naturally, endogenously expressing the corresponding mutant ras. In one of these cases, the tumor was autologous. These studies provide unequivocal proof that human tumor cells naturally process and present p21 ras in such a way as to present mutant peptides in association with human class I HLA molecules on their surface, and can be recognized and destroyed by human CTLs specific for these mutations. Moreover, the most common mutations at ras codon-12 and -13 can be presented by the most common class I MHC molecule, HLA-A2.1, more effectively than the wild-type peptide, as well as by at least one other human class-I molecule, HLA-B35, making these peptides potentially widely recognized as candidate tumor antigens despite the HLA diversity of the population. These results are promising for the ultimate development of mutant ras-based cancer immunotherapy.

FIGURE 16.4-1. Mutations in ras peptides affect binding to HLA-A2.1 as well as extracellular processing. Peptides shown from ras residues 4 to 20 or 5 to 14, with or without mutations at codon 12 or 13, were tested along with control peptides for binding to the most common human class I major histocompatibility complex molecule, HLA-A2.1, in a T2 cell-binding assay. The assay, described by Nijman et al. (34), takes advantage of the fact that T2 cells lack the transporter of antigenic peptides, and so do not load endogenous peptides to newly synthesized class I molecules. The few empty class I molecules that reach the cell surface are unstable and rapidly lost unless they bind a peptide, which stabilizes the conformation. Thus, in the presence of a peptide that can bind to HLA-A2.1, the steady-state level of HLA-A2.1 on the surface of the T2 cells increases and can be measured by fluorescence-activated cell sorter scan. The relative affinity is determined from the relative concentration required to induce a 50% increase in HLA-A2.1 expression. Some of the ras peptides bind better as decapeptides, such as ras-12-Asp and ras-12-Ala, whereas some bind better as 17-mers, such as ras-12-Cys and ras-13-Asp. However, most of the mutant ras sequences in one form or the other bind better than the wild-type peptide. The differences in binding between the longer and shorter peptides depend in part on the need for proteolysis of the longer peptides and the sensitivity to proteolysis of the shorter peptides, both of which appear to be influenced by the mutation at codon 12 or 13. The 17-mers were designed to include all possible 9-mers containing the point mutation. Note: Nine- and ten-residue peptides were tested in the presence of protease inhibitor 1, 10-phenanthrolene. (HIV, human immunodeficiency virus; NT, not tested; +, positive; +++, strongly positive; ±, marginally positive.) (Based on results described in Smith MC, Pendleton CD, Maher VE, Kelley MJ, Carbone DP, Berzofsky JA. Oncogenic mutations in ras create HLA-A2.1 binding peptides but affect their extracellular processing. *Internat Immunol* 1997;9:1085–1093, with permission.)

Mutant and Wild-Type p53

Part of "16.4 - Oncogenes and Mutations "

p53 Is a nuclear phosphoprotein located on chromosome 17p with specific DNA binding and transcriptional activation capabilities. p53 Is frequently abnormal in human cancer, with mutation rates of more than 50% of non-small-cell lung cancer and colon cancer, and more than 90% in certain tumors such as small-cell lung cancer (37). Compared to the relatively limited number of missense mutations commonly found in activated ras, mutations in p53 are of all types: missense, nonsense, splicing, and large deletions. Approximately 80% of all somatic mutations in p53 are single amino acid substitutions, but again unlike ras, these missense mutations occur throughout the open reading frame (ORF), though they tend to be concentrated in the central region, approximately codons 140 to 300 or exons 5 to 8. For most tumor suppressor genes, mutation is usually associated with decreased or absent expression. Missense mutations in p53, however, are associated with significantly prolonged protein half-life, and thus greatly increased steady-state protein levels (38), usually by orders of magnitude. The overexpressed protein can be detected by immunohistochemistry, whereas the p53 in normal cells is usually below the detection threshold, forming the basis for a simple "screening" immunohistochemical test of clinical material for the presence of p53 mutations. Positive immunostaining shows approximately a 66% correlation with the presence of a mutation (39). The locations of missense mutations in p53 are similar between different tumor types, but there may be a preference for mutations between codon 150 to 160 in non-small-cell lung cancer, and codon 175 mutations are common in colon cancer but are uncommon in lung cancer. The significance of these differences is unclear.

p53 As an Immunologic Target

Because it is so frequently mutated in cancer, when mutant p53 is usually highly overexpressed, p53 protein represents an excellent candidate as an immunotherapeutic target. Additionally, missense mutant p53 is thought to have a dominant transforming function, resulting in selection pressure to maintain expression throughout tumor evolution. It is also clear that p53 can be recognized by the immune system. Antibodies to p53 have been observed in lung cancer patients, and their presence is highly correlated with the presence of a p53 mutation in the tumor (40). In addition, in small-cell lung cancer, an association has been observed between the presence of antibodies to any tumor cell protein (not just p53) and improved survival. Antibodies to p53 may also precede the development of clinical cancer (41), and their titer varies with disease status, suggesting that continuous antigen stimulation is required (42).

Because p53 is a nuclear protein, however, it is unlikely that the antibodies themselves could have therapeutic effect, and it is more likely that T-cell responses directed toward short-peptide epitopes in the p53 protein would be the response of interest for therapy. Antibody responses usually require T-cell "help" so the presence of antibody responses suggested that T cells could indeed recognize p53 protein epitopes. In fact, immunization with anti-p53 antibodies can induce an "antiidiotype network" response and result in effective tumor protection (43,44).

The most tumor-selective potential epitopes would be the peptides containing the somatic mutation itself. If it could be recognized by CTLs, this mutant epitope would be absolutely restricted to tumor cells and not present in normal cells. Animal studies have demonstrated the induction of effective CTL responses against the mutant p53 protein. Using peptides that spanned the mutation site in human-mutant p53 coated on murine APCs to immunize animals, it is possible to show the development of p53-specific CTLs. Some of these CTLs recognized the mutant-peptide sequence and not the corresponding wild-type one (45). Specific responses to mutant epitopes were also observed to mutant p53 in the carcinogen-induced mouse tumor MethA (46). It is remarkable that a CTL response can be generated in such animals that are selective for the presence of a single amino acid substitution in the p53 protein. This underscores the specificity achievable when a finely tuned biologic process, such as the cellular immune system, is evoked, as opposed to the lack of specificity observed for standard chemotherapeutic agents. This CTL response provided tumor protection in control mice against subsequent challenge with tumor cells bearing specific mutation (46,47,48,49,50,51,52,53 and 54). It has also been possible to treat established tumors by immunization with peptide-pulsed dendritic cells (53,54) (Fig. 16.4-2) or peptide, plus IL-12 (51). Tumor size either stopped increasing and remained stable throughout the course of immunization (compared to tumors in control animals that grew rapidly) (see Fig. 16.4-2), or actually decreased. Enhancement of the immunogenicity of a mutant p53 epitope was also observed after transduction of the costimulatory molecule B7 via recombinant adenovirus (55). Improved effectiveness of peptide immunization has also been reported if the immunization is done together with IL-12 (51), or with IL-12 and peptide-pulsed dendritic cells (52,53). This underscores the fact that appropriate antigens may be present in the tumor but not recognized without therapeutic manipulation of cytokines, costimulatory molecules, or APCs.
FIGURE 16.4-2. Ability of immunization with mutant p53-pulsed dendritic cells to inhibit growth of established tumors in mice (54). Groups of 5 BALB/c mice were injected subcutaneously with 2 × 10⁵ D459 fibrosarcoma cells expressing mutant human p53 gene T1272, with mutation of Cys to Tyr at position 135 creating a neoantigenic determinant with a new H-2Kᵈ-binding motif not present in the wild-type p53 (45). Immunizations were begun at day 8, when the tumors were palpable (2 to 4 mm diameter), and were given on day 8 [T1272 single] or on days 8, 14, 18, and 22 [T1272 and ventricular stomatitis (VSV) peptide]. The immunogen consisted of 1 to 2 × 10⁵ syngeneic dendritic cells generated from bone marrow of normal BALB/c mice and pulsed for 2 hours with either T1272 mutant p53 peptide or control VSV-8 peptide. Average tumor size (mm²) and SEM are given. *p* Values for differences between the group immunized multiply with T1272 peptide-pulsed dendritic cells and the group immunized with the VSV peptide-pulsed dendritic cells are indicated by the numbers above the points. No significant difference occurred between the group immunized only once with T1272 and the control group. Similar results were obtained in three independent experiments. (From Gabrilovich DI, et al. Dendritic cells in antitumor immune responses. II. Dendritic cells grown from bone marrow precursors, but not mature DC from tumor-bearing mice, are effective antigen carriers in the therapy of established tumors. *Cell Immunol* 1996;170:111–119, with permission from Academic Press.)

Although there are a few hotspots for mutations in p53 (such as codons 175, 248, and 273), these make up only a small fraction of the mutations observed. This complicates mutation-specific

immunotargeting, as each patient is likely to have a different mutation, each requiring a different peptide vaccine. Mutant-specific epitope targeting may, however, not be necessary, as several authors have demonstrated efficient recognition of wild-type p53 sequences in murine models (46,53,56,57,58 and 59) or human cells *in vitro*(60). This occurs in spite of the fact that every normal cell in normal individuals expresses a low level of structurally identical p53 protein. The typical massive overexpression of the mutant protein may allow sufficient tumor-normal discrimination to be of clinical utility. The antibodies that develop in cancer patients recognize sequences in either the amino or carboxy terminal regions of p53, and not in the central DNA-binding region of the molecule, where most of the somatic mutations occur (61). Consequently, these antibodies recognize both mutant and wild-type p53 *in vitro*, in spite of the fact that individuals might be expected to be tolerant to these epitopes. These antibodies are found much less commonly, if at all, in patients without cancer or cancer patients whose tumors do not have missense mutations in p53. It is possible that anti-p53 antibodies are induced due to the resulting overproduction of the mutant protein, a conformational change associated with the mutation, or induction of T-cell help by the mutant epitope to break tolerance. The major practical advantage of targeting a wild-type epitope is that a single vaccine preparation can be used to target a wide variety of tumors producing different mutated p53 proteins, and these sequences can be selected to match the peptide-binding preferences of large classes of patients with common MHC antigens.

Many studies have shown the ability to kill murine tumors with T cells specific for wild-type–p53 epitopes (46,53,62,63). Adoptively transferred wild-type p53-specific T cells can also eradicate established tumors in mice (57). HLA-A2-restricted, wild-type, p53-specific T cells can be developed in A2-transgenic mice that exhibit antitumor effects in human-tumor nude mouse xenografts (64,65). One study used the intact wild-type p53 gene-transduced dendritic cells to induce specific immunologic and tumor responses in animal tumors expressing a variety of mutant p53 proteins (66).

Anti-p53 Cellular Immune Responses in Cancer Patients

Cellular immune responses specific for p53 have also been observed in humans. Induction of the humoral response described in the previous section requires antigen presentation on APCs and T-helper cells, so detection of these antibodies implies a T-cell response to the same antigen. CD4+ T cells (those which produce cytokines and proliferate in response to antigen) that respond to p53 peptides have been reported in breast cancer patients (67). All of the patients with detectable T-helper cell responses also had antibodies against p53, demonstrating the existence of a combined cellular and humoral response in these patients. CTLs have also been isolated that are specific for either wild-type or mutant-p53 epitopes. Kast and Melief showed *in vitro* induction of human CTLs to both normal and mutant p53 epitopes (60). Low levels of CTL precursors recognizing wild-type p53 epitopes have even been identified in the peripheral blood of individuals with no apparent cancer (68). It is unclear what the clinical significance of these responses is and whether they are *in vitro* primary responses (artifacts) or true recall responses. In breast cancer patients, significant CTL responses specific for the mutant p53 in a cancer patient's tumor have been observed (69). In most cases, these CTLs recognized mutant, but not the corresponding wild-type p53 sequences. The role of these CTLs in affecting the clinical course of the cancer is unclear, but the majority of patients in this study with these responses were apparently cured of their disease with surgery alone. Wild-type p53-specific T cells stimulated *in vitro* from a normal donor have been shown to be able to kill human squamous cell carcinoma cells naturally overexpressing mutant p53 (70,71). Therefore, p53 protein can behave as an antigenic target for CTLs during the natural process of tumorigenesis without external immunization or other immunotherapy.

Induction of Epitope-Specific Immunity to p53 in Cancer

For defined target antigens, induction of epitope-specific immunity in animals has been typically accomplished using synthetic peptides (72,73,74 and 75). The use of peptides as immunogens is complicated by their weak inherent immunogenicity and variable

chemical and physical properties, so a variety of strategies have been used to enhance the efficacy of peptide-based vaccines (75,76,77,78,79,80,81,82,83,84,85 and 86). The chemical and physical problems of protein or peptide-based vaccines can be avoided by the use of genetic vaccines, purified-plasmid DNA-expression vectors encoding the entire cloned ORF of proteins introduced into living animals. These DNA-vaccine vectors may generate substantial humoral and cellular immunity with little or no toxicity (87-91). We have shown the induction of T-cell epitope-specific (mutant p53) cellular immune responses and antitumor effects after introduction of a "genetic epitope" vaccine consisting of an expression cassette containing only an oligonucleotide coding for the desired epitope (48). In this study, we used a particle gun, which atraumatically delivers microscopic gold particles coated with the plasmid DNA into the shaved skin of living animals. A plasmid vector containing the adenovirus-E3 leader sequence, which facilitates transport of the mutant-p53 epitope into the endoplasmic reticulum, was constructed and used to show the importance of this transport for optimal CTL induction and tumor-protective immunity. The use of epitope-minigene genetic vaccines may thus have significant potential for the induction of responses against identified T-cell epitopes in tumors.

When the p53 gene was expressed in a recombinant poxvirus vector and used to immunize animals, protection from lethal tumor challenge was observed (56). The wild-type p53 was just as effective as the mutant p53 in this system. Studies with animals bearing pre-existing tumors (a more clinically relevant situation) have not yet been reported using recombinant viral immunization.

Human Clinical Trials of p53 Vaccines

Human clinical trials have been conducted that aim to induce CTLs in cancer patients using a custom p53-derived peptide corresponding to the mutant-p53 sequence in the particular patient's tumor. In one such trial, DNA from each patient's tumor was evaluated for mutations in p53 and if a mutation was found that altered the predicted protein sequence, a customized synthetic peptide was constructed and used to immunize the patient (Carbone et al., *manuscript in preparation*). Frequent T-cell immunologic responses to the peptide were observed, including both CTL and cytokine responses. Results showed that the T cells could distinguish between the mutant-p53 sequence, to which they responded, and the corresponding homologous wild-type p53 sequence, to which they did not, avoiding any potential for autoimmunity. Future studies are planned to use dendritic cells as antigen carriers and might be able to use peptides derived from normal p53 protein sequences or the intact p53 protein. A cocktail of p53 peptides is also possible, analogous to multivalent pneumococcal vaccines, particularly if wild-type sequences are used.

The use of a complex vaccine containing more than a single peptide epitope may have advantages. One study observed that the mutant site in human p53 was found statistically significantly less frequently in sites that matched the patient's MHC class I consensus sequence (92). Another study found that mutation of arginine to histidine at the hotspot codon 273 in human p53 altered the processing of the surrounding sequence and eliminated presentation of an epitope effectively presented in the absence of mutation (93).

Therefore, there is ample evidence that both wild-type and mutant-p53 sequences can be the specific targets of CTL recognition and can kill tumors overexpressing p53. The optimal immunization technique and the ability of such CTLs to effect clinically significant improvements in the outcome for human cancer patients remains uncertain. These issues are under clinical evaluation at this time.

Other Mutations as Tumor Antigens

Part of "16.4 - Oncogenes and Mutations "

In addition to known oncogenes and tumor suppressor genes that are commonly mutated, sporadic mutations in other proteins can create novel tumor antigens. These have often been identified when searches are made for tumor antigens in tumors by methods that do not assume the nature of the tumor antigenic protein in advance. Perhaps the first of these discovered is the tum¯P91A antigen in mutated P815-mastocytoma cells characterized by Thierry Boon's group in a novel cloning strategy that they developed (94). The point mutation in the novel antigen was shown to be an Arg-to-His mutation that created a sequence with strong binding to H-2L^d and allowed the induction of class I MHC H-2L^d-restricted CTLs. Another similar tumor antigen was also identified by Boon's group in a mutant P815 tumor, in this case a point mutation in the P198 antigen and not homologous to any other protein in the data banks (95). This mutation of Ala to Thr did not create a new binding site, as both the mutant and wild-type sequences bound to H-2K^d, but created a new epitope recognized by CTLs.

Using a different approach, acid elution of peptides from MHC molecules on tumor cells, Mandelboim et al. (96) identified a tumor antigen from the Lewis lung carcinoma. This was found to represent a point-mutated epitope from the connexin-37 protein presented by H-2K^b.

When a cloning approach similar to that pioneered by Boon's group in mice was applied to a human melanoma using tumor infiltrating lymphocytes as the source of CTLs to define the antigen, an interesting mutation in ß-catenin was discovered by Robbins et al. (97) that created a novel tumor antigen. The mutation, from Ser to Phe, created a neoantigen determinant by introducing Phe, which could serve as the C-terminal anchor residue for binding to HLA-A24, whereas the wild-type peptide did not bind. Thus, strikingly, the mutant peptide was found to sensitize targets for lysis at a million-fold lower concentration than the wild-type peptide (97) (Fig. 16.4-3). Because ß-catenin is involved in cell adhesion through its interaction with cadherins, it is possible that the mutation contributed to the malignant phenotype of tumor cells and provided a possible target for attack by the immune system.
FIGURE 16.4-3. Mutation in the ß-catenin gene creates a neoantigenic determinant that sensitizes targets at a million-fold lower concentration than the wild-type peptide. Mutant and wild-type peptides were titrated for sensitization of Epstein-Barr virus–transformed lymphoblasts for lysis by tumor-infiltrating lymphocytes from the patient in whose tumor the mutation was discovered. (Reprinted from Robbins PF, El-Gamil M, Li YF, et al. A mutated beta-catenin gene encodes a melanoma-specific antigen recognized by tumor infiltrating lymphocytes. *J Exp Med* 1996;183:1185-1192 by copyright permission of The Rockefeller University Press.)

Similarly, mutations have been found in other known critical proteins that might function as tumor antigens. P16Ink4a is a cyclin-dependent kinase inhibitor responsible for keeping the tumor suppressor Rb in its cell-cycle suppressive state. Mutations in p16 are frequently observed in a variety of cancers, and human CTLs have been identified from a patient

with melanoma that specifically recognize the mutant protein (98).

Mutations have also been found to create tumor antigens presented by class II molecules. A new technique has been developed that allows screening of a complementary DNA (cDNA) library in which the genes are fused to the invariant chain of class II molecules to target them to the class II processing pathway and transfected to a cell in which the appropriate class II molecule and other necessary genes have also been transfected (99). This approach has allowed the identification of novel mutant tumor antigens in melanoma, including a mutant form of CDC27 presented by HLA-DR4 and a mutated triosephosphate isomerase presented by HLA-DR1 (99). Of interest is the fact that both mutations, like the ß-catenin mutation presented by a class I HLA molecule, were found to be C to T mutations, consistent with a possible role of UV light in inducing the mutation (99). Similarly, another novel melanoma antigen presented by HLA-DR1 and recognized by CD4+ T cells was identified as a fusion protein created by a chromosomal rearrangement (100). All three melanoma tumor antigens so far identified, as presented by class II HLA molecules, are unique to the tumor, in contrast to many melanoma antigens presented by class I molecules that were parts of normal melanocyte proteins (83,101,102).

Thus, sporadic tumor-unique antigens can often be point mutations that occur in a variety of proteins and may or may not contribute to the malignant phenotype. In some cases, these novel tumor antigens are sufficiently immunogenic as to cause spontaneous regression of the tumor by immunologic rejection. Alternatively, it may be possible to boost the immunogenicity with custom vaccines containing these mutations or expand CTLs from tumor-infiltrating lymphocytes, preferably ones with high avidity (85,103,104,105 and 106) for adoptive immunotherapy.

Novel Fusion Proteins Created by Chromosomal Translocations

Part of "16.4 - Oncogenes and Mutations "

The use of translocation-specific fusion proteins as targets for CTL therapy is attractive for several reasons. First, they meet the criteria articulated earlier in this chapter—namely, that they would be expected to be uniquely expressed in tumor cells, and they are either presumed or proven to be causally related to the oncogenic process. Thus, loss of fusion protein expression to escape immune recognition would not permit maintenance of the transformed state. Second, because the expression of these tumor-specific fusion proteins are shared by most, if not all patients with a specific tumor, developing a successful vaccination strategy would be expected to be applicable to many patients whose tumors harbor the same translocation. There has been a growing interest in targeting tumor-specific, translocation fusion proteins for immunotherapeutic approaches. This section reviews work undertaken to determine the possibility of targeting tumor-specific, translocation-generated fusion proteins as targets for therapy.

Examples of Fusion Proteins Targeted for Immunotherapy

Cataloging the extensive list of tumor-specific translocations—and, hence, potential tumor-specific antigens that have been identified to date—is beyond the scope of this review. However, this chapter presents multiple examples of both preclinical and clinical models that attempt to generate tumor-specific CTL responses targeted at specific fusion proteins generated by the tumor-specific translocations. Several examples are discussed in detail in the following sections.

BCR-ABL

Among the best-studied fusion proteins is the BCR-ABL fusion protein generated by the t(9;22)(q34;q11), historically known as the *Philadelphia chromosome of chronic myelogenous leukemia* (CML) patients. The BCR-ABL fusion protein is present in more than 95% of patients with CML and in approximately 10% of children with acute lymphocytic leukemia (ALL) and 25% of adults with ALL (107). This translocation results in the fusion of exon 2 of the C-ABL tyrosine kinase on chromosome 9 with either exon 2 or exon 3 of the BCR gene on chromosome 22 at the amino-terminal region. If the fusion is from exon 2 of BCR, it is referred to as *b2a2*, and if the fusion is from exon 3 of BCR, it is referred to as *b3a2* (Fig. 16.4-4A). In either case, the ORF of BCR and ABL are fused in-frame to encode a 210-kd protein that includes 1,004 amino acids derived from C-ABL and either 902 or 927 amino acids derived from BCR (108). The resultant fusion has been shown to encode a protein with enhanced tyrosine kinase activity when compared to the normal C-ABL–encoded cytosolic tyrosine kinase activity (109,110 and 111). Furthermore, the p210[b2a2] and the p210[b3a2] have been shown to have transforming activity in fibroblasts and lymphoid cells, and thus are believed to play a critical role in leukemogenesis (112).

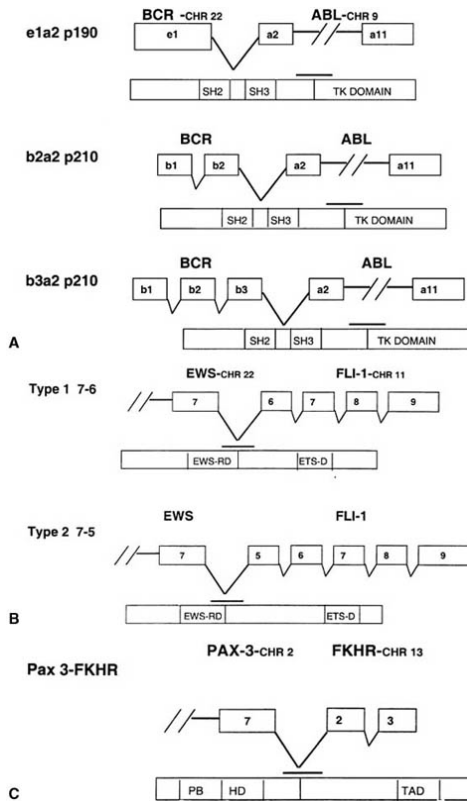
Approximately 40% of patients with BCR-ABL–positive CMLs have the b2a2 fusion, 40% have the b3a2 fusion, and 20% contain both fusions due to alternative splicing (113,114). In approximately 10% of children and 25% of adults with ALL, the same region of C-ABL is translocated to a region of BCR upstream of exon 2, called *e1*, yielding a p190[e1a2] BCR-ABL fusion protein with similar function to the p210 fusion protein (115,116).


FIGURE 16.4-4. Schematic depiction of t(9;22) translocation of chronic myelogenous leukemia (A), t(11;22) translocation of Ewing's sarcoma/peripheral primitive neuroepitheliomas (B), and t(2;13) translocation of alveolar rhabdomyosarcoma (C). Upper panel in each pair shows genomic organization. Lower panel is schematic of chimeric protein. The horizontal line represents the fusion region and a potential immunogenic peptide spanning the breakpoint. The vertical line centered below the horizontal line indicates the fusion breakpoint junction. Some critical regions of the fusion protein are indicated (not to scale). In the case of BCR-ABL, the fusion alters the target protein specificity of a tyrosine kinase, creating an oncogenic effect. In the case of EWS-FLI-1 and PAX-3-FKHR, the fusions bring together the activation domain of one parent molecule with the nucleotide-binding domain of the other parent molecule, creating an aberrant transcription factor that is transforming. (ETS-D, ETS DNA-binding domain of FLI-1; EWS-RD, EWS regulatory domain; HD, homeodomain of PAX-3; PB, paired box of PAX-3; SH2, SRC-homology-2 domain of BCR; SH3, SRC homology-3 domain of BCR; TAD, transactivating domain of FKHR; TK, tyrosine kinase domain of ABL.)

Chen et al. from the group of Cheever were the first to report the use of a p210[b3a2] fusion 12-mer peptide to immunize mice and generate MHC class II–restricted CD4[+] T-cell clones that specifically recognized the fusion peptide that contained six amino acids from BCR and five amino acids from ABL (117). tenBosch et al. (118) have gone on to demonstrate that a similar b3a2 17-mer peptide spanning the breakpoint region was capable of eliciting an *in vitro* CD4[+] T cell class II–restricted response. Furthermore, a DR4-restricted response was demonstrated against allogeneic p210[b3a2]-expressing leukemic blasts from a patient in blast crisis (118). This response required the expression of both DR4 and p210 in the same cell. These data strongly suggest that the p210[b3a2] oncoprotein is endogenously processed through the HLA class II pathway and presented on the surface of leukemic blast cells and thus fully capable of serving as a target for tumor-specific CD4 cells. Subsequently, Chen et al. (119) demonstrated the ability to elicit CD8[+], H-2K[d]–restricted CTLs using a breakpoint B392 peptide in mice. Despite lytic activity against syngeneic cells pulsed with the vaccinating peptide, however, the CTL clones did not lyse either syngeneic murine leukemia cells expressing the identical p210[b3a2] or human K562 cells expressing p210[b3a2] transfected with mouse H-2K[d] (119).

Greco et al. (120) showed that a nonamer peptide spanning the b3a2 fusion region was capable of binding HLA-A3. Subsequent studies using peptide-pulsed antigen-presenting cell (APC) *in vitro* immunizations led to specific CTL responses (120). Likewise, Bocchia et al. (121) found that 9-mer and 11-mer b3a2 spanning peptides were able to elicit an HLA-A3–restricted CTL response *in vitro* using peptide-pulsed APC vaccination approaches. The CTLs generated were shown to be capable of lysing autologous or HLA-A3–matched allogeneic peptide-pulsed targets. These investigators also used a 25-mer spanning the b3a2 breakpoint to show that this peptide could elicit HLA class II (DR11)-restricted peptide-induced CD4 proliferation (121).

TEL(ETV6)-AML-1

The TEL-AML-1 fusion protein seen in approximately 25% of childhood ALL is generated by a reciprocal t(12;21)(p13;q22) translocation (122,123). This translocation results most commonly in the in-frame fusion of exon 5 of TEL on chromosome 12, with exon 2 of AML-1 on chromosome 21. The resultant fusion protein generates a novel transcription factor combining helix-loop-helix TEL with the DNA-binding domain of the AML-1/CBFβ transcription factor.

The Lemonnier/Langlade-Demoyen group has tested a series of peptides spanning this translocation breakpoint for evidence

of binding to HLA-A2.1 (124). This group identified a nonapeptide spanning the translocation breakpoint that bound HLA-A2.1. They subsequently demonstrated that this nonamer could elicit a primary CTL response in peripheral blood lymphocytes from healthy donors. Furthermore, these CTLs were shown to specifically lyse HLA-A2.1–positive tumor cells that expressed endogenous TEL-AML-1 fusion protein. These investigators were also able to identify CTLs specific for this fusion peptide at high frequency in the bone marrow of a patient with TEL-AML-1-positive ALL. These CTLs were capable of lysing HLA-matched ALL tumor cells bearing the TEL-AML-1 translocation (124), making this a promising tumor antigen.

EWS-FLI-1

The EWS-FLI-1 fusion protein is generated by a reciprocal t(11;22)(q24;q12) translocation that is the hallmark of Ewing's sarcoma (ES)/peripheral primitive neuroepitheliomas (PPNET). The EWS-FLI-1 fusion is present in approximately 85% of such tumors (125,126). The translocation results in the fusion, most commonly, of exon 7 of the EWS gene on chromosome 22, with either exon 5 or exon 6 of the FLI-1 gene on chromosome 11. If the fusion is from exon 7 of EWS to exon 6 of FLI-1, it is referred to as the *type I* or *7 to 6 fusion.* If the fusion is from exon 7 of EWS to exon 5 of FLI-1, it is referred to as the *type II* or *7 to 5 fusion* (Fig. 16.4-4B). Either fusion results in an apparently enhanced nuclear transcription factor with transactivation domains derived from EWS and DNA-binding activity encoded by the ETS transcription family member, FLI-1. Studies have demonstrated both the transforming activity of EWS-FLI-1 in fibroblasts, as well as the critical role of EWS-FLI-1 in maintaining the transformed phenotype in ES cells (127,128). Of interest is the finding that there may be prognostic differences between the type I and type II fusion-positive ES tumors (129).

In an attempt to generate CTL responses aimed at the EWS-FLI-1 fusion protein, 15- to 18-mer peptides spanning the type I or type II breakpoints were synthesized and analyzed for potential binding motifs for MHC class I and class II molecules. Based on predictions for a variety of class I and -II human-binding motifs as well as mouse class I binding motifs, we went on to develop an *in vitro* model using peptide-pulsed mouse APCs. In these studies, intravenously administered peptide-pulsed APCs generated CD8+ CTLs capable of lysing peptide-pulsed targets *in vitro*. The cytolytic activity was shown to be class I H-2K^d-restricted, using mouse L-cell transfectants as targets. In these mouse experiments, the 18-mer peptides were incubated with APCs in the presence of serum that presumably contains proteolytic activity capable of generating smaller peptide fragments able to bind MHC class I molecules. Minimal epitope mapping identified a 9-mer overlapping the translocation breakpoint (130,131, and *unpublished data*).

We are currently attempting to generate an *in vivo* model using mouse tumor cells transfected with an EWS-FLI-1 cDNA. Although these data clearly demonstrate that peptides spanning the EWS-FLI-1 fusion protein can generate specific CD8+ CTLs, it remains to be determined whether such peptides are processed similarly in ES tumor cells and, thus, are capable of acting as targets for CTLs in patients bearing ES/PPNET tumors.

PAX-3-FKHR

PAX-3-FKHR is generated by the reciprocal t(2;13)(q35;q14) translocation and is present in approximately 80% of alveolar rhabdomyosarcomas. PAX-3 is a transcription factor that plays an important role in embryonic development, including skeletal muscle differentiation (132,133). PAX genes contain both paired box (PB) and paired-type homeodomain (HD) DNA-binding domains. FKHR is a member of the forkhead family of transcription factors that contain a conserved DNA-binding motif related to the homeotic gene *forkhead.* The PAX-3-FKHR fusion protein contains the PB and HD DNA-binding domains of PAX-3 at the amino-terminal end, fused to the carboxy-terminal end of FKHR, which retains its putative transactivation domain (Fig. 16.4-4C). Thus it appears that the DNA-binding specificity is encoded by PAX-3, whereas the transactivation domain is contributed by FKHR. The PAX-3-FKHR fusion has been demonstrated to transform chicken embryo fibroblasts (134).

Synthetic 18-mer peptides spanning the PAX-3-FKHR breakpoint were synthesized and pulsed onto the surface of murine splenocytes (containing APCs) or onto purified mouse dendritic cells using a 2-hour incubation in the presence of serum. Intravenous infusion of such peptide-pulsed, irradiated APCs led to the generation of CTLs specific for the peptide within 21 days, as assayed by chromium-release studies. Of further note, these CTLs also lysed mouse CT26 adenocarcinoma cells that had been transfected with the full-length PAX-3-FKHR cDNA (130,131). This finding demonstrates that the full-length fusion protein can be endogenously processed in CT26 tumor cells and presented in the context of class I HLA on the surface of the cell. The CTL activity was found to be H-2L^d-restricted. Minimal epitope mapping identified a 10-mer overlapping the breakpoint. Most recently, this same 10-mer was noted to bind a human HLA molecule (unpublished observations of the authors).

Based on the *in vitro* activity, we went on to study the activity of this approach using an *in vivo* model of CT26 cells transfected with the PAX-3-FKHR cDNA. Immunization using the same peptide-pulsed APCs in mice was shown to be specifically protective of PAX-3-FKHR expressing CT26 cells in tumor-challenge studies, and adoptive transfer of bulk-immunized splenocytes was shown to lead to tumor reduction in a micrometastatic model (130).

We have begun a clinical study to determine whether immunization of patients bearing either EWS-FLI-1- or PAX-3-FKHR–expressing tumors with peptide-pulsed APCs can lead to the generation of tumor-specific CTL activity.

Several other sarcomas have been shown to have tumor-specific translocations generating fusion transcription factors. Some of these currently under investigation in our laboratories include the EWS-ATF1 fusion protein generated by the t(12;22)(q13;q12) seen in clear cell sarcoma, the EWS-WT1 fusion protein generated by the t(11;22)(p13;q12) in desmoplastic small round cell tumor, and the SSX-SYT fusion protein generated by the t(x;18)(p11.2;q11.2) in synovial sarcoma (135,136).

As the efforts to develop CTL responses targeting tumor-specific translocations continue, several critical questions remain to be answered. Most important, the presence of these fusion peptides on the surface of tumor cells bound to MHC molecules must be formally proven. Although the generation of tumor-specific CTL responses would not be expected to affect normal cells, it is possible that CTLs recognizing epitopes contained within normal proteins also could be generated, with the possibility of developing autoimmune phenomena. We hope that ultimately the use of immunotherapy directed against tumor-specific fusion proteins may be used after more standard cytoreductive therapy to improve the outcome in patients with these tumors.

Other Oncogenes as Targets of Immunotherapy

Part of "16.4 - Oncogenes and Mutations "

When overexpressed, even nonmutated oncogene products may serve as tumor antigens. An oncogene that has received extensive scrutiny is known as HER-2/*neu.* HER-2/*neu* is a cell-surface receptor that was originally identified as a dominant oncogene from a rat neuroblastoma cell line. It has subsequently been shown to be amplified or overexpressed in many human solid tumors, particularly adenocarcinomas of the breast, lung, ovary, and pancreas. It is overexpressed in 20% to 30% of the cases, and in these cases it represents a potentially useful tumor-associated target antigen. Immunotherapeutic targeting of HER-2/*neu* has been reviewed in detail elsewhere (7). Antibodies to Her-2/*neu* have been found in 44% to 55% of breast cancer patients and are correlated with overexpression, compared to 4% to 5% of normal individuals, suggesting that overexpression in the tumor can break self-tolerance to this unmutated oncogene product (7,137). The fact that these were IgG antibodies also suggests the existence of T-cell help. Indeed, CD4[+] T-proliferative responses were observed in PBMCs of three of seven patients studied to HER-2/*neu* proteins and selected synthetic peptides from the HER-2/*neu* sequence (7,137,138). Additionally, human CTLs have been isolated that recognize HER-2/*neu* epitopes on human breast and ovarian cancer (7,138,139,140,141 and 142), as well as non-small-cell lung cancer (143), pancreatic cancer (144), prostate cancer (145), and gastric cancer (146). At least some of these human CTLs can kill a breast cancer cell line expressing HER-2/*neu* as well as HLA-A2.1 (7,138). In contrast, one study immunizing patients with HER-2/*neu* peptide 369-377 that binds to HLA-A2.1 found that CTLs could be induced that recognized peptide-pulsed target cells, but these CTLs failed to kill HLA-A2.1-positive human tumor cells, even after treatment with IFN-γ to upregulate class I HLA expression (147). Effective immunotherapy against animal model tumors expressing HER-2/*neu* has been demonstrated using nanoparticle/protein immunization (148), or this protein pulsed onto dendritic cells (149). In a novel approach to break tolerance, it was shown that HER-2/*neu* peptides could break tolerance and induce CD4[+] T-cell responses and antibodies to rat HER-2/*neu* in rats that were not able to be immunized with the intact rat HER-2/*neu* protein (7,150). A human phase 1 study is currently being conducted by Dr. Mary Disis at the University of Washington.

Conclusions

Part of "16.4 - Oncogenes and Mutations "

A number of oncogene products, mutant oncogene products, other mutant proteins, and fusion proteins created by tumor-specific chromosomal translocations have been identified in tumors that have the properties necessary to serve as tumor antigens. Oncogene products and tumor-specific fusion proteins have the advantage that they contribute to the malignant phenotype and thus cannot be lost under immune selective pressure without loss of this phenotype. Mutations and the breakpoint regions of fusion proteins also have the advantage of being unique to the tumor, allowing the immune system to distinguish the cancer cells from normal cells. This allows immunotherapeutic approaches to fully exploit the hallmark of the immune system, namely its exquisite specificity. Even in cases in which the oncogene product is not mutated, such as HER-2/*neu*, or in which the immune system recognizes a nonmutated epitope of an oncogene or tumor-suppressor gene product, such as p53, overexpression of this product can sometimes allow immune recognition of the tumor without autoimmune responses against normal cells expressing much lower levels of these proteins.

A number of examples have been given in this chapter that are promising tumor antigens for active or passive immunotherapy. These have been studied in both animal and human models. In many cases, human T cells recognizing these mutant or fusion epitopes specifically have been identified, and in some of these cases, the T cells have been shown to kill human tumor cells expressing the antigen. Currently, a number of clinical studies are ongoing that are designed to determine the clinical utility of these approaches. As this field is rapidly advancing, additional new tumor antigens of this type are likely to be identified. Concurrent rapid advances in new techniques to increase immunogenicity hold promise for producing more potent antitumor immune responses that have clinical benefit (85,86,151,152,153,154 and 155). Thus, the field is poised at the threshold of a new and promising era in the immunotherapy of cancer.

Basis for Focusing on Cancer Antigens That Are Carbohydrates

Part of "16.5 - Carbohydrate Antigens on Glycolipids and Glycoproteins "

Carbohydrate antigens have been surprisingly potent targets for immune recognition and attack against cancer cells, both because of their abundance at the cell surface and because of their unexpected immunogenicity. Despite these and other obvious advantages to the use of carbohydrate antigens as targets for immune attack, there are also limitations.

Vaccines Against Bacterial Diseases

Of the many well-defined bacterial antigens studied as targets for vaccine therapy, carbohydrate antigens are the most effective (1,2 and 3).

Antibodies against capsular polysaccharides on *Neisseria meningitidis, Streptococcus pneumoniae*, and *Haemophilus influenzae* type B protect against subsequent bacterial challenge, and these vaccines are approved and widely available for human use.

Abundant Expression at the Cancer Cell Surface

Cancer cells may occasionally express as many as 10^6 copies of individual protein antigens at the cell surface, as has been reported for epidermal growth factor and HER-2/*neu* (4,5), but most protein antigens are expressed in far smaller numbers. The number of carbohydrate epitopes expressed at the cell surface, however, is often far greater. Thus, the median number of glycolipid molecules, such as gangliosides GM2 and GD2 on melanoma cells, is close to 10^7 and for sarcomas and neuroblastomas is more than 5×10^7 (6,7 and 8). The median number of GD3 molecules expressed on melanoma and sarcoma cells is also approximately 5×10^7. The number of copies of a given glycoprotein carbohydrate epitope on cancer cells is less well defined. However, each mucin molecule has 30 to 100 tandem repeats, each of which can express five to 15 carbohydrate epitopes. Some of these mucins (e.g., MUC1) have transmembrane domains and are integral membrane components, whereas others (e.g., MUC2 and MUC5AC) are shed and surround the tumor cell *in vivo*, though they are not actually membrane components. Because the surface of epithelial cancer cells is covered by a dense glycocalyx of various mucins, most epithelial cancer cells are probably covered by at least 100,000 mucin molecules (9,10). Consequently, the number of small carbohydrate epitopes, such as Thomsen-Friedenreich antigen (TF), Tn, or sialyl Tn (sTn), at or near the cell surface is probably well in excess of 10^7.

Effective Targets for Immune Attack

In our series of 110 patients immunized with melanoma cell or melanoma cell lysate vaccines mixed with various adjuvants (11) and in the series of patients immunized with allogeneic melanoma cell vaccines described by Tai et al. (12), gangliosides GM2 and GD2 were the only antigens recognized by multiple patients. Gangliosides are acidic glycosphingolipids overexpressed at the cell surface of melanomas, sarcomas, and other tumors of neuroectodermal origin. Gangliosides have also been shown to be effective targets for immunotherapy with monoclonal antibodies (MAb), with major responses seen in patients after treatment with MAb against GM2, GD2, and GD3 (13,14,15,16,17,18 and 19). The experience with mono or disaccharide epitopes TF, Tn, and sTn that are expressed on mucins in a great variety of epithelial cancers has been similar. Immunization with Tn and TF protects mice from subsequent challenge with cancer cells expressing these antigens (20,21), and the presence of antibodies against TF and sTn in cancer patients has been increased by vaccination (22,23 and 24). Patients with increased antibodies against GM2 and sTn have been shown to have a more favorable prognosis (22,25). Hence, active and passive immunotherapy trials have identified carbohydrate epitopes on glycolipids and glycoproteins as uniquely effective targets for cancer immunotherapy. The chemical structure of these carbohydrate antigens is demonstrated in Figure 16.5-1 .
FIGURE 16.5-1. Structures of some of the defined carbohydrate tumor antigens used as targets in clinical tumor vaccine trials.

Limitations

The general inability of carbohydrate vaccines to induce T-cell immunity against carbohydrate epitopes and the probable inability of a strictly antibody response to alter the course of well-established cancers is a limitation that results from selecting carbohydrate antigens as targets for cancer immunotherapy. Carbohydrates are considered T lymphocyte-independent antigens. Whether this is invariably true is unclear at this time. Although T lymphocytes with γδ receptors can recognize nonpeptide antigens (26) and T lymphocytes with standard αβ receptors can recognize carbohydrate substituents on peptides (27), it has not been possible to use this knowledge to construct vaccines capable of inducing T-lymphocyte immunity against carbohydrate cancer antigens. This may be

in part because it is not known to which amino acids on which peptides any given carbohydrate epitope is linked, and whether the resulting glycopeptide sequences bind to HLA molecules. In any case, skin tests for delayed-type hypersensitivity, cytokine release assays, and cytotoxic T-lymphocyte responses have not been convincingly demonstrated against human cancer antigens or cells after immunization with antibody-inducing carbohydrate antigen vaccines.

Advantages

A number of advantages exist to using cell-surface carbohydrate antigens as targets for immunotherapy of cancer with vaccines, especially in the adjuvant setting. These include

- They are the most abundant antigens at the tumor-cell surface.
- They are immunogenic in terms of antibody response after vaccination with properly constructed conjugate vaccines.
- Antibodies induced against carbohydrate antigens are ideally suited for tumor eradication in the adjuvant setting where the targets are micrometastases and circulating tumor cells.
- Carbohydrates are uniquely effective targets for active and passive immunotherapy of cancer.
- It is possible to purify or synthesize these carbohydrate antigens in sufficient quantities for vaccine construction.
- Carbohydrates play key roles in intracellular interactions as targets for selectins and adhesins, which may be crucial, not discretionary, to tumor-cell survival and the metastatic process. Vaccine-induced antibodies may be capable of interfering with these processes.

Biologic Roles of Cell Surface Carbohydrates

Part of "16.5 - Carbohydrate Antigens on Glycolipids and Glycoproteins "

The great majority of the molecules of the mammalian plasma membrane are glycosylated such that glycan structures form a dense forest covering the cell surface. These glycan chains are found on glycolipids and integral membrane glycoproteins and

on more specialized glycoproteins such as mucins and proteoglycans. To some extent, these carbohydrates serve structural, protective, and stabilizing roles, but it is becoming increasingly recognized that they can have information-bearing functions in cell-cell recognition and adhesion (28,29,30,31 and 32). Much of this work has centered on carbohydrates as the ligands for selectins, sialoadhesins, and other cell-surface lectins. The E, L, and P selectins are involved in the interaction of endothelial cells, leukocytes, and platelets, respectively, with other cells. All three proteins recognize sialylated or sulfated Le^x (or Le^a)-bearing ligands, although in the context of different carriers (28,32). Sialoadhesins are more widely expressed and recognize α-2,6- and α-2,3-linked sialic acid–containing structures (33). Other carbohydrate structures have been implicated in such normal cell functions as embryogenesis, neural cell adhesion, and sperm adhesion. A large body of circumstantial evidence also links glycosylation to the biology of tumor cells. All tumors studied have changes in the expression of carbohydrate structures that are characteristic of the tissue of origin of the tumor. As a general rule, tumors of neural-crest origin (e.g., melanoma, sarcoma, and neuroblastoma) exhibit overexpression of gangliosides (sialylated glycolipids), whereas epithelial cancers (carcinomas) have altered fucosylated structures and mucin-core structures (TF, Tn, sTn) as their characteristic antigens. Although the precise role that these structures play in the aberrant behavior of tumor cells is unclear, numerous studies have shown a relationship between the expression of certain carbohydrate specificities (including Le^y, Le^b, sTn, and Tn blood group antigens) and metastatic potential and patient survival (34,35). The authors suggest that these effects be mediated through the influence of carbohydrate structures on the metastatic spread of tumor cells. Another glycosylation change frequently found on tumor cells—that is, a higher proportion of branched complex structures on Asn-linked chains of their glycoprotein—has also been correlated with metastatic properties in experimental systems (36). In contrast to the emerging picture of the role of oligosaccharides on glycoproteins, there is much less information on the role of cell-surface glycolipids. Evidence is accumulating that glycolipids may also play important roles in cell/cell interactions, cell proliferation, and tumor metastasis (37,38).

Basis for Cancer Vaccines That Induce Only Antibodies

Part of "16.5 - Carbohydrate Antigens on Glycolipids and Glycoproteins "

Antibodies prevent infections with viral or bacterial pathogens by preventing their spread through the bloodstream and by eliminating early tissue invasion. They are also ideally suited for eliminating circulating tumor cells and micrometastasis.

Evidence in Experimental Animals

The basis for vaccines that induce only antibodies is well documented in experimental animals (39). Experiments involving administration of MAb 3F8 against the ganglioside GD2 have been particularly informative (40). Administration of 3F8 before, 2 days after, or 4 days after intravenous tumor challenge with EL4 lymphoma (which expresses GD2) results in complete protection (cure) of most mice. Vaccinations with GD2-KLH initiated either before the challenge or immediately after the challenge has the same effect (Fig. 16.5-2). This timing may be comparable to antibody induction in the adjuvant setting, after surgical resection of the primary malignancy or lymph node metastasis, because in both cases the targets are circulating tumor cells and micrometastases. Administration of 3F8 7 days or longer after intravenous tumor challenge had little impact on tumor progression.
FIGURE 16.5-2. Prevention of EL4 lymphoma recurrence by immunotherapy with monoclonal antibody 3F8 or vaccination with GD2-KLH plus QS-21 after intravenous challenge. In the top panel, immunizations were administered on days -14, -7, and 1. (KLH, keyhole limpet hemocyanin.)

The adjuvant setting in the clinic has been more closely modeled by injecting EL4-lymphoma cells into the footpad on day 1, amputating the visible tumor and foot on day 17, and then treating with 3F8 or initiating a series of vaccinations with GD2-KLH plus immunologic adjuvant QS-21. All untreated mice died or were in obvious distress and were euthanized by day 50. All mice treated with 3F8 or vaccine survived at least 60 days, and 60% and 40%, respectively, were tumor free when they were sacrificed at day 100.

Evidence in Patients

Evidence that naturally acquired or passively administered antibodies are associated with a more favorable prognosis exists in cancer patients.

1. Patients with resected melanoma having natural antibodies against GM2 ganglioside had an 80% to 90% 5-year survival compared to the expected 40% rate in studies at two different medical centers (25,41,42).
2. Patients with small-cell lung cancer and naturally acquired antibodies against small-cell lung cancer had a prolonged survival compared to antibody-negative patients (43).
3. Paraneoplastic syndromes in cancer patients have been associated with high titers of natural antibodies against onconeural antigens expressed on neurons and certain malignant cells. The antibodies were apparently induced by tumor growth and have been associated with autoimmune neurologic disorders and with delayed tumor progression and prolonged survival (44,45).
4. Patients with resected Dukes' C colon cancer who were treated with monoclonal antibody (MAb) 17-1A in the adjuvant setting had a significantly prolonged disease-free and overall survival compared to randomized controls. This is the only randomized clinical trial of MAb therapy conducted in the adjuvant setting reported to date (46).

Mechanism of Action

The effect of all commonly used vaccines against infectious agents is thought to be primarily a consequence of antibody induction. Based on studies of bacterial infections, the mechanism of protection against tumors by antibodies probably includes complement-mediated attack and lysis, antibody-dependent cell-mediated cytotoxicity (ADCC), and Fc-mediated opsonization, with cell-surface tumor antigens as targets. Some antibodies may have direct effects, such as by inhibiting tumor-cell attachment or inhibiting growth hormone receptors, but in general the interaction of antibody and antigen is without consequence unless Fc-mediated secondary effector mechanisms are activated. Binding of antibody to antigen results in a functional change in the Fc portion of the antibody and activation of several effector mechanisms. For cancer carbohydrate antigens, immunoglobulin M (IgM) bound to antigen is the most active complement activator in the intravascular space and IgG1 and IgG3 are the most important complement activators extravascularly. Complement activation at the cell surface mediates inflammatory reactions, opsonization for phagocytosis, clearance of antigen or antibody complexes from the circulation, and membrane-attack complex-mediated lysis. Opsonization for ingestion and destruction by phagocytosis can occur through complement activation but also can occur directly as a consequence of Fc receptors on phagocytic cells. Fc receptors on cell-surface–bound IgG1 and IgG3 are the primary targets for adCC of tumor cells. FcδRI (CD64), FcδRII (CD32), and FcδRIII (CD16) receptors on a range of effector cells, including especially natural killer cells but also cells of myeloid lineage, react with tumor cell-bound antibody, resulting in activation of inherent cytotoxic mechanisms in these effector cells.

Selection of Carbohydrate Antigens for Vaccine Construction

Part of "16.5 - Carbohydrate Antigens on Glycolipids and Glycoproteins "

Carbohydrate antigens expressed at the cancer-cell surface have generally been identified first by antibodies, usually murine MAb. Immunohistochemistry with MAb of known specificity is the most widely used procedure for defining the distribution of carbohydrate antigens on cancers and normal tissues. This is performed on frozen sections when glycolipids are the target to prevent glycolipid loss during paraffin imbedding. Results with immunohistochemistry have been confirmed in the case of glycolipid antigens by extraction and thin-layer chromatography. This is possible because glycolipids can be extracted from biopsy specimens using chloroform and methanol, and because cancer biopsy specimens of neuroectoderm origin contain predominantly tumor cells. The identity of these glycolipids can be confirmed by immunostaining of thin-layer chromatography plates. GM2, GD2, and GD3 ganglioside-expression on melanomas, sarcomas, and neuroblastomas have been defined in this way (6,7,47). This approach is not applicable to carbohydrate antigens on glycoproteins because glycoproteins are difficult to fractionate and to isolate, and because these antigens are characteristic of epithelial cancers in which tumor cells frequently constitute only 10% to 20% of the biopsy specimen, the remainder being normal connective tissue or stroma. Using panels of MAb against carbohydrate antigens, we have screened a variety of malignant and normal tissues by immunohistochemistry (48,49). In general, ganglioside antigens have a different distribution on various malignancies than the other carbohydrate antigens. Melanomas, sarcomas, and neuroblastomas express GM2, GD2, and GD3 but none of the other antigens, whereas the epithelial cancers express a broad range of carbohydrate antigens but rarely express GD2 or GD3. The carbohydrate antigens expressed on 50% or more of tumor cells in 60% or more of biopsy specimens of various types of cancers are listed in Table 16.5-1 .

Table 16.5-1 Carbohydrate Targets for Vaccine Construction

Tumor	Antigens
Melanoma	GM2, GD2, GD3
Neuroblastoma	GM2, GD2, GD3, polysialic acid
Sarcoma	GM2, GD2, GD3
B-cell lymphoma	GM2, GD2
Small-cell lung cancer	GM2, fucosyl GM1, polysialic acid, globo H, sialyl Le^a
Breast	GM2, globo H, Le^y, TF
Prostate	GM2, Tn, sTn, TF, Le^y
Colon	GM2, Tn, sTn, TF, sialyl Le^a, Le^y
Ovary	GM2, globo H, sTn, TF, Le^y
Stomach	GM2, Le^y, Le^a, sialyl Le^a

Note: Antigens present on at least 50% of cancer cells in at least 60% of biopsy specimens.

Each of these antigens are also expressed on some normal tissues. GM2, GD2, and GD3 are all expressed in the brain, especially GD2, which is also expressed on some peripheral nerves and, unexpectedly, a subpopulation of B lymphocytes in the

spleen and lymph nodes. Also unexpectedly, GM2 as defined by MAb 696 is expressed at the secretory borders of most epithelial tissues. GD2 and GD3 are also expressed at low levels in connective tissues of multiple organs, and GD3 is known to be expressed on some human T lymphocytes (50). Fucosyl GM1 is expressed on occasional cells in the islets of langerhans and in some sensory neurons in the dorsal root ganglia. Polysialic acid is expressed significantly in brain and some bronchial epithelial cells. Globo H, Le^y, Tf, Tn, and sTn were expressed at the secretory borders of a variety of epithelial tissues. Le^x and sialyl Le^x were expressed at the secretory border of many epithelial tissues but also on polymorphonuclear leukocytes, and sTn was found on leydig cells of the testis.

The broad expression of most of these carbohydrate antigens on normal tissues raises concern for their suitability as targets for immunotherapy. However, there is sufficient experience from clinical trials with MAb against GD2, GD3, Le^x, sTn, and with vaccine-induced antibody responses against GM2, GD2, GD3, TF, Tn, sTn, globo H, and Le^y to draw conclusions about the consequences of antigen distribution on various normal tissues (11,13,14,15,16,17,18 and 19,22,23 and 24,51,52 and 53). Expression of gangliosides in the brain and expression of many of these antigens at the secretory borders of epithelial tissues has induced neither immunologic tolerance nor autoimmunity once antibodies were present, suggesting that they are sequestered from the immune system. The known expression of Le^x and sialyl Le^x on polymorphonucleocytes and the granulocytopenia seen after treatment of patients with MAb FC-2.15 (later found to recognize Le^x) (52) excludes these two carbohydrates as candidates for vaccine construction, and so they have been omitted from Table 16.5-1 . The expression of fucosyl GM1 on subpopulations of cells in the islets of Langerhans and the dorsal-root ganglia was initially of concern, but no evidence of autoimmunity has been detected in nine patients vaccinated with fucosyl GM1 who produced high titers of IgM and IgG antibodies against fucosyl GM1 (54). Administration of high doses of some, but not other, IgG MAb against GD2 has been associated with peripheral neuropathy in melanoma patients (18,19). High, but not lower, doses of anti-Le^y MAb-BR96 conjugated to doxorubicin has resulted in vomiting, hematemesis, and amylase elevations in some patients (55), whereas BR55, a second MAb against Le^y studied by the same investigators, resulted in no such toxicity. With regard to vaccines, ongoing trials with vaccines against GD2, fucosyl GM1, and Le^y have addressed these questions more directly (54,56,57). Moderate to high titers of IgM and IgG antibodies have been induced and have not been associated with any evidence of autoimmunity or other adverse clinical effects. Consequently, Table 16.5-1, which lists the carbohydrate antigens expressed at the cell surface of each of the common solid tumors, serves as a guide as single antigen or polyvalent antigen vaccine trials are planned.

Carbohydrate epitopes on tumor cells can be expressed on glycolipids with the carbohydrate epitopes covalently attached to ceramide that is anchored in the lipid membrane by hydrophobic forces or on glycoproteins linked to proteins. This is illustrated in Figure 16.5-3 . The carbohydrate epitopes of gangliosides are expressed exclusively as glycolipids. Carbohydrate epitopes of Tn, sTn, and TF are only known to be expressed O-linked to the hydroxy moiety of the many serines and threonines characteristic of mucins. Le^y and globo H are known to be expressed both on glycolipids and glycoproteins (especially on mucins). A clear dichotomy exists between the close association of glycolipid carbohydrate epitopes with the lipid bilayer of the cell membrane and the considerable distance between many glycoprotein epitopes and the cell membrane.
FIGURE 16.5-3. Comparison of the cell surface profiles of clinically relevant carbohydrate antigens expressed at the cancer cell surface as glycolipids or glycoproteins. Note the log scale. (NCAM, neural cell adhesion molecule; □, fucose; ○, glucose, galactose, N-acetylgalactosamine or N-acetylglucosamine; ◊, sialic acid.)

Distinctions Between Glycolipids and Glycoproteins as Targets for Immune Attack

Part of "16.5 - Carbohydrate Antigens on Glycolipids and Glycoproteins "

While analyzing the serologic responses in a series of vaccine trials in cancer patients immunized with various carbohydrate antigens, we noted that while sera in most of the trials were readily able to react with the tumor cell surface as detected by flow cytometry, only responses against glycolipid antigens were able to mediate complement-dependent cytotoxicity (CDC). The results of studies with immunized patient sera and with MAb against these same antigens are summarized in Table 16.5-2 .

Table 16.5-2 Complement-Dependent Cytotoxicity (CDC) is Mediated by Antibodies against Antigenic Epitopes on Glycolipids but not against Epitopes on Mucins

	Target Antigens on MCF7 or LSC Cells						
	Glycolipids			Glycoproteins			
	GM2	Globo H	Le^y	TF	Tn	sTn[a]	MUC1
Murine MAb	696	MBr1	S193	4911.8	13239.1	Cc49	HMFG2
Class/subclass	IgM	IgM	IgG3	IgM	IgM	IgG1	IgG
% positive cells (FACS)	4+[b]	4+	4+	4+	4+	4+	4+
% lysis (CDC)	2+[c]	4+	4+	0	0	0	0
Immune patient serum	Pt1[d]	Pt2	Pt3	Pt4	Pt5	Pt6	Pt7
Class/subclass	IgM	IgM	IgM	IgM	IgM	IgM	IgM
% positive cells (FACS)	2+	3+	2+	4+	3+	4+	2+
% lysis (CDC)	2+	3+	2+	0	0	0	0

FACS, flow cytometry; IgM, immunoglobulin M; MAb, monoclonal antibody; Pt, patient; TF, Thomsen-Friedenreich antigen; sTn, sialyl Tn.

[a]Target cells LSC colon cancer cell line in place of MCF7 breast cancer cell line.

[b]4+, >85%, 3+, 50% to 85%; 2+, 30% to 50%; 1+, 10% to 30% positive cells by FACS.

[c]4+, >85%; 3+, 50% to 85%, 2+, 30% to 50%; 1+, 10% to 30% lysis by chromium release assay.

[d]Each patient was immunized with the antigen shown above conjugated to keyhole limpet hemocyanin plus QS-21. These results are representative of all results obtained with immune sera from these trials.

Although MUC1 is a mucin peptide backbone and not a carbohydrate, it is included in Table 16.5-2 to demonstrate that the inability to mediate CDC is not unique to Tn, sTn, and TF but rather includes many, if not all, antigenic epitopes on mucins. Antibodies of the IgG1 and IgG3 subclasses and IgM antibodies (all of which are induced by these vaccines) are known to be able to mediate complement activation. It is likely that cell-surface reactivity demonstrated by flow cytometry results in complement activation, and that most of the complement and Fc-mediated effector mechanisms are activated by these antibodies. Complement activation by antibody binding to sites on cell-surface proteins that are distant from the cell surface may not be capable of mediating CDC. Even antibodies of lower titer that recognize glycolipid antigens that are intimately associated with the cell membrane have no difficulty lysing the same cells.

Summary

Part of "16.5 - Carbohydrate Antigens on Glycolipids and Glycoproteins "

Antibodies induced against tumor antigens are ideally suited for tumor eradication in the adjuvant setting where the targets are micrometastases and circulating tumor cells. Carbohydrate antigens have proved to be surprisingly potent targets for antibody recognition and attack against cancer cells, both because of their unexpected immunogenicity and because of their abundance at the cancer cell surface. Carbohydrates play key roles in intracellular interactions as targets for selectins and adhesins, which may be crucial, not discretionary, to tumor cell survival and the metastatic process. Vaccine-induced antibodies may be capable of interfering with these processes directly and are clearly capable of inducing complement-mediated inflammation and lysis and ADCC and of mediating opsonization, inflammation, and tumor cell death by other Fc-mediated mechanisms. Passively administered MAb and vaccine-induced antibodies can protect against growth of previously administered cancer cells in a variety of preclinical models for treatment in the adjuvant setting. Strong circumstantial evidence exists that antibodies against tumor antigens, especially against carbohydrate tumor antigens, can protect against tumor recurrence in humans. Carbohydrate antigens are expressed at the tumor cell surface as glycolipids or as glycoproteins (frequently on mucins). Carbohydrate epitopes on glycolipids appear to be uniquely potent at inducing complement-mediated cell lysis, probably as a consequence of their close association with the cell membrane. However, antibodies against both glycolipids and glycoproteins can activate complement- and other Fc-mediated effector mechanisms, and have been associated with prevention of tumor recurrence in preclinical models and in cancer patients.

- Newly Emerging and Potentially Promising Tumor Glycoproteins

Introduction

Part of "16.6 - Glycoprotein Antigens "

The term *tumor antigen* has been given a new and much more precise definition as a result of important developments in immunology in the 1990s, particularly in the area of antigen presentation and antigen recognition. For something to be a tumor antigen it must be recognized by specific immune effector cells or antibodies on tumor cells, but not on normal cells. If a tumor is recognized by CD8$^+$ cytotoxic T lymphocytes (CTLs), in the greatest majority of cases it can be assumed that the tumor antigen is a small peptide (eight, nine, or ten amino acids long) that has been processed from a larger protein from tumor cells and presented in the peptide-binding cleft of major histocompatibility complex (MHC) class I molecules on the surface of the tumor cell. If the antigen is recognized by CD4$^+$ T cells, it can be assumed that it is a slightly longer peptide (on an average 12 to 18 amino acids), most likely derived from a larger protein expressed or secreted by tumor cells and processed and presented in MHC class II molecules. Tumor-specific antibodies recognize either small linear peptides or conformational peptide- or nonpeptide-epitopes that are carried on proteins made by normal and tumor cells. Often, antibodies recognize tumor-specific carbohydrate epitopes on proteins that are otherwise identical in normal cells and tumor cells.

Because tumor specificity resides in small epitopes, the term *tumor antigen* must be dissociated from whole molecules and specifically applied to their much smaller fragments. Having reserved the tumor-antigen definition for small peptides, it may not be immediately obvious why we have chosen in this chapter to maintain the older definition "glycoprotein tumor antigens," which refers to the whole molecules. The glycoproteins that are discussed in this chapter are, by and large, products of normal genes that encode proteins whose amino-acid sequences are identical in normal and tumor cells. Thus, as whole proteins they do not warrant the tumor antigen designation. However, the fact that these proteins are glycosylated during their normal biosynthesis, combined with the fact that most tumor cells exhibit defects in the ability to correctly glycosylate proteins (1), creates a situation in which the repertoire of peptides derived from two differentially glycosylated but otherwise identical amino-acid sequences can be different between normal cells and tumor cells. Furthermore, antigen-presenting cells (APCs) appear to process the glycoproteins from tumor cells differently than the same molecules from normal cells, producing a tumor-specific repertoire of peptides. Some of the peptides in this new repertoire are apparently capable of stimulating a tumor-specific immune response.

Differential glycosylation affects the processed peptide repertoire not only qualitatively but also quantitatively. Aberrantly glycosylated proteins may be easier to process than their fully glycosylated normal counterparts, resulting in many more peptides derived from the same glycoprotein on the surface of tumor cells as compared to normal cells. Even though these peptides are not different in sequence from peptides presented

on normal cells, their increased density of expression on the cell surface can reach the threshold level necessary for immune recognition. Whereas low levels of peptide MHCs might be ignored on normal cells, their higher density on APCs and on tumor cells can lead to effector-cell activation.

Altered glycosylation of normal cellular proteins is associated with altered immunogenicity not only in cancer but also in many inflammatory and autoimmune diseases that are accompanied by changes in *N*- or *O*-linked glycosylation of normal cellular proteins, some of which become targets of the autoimmune response (2).

Altered Glycosylation of Glycoproteins in Cancer and Relationship to Immunogenicity

Part of "16.6 - Glycoprotein Antigens "

All glycoproteins are divided into two groups, those that carry predominantly *N*-linked and those that carry predominantly *O*-linked carbohydrate chains. Proteins are modified with *N*-linked glycans in the endoplasmic reticulum (ER) and the Golgi in a well-ordered process orchestrated by specific glycosyltransferases and glycosidases (3). *O*-glycans are added to proteins in the Golgi. The process of protein glycosylation involves a complex regulation of large families of enzymes that are tightly controlled at many levels, including gene expression, enzyme activity, presence or absence of specific cofactors, and correct trafficking of the protein substrate. All of these processes can differ or change, depending on the cell and tissue type and state of differentiation.

Transformation of a cell from a normal to a malignant phenotype can be accompanied by a dramatic change in its protein glycosylation (1). When hybridoma technology began to be used to identify tumor antigens, it was immediately noticed that many monoclonal antibodies raised against various types of tumors recognized carbohydrate epitopes that were either a novel form made by the tumor cell or more often a truncated form of the carbohydrate chain made in normal cells. A lot of work over many years on the *N*- and *O*-linked glycosylation pathways in tumor cells suggests that tumor cells lose control over the balance of their glycosyltransferases, upregulating some of them while simultaneously downregulating others (4). Another common change in tumors is truncation of the carbohydrate chains through increased action of capping glycosyltransferases. These changes have defined a whole group of carbohydrate tumor antigens, such as T or Tn, resulting from carbohydrate chain truncation and an unusual terminal oligosaccharide sequence Lewis$^{x/a}$, resulting from an inappropriate upregulation of a glycosyltransferase. Purified or synthetic versions of these carbohydrates, when coupled to carrier proteins, can be used to induce an antibody response against tumor cells.

For the purpose of this chapter, the importance of carbohydrate tumor antigens is that they are markers of glycoproteins that are aberrantly glycosylated in tumor cells. To a tumor immunologist, their presence raises the possibility that there might be changes in how the whole glycoprotein is handled and presented to the immune system by either the tumor cells or by APCs that take up glycoproteins secreted or shed from tumor cells.

Aberrant Glycosylation in Tumor Cells May Determine Aberrant Processing and Presentation of Tumor Glycoproteins

Part of "16.6 - Glycoprotein Antigens "

MHC class I molecules are primarily responsible for presenting peptides derived from endogenously synthesized proteins made and degraded by the proteasomes in the cytosol (5,6). All cellular proteins are made in the cytosol. Those that need to be further processed or are destined to the cell surface or secretion are translocated to the ER where they must be folded correctly, *N*-glycosylated if glycoproteins, transported to the Golgi, further glycosylated with *N*- and/or *O*-linked glycans, and finally trafficked to the cell surface. Parallel with this process is the continuous process of protein degradation that also takes place in the cytosol and is carried out by a large multicatalytic protease complex called the *proteasome.* Proteasomes generate small peptides that are transported to the ER through the transporters associated with antigen processing-1 and -2 (TAP-1 and TAP-2) molecules where they bind newly synthesized MHC class I molecules. MHC class I peptide complexes are then transported to the cell surface where they can be recognized by CD8+ T cells.

It is easy to imagine how the repertoire of the peptides presented on the surface of a cell would depend on the processing of proteins inside the cell. As Figure 16.6-1 illustrates, a normal cellular glycoprotein that finds itself in the cytosol is degraded predictably and consistently to a certain number of peptides, thus providing an expected repertoire of class I-restricted peptides on the cell surface (top left panel). Lack of an immune response to this normal peptide repertoire is maintained through numerous mechanisms of peripheral tolerance. If malignant transformation results in a profound difference in glycosylation or other posttranslational modifications of this same glycoprotein, proteasomes may handle it differently, resulting in the appearance of certain peptide fragments not otherwise generated from the normal glycoprotein (top right panel). These new peptides carried to the cell surface in class I molecules are not subject to the established tolerance mechanisms specific for the normal peptides and may now elicit a class I-restricted T-cell response. This response is then, by definition, a tumor-specific response.
FIGURE 16.6-1. Normal pathways of antigen processing and presentation can yield tumor-specific peptides. Upper left panel illustrates the process by which a normal glycoprotein *(indicated in white)* made by a normal cell is processed in the cytosol by proteasomes into a normal peptide repertoire. These peptides are transported into the endoplasmic reticulum by transporters associated with antigen-processing molecules where they bind to nascent major histocompatibility complex (MHC) class I chains. They are then transported to the cell surface where the normal repertoire *(white circles only)* is not reacted against by CD8+ T cells. The upper right panel illustrates what happens if the same glycoprotein is changed in a tumor cell to a tumor-specific form *(indicated in black).* Processing of this modified glycoprotein results in a different peptide repertoire *(white and black circles)* on the surface of the tumor cell, which could be reacted against by CD8+ T cells. Lower left panel illustrates the process by which a normal glycoprotein *(indicated in white)* is internalized from the cell surface or extracellular space into endocytic vesicles where it is degraded into normal peptides *(all white).* Fusion of these vesicles with vesicles containing MHC class II molecules loads the peptide fragments into MHC class II for presentation on the surface. The peptide repertoire is normal and not reacted against by T cells. Lower right panel represents uptake and processing of the same glycoprotein made in tumor cells *(indicated in black).* Processing of this tumor form of the glycoprotein results in a different MHC class II–presented peptide repertoire *(white and black circles)* on the surface of tumor cells, which could be reacted against by CD4+ T cells.

Proteins destined to be presented to CD4+ T cells are also degraded into peptide fragments, but this is accomplished by the action of vesicular proteases in specialized vesicles. This pathway is used for the processing of internalized antigens, either cell-surface molecules or soluble proteins taken up from the outside of the cell by endocytosis (6). Endocytosed proteins become enclosed into vesicles called *endosomes,* which travel into the interior of a cell where they meet with vesicles carrying MHC class II molecules. The repertoire of peptides generated by this process from glycoproteins derived from normal cells versus tumor cells can also be very different. As Figure 16.6-1 shows, endocytosed normal cell-surface glycoproteins result in a predictable, and most likely tolerated, peptide repertoire (lower left

panel), whereas modified tumor glycoproteins can be processed to present new class II–restricted epitopes (lower right panel).

The same phenomenon described in Figure 16.6-1 for normal and tumor cells is operational at the level of APCs. Normal glycoproteins that are shed from surfaces of normal cells and picked up by APCs are processed into an expected repertoire of self-peptides that are not recognized by T cells. Any change in the glycoproteins shed from a malignant cell may be reflected in how it is handled by APCs. For example, if a certain glycoprotein is overexpressed by tumor cells compared to normal cells, it might be considered a potential tumor antigen. But the effect might be just the opposite if overexpression is accompanied by a loss or a change in its glycosylation. The result of this change may be a protein that cannot be efficiently internalized by specialized receptors on APCs. If not taken up and presented by APCs, this highly expressed tumor protein can remain hidden from the immune system. On the other hand, a specific change in glycosylation that puts a different sugar on, or truncates a sugar chain and reveals otherwise concealed core sugars on the tumor glycoprotein, may make it a much better ligand for some of the receptors, thereby increasing its uptake by APCs and thus its potential immunogenicity. Additionally, new epitopes may be generated from the aberrantly glycosylated polypeptide if certain enzyme-sensitive sites have been exposed due to the lack of glycosylation.

All of these possibilities have been documented for one or another tumor glycoprotein and are highlighted in the following specific examples.

Melanoma Glycoproteins

The best known and most studied of melanoma glycoproteins are tyrosinase, glycoprotein 100 (gp100), and gp75. Their biochemical structure has been elucidated, and they have been confirmed as glycoproteins. The biochemical nature as glycoproteins of several other melanoma antigens, in particular MART1/Melan-A, has not yet been confirmed.

Tyrosinase

Tyrosinase is a part of the melanin biosynthesis pathway and catalyzes the synthesis of the melanin precursor dihydroxyphenylalanine. That this glycoprotein, a normal tissue differentiation antigen, is recognized as a tumor antigen was first shown by the reactivity of melanoma-specific CTLs with a COS-7 cell cotransfected with both a complementary DNA (cDNA) library derived from a melanoma tumor and a plasmid-encoding HLA-A2 (7). It was subsequently shown that it contains multiple antigenic peptides restricted by a number of human HLA class I and class II molecules. Most of these peptides are derived from the normal tyrosinase sequence.

Tyrosinase-specific T cells have only been detected in melanoma patients, suggesting that *in vivo* the immune system is faced with different processing and presentation of this antigen when it is derived from melanomas rather than from normal melanocytes. *In vitro*, using optimal priming conditions, which most likely activate APCs as well as present high density of antigen, tyrosinase-specific CTLs have also been generated (8). One example of antigenicity being dependent on posttranslational modifications is the naturally occurring HLA-A2.1–associated peptide YMDGTMSQV that was identified by mass spectrometry from peptides extracted from purified HLA-A2.1 molecules expressed by melanoma cells. The peptide corresponded to residues 368 to 376 of tyrosinase except that it contained aspartic acid (D) instead of asparagine (N) predicted by the tyrosinase gene sequence (9). The peptide with aspartic acid sensitized target cells for CTL lysis at a 100-fold lower concentration than

the asparagine-containing peptide. It was determined that the naturally processed peptide arose as a result of a posttranslational modification that converts a glycosylated asparagine to aspartic acid by enzymatic deamidation through the action of peptide:*N*-glycanase. This is a clear example of how changes in the posttranslational modification of glycoproteins in tumor cells may lead to the generation of new peptide epitopes that could be relevant to tumor rejection. One can also postulate that aberrant glycosylation in some tumors might instead leave the asparagine unglycosylated, which would result in a completely different peptide being presented in HLA class I, with a completely different, in this case inferior, potential as a CTL target.

Tyrosinase is also processed into peptides that can be presented by class II MHC molecules and recognized by CD4+ T cells (10,11). These class II-restricted peptides have been identified by *in vitro* stimulation with either autologous Epstein-Barr virus-immortalized B cells loaded with lysates of COS-7 cells transfected with tyrosinase cDNA or with autologous APCs infected with vaccinia virus encoding tyrosinase. Neither of these preparations that have been used to identify the epitopes mimics the tyrosinase glycoprotein synthesized by melanomas. This makes it difficult to predict with certainty that the tumor-derived glycoprotein would be processed and presented exactly the same way as the recombinant molecule. For any of these peptides derived from normal tissue differentiation antigens to become serious candidates for vaccines, issues of their tumor-specific processing and presentation should be fully resolved.

Glycoprotein 100

gp100 Is a lineage-specific antigen that is expressed in melanomas but not in other tumor-cell types or normal cells, with the exception of melanocytes and pigmented cells in the retina. It was defined as a melanoma-specific T-cell antigen when it was first demonstrated that transfection of this gene into target cells could reconstitute the epitope recognized by CD8+ HLA-A2.1-restricted tumor-infiltrating lymphocytes (TILs) (12,13). The antigenic peptide YLEPGPVTA responsible for this specificity was identified through mass spectrometric isolation of a naturally processed peptide eluted from HLA-A2.1 molecules on a melanoma cell line (14). Many other HLA-A2-restricted gp100-derived peptides have been reported to date, and TILs containing a strong anti-gp100 activity have been shown to be effective in adoptive immunotherapy of melanoma, making these peptides promising candidates for inclusion into a melanoma vaccine preparation. Importantly, there are reports that peptides derived from gp100 have also been eluted from HLA class II antigens on melanomas and found to be able to stimulate CD4+ T cells (15).

Glycoprotein 75

Similar to gp100 and tyrosinase, gp75 is expressed in human melanocytic cells and melanoma tumors. It was first identified using serum immunoglobulin G antibodies from a melanoma patient (16,17) and later found to encode a shared melanoma antigen recognized by HLA-A31-restricted TILs (18). Unlike the other melanoma differentiation antigens, however, the peptide MSLQRQFLR recognized by the TILs was not derived from the normal gp75 protein but from an alternative open reading frame that directs the translation of a small 24 amino acid protein. Alternative translation of otherwise normal cellular genes, in addition to alternative posttranslational modification and processing, is another way by which new tumor-specific antigens may be derived.

MART-1/MelanA

MART-1/MelanA was first defined by melanoma-specific HLA-A2.1-restricted CTLs (19,20). It is a transmembrane protein whose expression parallels that of tyrosinase. Several other peptide epitopes contained in this glycoprotein sequence have been identified as CTL targets. Although considerable information exists about the gene structure and antigenicity of this protein, little is known about its biochemical nature, including whether it is a glycoprotein. Monoclonal antibodies have been generated that react with this protein, and they are going to be useful in deciphering its primary structure and posttranslational modifications (21). Already, it is obvious that the precipitated protein is larger (23 kd) than its predicted molecular weight (13 kd) from the gene sequence. It is not clear yet if this additional weight is a result of glycosylation or other posttranslational modifications. Regardless of the precise modification of the primary structure, however, the chance that a tumor may modify this protein differently than a normal cell provides an opportunity for the immune system to see it as a tumor-specific antigen.

Glycoproteins from Epithelial Tumors

Part of "16.6 - Glycoprotein Antigens "

Among the best known epithelial cell glycoproteins, which are also classified as tumor antigens, are carcinoembryonic antigen (CEA), CO17-1A, prostate-specific antigen (PSA), HER-2/*neu*, and MUC1. All of them have been first identified by antibodies and later shown to also contain T-cell epitopes.

Carcinoembryonic Antigen

The CEA glycoprotein belongs to a family of cell-surface glycoproteins extensively explored to date for potential application in diagnosis and treatment of cancer (22,23). It is expressed primarily on colon, breast, and lung adenocarcinomas, but it is assumed that most tumor cells of epithelial origin express some low level of this antigen. It is also expressed on normal epithelia, primarily colon, and to a lesser extent other normal epithelial as well as endothelial cells. Its expression on epithelial tumors is characterized by drastically different levels of expression and differences in posttranslational modification of the protein (24). For a long time it was not clear if this difference between CEA expression on normal cells and tumor cells would have any consequence on its immunogenicity. Although low titers of CEA antibodies were found occasionally in cancer patients, it was difficult to show T-cell reactivity. Using advances in recombinant expression vector technology as well as antigen presentation, numerous peptide epitopes have been identified that can stimulate

human CTLs. CEA has also been tested in phase 1 and 2 clinical trials as a vaccine against colon cancer (25). All of the immunization protocols, both *in vitro* and *in vivo*, have used some form of recombinant CEA. Having the tumor form of the molecule would appear more likely to generate immune responses against epitopes presented on tumor cells. However, published data suggests that quantitative rather than qualitative differences in CEA expression on tumor cells may be important in the tumor-specific effector phase of an immune response, whereby low levels of CEA on normal tissues are ignored by the immune system, whereas high levels on tumors specifically target those cells for killing by CTLs.

CO17-1A

CO17-1A is another human colorectal cancer antigen with a promising role in cancer immunotherapy. This 40-kd glycoprotein is expressed on gastrointestinal cancers and treatment with an anti-17-1A antibody has been shown in a randomized phase 2 trial with 189 patients and a placebo control to significantly prolong survival of colon cancer patients over a median follow-up of 5 to 7 years (26,27).

Prostate-Specific Antigen

PSA is present in the circulation of prostate cancer patients at elevated levels and has been used for diagnosis of prostate cancer (28). It is a glycoprotein of 33-kd molecular weight, and it is a member of the serine protease family with trypsin-like and chymotrypsin-like protease activity (29). PSA can also be found in milk of lactating women and in amniotic fluid, and its production by normal breast can be stimulated by oral contraceptives (30,31). PSA expression has been documented in various other tumors in addition to prostate, most frequently in breast, and some tumors of the skin, ovary, and salivary gland. A lot of interest in this molecule as a possible immunogen exists, but only limited information is available to date about its antigenicity to human T and B cells. No differences have been observed between the PSA glycoprotein expressed on tumors versus normal tissues. Two studies report generation of human CTLs against PSA. One defines two HLA-A2-binding peptides designated PSA-1 (amino acids 141 to 150) and PSA-3 (amino acids 154 to 163) that stimulate human CTLs that can kill HLA-A2$^+$ PSA$^+$ tumor cells (32). The other uses a longer PSA peptide of 30 amino acids to show an additional HLA-A2- and -A3–restricted CTL activity (33). These results encourage further study of PSA as a possible prostate tumor-specific antigen.

It is important to mention that other prostate glycoproteins have begun to be explored for use in prostate tumor immunotherapy. These are prostatic acid phosphatase (34) and prostate-specific membrane antigen (35). Both have been shown to induce an immune response, but this response is directed against normal as well as malignant prostate cells. Breaking of tolerance to these antigens and induction of autoimmune prostatitis is considered to be one possible approach to prostate tumor therapy.

Also promising are molecules that are being identified by representational differential analysis as genes that are upregulated during prostate cancer progression. An interesting cell-surface glycoprotein, prostate stem cell antigen, has been reported (36). It encodes a 123-aa protein with an amino-terminal signal sequence, carboxy-terminal glycosylphosphatidylinositol anchoring sequence, and multiple *N*-glycosylation sites. It is of interest to attempt to target this molecule by the immune system.

The technique of cDNA library subtraction in conjunction with a high-throughput screening has identified additional genes that were shown by reverse transcriptase-polymerase chain reaction, Northern blot, and real-time polymerase chain reaction to be overexpressed in prostate tissues or prostate tumors, or both (37). The proteins have not yet been identified, but potentially one or all of these new gene products could be explored for cancer diagnosis and immunotherapy.

HER-2/neu

Another category of cell surface glycoproteins that have been studied by tumor immunologists as candidate tumor-rejection antigens are various cell surface growth-factor receptors that are aberrantly expressed on tumor cells and provide autocrine growth signals. The best described to date is HER-2/*neu*, a proto-oncogene product with homology to the epidermal growth factor receptor. It is expressed in breast, ovarian, and several other types of epithelial tumors, but primarily explored in the setting of breast cancer immunotherapy. Anti-HER-2/*neu* antibodies are thought to mimic the natural ligands of this molecule, several of which have been described elsewhere (38). It has been shown that treatment with one such anti-HER-2/*neu* antibody known by the name of *trastuzumab* (Herceptin) has some therapeutic effects in metastatic breast cancer (39). On tumors, HER-2/*neu* is characterized by an increased rather than mutated expression. Like many antigens discussed in this chapter, it is also weakly expressed on normal tissues (40). The normal expression apparently fails to induce tolerance, as both antibodies (41) and T cells specific for this molecule can be found in cancer patients (42,43). This encourages further manipulations of this antigen or its gene to be used as an anticancer vaccine (41). Several clinical trials based on this immunogen are in progress.

Although HER-2/*neu* is touted primarily as a breast cancer antigen, there are reports of a successful elicitation of HER-2–specific T-cell responses in other malignancies, such as gastric cancer (44) and renal and colon cancer (45).

MUC1 Mucin

One of the first epithelial tumor antigens to be shown to be a target of human T-cell immunity is a mucin-like glycoprotein MUC1 (46,47 and 48). MUC1 is the only integral membrane glycoprotein among a large number of other mucins that are expressed at high levels on the surface of epithelial cell tumors, primarily breast, pancreas, colon, ovary, and lung adenocarcinomas (49). Expression of these molecules on normal tissues is usually at a much lower level and characterized by a different repertoire of immune epitopes (50). Some of the epitopes are exquisitely tumor specific (51). MUC1 is a high-molecular-weight glycoprotein extensively *O*-glycosylated on serines and threonines that are

found in tandemly repeated 20 amino acid-long segments. The carbohydrate chains on the tumor-produced mucin are shorter than those on mucin produced by normal cells. An indication also exists that in tumor mucin not all the potential glycosylation sites are used. This results in the unmasking on tumor mucin of cryptic protein-core epitopes that serve as tumor-specific antigens. The same epitopes are concealed in normal mucin by complete glycosylation. In the latest International Workshop on Monoclonal Antibodies against MUC1 (52), it was observed that antibodies that recognize MUC1 only when expressed on human epithelial adenocarcinomas but not on the corresponding normal tissue were all specific for the same epitope on the tandem repeats. The amino-acid sequence of the tandem repeat is GVTSAPDTRPAPGSTAPPAH. The tumor-specific epitope includes amino acids APDRTP, highlighted in bold type in the preceding sequence. The nuclear magnetic resonance data revealed that the PDTRP sequence forms the tip of a protruding knob exposed to solvent and forming a stable type II β-turn (Fig. 16.6-2) (53). The formation of these "knobs" is a result of underglycosylation of serine and threonine residues just preceding and just after the knob sequence. Normal MUC1 with completely and extensively glycosylated serine and threonine residues does not form the knob-like epitopes. Differences in glycosylation between MUC1 in normal cells and MUC1 in tumor cells thus create profound changes in the 3-D structure of the native molecule, which in turn affects direct recognition, processing, and presentation of peptide epitopes derived from this molecule. The knobs are immunogenic, and antibodies against them have been detected in cancer patients (54,55). There appears to be a correlation between the presence of the antibody and increased disease-free survival (56). There are also T-cell responses against the knobs and against processed peptides presented by HLA molecules.
FIGURE 16.6-2. Three-dimensional structure of the tumor form of the MUC1 glycoprotein. Inability of tumor cell to glycosylate the polypeptide core leads to a formation of new knob-like epitopes *(indicated in white)* that are recognized by tumor-specific antibodies and T cells

In patients *in vivo*, anti-MUC1 immune responses are characterized by low titer of immunoglobulin M antibodies and low frequency of MHC unrestricted CTLs. MUC1-specific T-helper cells had not been identified *in vivo*, but they have been generated by *in vitro* priming (57), suggesting that helper-cell unresponsiveness was not due to a deletion of MUC1-specific CD4⁺ T cells. It was determined that the glycosylated soluble form of MUC1 that is cleaved off of the tumor cell surface and made available for APCs to take up, process, and present to T-helper cells is in fact not processed by the APCs. This hampers the development of both class I (58) and class II (59) restricted T-cell responses. When the antigen is supplied in a synthetic or a recombinant form as unglycosylated polypeptide, vigorous CTL and T-helper cell responses are generated that also react with the MUC1⁺ tumor cells.

The inability of APCs to present the form of MUC1 available *in vivo* explains in great part the inability of this potentially good tumor-cell target to serve in its native state as a tumor-rejection antigen. On the other hand, it appears that if the unglycosylated form is used as a vaccine to prime the T-cell responses, this problem might be solved. A synthetic MUC1 peptide, at least 100 amino acids long and composed of five or more tandem repeats, has been successfully used to prime T-helper and CTL responses in primates (60) and in several ongoing phase 1 clinical trials in patients with metastatic colon, breast, and pancreatic cancer (61) and in early diagnosed and/or resected pancreatic cancer (Finn et al., *unpublished data*, 1999).

Several other investigators around the world are testing MUC1 peptide-based vaccine approaches. One peptide vaccine strategy is designed to facilitate presentation of the peptides by both MHC class I and class II molecules. This is accomplished by conjugating a similarly long MUC1 peptide to mannans (polymannose) that then targets this conjugate to the mannose receptors on APCs. Patients were immunized subcutaneously eight times over a 13-week period, and antibody delayed-type hypersensitivity and CTL responses were monitored (62). This treatment resulted in the development of antibody responses of the immunoglobulin G isotype, T-helper cell responses and, in a small number of patients, a CTL response. These results collectively suggest that MUC1 peptide vaccines may serve as a powerful method to enhance or induce T-cell responses to class I and class II MUC1 epitopes.

Other MUC1-based immunogens that are also being tested in phase 1 clinical trials have included the whole protein, short peptides derived from its amino-acid sequence, or carbohydrate moieties mimicking those exposed on the tumor MUC1 due to its aberrant glycosylation (63,64 and 65). These antigenic preparations have been expressed in bacterial or viral vectors as fusion proteins, expressed in or pulsed onto several cell types, or used with different adjuvants. Some success has been seen in eliciting immune responses to these various immunogens as well.

MUC1 is an excellent example of how changes in a normal glycoprotein caused by the inability of tumor cells to glycosylate it fully can make this glycoprotein immunogenic. Clever design of vaccine approaches that take advantage of these changes can lead to development of immune responses that are tumor specific.

Newly Emerging and Potentially Promising Tumor Glycoproteins

Part of "16.6 - Glycoprotein Antigens "

Even though many tumor-associated antigens are fully characterized and their immunogenicity is being explored, continuous

developments of new techniques of antigen discovery prompt further searches for new and perhaps better candidates for tumor antigen-based immunotherapies. The road to discovery of new antigens has two parts, one that is biochemical or genetic and traveled a little faster, yielding at its destination numerous potential candidates. It is at that point in the journey that the road turns unpaved and the travel a lot slower. The destination is to determine antigenicity, immunogenicity, and modes of delivery of these antigens to the immune system. Several tumor glycoproteins are taking the later part of the road for the first time. One of them is the secreted glycoprotein Mammaglobin, a product of a mammary-specific member of the uteroglobin gene family overexpressed in breast cancer (66). Another interesting tumor glycoprotein is designated 90K (67,68). It is not so much a tumor antigen as it is a stimulator of APCs and may facilitate presentation of other tumor antigens. Human A33-antigen is a 43-kd glycoprotein with characteristics similar to the members of CEA family. It is a novel palmitoylated cell surface, *N*-linked glycoprotein expressed on normal human colonic and small-bowel epithelium and on more than 95% of primary and metastatic colon cancer cells (69,70).

Many more candidate molecules are being identified through a screening strategy using patients' humoral responses to screen cDNA expression libraries derived from human tumors. This is known as *SEREX technology* (*ser*ological analysis of *r*ecombinant *ex*pression libraries with autologous serum) (71). The candidates obtained by this approach are already numerous (72,73 and 74) (see Chapter 16.7), but they are for now mostly recombinant unmodified proteins that require extensive study until their biochemical characterization is completed. None of them are yet confirmed glycoproteins and for that reason are not described in this chapter.

An important lesson that has been learned from working with the "old" tumor glycoproteins, and that should be applied to the "new" antigens, is that posttranslational modifications of these proteins differ between normal cells and tumor cells and between different tumor types. This may determine whether these molecules are presented to the immune system and how they are presented to the immune system. In testing their immunogenicity and antigenicity, it is important to use the form of antigen found on a tumor cell of interest that is known to be processed by APCs and that can generate an immune response that is likely to react with tumor cells and not with normal tissues.

Introduction

Part of "16.7 - Identification of Human Tumor Antigens by Serological Expression Cloning "

The search for antibodies that distinguish cancer cells from normal cells is one of the longest uninterrupted inquiries in cancer research (1). The history of this pursuit can be divided into four phases. The first, dominated by immunologists such as Witebsky and Hirszfeld, dealt mainly with the analysis of heteroimmune serum obtained from rabbits and other animals immunized with human cancer (2). The challenge, generally unmet, was to remove antibodies reactive with normal tissue antigens; a variety of absorption techniques were devised to accomplish this. Complement fixation and, later, agar gel immunoprecipitation provided the primary systems to analyze the heteroimmune sera. Although little of enduring value came from this vast effort, two useful antigens were identified—alpha fetoprotein, a serum marker for hepatoma and germ-cell tumors (3); and carcinoembryonic antigen, a serum marker for colon and other epithelial cancers (4). The second phase in this odyssey was initiated by the work of Peter Gorer, a scientist best known for his discovery of the mouse histocompatibility locus. Gorer also had an intense interest in tumor antigens, and he introduced the approaches and test systems involving cytotoxic alloantibodies prepared in inbred mice that led to the serological dissection of normal and malignant lymphoid cells and the discovery of cell surface "differentiation antigens" such as TL, Ly1, Lyt2 (CD8), Thy-1, and PCA (5), and endogenous retroviral-coded antigens such as Gross cell surface antigen, G_{IX}, and ML (6). The emergence of hybridoma technology (7) transformed the field of serology and opened the floodgates for identifying new cell-surface antigens in mice and humans and for analyzing the antigenic phenotype of human cancer. Although there was great hope that monoclonal antibodies (MAb) would uncover tumor-specific antigens in humans, this has not proven to be the case. Rather, experience has shown that even the most restricted tumor antigen generally turns out to be a restricted normal differentiation antigen (8). In addition to the use of polyclonal and MAb of heterologous and allogeneic origin in the search for tumor-specific antigens, there has been a sustained effort to determine whether the autologous host recognizes cancer cells.

To establish as rigorous and unambiguous a serological test system as possible for this purpose, an approach called *autologous typing* was developed (9), initiating what can be seen as the third phase in human cancer serology. The intention of autologous typing was to restrict the analysis to autologous reagents—tumor cells, serum, and normal cells such as fibroblasts and lymphocytes from the same patient—to eliminate the contribution of alloantigens in the reactions observed and to establish tumor specificity by absorption with autologous normal cells. With the exception of leukemia cells (10), cultured tumor-cell lines were required for autologous typing, and this limited analysis to tumor types that could be adapted to growth *in vitro* with some regularity [i.e., melanoma (11,12), renal cancer (13), and brain cancer (14)]. The conclusion coming from the autologous typing of a large series of patients is that a small fraction of patients do develop autologous antibody with specificity for cell-surface antigens of the tumor. With few exceptions (15,16,17 and 18), however, molecular characterization of the antigen was generally beyond reach, primarily because the antibodies were not of sufficient titer to monitor biochemical purification or cloning.

This limitation in autologous typing has been overcome by a new approach introduced by Michael Pfreundschuh and his colleagues Ugur Sahin and Özlem Türeci at the University of Saarland (19,20). They called their approach *SEREX*, for *s*erological analysis of *r*ecombinant cDNA *ex*pression libraries of human tumors with autologous serum. In their initial application of the method, tumor antigens, such as MAGE and tyrosinase that had originally been defined as T-cell–recognized epitopes, were detected by autologous antibody. SEREX analysis has identified a series of provocative cancer antigens that have relevance to the etiology, diagnosis, and therapy of cancer. What is so encouraging about SEREX is that it provides a way to analyze the humoral immune response to intracellular cancer antigens, a generally impenetrable forest for cancer serologists in the past. The development of the SEREX technique has inaugurated the fourth phase in cancer serology, bringing with it the prospect of providing a comprehensive view of the immune recognition of human cancer.

SEREX: The Technique and Steps Involved in the Analysis of SEREX-Defined Antigens

Part of "16.7 - Identification of Human Tumor Antigens by Serological Expression Cloning "

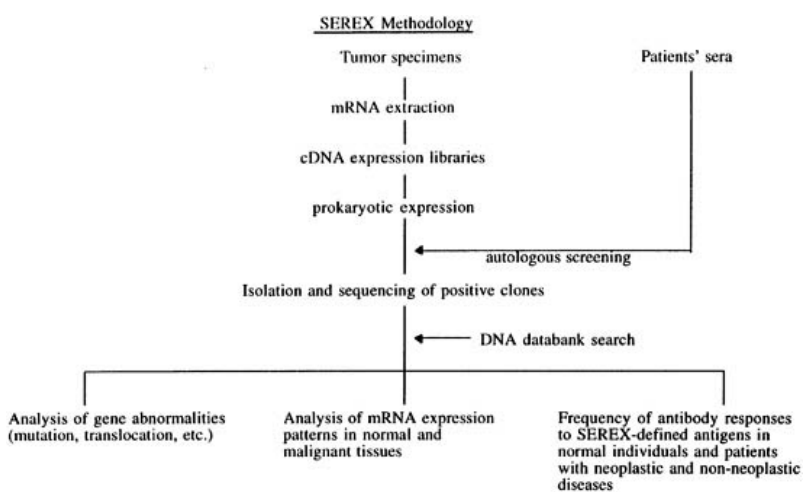
SEREX was developed to combine serological analysis with antigen cloning techniques to identify human tumor antigens eliciting high-titer immunoglobulin G (IgG) antibodies. The SEREX technique is shown schematically in Figure 16.7-1 . Although the concept behind SEREX is straightforward, a number of technical challenges needed resolution. One of the most crucial involved eliminating antibodies in human sera that react with bacterial or phage components. This step, usually done by repeated absorption of the diluted serum with bacterial and phage lysates, is absolutely essential because such contaminating antibodies would completely obscure the detection of other classes of antibodies. The second challenge is the presence of B cells in tumors, sometimes in quite large numbers. These B cells give rise to IgG complementary DNA (cDNA), which is expressed and detected in SEREX. The frequency of such IgG clones varies in each library but can represent substantial percentages of the clones. When present in high numbers, these clones have to be distinguished before the human serum screening step, and Türeci et al. (21) have devised a prescreening procedure that serves this purpose quite effectively. The third challenge, at least initially, was the suspicion that the majority of antibodies detected in SEREX would be autoantibodies with little or no relevance to cancer. Although known autoantigens do constitute a fraction of the SEREX antigens identified to date, such antigens have not been overrepresented. Part of the reason may be attributed to the initial decision of Pfreundschuh and his colleagues to exclude IgM from the analysis (by using secondary antibodies specific to IgG) and to focus on high-titered IgG antibodies (by performing the immunoscreening at serum dilution of 1:100 to 1:1,000).


FIGURE 16.7-1. Serological expression cloning (SEREX) approach to defining human tumor antigens. (cDNA, complementary DNA; mRNA, messenger RNA.)

After the initial selection of antibody-reactive clones in SEREX analysis, subsequent steps in SEREX analysis are directed to answering the following questions:

1.   Why is the antigen immunogenic?
2.   What role, if any, does the antigen have in the malignant process?
3.   Is the immune response to the antigen cancer related?

To address these issues, the first step is to sequence the clone to determine its relationship to known genes or motifs and to search for structural or functional modifications in the gene (e.g., mutations, translocations, and gene amplification). The messenger RNA (mRNA) expression pattern of the gene in panels of normal tissues and malignancies by reverse transcriptase-polymerase chain reaction (RT-PCR) and Northern analysis represents the next step to determine whether the gene has a restricted or nonrestricted pattern of expression. This expression pattern of the gene product is then extended to the protein level by generating polyclonal or MAb from animals immunized with recombinant SEREX-defined proteins and using them for biochemical characterization of the cellular protein and for immunohistochemical analysis. If not previously known, chromosomal mapping of the SEREX-defined gene is another important aspect of characterizing SEREX antigens. In evaluating the importance of SEREX-defined antigen in the context of cancer, the serological screening of sera from normal individuals, cancer patients, and patients with nonneoplastic diseases is of critical importance. These surveys of antibody responses to SEREX-defined antigens define whether the immune response is cancer restricted or whether the antigen is recognized by humans in a non-cancer-restricted fashion. To initiate such serological surveys, a small panel of sera from normal individuals and patients with cancer are screened against the SEREX-defined bacteriophage clone, a process called *petit serology.* SEREX isolates showing a cancer-restricted seroreactivity can then be tested in larger-scale serological surveys (grand serology) using purified recombinant protein as the antigenic target in enzyme-linked immunoassay (ELISA).

At this stage in the development of SEREX, few SEREX-defined antigens have been through this battery of steps in SEREX analysis. However, it is already known that the vast majority of SEREX-defined antigens appear to show universal or near universal mRNA expressions in normal tissues. Examples of differentially expressed SEREX genes have been found, but these are uncommon. Also, mutations and other structural modifications are rare, but more extensive sequencing should be carried out to exclude structural changes in the coding genes. What is encouraging is that SEREX has identified a number of gene products that have known or suspected relevance to cancer development (e.g., oncogenes and suppressor genes) and other products that have potential as targets for cancer vaccine. Additionally, the finding of SEREX-defined gene products that appear to be recognized by the humoral immune system of subsets of cancer patients but not normal individuals further emphasizes the potential of SEREX. The fact that a number of these genes are widely expressed in normal tissues indicates that cancer-specific recognition can occur in the absence of cancer-specific expression. The basis for this cancer-specific immunogenicity is one of the central challenges that need resolving.

Modifications in the SEREX Technique

Part of "16.7 - Identification of Human Tumor Antigens by Serological Expression Cloning "

Although SEREX analysis was initially developed to analyze the autologous humoral response to cancer—that is, tumor and serum from the same patient—a number of modifications on the original SEREX design have been introduced or are being considered (Table 16.7-1). The first variation, developed to discover new antigens belonging to the cancer-testis (CT) category—that is, antigens with restricted expression in normal testis and in cancer (see below)—involves the screening of sera from cancer patients on allogeneic testicular cDNA libraries, either unsubtracted or after subtraction with cDNA derived from nontesticular normal tissue. This approach has led to the recognition of several CT antigens, including new members of the SSX family (22), SCP-1 (23), and HOM-TES-85/CT8 (24). Another modification involves established tumor cell lines rather than fresh tumor as the source of cDNA for SEREX analysis. Although one of the great advantages of SEREX is that it circumvents the requirement for cultured tumor cells, cell lines can be a useful alternative target source of cDNA. This is illustrated by the analysis of SK-MEL-37, an established melanoma cell line that was chosen for SEREX because it expressed most, if not all, of the known CT antigens (25). A cDNA library from SK-MEL-37 was screened with allogeneic sera from a patient having high titers of antibody to two CT antigens, NY-ESO-1 and MAGE-1. This screening resulted in the isolation of the two known CT antigens, NY-ESO-1 and MAGE-4, and the discovery of a new member of the CT family, CT7. The use of cell lines for SEREX may be particularly useful in the case of tumors in which tumor specimens are difficult to obtain (e.g., small-cell lung cancer). A third modification involves a combination of representational difference analysis (RDA) (26) and SEREX. This approach is not SEREX-based cloning in the strictest sense, but rather uses

SEREX-based serology to identify seroreactivity to the products of genes cloned by the RDA approach. An example of this was the cloning of CT10 (27). CT10, a gene sharing homology to CT7 and members of the MAGE family, was initially cloned by RDA as a gene abundantly expressed in SK-MEL-37 but not in normal skin. After initial RDA cloning, the cDNA was subcloned into the same expression vector used for SEREX, and the resulting phage clone was tested against a panel of absorbed serum samples from tumor patients. In this manner, the immunogenicity of RDA-identified gene products can be analyzed and documented.

Table 16.7-1 Variations in SEREX Methodology

cDNA library source
  Allogeneic tumor
  Testis
  Tumor cell lines
Vector system
  Filamentous phage and other prokaryotic expression systems
  Baculovirus and other eukaryotic expression systems
Antibody source
  Allogeneic sera from cancer patients
  Sera from cancer patients after cancer vaccination
  IgM and other Ig subclasses
  Oligoclonal or monoclonal human antibody
  Recombinant clonal IgG
Combined approaches of SEREX with other cloning methods
  RDA/SEREX, SAGE/SEREX, differential display/SEREX

cDNA, complementary DNA; Ig, immunoglobulin; RDA, representational difference analysis; SAGE, serial analysis of gene expression; SEREX, serological expression cloning.

In addition to extending the antigenic targets for SEREX analysis beyond the autologous tumor (e.g., testis, tumor-cell lines, and RDA) different sources of antibodies other than autologous and allogeneic sera are being explored. Human oligoclonal or MAb generated from B cells (directly after isolation or after expansion *in vitro*) from peripheral blood, tumor, or draining lymph nodes of cancer patients are promising sources that need investigation. Additional serological probes could come from cDNA cloning of IgG sequences expressed by tumor-infiltrating B cells of cancer patients.

SEREX-Defined Antigens by Tumor Type

Part of "16.7 - Identification of Human Tumor Antigens by Serological Expression Cloning "

SEREX has been applied to a range of tumor types, including melanoma (19,22,25), esophageal cancer (28), colon cancer (29), lung cancer (30,31 and 32), renal cancer (23,33), gastric cancer (34), breast cancer (35-37), astrocytoma (19), prostate cancer (38,39), seminoma (24), and hematologic malignancies, including Hodgkin's lymphoma (19) and leukemia (40). These SEREX studies and examples of the clones isolated are summarized in relation to individual tumor types in Table 16.7-2 .

Table 16.7-2 SEREX Analysis of Human Cancer

cDNA Source	Serum Source	No. Positive Clones	No. Genes (Known/Unknown)	Examples of Genes	References
Melanoma	Autologous	40	10	MAGE-1, tyrosinase, SSX2	Sahin et al. (19)
Testis	Allogeneic melanoma	8	8 (7/1)	SSX2, SSX3	Güre et al. (22)
Melanoma cell line	Allogeneic melanoma	61	16 (10/6)	CT7, KOC, MAGE-4	Chen et al. (25)

Gastric cancer[a]	Autologous	297	135(87/48)	E-cadherin/gene Y, AKT1	Obata et al. (33)
Renal cancer	Autologous	7	5	Carbonic anhydrase XII	Sahin et al. (19)
Testis	Allogeneic renal cancer	5	3	SCP1	Sahin et al. (23)
Renal cancer[a]	Autologous	169	65 (36/29)	LKB/STK11, *bcr*, LUCA15, g21	Scanlan et al. (33)
Lung cancer	Autologous	35	19 (10/9)	eIF-4 gamma, amplified genes	Brass et al. (30,31)
Lung cancer	Autologous	20	12 (5/7)	Aldolase A, NY-LU-12/g16	Güre et al. (32)
Breast cancer	Autologous	38	16 (13/3)	NY-ESO-1, SSX2, *ING1*	Jäger et al. (35)
Breast cancer	Allogeneic	23	9 (9/0)	NY-ESO-1	Jäger et al. (35)
Testis	Allogeneic breast cancer	28	10 (8/2)	SSX2, *ING1*	Jäger et al. (35)
Breast cancer[a]	Autologous	86	48 (26/22)	CDC10, Notch/int3-like, helicase-like	Scanlan et al. (36)
Breast cancer[a]	Autologous	94	55 (34/21)	SSX2, hsp105	Obata et al. (37)
Hodgkin's disease	Autologous	14	4	Galectin-9, restin	Türeci et al. (21)
Prostate cancer	Autologous	19	18 (10/8)	Replication licensing factor B unit	Chen et al. (38)
Prostate cancer	Autologous	56	30 (17/13)	eIF-4 gamma, NFκB p105	Obata et al. (39)
Astrocytoma	Autologous	48	5	Tegt	Sahin et al. (19)
CML	Autologous	8	8(6/2)	clone no. 4 (CT gene?)	Ling et al. (40)
Bladder cancer line	Allogeneic hepatoma	1	1	p62/KOC3	Zhang et al. (43)
Testis	Allogeneic seminoma	9	6(4/2)	CT8, hook-1 protein	Sahin et al. (23)

cDNA, complementary DNA; CML, chronic myeloid leukemia; CT, cancer-testis; Tegt, testis-enhanced gene transcript.
[a]Multiple libraries screened: four colon cancers, five gastric cancers, four breast cancers, and four renal cancers (including one autologous renal cancer cell line).

Melanoma

Several SEREX studies have focused on melanoma tumor specimens, melanoma cell lines, and sera from melanoma patients (19,22,25). In their initial analysis, Sahin et al. (19) screened a melanoma library of 1.0 × 10⁶ clones and isolated 40 positive clones representing ten different gene products. These included tyrosinase and two CT antigens, MAGE-1 and HOM-MEL-40/SSX2. To extend the search for CT antigens recognized by melanoma patient sera, a testicular cDNA library was screened by Güre et al. (22). This resulted in the isolation of eight gene products, including six universally expressed genes and two members of the SSX family, SSX2 and a new member SSX3. Southern blot analysis confirmed SSX as a multigene family, and subsequent PCR-based cDNA cloning led to the identification of two additional SSX members, SSX4 and SSX5, both transcribed in testis and in malignancy (see below).

To further extend this search for CT antigens, a cDNA library was constructed from SK-MEL-37, a melanoma cell line expressing multiple CT antigens, and the library was screened with an allogeneic melanoma patient serum known to have antibodies to two CT antigens, NY-ESO-1 and MAGE-1 (25). Sixty-one positive clones were identified, including four CT antigen genes: MAGE-4a, NY-ESO-1, LAGE-1 [a gene closely related to NY-ESO-1 (28,41)], and a new CT antigen CT7. Additionally, the most abundantly represented clones in this screening, 33 of 61 positive clones, were derived from three closely related genes. One of these three

genes, called *KOC* (*K*H domain-containing gene *o*verexpressed in *c*ancer), had been previously identified as a gene overexpressed in pancreatic cancer (42). These three genes were designated KOC1 (the original KOC gene), KOC2, and KOC3, of which KOC3 was most abundantly expressed (30 of 33 isolated clones). Northern blot analysis of KOC3 expression showed variable levels of mRNA expression in melanoma cell lines and no detectable mRNA in any normal tissue examined. Subsequently, KOC3 was also cloned from a bladder cancer line by antibody screening using serum from a hepatocellular carcinoma patient (43) (see below).

Esophageal Cancer

An esophageal cancer cDNA library derived from a squamous cell carcinoma has been analyzed (28). Thirteen positive clones were identified, derived from eight different genes, designated NY-ESO-1 through NY-ESO-8. Among these, NY-ESO-1 showed a characteristic cancer-testis expression pattern, and NY-ESO-5 appeared to be preferentially expressed in squamous epithelium. Other genes were found to be universally expressed, including two genes coding for autoimmune antigens in the U1 small nuclear ribonucleoprotein family.

Colon Cancer

SEREX analysis of four colon cancer cDNA libraries has been carried out by Scanlan et al. (29). A total of 234 immunoreactive cDNA clones encoding 48 different antigens were identified. Sequence analysis revealed 17 novel genes and 31 known genes coding for a vast array of cellular components. A large proportion of the antigens were nuclear proteins, such as transcription factors, mRNA splicing factors, and DNA-binding proteins, and a smaller percentage represented metabolic enzymes, molecular chaperones, signaling molecules, cytoskeletal proteins, and membrane-associated proteins. In addition to these common cellular constituents, however, several of the colon cancer antigens stood out as having a known or suspected etiologic association with human cancer; the most obvious example of this being the isolation of a mutated version of p53 tumor-suppressor gene (NY-CO-13). RT-PCR analysis and Northern blotting showed that transcripts encoding 3 of the 48 antigens were differentially expressed, whereas the other 45 genes were universally expressed. NY-CO-27 is identical to the S-type lectin galectin-4 (44), and is expressed primarily in normal colon and small intestine. The other two differentially expressed antigens, NY-CO-37 and NY-CO-38, are related isoforms encoded by a previously unknown gene that maps to chromosome 11p15.4-p15.1 (45). These two antigens are members of a group of differentially expressed isoforms that are characterized by a variable number of PDZ domains, the presence or absence of a PEST protein degradation motif, a large coiled-coil domain, and the existence of a putative C-terminal module that may function as a binding site for PDZ domains (indicating that it may form homomeric or heteromeric protein complexes). In general, PDZ domains function as scaffolding sites for the organization of signal transduction complexes, cell junctions, and cytoskeletal-plasma membrane linkages (46). A yeast 2-hybrid screen of proteins that interact with the Coxsackie and adenovirus receptor identified NY-CO-38 (or a related isoform) as an interacting protein (R. Finberg, *personal communication*, 1999). One of the NY-CO-38 isoforms is expressed in some normal tissues but is not found in normal colon. In contrast, this isoform is expressed in colon cancer, and this aberrant expression of a normally expressed isoform in cancer may be the basis for its immunogenicity in cancer patients (see below).

Gastric Cancer

SEREX analysis of five cases of gastric carcinoma derived from tumors of various histologic types and grades has been carried out by Obata et al. (34). The screening of each cDNA library with autologous serum was continued until approximately 50 positive clones were isolated from each library. In total, 297 positive clones were obtained, representing 135 distinct genes, 87 of which were previously known. Of the 135 gene products, 21 were identified in two or more gastric cancer libraries and 24 were identified in SEREX analysis of other tumor types. No CT antigens were isolated, consistent with the low frequency of CT gene expression in gastrointestinal cancer (28,47).

Of the genes isolated, two showed possible etiologic significance for gastric cancer. One was derived from a fusion gene product between E-cadherin (E-Cad) and a novel gene designated as *GeneY*. E-Cad is an adhesion molecule involved in the regulation of various cellular functions, including normal differentiation and tumor invasion (48). Mutations in E-Cad have been identified in gastric and other cancers and inherited mutations have been related to familial gastric cancer (49,50). Nine independent cDNA clones encompassing the fusion gene were isolated and the combined sequencing data indicated that the 5" end of E-Cad was fused to the 3" end of GeneY. RT-PCR using a 5" primer derived from E-Cad and a 3" primer derived from GeneY showed that the amplification product was restricted to the tumor and was not detected in autologous nonneoplastic tissue or allogeneic normal or tumor tissues. This finding indicates a somatic translocation event involving E-Cad and GeneY in the cancer, an event possibly contributing to the cancer's origin or progression. Although this translocational event was not found in five other cases of gastric cancer in this small series or reported in the literature, a larger panel of gastric cancer specimens should be evaluated to assess the frequency and significance of this genetic alteration.

A second gene, recognized by the serum of a different gastric cancer patient and also related to gastric carcinogenesis, is the AKT1 (PKB) oncogene. AKT1 gene is thought to promote cell survival by modulating antiapoptotic signals, and AKT1 gene amplification has been reported in a primary gastric cancer (51). AKT1 expression was elevated in five of eight gastric cancers, and one of the five patients with amplified AKT1 expression had an anti-AKT1 antibody response. Overexpression of this gene presumably forms the basis for its immunogenicity in cancer patients.

Renal Cancer

In the initial study by Sahin et al., five different antigens were isolated from a single renal cell carcinoma cDNA library screened with autologous serum (19). Of these, HOM-RCC-3.1.3

is a type I integral-membrane protein (40 kd) representing a novel tumor-associated carbonic anhydrase (CA XII). The coding gene for CA XII maps to chromosome 15q22 (52). CA XII is expressed in normal kidney, small intestine, and renal cancer. In 10% of the renal cancer examined, RCC-3.1.3 mRNA was expressed at a much higher level than in adjacent normal kidney tissue (19,52).

In a subsequent study by Sahin et al. (24), serum from a patient with renal cancer was used to screen a testicular library subtracted with a range of normal tissues. The aim of the screening was to uncover new members of the CT family. Five positive clones representing three genes were isolated, one encoding synaptonemal complex protein 1 (SCP1), a protein involved in chromosome reduction during meiosis. The expression of SCP1 is normally restricted to germ cells and was not previously known to be expressed in cancer. However, Sahin et al. found SCP1 mRNA and protein expression in a subset of malignant gliomas, breast cancers, renal cancers, and ovarian cancers. Thus, SCP1 belongs to the CT antigen category.

Four additional cases of renal cancer were analyzed in SEREX by Scanlan et al. (33) using autologous patient sera. These studies yielded a total of 169 clones representing 65 different gene products. Sequence analysis showed that 36 were coded by known genes and 29 were novel gene products. Four of the antigens, NY-REN-9, -10, -19, and -26, have a known association with human cancer. NY-REN-9 (LUCA-15) and NY-REN-10 (gene 21) map to the p21.3 locus on chromosome 3, a region presumably containing tumor suppressor gene(s), which is often deleted in small-cell and non-small-cell lung cancer (53) and renal cancer (53,54). REN-19 is identical to LKB/STK11 serine-threonine kinase. Defects in the LKB/STK11 gene are responsible for Peutz-Jeghers syndrome, a disease characterized in part by an increased risk of gastrointestinal cancer (55). Somatic mutations in the LKB1/STK11 gene have also been reported in cases of colon cancer (56), breast cancer (57), and gastric cancer (58). NY-REN-26 is encoded by the *bcr* gene involved in the [t(9:22)] *bcr/abl* translocation associated with chronic myelogenous leukemia (59). No evidence of gene mutation was detected in the cDNA sequences of clones defining NY-REN-9, -10, -19, or -26. In addition to these four genes, two others, NY-REN-33 and NY-REN-65, are related to less well-characterized potential tumor suppressor genes. NY-REN-33 is identical to a possible tumor suppressor, SNC6 (GenBank U28918), which maps to 22q13.1, a region known to be deleted in cases of breast cancer (60). NY-REN-65 maps to 11q12 and is a possible human homologue of the rat HREV107 tumor suppressor gene (GenBank X92814).

With regard to tissue mRNA expression, transcripts encoding all 65 antigens are expressed in a range of normal tissues as determined by expressed sequence tag analysis, RT-PCR, and/or Northern blotting. However, three antigens, NY-REN-3, NY-REN-21, and NY-REN-43, have a differential mRNA expression pattern. NY-REN-3 is identical to NY-CO-38 (described above), belonging to a family of differentially expressed isoforms with PDZ domains. Both NY-REN-21 and NY-REN-43 transcripts are expressed at higher levels in testis than in other normal tissues. NY-REN-21 represents a possible human homologue of mouse zinc finger protein-38 (61), a DNA-binding protein thought to be involved in meiosis, and NY-REN-43 cDNA encodes a putative protein containing a ring-zinc finger domain and a polyserine domain.

Lung Cancer

Two SEREX studies of lung cancer have been reported (30,31 and 32). Brass et al. (30,31) derived 35 positive clones representing 19 genes from the autologous screening of a squamous cell carcinoma cDNA library. Six clones coded for eIF-4 gamma, an eukaryotic translation initiation factor, which maps to chromosome 3q26.1-3q26.3, a region that is amplified in 30% of squamous lung cancer (62). By comparative PCR analysis, the authors showed that eIF-4 gamma and eight other genes were amplified in the tumor of origin, including DnaJ heat shock protein and Jk-recombinant signal binding protein, two genes also found in the SEREX analysis of renal cancer (NY-REN-14, NY-REN-30) (29). Three of the amplified genes were located on chromosome 3, and two of these mapped to the 3q region. The authors suggested that immune recognition is a consequence of amplified gene expression, and that amplified eIF-4 gamma may be important in the development of squamous cell carcinoma.

In a separate study, Güre et al. (32) analyzed a moderately differentiated adenocarcinoma of the lung with autologous serum and isolated 20 positive clones representing 12 genes. One of these was aldolase A, a gene known to be expressed at high levels in most lung cancer (63,64). Aldolase A has been subsequently isolated in SEREX analysis of breast cancer (35), indicating a possible linkage of aldolase A overexpression to adenocarcinomas of various tissue origin. Another SEREX-defined gene of special interest, NY-LU-12, maps to the tumor suppressor gene locus on chromosome 3p21.3, as do NY-REN-9 and NY-REN-10 from renal cancer (see above). NY-LU-12 encodes a nuclear zinc finger protein with two RNA-binding domains. To date, no mutations have been found in the NY-LU-12, NY-REN-9, or NY-REN-10 coding genes. What is the basis for the immunogenicity of these 3p antigens? Further sequencing is necessary to exclude the possibility of mutation as the immune stimulus. Another possibility is that loss or downregulated expression of a gene product such as allelic 3p deletion can result in an immune response, just as gain or overexpression can be an immunogenic event.

In addition to the published studies, Güre and Chen *(unpublished data)* have screened three additional non-small-cell lung cancers. These three screenings yielded only eight positive clones from a total of more than 2×10^6 bacteriophages, and the clones represented two known genes and two unknown genes, all of them widely expressed in normal tissues. Low-yield SEREX screening is, in fact, not uncommonly encountered, most likely reflecting low tumor immunogenicity or low host immune reactivity, or both. Such essentially negative studies should be recognized because they are unlikely to be published and are therefore underrepresented in the literature.

Breast Cancer

A number of studies targeting breast cancer are ongoing within the SEREX efforts coordinated by the Ludwig Institute for Cancer Research (see below).

Jäger et al. (35) screened one breast cancer library with two separate serum sources—autologous serum and a pool of seven allogeneic sera from breast cancer patients. Additionally, a testicular library was also screened with the autologous serum. These analyses led to the isolation of 89 clones derived from 30 different genes, 27 known and three unknown. Among the known genes were two encoding CT antigens, NY-ESO-1 and SSX2, and these were prominently represented, constituting 31 (14 NY-ESO-1, 17 SSX2) of the 89 positive clones. In addition to these two genes, a candidate breast tumor suppressor gene, *ING1*, was isolated from both the breast cancer library and the testicular library. *ING1* was initially identified in the cloning of genes preferentially expressed in a normal breast epithelial cell line but not in breast cancer lines; transfection of a breast cancer cell line with the *ING1* gene was shown to lead to growth inhibition (65). No mutation has been found in the SEREX-defined *ING1* gene from the breast cancer specimen. By analyzing cDNA clones obtained by hybridization screening of the testicular library, however, three splice variants of *ING1* (variants A, B, and C) were identified. These three variants differed in their 5" sequences, encoding putative products with different amino terminal sequences. By RT-PCR analysis, only variant A showed universal expression in all tissues examined. Variants B and C were expressed in a tissue-specific fashion, whereas variant C showed expression almost exclusively in the testis. Among tumor cell lines, variant C was silent in six breast cell lines tested, and variant B, although not expressed in normal breast, was weakly expressed in four of six breast cancer cell lines tested. As discussed above in relation to NY-CO-37/38, perturbation in the tumor expression of *ING1* splice variants may account for immune recognition in the human host.

Scanlan and Gout (36) have screened four breast cancer cDNA libraries with autologous sera, yielding 53 different genes, half of them known genes and half of them novel. Of the novel gene products, three may be of etiologic significance for cancer: LONY-BR-23, which is structurally related to members of the CDC 10 family of cell-cycle regulators; LONY-BR-49, which is similar to Notch/int3; and LONY-BR-53, which shows homology to SNF2/RAD54 helicase.

Obata et al. (37) have performed autologous SEREX screenings of two breast cancers and isolated 94 reactive clones. These clones represented 55 different genes, 34 known and 21 unknown. Eighteen (33%) of the 55 were also identified by previous SEREX analysis of other breast cancers or other cancers. Among the gene products identified in these two screenings were the CT antigen SSX2, heat shock protein hsp105 (nine clones), and guanylate binding protein isoform II (five clones).

Hodgkin's Disease

A case of Hodgkin's disease was analyzed in the initial SEREX study of Sahin et al. (19). Of 1.0×10^6 clones screened, 14 positive clones were identified, representing four genes. Of most interest was HOM-HD-21, which encodes a new member of the galactoside-binding protein family, designated galectin-9 by Türeci et al. (21). This gene contains two lectin domains with galactoside binding capacity, and its expression was found to be restricted to peripheral blood leukocytes and to lymphoid tissues. Serum reactivity to galactin-9 has been found to be restricted to patients with Hodgkin's disease, supporting a close association of galectin-9 with the disease. Another clone identified in this initial SEREX screening was a splice variant of the intermediate filament protein restin. Unlike seroreactivity to galectin-9, antibody to the restin splice variant was frequently found in normal individuals, as well as in patients with Hodgkin's disease (19).

Prostate Cancer

SEREX analysis of prostate cancer with autologous sera is being carried out by Chen et al. (38) and by Obata et al. (39). Chen et al. isolated 19 positive clones derived from 18 genes (ten known and eight unknown), including genes encoding DNA replication licensing factor β subunit, acid finger protein, and scaffold attachment factor. Obata et al. isolated 56 positive clones, representing 30 different genes, 17 known and 13 unknown. Among the known gene products were eIF-4 gamma and NFκB p105. The known and unknown genes derived from these studies of prostate cancer were found to be widely expressed in normal tissues.

Other Tumor Types

SEREX analysis of astrocytoma (19), chronic myeloid leukemia (40), hepatocellular carcinoma (43), and seminoma (24) have also been initiated.

In the study of astrocytoma by Sahin et al. (19), 48 positive clones were isolated representing five gene products. One of the genes was Tegt (testis-enhanced gene transcript), a gene developmentally regulated in the testis (66). Tegt was found to be overexpressed in 8 of 12 astrocytomas, but not in other cancers.

SEREX analysis of a cDNA library from a case of chronic myeloid leukemia with autologous serum identified eight positive clones, corresponding to six known and two unknown genes (40). One of the two unknown genes, referred to as *clone #4*, was shown to be expressed exclusively in testis, and not in the normal tissues tested (bone marrow, brain, lung, small intestine, muscle, or spleen), suggesting that it is a new member of the CT family.

Zhang et al. (43) have carried out an analysis of T24 bladder cancer cell line with serum from a patient with hepatocellular carcinoma. The KOC3 gene, previously identified as SEREX-defined antigen in melanoma, was isolated (see above). This indicates that KOC-related gene products are overexpressed in more than one tumor type and are often immunogenic.

In one study, Sahin et al. (24) screened a cDNA library enriched for testis-specific transcripts with serum from a seminoma patient. Nine clones were isolated, derived from four known and two unknown genes. The known genes included human hook-1 protein and a mitotic protein. One of the two unknown genes, HOM-TES-85, was found to encode a new CT antigen, and this gene was designated CT8. Sequence analysis revealed that CT8 gene product is a leucine zipper protein. Of interest, the leucine zipper region of the CT8 protein shows an atypical amphipathy, a feature that has only been observed in the N-myc proto-oncogene (24).

Classification of SEREX-Defined Antigens

Part of "16.7 - Identification of Human Tumor Antigens by Serological Expression Cloning "

Given the large number of gene products identified by SEREX, it would be useful to develop a classification system that could organize them into meaningful categories. The challenge is to decide on which characteristic or characteristics of the antigen should be chosen to form the basis for categorization. As unknown genes are responsible for approximately 30% of the SEREX sequences and the number of SEREX-defined antigens continue to increase at a rapid rate, it is clearly premature to attempt a comprehensive classification at this time. However, antigens with related characteristics can readily be identified at this point. For instance, antigens can be grouped according to their cellular location, and it is particularly striking that so many of the SEREX-defined antigens are nuclear proteins (e.g., enzymes and factors involved in DNA replication, transcriptional control, RNA elongation, DNA repair, including zinc finger proteins, RNA helicases, proteins related to the mitotic apparatus, and chromosome condensation proteins). Although it is tempting to conclude that the immune responses to these nuclear antigens are nonspecific and are related to the high cell turnover and necrosis associated with cancer, it would be premature to exclude the possibility that immunogenicity is a consequence of specific structural changes in these proteins or their expression patterns.

Another way to group the antigens would be by functional characteristics, and a broad array of functionally related proteins can be found among SEREX-defined antigens, including metabolic enzymes (e.g., lactic dehydrogenase, aldolases, pyridoxal kinase, adenylosuccinate lyase, glyceraldehyde-3-phosphate dehydrogenase), transcriptional and translational factors (e.g., zinc finger proteins, translation initiation factors), structural proteins (e.g., histone proteins, keratin, restin, and lamin), and stress proteins (e.g., heat shock proteins). In the context of tumor biology and tumor immunity, however, antigens of greatest interest would be those having a known relation to cancer or showing cancer-restricted expression or cancer-restricted immunogenicity. These would be tumor antigens of most importance for diagnostic or therapeutic applications (e.g., vaccine use). A number of SEREX antigens with these cancer-related characteristics have been identified and can be classified into one of the following six categories (Table 16.7-3).

Table 16.7-3 Categories of SEREX-Defined Human Tumor Antigens

Antigen Category	Examples	Serum Source for Initial Isolation
Cancer-testis	NY-ESO-1	Esophageal cancer
	SSX	Melanoma
	CT7	Melanoma
Mutational	p53	Colon cancer
Differentiation	Tyrosinase	Melanoma
	Galectin-4	Colon cancer
Amplified/overexpressed	Carbonic anhydrase XII	Renal cancer
	KOC3	Melanoma, hepatoma
	eIF-4 gamma	Lung cancer
	HER-2/*neu*	Breast cancer
Splice variant	Restin	Hodgkin's disease
	NY-CO-37/38	Colon cancer
Retroviral	HERV-K10	Renal cancer

HERV, human endogenous retrovirus; KOC, *K*H domain-containing gene *ov*erexpressed in *c*ancer.

Cancer-Testis Antigens

CT antigens share the following characteristics:

- Predominant mRNA expression in testis, but generally not in other normal somatic tissues.
- Gene activation and mRNA expression in a variable proportion of a wide range of human tumor types.
- Existence of multigene families.
- Frequent mapping of coding genes to chromosome X.

Table 16.7-4 summarizes the CT antigens identified to date. Of these, MAGE, BAGE, and GAGE were initially identified as cytotoxic T lymphocyte (CTL)-recognized antigens (47,67), and SSX, NY-ESO-1, SCP1, CT7, and CT8 were discovered by SEREX analysis. MAGE-C1, a gene identical to CT7, was independently cloned by representational difference analysis (RDA) using testicular cDNA after subtraction hybridization with other

normal tissue cDNAs (68). Similar RDA approaches have also led to the identification of LAGE-1 (42), a second gene in the NY-ESO-1 family, and CT10 (27). Both LAGE-1 and CT10 have subsequently been found to be recognized by antibodies in patient sera, confirming that they are immunogenic. CT9 was identified through mRNA-expression analysis of known or suspected testis-specific genes in tumors (69), but has not been shown to elicit an antibody response in humans.

Table 16.7-4 Characteristics of Human Cancer/Testis Antigens

Gene/Gene Family	No. of Genes	Chromosome	CTL Recognition	Ab Recognition	References
MAGE	16	Xq28/Xp21	+	+	19, 67, 85
BAGE	Unknown[a]	Unknown	+	Unknown	67
GAGE	6	Xp21-pter	+	Unknown	67
SSX	5	Xp11	Unknown	+	22, 67, 85
NY-ESO-1	2	Xq28	+	+	28, 41, 85, 86
SCP1	Unknown[a]	1p13	Unknown	+	23
CT7/MAGE-C1	1	Xq26	Unknown	+	25, 68
CT8	Unknown	Unknown	Unknown	+	24
CT9	1	1p	Unknown	Unknown	69
CT10	1	Xq27	Unknown	+[b]	28

CT, cancer-testis; CTL, cytologic T lymphocyte.

[a]Southern blot analysis suggests a multigene family for both BAGE and SCP1.

[b]CT10 recognition by human serum has been shown by enzyme-linked immunoassay.

Of the MAGE family, MAGE-1, first defined by CTL epitope cloning (47,67), was also isolated by SEREX from a case of melanoma (19). MAGE-4a, another member of the MAGE family, though not as yet been shown to elicit a CTL response, has been isolated from melanoma and ovarian cancer by SEREX (25). Other members of the MAGE family (e.g., MAGE-3 and MAGE-6), although shown to be CTL targets (47,67,70), have not been identified by SEREX.

SSX2, also known as *HOM-MEL-40*, was isolated from melanoma by SEREX (19). SSX2 was originally recognized as a gene mapping to chromosome X that was involved in the t(X;18) translocation invariably associated with synovial sarcoma (71). Additional members of the SSX family have been cloned (71,22), and the five members of the SSX family have been shown to be transcribed in testis. Of these, only SSX1, -2, and -4 show significant expression in cancers. Expression pattern analysis revealed expression of SSX1, -2, and -4 in a proportion of malignancies of various origins, whereas SSX5 is only rarely expressed (~1% of the tumors examined), and SSX3 is silent in all tumors examined. This pattern of discordant expression of SSX genes and other CT genes mapped to chromosome X suggests the existence of gene-specific mechanisms for activation of CT antigens, in addition to other general mechanisms of gene activation, such as global demethylation (72).

NY-ESO-1 was isolated from an esophageal squamous cell carcinoma by SEREX and has been shown to be expressed in 20% to 40% of several common tumor types, including breast cancer, lung cancer, prostate cancer, bladder cancer, head and neck cancer, and melanoma. A highly homologous gene (84% amino acid identity), LAGE-1, has been found by RDA by Lethè et al. (42). Both NY-ESO-1 and LAGE-1 appear to be expressed in tumors in similar frequencies, and both are recognized by patients' sera (25).

SCP1 is a synaptonemal complex protein involved in chromosome reduction in meiosis (73) and was detected in a subtractive testicular library with serum from a patient with renal cancer (23). SCP1 has the distinction of being the only CT antigen with a defined function. The finding of a meiotic protein aberrantly expressed in a somatic neoplastic cell raises the provocative question of its role in the chromosomal aneuploidy of cancer.

CT7 was isolated by allogeneic screening of melanoma cell line SK-MEL-37 with a melanoma patient serum. This gene encodes a protein of 1,142 amino acid residues, with a carboxyl terminus highly homologous to the MAGE-10 gene over an ~210 amino acid stretch (57% identity, 75% homology, including conserved substitutions). Sequences N-terminal to this segment, however, show no homology to the MAGE family, having instead a striking repetitive pattern, with a core of ten almost exact repeats of 35 amino acids. This gene has also been isolated by Lucas et al. (68) using the RDA approach and has been designated MAGE-C1.

CT8 was isolated by Sahin et al. (24) by SEREX analysis of a subtracted testicular library with serum from a seminoma patient. It encodes a 36-kd protein with a leucine zipper motif, characteristic of proteins involved in DNA binding and gene transcription.

CT9 (69) is the bromo domain, testis-specific gene product BRDT (74). BRDT is a putative nuclear protein of 947 amino acids (108 kd) containing two copies of the bromo domain, a motif associated with transcriptional regulation. BRDT was identified as a CT antigen during the screening of previously defined testis-specific genes for expression in malignancies. Unlike other CT antigens that are expressed in a wide range of tumors, CT9 appears to show preferential expression in lung cancer.

CT10 was isolated from melanoma using RDA by Güre et al. (27). It is structurally closely related to CT7 but lacks the repetitive sequences of CT7. It maps to chromosome Xq27 in close proximity to CT7 and MAGE genes. ELISA analysis of 100 melanoma patient sera against recombinant CT10 protein revealed seroreactivity in two cases, demonstrating the immunogenicity of CT10.

Mutational Antigens

A mutated p53, identified during a SEREX analysis of a colon cancer (29), carried a single-base substitution (TAT to TGT). Another example in this category is the translocation involving E-Cad, detected in the SEREX analysis of gastric cancer (34). These findings illustrate the capacity of SEREX to identify products of mutated genes. As discussed above, three genes coding for products identified by SEREX are clustered in chromosome 3p21, a region long known to be a hot spot of genetic aberrations in many cancer types and postulated to harbor tumor suppressor genes (53,54). Two of the three genes, NY-REN-9 and NY-REN-10, were derived from renal carcinoma and correspond to LUCA-15 and gene 21, respectively (33). The third gene, NY-LU-12, isolated from lung cancer, was identical to gene 16, which maps to the telomeric breakpoint of a small-cell lung cancer line NCI-H740 (32). Although no mutation has been detected to date in these three genes, mutations may have been missed: wild-type rather than the mutated allele of the 3p genes might have been isolated in SEREX because the antibody elicited by the mutated 3p product cross-reacts with the wild-type product.

Differentiation Antigens

The classic example of a differentiation antigen recognized by SEREX is the melanocyte-specific protein tyrosinase (19). Another example is NY-CO-27, a gene identical to galectin-4, that was isolated during a SEREX analysis of colon cancer (29). Normal tissue expression of galectin-4 is restricted to normal colon and small intestine. Because galectin-4 is localized to the leading edge of lamellipodia, it is thought to have a role in cell adhesion (44).

A number of other genes isolated by SEREX could also be classified as differentiation antigens because they show a differential pattern of gene expression in normal tissues. For instance, CT antigens, because of their restricted expression in normal

testis, represent a special category of differentiation antigens. As many of these other SEREX-defined genes with differential expression are either amplified, overexpressed, or show aberrant splice variants in cancer, however, they are discussed under these categories of tumor antigens.

Amplified or Overexpressed Antigens

Overexpression of normal gene products in cancer may be a major underlying mechanism for the immunogenicity of cancer antigens in cancer patients. Examples of amplified or overexpressed SEREX-defined antigens include carbonic anhydrase XII in renal cancer (52), galectin-9/HOM-HD-21 in Hodgkin's disease (21), eIF-4 gamma (30) in lung cancer, aldolase A in lung cancer (32) and breast cancer (35), KOC family genes in melanoma (25), hepatoma (41), and AKT1 (37) and HER-2/*neu* (36) in breast cancer. Several mechanisms can account for amplified expression of gene products in cancer, including gene amplification (e.g., eIF-4 gamma), increased steady-state mRNA (e.g., KOC3), and increased protein stability (e.g., p53) (75). The frequency of gene amplification in SEREX-defined genes has been examined by Brass et al. (31), and 9 of 14 genes detected in a SEREX analysis of lung cancer were shown to be amplified by quantitative PCR, including three genes from chromosome 3, at least two of which were from a region known to be amplified in squamous cell carcinoma.

Splice Variant Antigens

Another category of SEREX-defined antigens are splice variants of genes that are differentially expressed in normal tissues. In the initial SEREX study by Sahin et al. (19), a splice variant of the intermediate filament protein restin was isolated from Hodgkin's lymphoma and was found to react with sera from both cancer patients and normal donors. In the SEREX analysis of colon cancer (29), two of the isolated antigens NY-CO-37 and NY-CO-38 represent differentially expressed isoforms of a previously unknown gene containing PDZ protein-protein interaction domains (45). In total, five splice variants of NY-CO-38 have been defined [PDZ-37, PDZ-45 (NY-CO-37), PDZ-54, PDZ-59, and PDZ-73 (NY-CO-38)], and their expression patterns in normal and malignant tissues have been characterized. One of these variants, PDZ-54, is normally expressed in normal kidney and brain but not in normal colon. However, PDZ-54 is expressed in all cases of colon cancer tested.

Viral Antigens

Human endogenous retrovirus (HERV)-related sequences have been shown to represent at least 1% of the human genome, and their gene products have been linked to the development of autoimmune and neoplastic diseases, including systemic lupus erythematosus (76), rheumatoid arthritis (77), and germ cell tumors (78). Of these sequences, HERV-K exists in 25 to 30 copies per haploid human genome, and HERV-K-encoded env and gag proteins are expressed consistently in germ cell tumors, leading to high-titer antibodies in 60% to 85% of patients with these tumors (78,79). Although HERV-K has not been shown to be expressed in renal tissue, the env protein of this retroviral sequence, HERV-K10, was isolated from renal cancer by SEREX (19) and represents the sole example of a SEREX-identified viral antigen to date.

Basis for the Immunogenicity of SEREX-Defined Antigens

Part of "16.7 - Identification of Human Tumor Antigens by Serological Expression Cloning "

In the case of the great majority of SEREX-defined antigens, it is unclear why they elicit a humoral immune response. The important point would be to distinguish antigens that have no direct relevance to cancer (e.g., antigens detected by preexisting autoantibodies or antibodies elicited by antigens related to necrotic tumor products) from antigens that have some casual relation to cancer etiology or cancer phenotype. Past studies have demonstrated a high frequency of autoantibodies to known normal tissue autoantigens in cancer patients (80), and it would not be surprising that a significant proportion of the currently defined SEREX antigens are autoantigens of this kind. However, the importance of these antigens in the context of cancer antigens should not be dismissed without understanding the reason for their immunogenicity in cancer patients. For instance, mutational events in the tumor may elicit antibodies that cross-react with the corresponding nonmutated counterparts in normal cells. Under these circumstances, the immunogenic stimulus for the antibody response in cancer patients is in fact a mutated or altered gene product, but, because the resulting antibody cross-reacts with the wild-type protein, the wild-type gene (from admixed normal cells or nonmutated alleles) might be isolated in SEREX. Unless the mutated gene is identified, such antibodies would be classified as conventional autoantibodies. This scenario has been recognized as a major problem in interpreting the fact that mutations have been detected so rarely in SEREX-defined genes (29). Sequencing of repeated isolates of the gene from the cancer, microdissected cancer cells, or cell lines derived from the cancer would be one way to address this critical issue. Given the large number of SEREX-defined antigens, however, this clearly represents a daunting task.

With regard to SEREX antigens with obvious or suspected cancer relatedness, immunogenicity can be ascribed to one of several mechanisms: gene activation or depression, mutation, amplification, mRNA overexpression, or expression of abnormal splice variants. The immune response to CT antigens is clearly related to anomalous expression of gene products in cancer that are normally only expressed in primitive germ cells. CT antigen expression in cancer has been ascribed to abnormal demethylation (72), although other mechanisms may well be involved. Anomalous antigen expression also appears to be the basis for certain paraneoplastic syndromes affecting the central nervous system. These syndromes are believed to result from autoimmune recognition of neural antigens aberrantly expressed by nonneural cancers, and specific autoantibodies are often found to be associated with specific tumor types (81). For example, in paraneoplastic cerebellar degeneration, a syndrome seen in patients with breast and ovarian cancers, autoantibodies have been found to react with neuronal antigens, including CDR34, an antigen strongly expressed in Purkinje cells of the cerebellum (82). The experimental precedent for immunogenicity due to anomalous activation of a gene in cancer comes from the study of the TL system of antigens in the mouse (83). In some mouse

strains (TL+ strains), TL is a normal alloantigen whose expression is limited to thymocytes. In other strains (TL- strains), no normal cell types express TL. However, leukemias arising in TL- as well as TL+ strains can express TL, and a strong humoral immunity against TL can be elicited in TL- mice.

With regard to mutations as a basis for immunogenicity, p53 can be considered the prime example among SEREX-defined antigens. However, it is unclear whether mutation or accumulation of high levels of p53 in cells harboring p53 mutations represents the initial antigenic stimulus leading to the development of p53 antibodies. Nevertheless, what is clear is that the resulting p53 antibodies recognize wild-type p53 sequences rather than showing specificity for mutated sequences (84).

Amplified expression appears to be one of the most frequent reasons for immunogenicity of antigens isolated by SEREX, and many examples of antibodies to overexpressed gene products in cancer have been detected in SEREX analysis. Thus, the immune system appears poised to respond to quantitative as well as qualitative changes in antigen expression in cancer cells. Until the basis for amplification or overexpression has been understood and the specificity established, however, the relation between antigen overexpression and antibody response can only be regarded as a strong correlation rather than a causal relationship.

Finally, another stimulus for an immune response has been postulated to be splice variants of genes, which are differentially expressed in normal tissues but aberrantly expressed in cancer. For example, PDZ-54, one of five splice variants of NY-CO-38 normally expressed in kidney, brain, but not colon, was found to be expressed in colon cancer (see above). Thus, tolerance may not extend to normal splice variants that are aberrantly expressed in a cancer, but this idea remains to be formally demonstrated.

Seroepidemiology of SEREX-Defined Antigens

Part of "16.7 - Identification of Human Tumor Antigens by Serological Expression Cloning "

Serology plays a central role in three phases of SEREX analysis.

1. In the initial identification of reactive clones
2. In screening small panels of sera from normal individuals and cancer patients for antibody (petit serology)
3. In large-scale surveys of human sera (grand serology)

Petit serology, using the isolate as target antigen, provides some indication of cancer-specific recognition of the antigen, whereas grand serology, using recombinant protein as target antigen, establishes the seroreactivity pattern of humans with or without cancer on a larger scale. Although only a small percentage of SEREX-defined antigens has been subjected to petit or grand serology, there is a growing list of antigens that show a promising degree of cancer-specific recognition in petit serology. For instance, in the SEREX analysis of four colon cancers by Scanlan et al. (29), 6 of 48 antigens isolated in the study showed a cancer-restricted recognition pattern in tests with 16 normal sera and 29 colon cancer sera. In a SEREX analysis of four renal cancers by Scanlan et al. (33), 12 of the 65 antigens isolated in the study showed a cancer-restricted recognition pattern in tests with 19 normal serum and 32 renal cancer patients. As a rule, the highest reactivity frequency with these antigens is 20% to 25% of patients, and there is a distinctive seroreactivity pattern with each of the antigens. As a consequence, the combined use of the six restricted antigens in the colon cancer panel detected 69% of sera from colon cancer patients, and the 12 restricted antigens in the renal cancer panel detected 72% of sera from renal cancer patients. Reactivity is not restricted to patients with the corresponding cancer type; sera from patients with other forms of cancer (e.g., lung or breast cancers) recognize a proportion of the antigens derived from colon and renal cancer. Table 16.7-5 shows an updated seroepidemiologic survey by Scanlan et al. (29,33, and *unpublished data*) of seven SEREX-defined antigens showing a cancer-restricted recognition pattern identified in our analysis of colon and renal cancer.

Table 16.7-5 Seroepidemiological Analysis of Seven SEREX-Defined Antigens from Colon and Renal Cancer with a Cancer-Restricted Recognition Pattern

Clone Number	Gene	Serum Source (No. Positive/Total No. Tested)					
		Normal Sera	Colon Cancer	Renal Cancer	Lung Cancer	Breast Cancer	Esophageal Cancer
NY-CO-8	Leucine zipper protein	0/26	8/29	5/31	2/29	0/10	0/15
NY-CO-9	Histone deacetylase	0/26	5/29	1/31	1/29	0/10	0/15
NY-CO-13	p53	0/26	6/29	0/13	1/29	0/10	2/15
NY-CO-38[a]	PDZ-73	0/26	7/37	8/32	0/29	1/26	0/15
NY-REN-21	Zfp38 homolog	0/22	3/16	3/32	2/21	0/16	0/15
NY-REN-31	Syntaxin	0/19	0/16	5/32	2/21	0/16	1/15
NY-REN-60	Tre oncogene-related	0/19	0/16	7/32	0/21	0/16	0/15

SEREX, serological expression cloning.
[a]Same as NY-REN-3.

Petit serology, although useful to identify antigens worthy of future study, is laborious and has several limitations:

1. It requires large amounts of sera.
2. Sera must be preabsorbed to remove *Escherichia coli* or phage reactivity.
3. Only small numbers of sera can be tested at one time.

For this reason, ELISA tests with recombinant protein (grand serology) offers a number of advantages (e.g., does not require preabsorbed sera, requires small amounts of sera, a large number of sera can be tested, and the analysis is quantitative). However, some degree of sensitivity (~1 log) is sacrificed in grand serology as compared to petit serology. NY-ESO-1 is the first SEREX-defined antigen to be analyzed in grand serology (85). No reactivity was found with 70 sera from normal individuals. Antibody to NY-ESO-1 was found in ~10% of sera from unselected patients with melanoma and ovarian cancer. To investigate the relation between NY-ESO-1 expression in the tumor and antibody response, a series of 62 melanoma patients were tested, 15 with NY-ESO-1+ tumors and 47 with NY-ESO-1- tumors. The conclusions were clear—NY-ESO-1 antibody was only found in patients with NY-ESO-1+ tumors, and up to 50% of patients with advanced NY-ESO-1+ tumors formed NY-ESO-1 antibody.

SEREX-defined antigens showing cancer-restricted seroreactivity offer a range of opportunities for cancer diagnosis and disease monitoring. To explore these applications, the current approach using ELISA technology and recombinant SEREX-defined antigens provides a satisfactory methodology. In the future, however, protein chip technology holds great promise for miniaturized, rapid, and large-scale screening of human sera for antibodies against SEREX-defined antigens.

T-Cell Recognition of SEREX-Defined Antigens

Part of "16.7 - Identification of Human Tumor Antigens by Serological Expression Cloning "

The detection of tyrosinase and MAGE-1 by SEREX, two tumor antigens initially recognized by epitope cloning as targets for CD8 T cells, established the critical principle that the analysis of humoral immunity to tumor antigens has the potential for identifying CD8 T-cell recognized antigens. In addition, because production of IgG antibodies is known to require CD4 T-cell help, SEREX analysis can be viewed as a way to define the CD4 T-cell repertoire against human tumor antigens. A number of laboratories are developing approaches for defining the peptide targets for CD8+ and CD4+ T-cell recognition of SEREX-defined antigens. NY-ESO-1, one of the first antigens isolated by SEREX, provides a model for defining the T-cell recognized peptides of a tumor protein initially identified by antibody (86). In the case of CD8 T cells, an HLA-A2+ melanoma patient with high-titered NY-ESO-1 antibody was also found to have strong CTL reactivity against the autologous NY-ESO-1+ melanoma. To investigate the possibility that NY-ESO-1 was the target for the CD8 recognition in this patient, COS cells were cotransfected with HLA-A2 and the NY-ESO-1 coding gene, and these transfectants were found to be lysed by CTLs from the patient with high-titered NY-ESO-1 antibody. Additionally, the reactivity of these CTLs cotyped with NY-ESO-1 expression in a panel of HLA-A2+ melanoma. To identify the NY-ESO-1 peptide epitopes recognized by the CTLs, a series of overlapping peptides were synthesized on the basis of known HLA-A2 peptide-binding motifs, and three of these peptides were found to be specifically recognized. Subsequent studies with CTLs from other HLA-A2+ patients with NY-ESO-1+ tumors and NY-ESO-1 antibody showed recognition of these HLA-A2 restricted peptides. For the identification of CD4-recognized NY-ESO-1 peptides, a similar general strategy was followed (87). CD4 T cells from two patients with NY-ESO-1+ melanoma and NY-ESO-1 antibody recognized NY-ESO-1 target cells pulsed with NY-ESO-1 protein in a HLA-DRB4 0101-0103-restricted fashion in enzyme-linked immunospot (ELISPOT) analysis. Overlapping NY-ESO-1 peptides were synthesized, and three of these were recognized by CD4 T cells in ELISPOT and proliferation assays using peptide-pulsed target cells.

Because the definition of targets for T-cell recognition is a far more complex and laborious task than defining antibody targets, current technologies place a limit on the number of antigens that can be analyzed from the T-cell perspective. In our opinion, SEREX-defined antigens eliciting high-titered antibodies with a cancer-restricted pattern in a substantial number of patients constitute the most promising targets for T-cell analysis. Newer techniques involving efficient transfection of coding genes with viral or nonviral vectors, better methods for long-term propagation and stabilization of specifically reactive CD8 and CD4 T cells, and new approaches to identify and expand low-frequency-specific T-cell populations should facilitate T-cell analysis of SEREX-defined antigens.

Cancer Immunome

Part of "16.7 - Identification of Human Tumor Antigens by Serological Expression Cloning "

The past decade has seen enormous strides in our understanding of the immune response to human cancer. In major part, this has been due to the development of methodologies capable of defining the antigenic targets on cancer cells that elicit an immune response (19,67,88). The cloning of T-cell recognized epitopes by Boon et al. (67) and Kawakami and Rosenberg et al. (88) has provided a growing list of tumor peptides that allows detailed monitoring of CD8 T-cell responses to these antigens in cancer patients and offers promising targets for cancer vaccine development. SEREX technology, because it is generally applicable to all tumor types and is less technically demanding than T-cell epitope cloning, holds promise for greatly extending the understanding of the immune response to cancer. In fact, identifying the complete repertoire of immunogenic gene products in human cancer—what is becoming known as the cancer immunome—is now an achievable goal for tumor immunology. To this end, a SEREX collaborative group was established in 1996 by the Ludwig Institute for Cancer Research, involving investigators at the University of Saarland (Homburg, Germany); Ludwig Institute Branches in New York, Melbourne, and London (University College); Aichi Cancer Center (Japan); Krankenhaus Nordwest (Frankfurt, Germany); and Moscow State University (Russia). A SEREX database has been organized by Victor Jongeneel (Director of Information Technology, Ludwig Institute for Cancer Research, http://www.licr.org/SEREX) and more than 500 SEREX-identified antigens have been deposited at last count (February 2000). Even at this early stage of SEREX analysis, repeated isolation of the same gene is being seen, indicating the limited range of immunogenic cancer antigens and the feasibility of defining the cancer immunome.

Cancer Vaccines: Basic Principles

17.1

General Concepts and Preclinical Studies

Nicholas P. Restifo

- Introduction
- Conclusion

Introduction

Part of "17.1 - General Concepts and Preclinical Studies "

What are the basic principles of the design of cancer vaccines? Because a number of efficacious tumor vaccines are not available to draw "principles" from, the answer to this question, at least in the clinic, is far from definitive. It is only in experimental animals where enough progress has been made that patterns of efficacy begin to emerge. Thus, the general concepts and "principles" of cancer vaccination described in this chapter are largely derived from work in laboratory animals, especially from preclinical mouse models.

Human clinical trials using experimental cancer vaccines are being performed at an accelerating pace. These trials have confirmed some early findings obtained from animal studies while refuting others. Most important, findings in human clinical trials are an engine for hypotheses about how cancer vaccines work. Once generated, these hypotheses can be explored in experimental animals (1). It is through the interplay of *in vivo* and *in vitro* data from experimental animals and human clinical trials that a set of general immunologic principles is emerging, which may guide the immunotherapist in the successful vaccination against cancer (Table 17.1-1).

Table 17.1-1 Seven Principles to Consider When Designing an Anticancer Vaccine

Human cancers are poorly immunogenic.
The vaccine must express an appropriate tumor antigen target.
Immunizations most effective in generating reactive T cells are the most therapeutically effective.
Dendritic cells mediate vaccine function.
Vaccination can be enhanced with cytokines, chemokines, and costimulatory molecules.
The immunogen chosen must be effective in the treatment of established disease.
Optimal dose, boosting, and route of the immunization are determined by basic immunologic principles.

Vaccines are traditionally thought of as preventing infectious diseases, but they may have new uses in the treatment of malignancies. In the case of cancer, it is clear that the immune system can recognize and destroy even large quantities of established tumor. Evidence for this immune-mediated destruction comes primarily from clinical trials using interleukin-2 (IL-2), which is a U.S. Food and Drug Administration–approved treatment for melanoma and renal cell carcinoma (2). New immunotherapies based on vaccines designed to treat cancer have been used in the clinic. These therapeutic vaccines have been clearly demonstrated to elicit antitumor immune responses. In a number of cases, these vaccines have also been reported to mediate the destruction of established cancer (3 ,4 and 5).

Although the notion of vaccines designed to prevent cancer may be appealing, a variety of practical and theoretical problems arise in creating such a prophylactic vaccine. One problem has to do with predicting which patients will develop cancer, although an increased knowledge of genetic and environmental factors that contribute to carcinogenesis may enhance our ability to make these kinds of predictions. In addition to these practical considerations, theoretical reasons exist as to why prophylactic vaccination against defined antigens may be problematic. For example, the difficulty in predicting which of a myriad of mutations may occur in any one of a large number of genes makes vaccination against mutated tumor antigens unlikely to be successful. Similarly, vaccination against unmutated "self" antigens may be subject to chronic immunologic toleration or may produce untoward side effects resulting from the destruction of normal tissues that express the same antigen.

The only true preventive cancer vaccines that are under serious consideration are really variants of vaccines designed to prevent infectious diseases (6 ,7). For example, vaccines that prevent human papilloma virus or hepatitis infections should also prevent cervical cancer and liver cancer, respectively. Most cancers affecting individuals in developed cancers, however, have not been associated with viruses. Thus, prophylactic vaccines for cancer are likely to be the exception rather than the rule. Most research in the field of cancer vaccines is devoted to vaccines designed to activate the immune system to destroy established cancer cells. These vaccines are the primary focus of this chapter.

Seven Principles to Consider When Designing an Anticancer Vaccine

We attempt to enunciate a few of the basic immunologic principles that may be useful in the design of anticancer vaccines, whether these vaccines are based on irradiated or gene-modified tumor cells or synthetic or recombinant forms of a tumor antigen. Some general principles follow:

Human Cancers Are Poorly Immunogenic

Every cancer that kills a person is a cancer that has not been destroyed by the immune system. The reason for this apparent lack of immunogenicity may be that cancer antigens are generally not presented to the immune system in a microenvironment that favors the activation of immune cells. Although no

single known mechanism can explain poor tumor immunogenicity in all experimental models studied, the molecular bases can be separated conceptually into two distinct groupings. The first concerns mechanisms of poor immune activation shared by normal cells in the body, whereas the second has to do with the inherent genetic instability of cancer cells (Table 17.1-2). This instability leads to a great deal of heterogeneity among tumor cells, making the immune destruction of all tumor cells in the body an extremely difficult task (8).

Table 17.1-2 Why Tumor Cells Are Poorly Immunogenic

Lack of expression of costimulatory molecules (B7-1/CD80, B7-2/CD86, and CD40L)

Production of immunoinhibitory substances (transforming growth factor-ß and interleukin-10)

Poor antigen processing and presentation (loss or poor expression of B2m, major histocompatibility class I, TAP, and LMP)

Variability in the expression of antigen by tumors

Tumor Microenvironment May Inhibit Immune Activation

Like most normal cells in the body, tumor cells generally do not express costimulatory molecules, such as B7-1 (CD80) and B7-2 (CD86). In the absence of costimulation, T cells tend to become anergic. For self-antigens, this may protect against autoreactivity. B7-1 and B7-2 are expressed on professional antigen-presenting cells (APCs) and on a variety of other tissues after exposure to inflammatory cytokines (9). Transfection of tumor cells with both isoforms has been used successfully to trigger their immune-mediated rejection of experimental mouse tumors, which have some inherent immunogenicity (10 ,11). This strategy, however, is insufficient for nonimmunogenic tumors, a category into which most, if not all, human tumors would fall (11).

Another mechanism that may explain why patients with cancer usually do not reject their tumors involves the lack of inflammation at the tumor site. Important differences exist between the site of a tumor deposit and a site of infection. Tumors produce few, if any, immunologic "danger signals" to stimulate the immune response (12 ,13). In contrast, at a site of infection, the innate immune response is triggered because of tissue destruction. Inflammatory cells, such as monocytes, macrophages, and dendritic cells (DCs), are activated as a result of this tissue destruction, and because of components of the infectious agents themselves, such as lipopolysaccharide, nonmethylated CpG sequences, and double-stranded RNA, each of which are components of invading microbes that are not shared by normal host cells or growing cancer cells. In the absence of these "danger signals," the immune system may not be fully activated (14).

Induction of Tolerance by Tumor Cells

Despite cancer cells' expression of clearly immunogenic molecules, the host does not always mount an effective immune response to these antigens. A number of groups have conducted experiments in which highly immunogenic foreign antigens, such as the hemagglutinin protein from influenza (15), the ß-galactosidase (ß-gal) enzyme from *Escherichia coli* (16), and the ovalbumin protein from the chicken are expressed in tumor cells (17). The results are fairly uniform: tumors tend to grow progressively, retaining their lethality despite the expression of a foreign and highly immunogenic protein by the tumor cell.

Alternative immune mechanisms, designated *tolerance* and *ignorance*, have been used to explain why the immune system fails to recognize such tumors. *Tolerance* generally refers to the lack of a destructive immune reaction to a given antigen. In the tumor context, an active state of tolerance may be distinguished in which the immune system undergoes a functional and phenotypic change after encounter with antigen from ignorance, a passive process where immune cells do not have any contact with the antigen that alters their phenotype or function (18 ,19 ,20 and 21). Both mechanisms likely play a role in the immune system's unresponsiveness to tumor cells.

Tumors Produce Immunoinhibitory Factors

Tumor cells may ectopically use normal immunosuppressive mechanisms, such as the production of transforming growth factor-ß, normally produced by certain immune and other somatic cells, but potentially antiproliferative for cytotoxic T lymphocytes (CTL), natural killer cells, and lymphokine-activated T cells (22 ,23 ,24 and 25). Another example, IL-10, produced by activated T cells, B cells, monocytes, and keratinocytes, may be produced by certain solid tumors and may interfere with macrophage-mediated antigen presentation and other immune functions.

Hahne et al. reported in 1996 that expression of Fas ligand (FasL/CD95L) by melanoma cells was responsible for their escape from immune recognition (26). Because FasL was reportedly expressed in areas of immune privilege, such as the eye and testis, it was reasoned that expression of FasL by melanoma cells indicated that the tumor bed was also an "immune privileged" site. In our own study, however, we found no FasL expressed by a panel of 26 human melanoma lines we tested (27 ,28 and 29). Thus, our data do not support a role for FasL expression in the escape of melanoma cells from immune destruction.

Tumor as a "Moving Target"

Tumor cells can be a moving target when it comes to immune recognition. The field of chemotherapy has produced a number

of well-known examples of tumor escape from treatment, including the induction of the expression of the multidrug resistance gene. As recombinant and synthetic vaccines become more effective, the selective pressure on the loss of particular target antigens may increase. Indeed, some evidence exists that tumor cells may preferentially lose the gp100 tumor antigen as a result of treatment with the gp100 209-217 (2M) peptide plus IL-2 (FM Marincola, *unpublished*, 1999 and 30 ,31).

Tumors have unstable genomes, which leads them to be heterogeneous for the expression of tumor-associated antigens. Further, their unstable genomes may enable them to escape immune recognition because they lose or mutate key elements of the antigen-processing machinery, such as the TAP transporters, β_2-microglobulin, or the major histocompatibility complex (MHC) class I α chain molecules (32 ,33 ,34 ,35 ,36 and 37). Other mechanisms underlying the poor immunogenicity of tumors includes the downregulation of two interferon-γ-inducible proteasomal components, called *LMP2* and *LMP7*, in certain human tumors (32). The proteasome is a large multicatalytic complex involved in the degradation of many of the peptides that later find their way into the MHC class I pathway.

Not All Tumor-Associated Antigens Are Suitable Targets for Vaccine Development

How does one go about choosing an antigen appropriate for use in the design of a cancer vaccine? Some workers have picked target antigens because they are frequently mutated in tumors, as in the case of p53 (38) or Ras (39 ,40 ,41 and 42), at the site of joining a translocation, such as bcr-abl (43), or are aberrantly glycosylated and thus the subject of recognition by antibodies, as is the case for MUC1 (44 ,45 and 46) and carcinoembryonic antigen (47 ,48).

What Fraction of Potential Tumor Antigens Can Actually Be Found on the Tumor Cell Surface?

A simple estimate of the number of possible epitopes in expressed proteins to the number of expressed MHC molecules clearly reveals that only a fraction of all antigenic peptides are presented by MHC on the cell surface. Estimates place the total number of MHC/peptide complexes on the cell surface at between 10^5 and 10^6 molecules per cell (49). T lymphocytes, however, may be able to recognize a single peptide on the surface of a target cell (50 ,51 and 52). Nevertheless, many of these MHC/peptide complexes presented on the cell surface are redundant, and some "self," particularly stable, complexes may be present in quantities of hundreds or even thousands of copies per cell (53 ,54), making the total number of different complexes significantly lower than the total number of MHC class I molecules per cell. Consequently, a tumor with excellent MHC expression and antigen-processing capacity is likely to express a maximum of approximately 10,000 different MHC/peptide complexes on its surface.

On the other side of the ledger, how many possible tumor-derived antigenic peptides are expressed by a tumor? An individual tumor cell may express approximately 20,000 of an estimated 100,000 genes in the genome. Each encoded protein contains dozens of epitopes that could bind to any given MHC molecule. For example, a total of ten different epitopes derived from the 661 amino acid-long gp100 molecule have been shown to be presented by the HLA-A*0201 molecule. These ten were chosen, however, from a list of actual binders that exceeded 50 different potential binders in the primary open reading frame of the molecule. Peptides derived from alternative open reading frames can also load MHC molecules, further increasing the number of potential epitopes encoded by the tumor genome (55 ,56).

A conservative estimate of the total number of peptides that are actually able to bind to any given MHC molecule may thus be greater than a million. Furthermore, each MHC molecule is codominantly expressed, so a tumor may express six different "classical" MHC class I molecules. Thus, using conservative estimates, millions of potential binders exist competing for tens of thousands of MHC molecules.

It is then clear that not every peptide that can be generated is presented in an MHC class I-restricted fashion. Peptides can be created or destroyed by a large number of specificities in the proteolytic machinery. Furthermore, after their creation, peptides must traffic to the appropriate compartment for binding to MHC class I (the endoplasmic reticulum) or class II (the compartment for peptide loading).

Based on the numbers presented above, we estimate that the chances that any given peptide will be presented on the tumor cell surface are approximately 1%, although this number is an estimate. Because not every good MHC-binding tumor-derived peptide is actually presented on the tumor cell surface, it is possible to make a CTL that can kill peptide-pulsed targets but not actual tumors (43 ,57).

Identifying Tumor Antigens Recognized by T Lymphocytes

The molecular identification of the antigens present on cancers that are recognized by the immune system is central to the development of recombinant and synthetic vaccines. Because of the difficulty in predicting what peptides are present on the cell surface, one of the most successful approaches to identifying tumor-associated antigens suitable for the development of cancer vaccines starts with the antitumor immune response. The specificity of this response is then used to identify tumor-associated antigens (58). One approach has been to start the cloning process using T cells with antitumor reactivity to screen complementary DNA libraries made from melanoma cell lines. In many cases, the antitumor T cells were derived from cultures of tumor-infiltrating lymphocytes that had been adoptively transferred to patients with cancer. Our group focused on the T-cell reactivities that were associated with objective regressions of metastatic melanoma lesions after their adoptive transfer (59).

Complementary DNA libraries of expressed melanoma genes were screened by transfecting these genes along with the gene for the restricting MHC molecule into an antigen-negative cell line, which is then admixed with T lymphocytes that have antitumor activity. If the T cells recognize the transfected cell line, they lyse it and release cytokines, such as granulocyte-macrophage colony-stimulating factor, tumor necrosis factor-α, and interferon-γ, any of which can be measured. The process of

cloning genes encoding tumor antigens is under constant improvement and has become considerably faster and more streamlined (60 ,61 and 62).

Targeting "Self" Antigens

Many of the tumor antigens that have been identified are tissue differentiation antigens in melanocytes and include gp100 (63 ,64 ,65 ,66 ,67 ,68 and 69), MART-1/MelanA (70 ,71 ,72 ,73 and 74), tyrosinase (65 ,75 ,76 ,77 and 78), and tyrosinase-related protein-1/gp75 (79) and -2 (62 ,80 ,81). These antigens are involved in the synthesis of melanin and give melanocytes and deposits of melanoma tumor their dark pigment.

The fact that differentiation antigens are nonmutated in most tumors has two important implications. First, expression of these tissue differentiation enzymes are shared by the great majority of melanoma nodules from the great majority of patients, and thus an "off-the-shelf" vaccine strategy targeting these antigens is possible (a strategy that targets a mutated antigen may have to be individualized for every mutation). Second, the nonmutated nature of these antigens suggests that immunotherapies that target these antigens could elicit autoreactivity. One consequence of this "autoreactivity" may be vitiligo, the patchy and permanent loss of pigment from the skin and hair thought to result from the autoimmune destruction of pigment cells. Vitiligo has been correlated with objective shrinkage of deposits of metastatic melanoma in patients receiving high-dose IL-2, a cytokine known to activate and expand T lymphocytes (2 ,82).

Thus, evidence exists that vitiligo can be coupled with tumor regression, and that adoptive transfer of antitumor T cells recognizing differentiation antigens is associated with objective shrinkage of melanoma deposits. Although the focus of this review is on melanocyte differentiation antigens, two other groups of antigens should be mentioned. Those in the first category are expressed by a diversity of tumor histologies, but are not expressed by normal tissues (other than testis). Cloned in large part by Boon and colleagues, these antigens are encoded by genes with family names like *MAGE, BAGE, GAGE, RAGE*, and *LAGE* (83 ,84 and 85). *NY-ESO-1* also falls into this group and is expressed in a significant proportion of human melanoma cells, as well as other tumor histologies, including breast, ovary, bladder, prostate, and liver (60 ,86 ,87 ,88 and 89).

Are Mutated Tumor Antigens Better Targets for Immune Recognition?

Tumor protection experiments using experimental animals have shown that protective responses are generally tumor specific, leading to the conclusion that, at least in mice, tumor rejection antigens are often unique (90). These antigens are thought to be the result of mutations in the genome. Human tumors also express mutated antigens that can be processed and presented for recognition by T cells. Neoantigens produced as a result of mutation often are found to originate in ubiquitously expressed proteins. Examples include epitopes from beta-catenin (91), CDK4 (92), MUM1 (93), FLICE (caspase-8) (94), HLA-A2 (95) and, most recently, a mutant gene from a bladder carcinoma that is recorded in databases under the name *KIAA0205*, whose function is unknown (94 ,96). Some of these antigens are also oncogenic, including the mutations described for beta-catenin and CDK4.

Mutated antigens may not lend themselves easily to off-the-shelf vaccines consisting of purely recombinant and synthetic components because each neoantigen for each patient must be checked for sequence, and that sequence must be verified to be present on the surface of a tumor cell. Some workers, however, have asserted that mutated tumor antigens are superior targets for vaccine design because immune cells are not tolerated to these antigens (97). Recent work, especially by Levitsky's and Sherman's groups, has shown that even the most immunogenic "foreign" antigen, such as the hemagglutinin antigen from the influenza A virus, can be tolerating when expressed peripherally (i.e., outside the thymus) in normal cells (98) or in tumor cells (15). Thus, mutated or otherwise "foreign" antigens may also induce peripheral tolerance when expressed by tumor cells.

Immunizations Most Effective in Generating Reactive T Cells Are the Most Therapeutically Effective

The principle that T cells were critically important in the immune response was derived originally in mice with methylcholanthrene-induced tumors. A large body of work in which T-cell subsets were depleted using antibodies or gene knockout mice revealed that CD8+ and CD4+ T cells could play a role in the antitumor immune response.

Role of CD8+ T Cytotoxic Cells in Antitumor Immunity

It has long been known that elements of the cellular immune response are capable of specifically recognizing and destroying tumor cells. Classic studies showed that mice immunized with irradiated methylcholanthrene-induced sarcoma cells were fully protected against a subsequent challenge with that same tumor, but not with other tumors (99). This protection was dependent on CD8+ T lymphocytes, whereas CD4+ T lymphocytes often played little if any role. Furthermore, adoptive transfer of pure populations of CD8+ T lymphocytes was shown to mediate tumor regression in mice (100 ,101 and 102). Thus, many efforts to develop therapeutic anticancer vaccines have focused on CD8+ T lymphocytes, and the molecular targets of these cells have been identified in human and mouse systems (1 ,103).

"Mini-gene" constructs have been created to favor immune responses against the heterologously inserted target antigen. These viruses are constructed to encode immunodominant epitopes (i.e., the fragments of antigens that are presented by MHC molecules) from cancer antigens alone or in combination with endoplasmic reticulum insertion signal sequences that can bypass the TAP transporters, in some cases profoundly enhancing the function of virus-based vaccines in animal models (17 ,104 ,105).

The use of synthetic peptide vaccines that have been altered to increase their ability to bind MHC class I molecules is a promising new avenue to augment CD8+ T-cell function. Crystal structures of peptide MHC complexes, together with mass sequencing of peptides eluted from class I molecules, have revealed that peptides bind to their restricting class I molecules

in large part by "anchor" residues. These residues can be modified to increase the peptide-MHC interaction without compromising the interaction of this complex with the T-cell receptor (106 ,107).

Role of CD4+ T "Helper" Cells in Antitumor Immunity

Compared with the comprehensive studies using CD8+ T cells in tumor models, relatively little is known about how CD4+ T cells influence antitumor immunity. Early work demonstrated that disseminated murine leukemia could be eradicated by a combination of cyclophosphamide and adoptively transferred cells, then known as *Lyt1+2- cells*, a phenotype later shown to be L3T4+, Lyt2- cells, now designated *CD4+ T cells* (108 ,109). The most dramatic examples of the power of CD4+ T cells in the immune response to "self" proteins can be found in murine models of autoimmune diseases, such as experimental allergic encephalomyelitis, systemic lupus erythematosus, and diabetes. In these models, disease can often be transferred to naïve mice with purified, "self" reactive CD4+ splenocytes or specific CD4+ T lymphocyte clones (110 ,111 ,112 ,113 ,114 and 115). These studies and others suggest that the full activation of autoreactive CD4+ T cells may be a key element missing from many current clinical cancer vaccine trials.

We understand how CD4+ T lymphocytes help initiate and maintain the antitumor immune response (116 ,117). CD4+ T cells regulate antigen-specific immune responses by regulating the functions of other components of the immune system, including B lymphocytes and CD8+ T lymphocytes (118 ,119). Conversely, CD4+ T cells can be preferentially activated by B cells under some conditions (120). In the experimental B16 tumor system, B lymphocytes, under the control of CD4+ T cells, play an important role in inducing autoimmunity and antitumor immunity (121 ,122 ,123 ,124 ,125 and 126). CD4+ T lymphocytes also appear to attract and activate other non–antigen-specific components of the immune system, including eosinophils and macrophages (127).

CD4+ T cells have recently been shown to alter the function of DCs, as well as other APCs (128 ,129). This activation occurs, in part, through the interaction of CD40 on the APC surface with its ligand (gp39), which is expressed on the surfaces of activated CD4+ T cells (129 ,130). Engagement of CD40 prompts the APC to secrete proinflammatory cytokines, such as interferon-γ and IL-2, and attract a host of other cells to the site of immune reactivity (128 ,129).

One potentially important experimental thrust in the use of adoptively transferred T cells may be the intentional addition of "helper" CD4+ T cells to adoptively transferred CD8+ T cells. In studies using T cells specific for cytomegalovirus, Greenberg and his colleagues have reported that the cytotoxic activity of adoptively transferred CD8+ clones declined in patients deficient in helper CD4+ T cells specific for cytomegalovirus (131). These results suggested that CD4+ T-cell function is needed for the persistence of transferred CD8+ T cells. Attempts to identify the molecular targets of antitumor CD4+ T cells have already been successful (132 ,133 ,134 ,135 ,136 and 137). Thus, work focuses on efforts to harness the potential capabilities of antitumor CD4+ T cells.

Dendritic Cells Mediate Vaccine Function

The initiation of T-cell immunity is largely the result of a specialized subset of APCs, called *dendritic cells* (138 ,139). DCs activate T-cell responses because they are able to capture, process, and present antigens in the context of MHC molecules to T lymphocytes. Signaling through the interaction of T-cell receptor and peptide/MHC, however, is insufficient to activate a T cell. In this light, DCs also have another more specialized function: they are capable of costimulating T cells. The importance of costimulation comes from understanding the "two signal" hypothesis of T-cell activation, first proposed by Bretscher and Cohn (140). Although the first signal delivered through the T-cell receptor is necessary, it is not sufficient to activate the T cell. It is known that T cells receive a large number of second signals through the interaction of what are generally integral membrane glycoproteins on the surfaces of T cells and APCs (141). These signals are mediated through the interactions of intracellular adhesion molecules and through the lymphocyte function–associated antigens.

The interaction of the B7 molecules B7.1 (CD80) and B7.2 (CD86) with their ligands on the surface of T cells, known as *CD28* and *CTLA4*, are critical to the provision of a "second signal" (142 ,143). Whether B7 family molecules trigger the activation or inhibition is dependent on their interaction with molecules on the T cell: engagement of CD28 is associated with proliferation and differentiation, whereas an encounter with CTLA-4 may trigger functional unresponsiveness (144 ,145). Blocking CTLA-4 engagement has been reported to enhance immune responses to tumor cells (146). Activating T cells by DCs is thus accomplished by presenting antigen/MHC complexes in the context of a variety of other activating signals.

Optimizing Vaccine Function in Dendritic Cells

One line of evidence illustrating the importance of DC in anticancer vaccines comes from studies using recombinant viral vectors encoding tumor-associated antigens. Poxvirus-based immunogens are one class of candidate vectors that has been explored extensively. Poxvirus-specific promoters placed upstream of a heterologous sequence can determine the timing and quantity of antigen production. In a mouse model system, we explored the capacity of recombinant vaccinia virus promoters to mediate tumor regression and the elicitation of T cell responses (147). The recombinant poxviruses mediating the highest expression of ß-gal under the control of an "early" promoter (i.e., a promoter operating before viral DNA replication) expressed approximately 30-fold less ß-gal than the best construct using a "late" promotor (i.e., active after viral DNA replication in permissive tissue culture cells). Only the recombinant vaccinia virus using early promoters prolonged the survival of mice bearing established tumor expressing the model antigen, ß-gal. When a variety of cells were infected with the panel of viruses *in vitro*, DCs were found to express ß-gal only under the control of the early promoters. Moreover, in a functional assay, DCs infected *in vitro* with recombinants using late promoters did not activate ß-gal-specific CTLs, whereas the CTL responses were powerful and specific when early promoters were used. These

data suggested that promoter strength was not the most critical quality of a recombinant poxvirus-based vaccine. Rather, the success of recombinant poxviruses in the immunotherapy of established cancer may require the use of early promoters capable of driving the production of the heterologous protein in infected DCs and other "professional" APCs.

In another study using cutaneous DNA bombardment (the so-called gene-gun), substantial expression of an encoded model antigen was found in the epidermal layer (148). In addition, a low but detectable level of expression was also found in DCs and in draining lymph nodes. Under these conditions, it was clear that two possible modes of DC antigen presentation to naive CD8+ T cells might exist: (a) presentation directly by gene-transfected DC trafficking to local lymph nodes, and (b) cross-presentation by untransfected DCs of antigen released from or associated with transfected epidermal cells. When the relative contributions of these distinct modes of antigen presentation to priming of CD8+ T cells was evaluated, however, the predominant pathway for T-cell activation was the presentation of directly transfected DCs, indicating that augmenting direct DC gene expression may enhance the function of gene-gun-based DNA-based immunization (148).

Vaccine Efficacy May Depend on the "Super-Activation" of Dendritic Cells

DCs can undergo maturation or "super activation" through the activity of tumor necrosis factor-α and other macrophage-derived cytokines, as well as through the engagement of CD40 by CD40L on the surfaces of activated T cells. On activation, DCs can effectively activate naïve T cells. Other key noncytokine immunomodulators include molecules vital to costimulation. One of these, CD40 and its ligand, which, like other members of the tumor necrosis factor family, naturally forms homotrimers, has been shown to be important in B-cell activation, the production of type 1 cytokines by T helper cells, and the generation of cytotoxic memory responses. We and others have found that the addition of CD40L trimer to DNA vaccination can significantly increase antitumor efficacy (149). Another molecule, called *FLT3 ligand*, can induce the apparent growth and differentiation of functional DCs and has been reported to have antitumor effects (150 ,151). The role, if any, of FLT 3 ligand in the augmentation of the function of recombinant and synthetic anticancer vaccines is the subject of a great deal of investigation in experimental mouse models.

Vaccination Can Be Enhanced with Cytokines, Chemokines, and Costimulatory Molecules

A number of immunomodulatory molecules can augment immunization. One group of these molecules, called *cytokines*, are substances that generally act locally on immune cells and usually have a limited half-life in circulation. Cytokines can be produced by and have activity on cells outside of those with specialized immune function cells. These effects may blur the distinction between cytokines and other classes of soluble intercellular signals, such as hormones and growth factors.

The ILs are a subset of cytokines that are produced by leukocytes and have activity on leukocytes, although they have direct and indirect effects on a wide range of cells. Cytokines and, in particular, the ILs, have powerful effects on the activation and proliferation of T cells. Cytokines that are chemoattractant are called *chemokines.* Chemokines induce the activation and directional migration in a variety of immune cells (152 ,153 ,154 ,155 ,156 ,157 and 158). Chemokines are produced locally in the tissues, often as a result of the presence of pathogens, and act on leukocytes through a family of at least a dozen receptors. They function as regulatory molecules in leukocyte maturation, traffic and homing of lymphocytes, and the development of lymphoid tissues.

Cytokines, Chemokines, and Costimulatory Molecules as Molecularly Defined Adjuvants

From the vaccinologist's point of view, cytokines, chemokines, and costimulatory molecules can be used as molecularly defined adjuvants, significantly improving vaccine-induced immune responses. They can be administered systemically as protein or their genes can be inserted into recombinant vaccines (159 ,160 ,161 and 162). Mouse models have been used to evaluate large panels of molecularly defined adjuvant antitumor activity elicited by a vaccine. We have found that gene-gun delivery of a model antigen was protective by itself but was only therapeutic when codelivered with IL-2, IL-6, IL-7, or, especially, IL-12 (160). Other useful cytokine adjuvants include granulocyte-macrophage colony-stimulating factor, a cytokine thought to play an important role in the recruitment and maturation of DCs (163 ,164 and 165). Studies using vaccinia virus–based immunogens have revealed that IL-2 and IL-12 (151 ,152 ,153 ,154 ,155 ,156 ,157 ,158 ,159 ,160 and 161) are extremely potent in their ability to increase the efficacy of cancer vaccines. In addition, the costimulatory molecules B7-1, B7-2, and CD40L also have a beneficial effect on vaccination (149 ,161 ,162 ,166).

Importantly, not all of the findings in murine models were confirmed in human clinical trials. When patients with metastatic melanoma were immunized with a modified immunodominant peptide derived from gp100, no increase in efficacy as measured by objective clinical response was observed using granulocyte-macrophage colony-stimulating factor or IL-12. Only IL-2 was found to have a beneficial effect as an adjuvant for peptide immunization.

Bacterial DNA sequences, called *immunostimulatory sequences*, have been reported to be potent adjuvants. Nonmethylated palindromic DNA sequences containing CpG-oligodinucleotides can activate an "innate" immune response by activating monocytes, natural killer cells, DCs, and B cells in an antigen-independent manner (167 ,168 ,169 and 170). Indeed, methylation of the CpG-oligodinucleotides reportedly abrogates the immunogenicity of the DNA vaccine. Thus, the use of large amounts of plasmid for immunization may not only overcome the low transfection efficiency *in vivo*, but may also serve as an adjuvant driving a Th1-response (171 ,172).

Not All Immunogens Are Created Equal

Early attempts at developing cancer vaccines were based on the use of tumor cells that were irradiated; admixed with a number

of adjuvants, including *Corynebacterium parvum* and bacille Calmette-Guérin; or infected with viruses to create "oncolysates." Since the 1990s, tumor cells have been gene-modified in an attempt to turn them into effective vaccines. Because cancer cells are notoriously poor immunogens, workers in a number of laboratories have attempted to remove tumor antigens from the tumor microenvironment with strategies, such as purifying heat shock proteins, which are thought to bind precursors of peptides destined for the MHC complex (173 ,174). Others have acid-eluted peptides to pulse them onto DCs (175 ,176). Yet another approach is transfecting DCs with tumor-derived RNA (177).

The use of recombinant and synthetic vaccines is predicated on the identification of tumor-associated antigens. A large number of recombinant vectors are available. A partial list of recombinant viral immunogens includes vaccinia, fowlpox, canarypox, adenovirus, influenza, polio, and Sindbis (178). Recombinant organisms include *Listeria, Salmonella*, and bacille Calmette-Guérin (179 ,180). In addition, "naked" nucleic acid-based vectors include the administration of DNA by intramuscular or intradermal injection or by gene-gun and, most recently, the administration of "self-replicating" nucleic acid-based immunogens (160 ,181).

Recombinant Virus-Based Vaccines

Recombinant virus-based cancer vaccines are created by inserting genes encoding tumor antigens into the viral genome. The safety of these recombinant viruses, always of paramount importance, can be insured in a number of ways. For example, some of the recombinant vaccines are comprised of viruses incapable of replicating in mammalian cells because of their host range (e.g., the avian poxviruses) (16), whereas others are highly attenuated (like certain influenza A viruses) (182) or the Wyeth and modified vaccinia virus Ankara strains of vaccinia virus (183), and still others are made safe by the removal of viral genes that are critical to viral replication and virulence, such as adenoviruses (184).

Vaccines based on live, attenuated, or killed viruses can be highly effective in preventing human viral diseases, such as polio, smallpox, and even influenza A. Recombinant viruses encoding tumor antigens, however, have an important shortcoming that is not shared by the viral vaccines from which they derive. Any immune response elicited by a viral vaccine is, at least potentially, virus-specific, and thus relevant to the immune response against the viral challenge. This is not the case for cancer vaccines where the only component of the immune response that can be tumor specific is the response elicited by the expression of the transgene(s) encoding the tumor antigen(s). Although viral elements might help boost immune reactivity through their activity as helper epitopes, they do not contribute any specificity of immune reactivity for tumors. The only exception to this generalization would be if a recombinant virus-based immunogen were used to vaccinate against a virally induced cancer (e.g., the use of recombinant human papillomavirus to treat cervical cancer).

Problem of Preexisting Immunity to Viral Immunogens

Although viral vaccines are potent inducers of antitumor immunity in animal models, the obstacle of preexisting immunity remains an important problem in the translation of these strategies to the clinic. We have learned in the conduct of our own clinical trials that humans have high neutralizing titers to recombinant viral vaccines based on adenoviruses (185). These antibodies are likely owing to the ubiquitous environmental presence of adenoviruses and heterotypic immunity resulting from pandemic adenoviral infection, especially in children and in military recruits (186 ,187 and 188). Adenoviruses frequently are the causes of respiratory illness, conjunctivitis, and gastroenteritis (189 ,190). Our patients almost uniformly have been exposed to adenovirus because of its ubiquitous presence in the environment in each of our upper respiratory systems (185).

Vaccinia virus was widely used in the campaign to eradicate smallpox (191 ,192 and 193). Thus, anyone born in the United States before approximately 1970 (the majority of patients who currently have cancer) have already been immunized to vaccinia (194 ,195). Elsewhere in the world, immunization with vaccinia was continued well after the early 1970s (196). Indeed, most patients appear to be able to rapidly clear these viruses, making it difficult or impossible to effectively use cancer vaccines based on these viruses. One way of circumventing the problem of preexisting immunity is the use of viruses whose natural hosts are nonmammalian, such as the avian poxviruses (16).

Recombinant Vaccines Based on "Naked" Nucleic Acid

Reports dating from the early 1990s indicated the finding that the intramuscular injection of "naked" plasmid DNA (i.e., DNA without a viral coat) could result in an immune response (197). Like viral vaccines, the activity of DNA vaccines appears to be mediated through DCs and other "professional" APCs. Clear evidence exists for a predominant role for directly transfected DCs in antigen presentation to CD8$^+$ T cells after nucleic acid immunization (148).

In contrast to vaccines that use recombinant bacteria or viruses, naked nucleic acid vaccines consist only of DNA or RNA, which is taken up by cells and translated into protein. In case of gene-gun delivery, nucleic acid is precipitated onto an inert particle (generally gold beads) and forced into the cells with a helium blast. Transfected cells then express the antigen encoded on the plasmid, resulting in an immune response. Like live or attenuated viruses, DNA vaccines effectively engage MHC class I and II pathways, allowing for the induction of CD8$^+$ and CD4$^+$ T cells, whereas antigen present in soluble form, such as recombinant protein, generally induces only antibody responses.

DNA-based vaccines are relatively safe and easy to engineer and produce. In animal models, they are generally not as potent as recombinant viruses at eliciting immune responses capable of destroying tumors. Significant effort has been exerted to improve the efficacy of DNA vaccines. Important innovations in the design of these vectors include promoter optimization, enhancement of polyadenylation sequences, the removal of 5" and 3" untranslated regions from the inserted gene, and the use of intronic sequences to improve nuclear export.

Clinical trials using naked DNA vaccines encoding tumor antigens have begun. One of the first of these trials was launched in 1999 at the Surgery Branch, National Cancer Institute.

It uses a plasmid encoding a modified form of the human gp100 melanoma antigen first alone, then in combination with IL-2, previously shown in murine study to enhance vaccination with plasmid (160).

Naked nucleic acid vaccines are potentially useful candidates as therapeutic vaccines for patients with cancer, but their clinical efficacy has not been demonstrated. One promising approach to the development of nucleic acid vaccines may be strategies designed to make them "self-replicating." Self-replication can be accomplished by using a gene encoding an RNA replicase polyprotein derived from alphaviruses, a family of viruses that includes Semliki Forest virus, Sindbis virus, and the Venezuelan equine encephalomyelitis virus. A gene encoding a tumor antigen can be added to such a construct under the control of viral promoter. Such constructs can elicit antigen-specific antibody and $CD8^+$ T-cell responses at doses as low as 0.1 μg (198). Although the self-replicating vectors do not mediate the production of substantially more model antigens than a conventional vaccine, the enhanced efficacy of the vector may be owing to its ability to induce caspase-dependent apoptotic death in transfected cells. Such death has been shown to facilitate the uptake of apoptotic cells by DCs, providing a potential mechanism for enhanced immunogenicity.

Synthetic Peptide Vaccines

Knowledge of the amino acid sequences of the epitopes presented by MHC molecules on the surfaces of tumor cells can be used to generate synthetic peptide immunogens for use as vaccines. When admixed with adjuvant, these peptide immunogens have been shown to enhance antitumor T-cell responses in cancer patients. A variety of adjuvants can be used, including oil-in-water-based adjuvants, like incomplete Freund's adjuvant, saponin-based adjuvants like QS-21, and others, like the monophosphoryl lipid A and trehalose dimycolate adjuvant system (199 ,200 ,201 ,202 ,203 ,204 and 205).

In a 1996 study, we used a synthetic peptide immunogen corresponding to an epitope from the gp100 melanoma antigen. When the second amino acid from the amino terminus was modified from a threonine to a methionine to create a peptide called *g209-2M*, binding to the HLA-A*0201 molecule could be increased ninefold in an *in vitro* competitive binding assay (106). *In vivo*, 91% of patients vaccinated with this peptide were successfully immunized on the basis of immunologic assays. Perhaps more important, when the T-cell growth and differentiation cytokine, IL-2, is added to the treatment regimen, 13 of 31 patients (42%) who were given IL-2 had objective clinical responses, and four additional patients had mixed or minor responses (see Table 17.1-2) (3). These results compare favorably and are significantly different than results from clinical trials using high-dose IL-2 alone where objective response rates generally fall between 15% and 17%.

Future directions in the development of synthetic peptide vaccines may include the use of modified peptides embedded into microspheres, a maneuver that can target antigen for uptake and MHC class I-restricted presentation by professional APCs. Other promising novel strategies developed in experimental animal systems use toxin-linked peptides (206 ,207) and peptides linked to endoplasmic reticulum insertion signal sequences covalently attached to the amino terminus of a peptide immunogen (208). The enhanced hydrophobicity of the resultant peptide may be responsible for its increased immunogenicity, but the mechanism of action is not fully understood.

Optimal Dose, Boosting, and Route of the Immunization Is Determined by Basic Immunologic Principles

The immunotherapist faces a number of bewildering choices when administering an anticancer vaccine. In addition to the issues already described (choice of antigen, immunogen, and adjuvant), a number of additional questions immediately present themselves. What is the appropriate dose of the immunogen? What route is most effective? Is a boosting of the immune response required and, if so, how many times and at what intervals? Should the vaccine be administered monthly, weekly, or daily? Answering these questions requires an understanding of the immunophysiology of vaccination *in vivo. In vitro* work with human cells is of limited benefit, whereas work in human subjects must necessarily be limited in its scope. Too many questions exist that must be answered in what are ultimately a limited number of clinical trials, each of which is based on a relatively small number of patients. Thus, in practice, questions regarding dose, route, and boosting are generally addressed in mouse models.

Evidence from animal models suggests that increasing the dose of immunogen beyond certain limits can hinder, or even abrogate, an immune response against that antigen. This has been shown to be the case after infection with high doses of a virus called *lymphocytic choriomeningitis virus*, as well as after administration of large amounts of peptide antigen (209 ,210 ,211 and 212). On the other hand, this observation may not be generalizable to all viruses or all immunogens based on synthetic peptide immunogens. For example, in early clinical studies using patients with melanoma, a similar state of immune unresponsiveness has not been observed at immunizing doses as high as 10 mg (213). It may be difficult to administer doses of viruses or peptides to humans that are equivalent to the large doses given to mice.

Based on the idea that more antigen is better, most viral and DNA vaccines are geared towards maximum expression and use the strongest available promoters. In our own preclinical trials using immunogens based on vaccinia viruses, as well as DNA given by blasts with the gene-gun, efficacy improves as the dose of immunogen increases (104 ,160).

It has long been known that boosting an immune response can increase its intensity. We now understand, however, that the efficacy of synthetic and recombinant anticancer vaccines can be enhanced with prime/boost regimens that use two different vectors. When primary and booster treatment regimens using a single vector (i.e., homologous boosting) are compared with regimens that used two different vectors (i.e., heterologous boosting), the heterologous boosting regimens generally result in significantly more potent antigen-specific CTL responses than are seen in animals who receive homologous boosting (214 ,215).

Using the optimal route of administration of any given immunogen can significantly improve the efficacy of an immunization strategy. Indeed, the administration of a synthetic peptide immunogen by the intraperitoneal route can lead to toleration, whereas administration of the same peptide immunogen subcutaneously leads to activation (210). For poxviral vectors, the intravenous route of immunization is optimal in mice (216). For any given immunogen, we surmise that the optimal route of immunization is likely to be dictated by the route that leads to the presence of the antigen on the maximal number of activated DCs, perhaps with the least amount of antigen presentation by normal, immunologically quiescent cells.

Conclusion

Part of "17.1 - General Concepts and Preclinical Studies "

In this chapter, we have attempted to describe the basic immunologic principles that may be useful in the design of anticancer vaccines. These principles are derived in large part from a deeper understanding of immune function that has resulted from a "reductionistic" approach characterized by understanding the interactions between the immune system and tumor cells on a molecular level (217). We have described the weak immunogenicity of human tumors, perhaps owing to their lack of expression of important immune activating signals *in vivo.* Specifically, tumors may lack expression of appropriate costimulatory molecules, tumor antigens, and MHC molecules, and they may directly suppress immune function through the expression of suppressive molecules, such as transforming growth factor-ß and IL-10.

Nevertheless, tumor-associated antigens can be identified, making possible the design of recombinant and synthetic vaccines for cancer. Potential targets include the products of mutations in tumor cells, as well as normal (nonmutated) differentiation antigens. To achieve direct recognition of the tumor cell, target antigen must be presented on the tumor cell surface. Work with these antigens in animal models and preliminarily in human clinical trials has shown that immunizations that are most effective in generating reactive T cells are the most therapeutically effective. T lymphocytes provide the specificity of recognition of the cellular immune response. Independent and collaborative roles for the CD8[+] and CD4[+] T-cell subsets are being elucidated. The activation of T cells by cancer vaccines is likely to be effected largely by DCs. Thus, the function of promoters for recombinant vaccines must be optimized in these "professional" APCs. Further adjuvants might best be designed to "super-activate" DCs.

A variety of immunogens can be used as cancer vaccines, including physically altered or gene-modified tumor cells. In the case of recombinant and synthetic vaccines, a number of different classes of immunogens are available, including peptides and proteins, naked nucleic acids, and recombinant viruses or organisms. The immunotherapist can add cytokines, chemokines, and costimulatory molecules to a vaccination to enhance its efficacy. To get the best response from a cancer vaccine, considerable evidence exists that more antigen is usually better, although some evidence exists to the contrary. The vaccine should be administered by a route that places it in contact with a maximal number of DCs, and heterologous boosting is usually better than homologous boosting. Finally, it is likely that mutable tumor cells are capable of altering their phenotype in a way that can result in their escape from immune recognition, but it is also abundantly clear that the immune system can recognize and destroy even large deposits of solid tumors in patients with cancer.

Introduction

Part of "17.2 - Immune Adjuvants "

The general principle of adjuvants is to promote, expedite, or lengthen the immune response to a given vaccine. The development of vaccines directed against human cancer has been facilitated by concurrent progress in the arena of adjuvants. Adjuvants aid immunotherapy by enhancing reactivity to tumors. This is true regardless of the immunogenicity of the tumor, although the most use would be found with those cancers of poor immunogenicity. For the purpose of this chapter, we usually do not discriminate between the establishment of immunogenicity *in vitro* versus *in vivo.* Some of the agents described herein have established themselves in the laboratory or in animal models, whereas others have shown promise in human clinical trials. For the purpose of this review, it is also of less importance whether the primary treatment uses defined

(epitopes associated with tumor rejection) or undefined immune targets (whole cells or lysates). Using intact tumor cells as immunogens has achieved protective immunity (protection against a subsequent challenge with tumor cells) in murine experiments. Most human cancers, however, are markedly less immunogenic, thereby validating the need for additional stimulation (1). Augmenting the response to weak immunogens is not the only reason for including an adjuvant. They can also: (a) increase vaccine potency with immunocompromised subjects, (b) bolster CD8⁺ T-cell-mediated immunity without diminishing humoral responses, (c) potentially decrease the vaccine titer needed, and (d) potentially decrease the number of booster vaccinations required (2).

Adjuvants possess diverse mechanisms of action (2 ,3 and 4), the discussion of which is beyond the scope of this summary. Initially, immunization with an adjuvant increases the durability, concentration at site of introduction, and stability of the antigen. After this, an adjuvant can enhance antigen uptake by antigen-presenting cells, even targeting certain cells of interest, such as macrophages or dendritic cells (DCs). It is important that the adjuvant not hinder antigen processing and presentation to immune cells that are major histocompatibility (MHC) class I-, class II-, or non-MHC-restricted. Lastly, potent adjuvants stimulate T- and B-cell responses via cytokine secretion after immunostimulation, thereby attracting and activating cell subsets. Certainly, many adjuvants mediate effects during more than one step of this process.

This chapter emphasizes those adjuvants under intense investigation as opposed to more classic agents, such as *Corynebacteria parvum*, whose clinical development is being deemphasized at this juncture. The list of adjuvants discussed in this chapter is outlined in Table 17.2-1 .

Table 17.2-1 Types of Immunomodulatory Adjuvants

Category	Example
Gel-type	Alum (aluminum hydroxide)
	Calcium phosphate
Synthetic	Nonionic block copolymers
	Muramyl peptides and peptide analogues
Emulsifier-based or oil emulsion	Saponins
	Freund's incomplete adjuvant
	MF59
Particulate	Immunostimulatory complexes
	Liposomes and liposomal complexes
Bacterial	Bacillus Calmette-Guérin
	Oligodeoxynucleotides
	Monophosphoryl lipid A
Immunogenic proteins and peptides	Keyhole limpet hemocyanin
	Pan-DR epitopes
Cytokines and growth factors	Interleukin-2
	Interleukin-4
	Interleukin-12
	Interferon-α and -γ
	Granulocyte-macrophage colony-stimulating factor
Haptens	Dinitrophenyl
	Trinitrophenyl

Gel-Type Adjuvant

Part of "17.2 - Immune Adjuvants "

Alum

The most common adjuvants in human clinical trials are aluminum hydroxide (alum) and aluminum phosphate (5). As of 1996, alum remained the only adjuvant licensed for human use in the United States (3). The principal function of alum adjuvants is to enhance humoral immune responses. The extensive surface area of aluminum salts—in particular, the hydroxide and phosphate variants—possess a large absorptive capacity for immunogens (6). Early studies showed stimulation primarily of Th2-type responses, as reflected by the interleukin-4 (IL-4), immunoglobulin 1 (IgG1), and immunoglobulin E (IgE) production they elicited. Most alum-based adjuvants involve the admixing of antigen with preformed aluminum salts, a process known as *aluminum absorption.* Owing to their biochemical characteristics, such as charge and surface area, alum-based adjuvants can be difficult to reproducibly produce. Yet these formulations possess an extensive and excellent safety record with human testing (7). As a result, alum is a component of several licensed human vaccines for diseases, including hepatitis B, diphtheria, and rabies (7). A novel class of adjuvant combining alum with gamma-inulin (Algammulin) is under development. The inulin component is a polysaccharide and is nontoxic and nonpyogenic in humans (8). Algammulin produced high titers of antibody against infectious agents, such as *meningococci,* after injection of the adjuvant and immunogen into mice (9). It elicits the Th1 and Th2 immune pathway. Lastly, immunization of mice with Algammulin and the E7 protein of human papillomavirus-16 (HPV-16) produces tumor regression in a 14-day tumor protection experiment (10). Future studies will determine how effective it is for augmenting cell-mediated antitumor activity in human subjects.

Synthetic Adjuvants

Part of "17.2 - Immune Adjuvants "

Nonionic Block Copolymers

Block copolymers are similar to saponin-based adjuvants in that they use a noninfectious, chemically defined formulation (11). Nonionic block copolymers are surfactants manufactured with propylene oxide and ethylene oxide (12). The adjuvant activity of a particular copolymer is directly related to its ability to bind protein antigen and capacity to stimulate complement and macrophages. In an *in vitro* system, a copolymer consisting of a central core of hydrophobic polyoxypropylene [POP; $(C_3H_6O_n)$] between two side blocks of hydrophobic polyoxyethylene [POE; $(C_2H_4O_n)$] demonstrated increased presentation of exogenous ovalbumin (OVA) via MHC class I and II pathways (13). Animal studies used mice immunized with a crude oil-in-water emulsion of block copolymer admixed with OVA or the gp120 protein derived from human immunodeficiency virus. MHC class I-restricted cytotoxic T lymphocyte (CTL) were induced that could recognize targets exogenously pulsed with the OVA253-276 synthetic peptide. Vibrant cytolytic activity was noted as long as 4 months after a single treatment (11). A later derivation of this compound, termed *CRL1005*, was used in subsequent studies and had a

slightly greater molecular weight. The CRL1005 copolymer elicited high titers of IgG_1 and IgG_{2b}. Its construction overcame a major deficiency of smaller block copolymers—poor solubility in aqueous solution that necessitated their use in oil-based formulations. The ability to administer CRL1005 in aqueous solution lessened the risk of systemic toxicity and localized reactivity at the site of injection. It aggregated into particles in aqueous solution, thus making it compatible with protein-based vaccines and enhancing its ability to act as a carrier moiety (14).

Muramyl Dipeptides and Tripeptides

Muramyl dipeptide (MDP) and tripeptide (MTP) are minimal components derived from the cell walls of bacterial peptioglycan that retain adjuvant activity (15). Their adverse effects, primarily vasculitis and nephrotoxicity, were initially demonstrated in early animal experiments (16). By loading MDP and MTP into liposomal microcarriers (17) or modifying them into analogues of the parent compound, such adverse effects were mitigated without affecting adjuvant potency (18). One derivative, glucosaminyl-MDP, displayed greater antitumor activity than MDP in a Meth A fibrosarcoma murine model. Glucosaminyl-MDP induced activated macrophages to produce IL-1, IL-6, and tumor necrosis factor-α (TNF-α) (19). When encapsulated into liposomes, the derivative MTP-phosphatidylserine (MTP-PE) demonstrated promise as a potent adjuvant in an interferon-γ (IFN-γ)-based therapy regimen for bladder cancer in athymic nude mice (17). The results of a randomized trial for osteosarcoma (20) and mammary carcinoma (21) in dogs, however, showed no survival advantage using adjuvant therapy with liposome-encapsulated MTP-PE compared with treatment with cisplatin or a placebo (empty liposomes), respectively. A 1989 phase 1 trial of liposomal MTP-PE in patients with renal cell carcinoma (RCC) (22) found no objective tumor regression. These disappointing results have greatly diminished the interest in MDP and its derivatives as a vaccine adjuvant, and, to our knowledge, no current clinical pronouncements have reached the literature.

Oil/Emulsifier-Based Surface Active Agents

Part of "17.2 - Immune Adjuvants "

Saponins

A crude saponin mixture, known as *Quil-A,* was initially shown to produce primarily a Th1 response. That is, it stimulated T cells and generated large titers of IL-2 and IFN-γ (23). Experiments with a more purified form showed it also upregulated Th2 responses, evoking strong humoral activity, including IgG1 and IgG2a production (24 ,25). It enhanced IL-10 production after immunization in mice. Human preclinical studies with Quil-A have targeted the HPV-16 protein after the demonstration that more than 90% of cervical cancer cells contain HPV genetic material integrated into the host genome (26). The E7 protein derived from HPV-16 is required for maintenance of the transformed state. Furthermore, the HPV-16-derived protein can serve as a tumor-rejection antigen (27 ,28 and 29), and peptides contained within it are immunogenic *in vitro* (30). Fernando et al. (31) vaccinated mice with various adjuvants and E7 protein. When admixed with Quil-A, the vaccine elicited Th1 responses, primarily CTL activity against an E7⁺-transfected EL4 murine thymoma cell line. E7 protein plus Quil-A also produced the most durable CTL activity. Quil-A, complete Freund's adjuvant (CFA), and Algammulin all produced similar titers of IgG_1. Quil-A plus E7 protein could not generate Th1-type immunity in immunized animals with a preexisting Th2-type response to E7. These data indicate that saponin adjuvants may be contraindicated in those patients with a preexisting Th2-type response to the immunogen.

More recently, experiments were conducted with highly purified saponins, such as QS-21, and, to a lesser extent, QS-7. C57BL/6 mice were vaccinated with soluble native or denatured OVA in a form containing various amounts of QS-21. OVA-restricted CTL responses were detected in splenocytes only from mice given antigen, including adjuvant. The antigen was effectively delivered to draining lymph nodes and spleen where, after a single vaccination, naïve lymph node cells were induced to proliferate and secrete IL-2 and IFN-γ. CD8⁺ T cells specifically recognized the OVA258-276 epitope, demonstrating the ability of QS-21 to evoke MHC class I-restricted, antigen-specific CTL after vaccination with soluble protein (32).

Human studies with QS-21 began in the 1990s, the majority of which were conducted at Memorial Sloan-Kettering Cancer Center. Such studies combined several adjuvants, among them QS-21, with gangliosides that are overexpressed in melanoma, including GM2, GD2, and GD3 (33). In addition, clinical trials were performed or are being planned that combine QS-21 with neutral glycolipids (Lewisʸ and Globo H), and glycoproteins (Tn and sialylated Tn antigens) (34). Investigators sought to improve their preexisting GM2/bacillus Calmette-Guérin (BCG) vaccine (35 ,36), which produced transient IgM and infrequent IgG titers. Indeed, the features of the antibody response included: (a) high IgM titers after initial administration, (b) swift secondary IgM production after booster administration, (c) prolonged IgM antibody titers as long as 10 weeks after booster administration, and (d) uniform IgG antibody production. The anti-GM2 humoral immunity displayed several hallmarks of a T-cell-dependent response, such as the prolonged induction of IgG1 and IgG3 antibodies (37). In addition, when coupled to the carrier keyhole limpet hemocyanin (KLH), a long-lasting, high-titer, anti-KLH antibody response was seen. The regimen was well tolerated with no severe side effects. After this, investigators began treating advanced melanoma patients with 1A7, an antiidiotypic antibody that mimicked the disialoganglioside GD2. After four weekly vaccinations with 1A7/QS-21, immune sera from all 12 subjects had detectable anti-antiidiotype responses. The hyperimmune sera specifically recognized tumor cells expressing GD2. One complete response (CR) and six instances of stable disease were achieved (38). Based on these results, a randomized phase 3 adjuvant trial with KLH/GM2 plus QS-21 was initiated in stage 2 and 3 melanoma patients by the Eastern Cooperative Oncology Group, the Southwest Oncology Group, the North Central Cancer Treatment Group, Cancer and Leukemia Group B,

Memorial Sloan-Kettering Cancer Center, and M. D. Anderson Cancer Center (39).

Incomplete Freund's Adjuvant

Incomplete Freund's Adjuvant (IFA) is composed of mineral oil and the emulsifier Arlacel A. It is the less toxic counterpart of CFA that includes *Mycobacterium tuberculosis.* Notwithstanding its long history of use in humans with only moderate toxicity, it has not been approved for commercial use (40). Despite its tendency to cause sterile abscesses and cysts, as well as carcinogenicity in mice, IFA does not appear to increase mortality, tumors, or autoimmunity in human recipients (7).

IFA has been included in tumor-associated peptide-based immunotherapeutics for patients with cervical cancer (41) and melanoma (42 ,43). In each instance, peptide epitopes were admixed with IFA before vaccination. In the melanoma study, 13 of 31 patients (42%) showed objective clinical responses (43). All melanoma patients received IL-2 in addition to IFA/gp100, however, making it difficult to assess the contribution of IFA to the observed effects. Enhanced T-cell reactivity *in vitro* could be demonstrated after treatment (44 ,45). Once again, though, it was not possible to separate the individual contributions made by IFA and IL-2 to the increased CTL and cytokine secretion observed in patient immune cells posttreatment versus pretreatment.

MF59

A number of submicron particulate adjuvants are under development as potential adjuvants for cancer treatment. MF59, a squalene-water emulsion, was planned as a delivery vehicle for the synthetic muramyl peptide MTP-PE. Early in its development, MF59 demonstrated an immunostimulatory capacity approaching that of the Freund's adjuvants, but without the concomitant toxicity (46). In fact, it was observed that the MTP-PE portion of the MF59-MTP-PE complex was responsible for the induction of major side effects. Further, the MTP-PE segment was inessential to evoke antibody reactivity. As a result, MF59 emulsion has been studied as a stand-alone intramuscular adjuvant. It has been further refined to reduce the size of the emulsion droplets from 1–2 mm to 200–300. This has resulted in a substantial increase in adjuvant activity, possibly owing to enhanced uptake of the smaller droplets by macrophages (7). A recombinant form of herpes simplex virus (HSV) type 2 (gD2) was complexed with MF59 and injected into Balb/C mice. Humoral responses of mice given MF59 were compared with animals injected with gD2 encapsulated into microparticles (47). The MF59 induced greater levels of serum IL-4 and IL-5 cytokines, implying a more Th2-type response. The microparticles induced more serum IFN-γ and IgG2a production, suggesting more of a Th1-type response. MF59 was again combined with gD2 in a 1998 report investigating how the immune system processes this adjuvant (48). MF59/gD2 was labeled with a fluorescent dye and injected intramuscularly into BALB/c mice. Only 3 hours after injection, a small portion of the MF59 could be detected in the subcapsular sinus of draining lymph nodes. At 48 hours, a majority of the MF59 was found within DEC-205⁺, MHC class II⁺ antigen-presenting cells. This observation strongly indicated that the vaccine was efficiently taken up by DCs. During this time, intracellular MF59 was also abundant in the paracortical (T cell) region of lymph nodes. This report indicates that MF59 interacts with DCs and later migrates to the draining lymph nodes, the site of efficient antigen presentation to naïve T cells (48).

MF59 has received its most extensive testing, more than 8,000 patients in several studies, combined with recombinant gp120 protein from human immunodeficiency virus–1, cytomegalovirus, HSV (7), influenza, and other viruses. It maintains an impressive record of safety and potency in seronegative and seropositive subjects (40 ,47). When combined with HSV type 2 in a phase 1/2 clinical trial, MF59 elicited antibody levels equivalent to that obtained with alum. Strong helper T-cell responses were induced as well (49). Safety and efficacy studies using MF59 as an adjuvant with cancer immunotherapy are planned.

Particulate Adjuvants

Part of "17.2 - Immune Adjuvants "

Immune-Stimulating Complexes

Immune-stimulating complexes are hydrophobically bonded micelles that are produced naturally after the admixture of cholesterol, lipid, and saponins (50). Immune-stimulating complexes form a particle of repeating units icosahedral in shape, approximately 30 to 40 nm in diameter (51). They were developed to enhance immunogenicity by: (a) physical presentation in the form of particles with multimeric formation of surface antigens, (b) guiding vaccine antigens to antigen-presenting cells and to the appropriate intracellular processing pathway, and (c) immune modulation (52). The saponin portion is derived from aqueous extracts of bark from the South American tree *Quillaja saponaria.* Although the extract is complex, the adjuvant activity is associated with the saponin component (53). During their creation, they may be combined with other moieties, such as hydrophobic glycoproteins or hydrophilic/amphipathic proteins (54). The ability to modify the chemical structure of immune-stimulating complexes greatly broadened their applicability.

Liposomes

The use of liposomes for targeted immunogen delivery has several favorable characteristics: (a) low cost, (b) low toxicity, (c) is itself a nonimmunogenic carrier, (d) stable, (e) biodegradable, and (f) can act synergistically with other agents (55). In the last decade, technical improvements simplified their construction and facilitated large-scale preparation. By using this improvement involving dehydration and rehydration, small vesicles are produced (˜100 nm), which have the ability to hold onto most of the loaded solute (55 ,56). Positively charged multilamellar vehicles are actively phagocytized by macrophages, beginning the cascade of events that culminate in the induction of CTLs (57 ,58 and 59). Negatively charged liposomes encapsulating OVA markedly bolstered IFN-γ production in mice vaccinated only once without boosting.

For a humoral antitumor approach, immunoliposomes are manufactured via linkage of antibody to a hydrophobic moiety stably integrated in the lipid bilayer (60). The antibody can be covalently or noncovalently attached to the hydrophobic region. Noncovalent linkages (e.g., to streptavidin or avidin), however, impart a strong binding constant to the molecule. The drawback of this approach is the potential immunogenicity of bulky side chains. It is largely for this reason that covalent coupling chemistry was developed (61). Complexing with lipid also promoted the monoclonal antibody stability in the circulation, increasing the terminal plasma half-life in rats fivefold as compared with its native form. In addition, the ability to detect the anti-HER2/neu immunoliposomes in the plasma 10 hours after vaccination indicated insignificant leakage or disassociation (60). Biodistribution and tumor localization studies further confirmed confidence in this adjuvant. The ability of immunoliposomes to treat established tumor xenografts was demonstrated in several nude mouse model reports (61 ,62). In another active treatment report, Zhou et al. (63) prolonged the survival of mice bearing an OVA-expressing tumor by immunization with OVA encapsulated in liposomes. Antitumor efficacy was ascribed to CTLs because cytolytic activity, not specific antibody, was detected.

The capacity of cytokines to enhance and regulate antitumor immunity made them attractive candidates to be combined with a liposomal delivery system. Owing to the superior efficacy of negatively charged liposomes, the charge and hydrophobicity of the cytokine had to be considered. Highly hydrophobic cytokines, such as IL-2, demonstrate incorporation rates of more than 80% (64). IL-2 was one of the first cytokines to demonstrate adjuvant activity in murine experiments, so it was not unexpected that it was the first to be tested as a vaccine adjuvant in concert with liposomes. Guinea pigs with established HSV-2 infections were given overlapping vaccinations with IL-2 liposomes and a soluble form of HSV-2 glycoprotein. Animals treated with both vaccinations showed a 70% decrease in disease recurrence compared with a 30% decrease for those animals given either agent alone. Soluble IL-2 was not beneficial. Importantly, it was demonstrated that a substantial clearance of the liposomal complex to regional lymph nodes occurred (65). In a similar study, male CD-1 mice received two injections intramuscularly with several tetanus toxoid-containing liposome formulations with or without IL-2/liposome complex. Secondary humoral immunity, as evidenced by IgG_1 secretion, was maximal when IL-2 was complexed with liposome-entrapped toxoid. IL-2 plus liposome-entrapped toxoid additionally augmented IgG_{2a} and IgG_{2b} titers, indicating concurrent induction of Th1 and Th2 cells (66). IL-1α, IL-7, TNF-α, and IFN-γ have also been efficiently incorporated into liposomes, and their adjuvant activity has been demonstrated in *in vivo* animal studies (64).

Bacterial Products and Derivatives

Part of "17.2 - Immune Adjuvants "

Bacillus Calmette-Guérin

BCG is a modified form of the *Tubercle bacillus.* It is most often used alone or admixed with tumor cells or lysates. It causes an inflammatory reaction at the site of administration, resulting in the recruitment and activation of macrophages, production of chemokines, and secretion of immunomodulators, such as IFN-γ, IL-2, and TNF-α. The putative mechanism of its antitumor activity is finally being elucidated. It is thought that it can induce antigen-specific effector cells, B and T lymphocytes, at the site of administration. Rapid proliferation and migration of specific immune effectors results in systemic response. It was established that BCG has profound effects on DCs, arguably the most efficient antigen-presenting cells in the body's arsenal. This is important because Langerhans' cells, a type of DC found primarily in the skin, is likely the first antigen-presenting cell to uptake antigen after intradermal or subcutaneous injection of BCG, its most common route of administration. Addition of BCG expedited homotypic adhesion of DCs. BCG increases expression of the DC maturation antigen CD83 and of the T-cell costimulator CD86 (B7-2) in a dose-dependent manner (67). BCG bacteria stimulates TNF-α gene transcription and TNF-α protein release from DCs also in a dose-dependent fashion. Furthermore, BCG augments the DC-derived production of IL-8, a potent chemokine of T cells and granulocytes, as well as the T-cell stimulatory potential of human DCs (68).

Since the 1970s, BCG administration has resulted in clinical regression of tumor. Morton et al. (69) injected BCG into the lesions of patients with cutaneous melanoma, resulting in tumor regression in five of eight subjects. In a study of 668 stage 2 melanoma patients, all those initially nonreactive to BCG became tuberculin-positive during treatment. The instances of disease-free and overall survival were statistically greater for those with negative skin reactivity before therapy (70). Over the years, BCG has been used in several studies as a postoperative adjuvant for those with high-risk primary metastatic lesions or lymph nodes (71 ,72 ,73 ,74 and 75). The number of patients varied from 30 to 327, and the duration of follow-up ranged from 1.8 to 6.0 years. None of these trials could demonstrate a significant impact of BCG on overall survival, disease-free survival, or recurrence. Berd and coworkers (76) treated 64 patients with melanoma, injecting a vaccine consisting of autologous, enzymatically dissociated, irradiated tumor mixed with BCG. Of 40 evaluable subjects, four partial responses (PRs) and one CR were achieved, with a median duration of 10 months. Delayed-type hypersensitivity (DTH) responses increased significantly during therapy, although any clinical correlation was not investigated.

Since the 1980s, BCG has remained the standard treatment for superficial bladder cancer (77 ,78 ,79 and 80) after transurethral resection owing to the 40% to 80% recurrence rate after surgery (81). The local cellular immune response in the bladder wall of patients receiving BCG has been studied. After a 6-week regimen, results showed a marker infiltration of T cells and mononuclear cells, mostly in suburothelial tissue. The ratio of Th:T suppressor cells in the bladder wall increased fourfold and remained detectable in biopsies for more than 1 year from treatment onset (82 ,83). No difference in lymphocyte infiltration pre- versus post-BCG treatment was observed in nonresponding subjects. The interaction of fibronectin on the extracellular matrix of the mycobacteria with tumor cells is thought to help prevent tumor cell motility (84).

BCG has been combined with mitomycin C to try to further reduce the rate of recurrence in patients with intermediate and

high-risk papillary superficial bladder cancer *in situ* (85). Treatment benefit was not significantly different with regard to time to initial recurrence (p = .53), frequency of recurrence (p = .36), progression (p = .70), or survival (p = .16). In a large, retrospective study organized by the European Organization for Research and Treatment of Cancer (86), 344 patients with papillary superficial bladder cancer *in situ* were randomized after resection to receive six weekly instillations with BCG or four weekly instillations with mitomycin C. Investigators were not able to establish that BCG was more effective than mitomycin C as a treatment option in high-risk patients with regard to disease recurrence.

The potential clinical benefit of BCG adjuvant therapy with other cancer types has been more difficult to assess. A prospective randomized trial at the Cross Cancer Institute (87) reported no therapeutic benefit of BCG treatment for 253 patients with Dukes' stage B_2 and C colorectal cancer after curative surgery. These findings contrasted with a 1984 report from The Johns Hopkins University (88) that demonstrated a significant enhancement in time to recurrence and disease-free survival for patients with stage B_2, C, or D colon cancer receiving BCG. In 1999, Vermoken et al. (89) randomized 254 patients with stage II or III colon cancer to receive three weekly vaccinations of autologous tumor cells and BCG or no additional treatment. A significant improvement in recurrence-free disease (p = .011) was obtained in stage II patients given active specific immunotherapy. In the studies demonstrating no treatment benefit, BCG was administered orally after surgery. In those studies reporting clinical efficacy, active specific immunotherapy (BCG was admixed with autologous tumor cells) was used. And so, conclusions are difficult because of the different protocols used. Different conclusions were also reached in two large clinical trials investigating the role of BCG in the treatment of non-Hodgkin's lymphoma (16 ,90).

In a large study of BCG-based active specific immunotherapy and RCC, 120 cancer patients were randomized to two groups: control (receiving no treatment) or experimental (receiving three weekly intradermal injections of 10^7 autologous irradiated tumor cells mixed with 10^7 BCG) (91). Fifty patients were classified as stages I-II with the remaining 70 patients classified as stage III according to the tumor node metastasis staging system. Treatment commenced 4 weeks after surgery to permit the subject to recover from any immunosuppression brought on by surgery and anesthesia. No systemic toxicity was observed. One month after the final injection, 38 of 54 immunized and evaluable subjects demonstrated a significant DTH response to tumor but not normal cells. Positive DTH responses were durable, remaining positive at 12 months follow-up in 16 of 28 patients. No enhancement of disease-free or overall survival was observed with patients given tumor/BCG therapy. Further, the contribution of BCG to the induction of DTH responses could not be determined because no subjects were given autologous tumor without BCG.

Reports of BCG adjuvant therapy for prostate cancer are infrequent. In 1982, Guinan and coworkers (92) randomized 42 patients with advanced prostate cancer to receive conventional therapy (consisting of exogenous estrogens and/or orchiectomy or observation alone) with or without four monthly injections of BCG. Forty-four percent of subjects receiving BCG had grade I or II tumors, whereas 62% of control patients had low-grade disease. Performance status and alkaline phosphatase levels were not significantly different between groups. The BCG-treated patients demonstrated a mean survival of 38 weeks compared with 28 weeks in control patients (p <.05). The BCG-treated patients, however, had a significantly reduced rate of infections, and so investigators acknowledged that this, rather than BCG-mediated tumoricidal activity, might account for the enhanced survival.

Oligodeoxynucleotides

Several diverse groups of bacterial proteins, such as lipopolysaccharide (93 ,94) are capable of inducing immune cell activation or increasing immune function (95). Bacterial DNA—but not mammalian DNA—activated B-cell proliferation and antibody secretion, whereas mammalian DNA did not (96). It is postulated that lymphocyte activation by bacterial DNA represents an early immune defense system in humans capable of distinguishing bacterial from host genetic material (97). Investigations of bacterial DNA mitogenicity revealed that CpG dinucleotides were detected at a frequency of 1 per 16 dinucleotides; approximately 25% as common in vertebrates and with markedly hypomethylated cytosines (98). Methylation of bacterial CpG motifs abrogated mitogenicity as determined by proliferative assay (98). Pretreatment of CpG motifs with deoxyribonuclease totally abolished lymphocyte stimulation, indicating that the observed effects were not owing to other culture components (96). Antigen-restricted B-cell activation by bacteria DNA requires antigen binding, as well as costimulation. Indeed, CpG oligonucleotides were able to provide such costimulatory signals by the synergistic activation of antigen-specific Ig production in the mouse B-cell line CH12.LX, which contains an antigen receptor for binding sheep red blood cells (98).

The molecular mechanism responsible for the immunostimulatory effects of oligonucleotides remains largely unclear. CpG motifs stimulated nuclear factor-κB (NF-κB) by inducing a reactive oxygen intermediate-dependent pathway. After enhanced NF-κB activity, increased levels of IL-6, a cytokine produced in response to microbial infection, were detected (99). Plasmid DNA was ingested by bone marrow-derived macrophages, as well as the macrophage cell line RAW 263, whereas methylated CpG dinucleotides were not (100). Ingestion induced a signaling pathway leading to NF-κB activation, and inflammatory gene (TNF-α) induction was demonstrated as indicated by Northern blot and electromobility shift analysis. To assess whether such effects occurred *in vivo*, mice were injected with bacterial DNA or calf thymus DNA. Within 4 hours of treatment, only the mice receiving injections with bacterial DNA demonstrated an increase in serum IFN-γ titers. Splenic natural killer (NK) cells from mice immunized with bacterial DNA were also induced to secrete IFN-γ (101).

In animal studies, Weiner and associates (97) used the 38C13 B-cell lymphoma model in which the idiotype (Id) of the 38C13 surface IgM acts as a highly specific tumor-associated antigen (102). Mice were immunized with 50 μg KLH, along with oligodeoxynucleotides (ODN) or CFA. The ODN-containing

CpG motifs induced the greatest amounts of anti-Id IgG2a (more effective than IgG1 at mediating antibody-dependent cellular cytotoxicity) and IgM as compared with ODN without such motifs. The absence of nonspecific IgM indicated that the humoral activity was directed against the idiotype of the 38C13 IgM. For *in vivo* survival experiments, mice received a single vaccination followed 2 weeks later by 38C13 cell administration. Mice given Id-KLH and CFA showed a median survival of 42 days with two animals remaining free of disease. Mice given Id-KLH and CpG ODN showed a median survival of 51 days with four animals remaining free of disease. In a subsequent study, the 38C13 model was again used to demonstrate the benefit of ODN and granulocyte-macrophage colony-stimulating factor (GM-CSF) combination therapy (103). CpG ODN and GM-CSF were additive in their ability to evoke anti-Id IgG after vaccination with Id-KLH. It was noteworthy that repeated vaccinations shifted the response from IgG1 to primarily IgG2a. In a 3-day tumor protection experiment, ODN plus GM-CSF resulted in 70% of mice remaining disease free—a superior finding compared with either agent by itself. Similar experiments demonstrated enhanced survival in mice treated with a combination of ODN plus IL-2 (104). Direct application of CgG ODN had no direct effect on tumor cell growth, and only minor treatment benefit was observed in the group immunized with CpG ODN alone. Therefore, it was most likely that the observed effects were owing to the CpG ODN-induced production of cytokines that caused greater susceptibility of the tumor cells to antibody-mediated cell cytotoxicity. Having established a relationship between ODN and B and NK cells, researchers went on to investigate the connection between ODN and human DCs. *In vitro*, treatment with CpG ODN induced the maturation of murine fetal skin DCs. That is, E-cadherin-mediated adhesion diminished, MHC class II was upregulated, and the cell surface expression of costimulatory molecules (CD40, CD80, CD86) increased. *In vivo*, CpG ODN injection augmented IL-12 production by DCs but had no effect on keratinocytes, indicating that, at least in murine skin, immunostimulatory DNA acted primarily on DCs (105). Lastly, the observation that subcutaneous injection of CpG ODN caused regional lymphadenopathy suggested that DCs activated by bacterial DNA could properly migrate to lymph nodes and, as per their normal function, stimulate DCs in lymphoid tissue.

Monophosphoryl Lipid A

Monophosphoryl lipid A (MPL) is produced after the acid hydrolysis of purified bacterial cell walls (16). This reaction produces a safe, immunogenic adjuvant. In the 1990s, MPL was shown to be nontoxic in mice and capable of increasing the extent of antibody responses to pneumococcal polysaccharides (106). In 1998, a vaccine construct consisting of a MUC-1-derived 24-MER synthetic peptide encapsulated with MPL in liposomes was tested in a mouse mammary adenocarcinoma model (107). Low-dose human MUC-1 peptide (5 μg) with MPL in liposomes given subcutaneously or intravenously generated enhanced survival and decreased the number of established lung metastases when administered three times before tumor challenge. The protective antitumor activity correlated with a Th1-type immune response involving MUC-1-restricted T-cell proliferation and the specific production of IgG2a antibodies.

As an adjuvant in humans, MPL has most frequently been used as a component of DETOX. DETOX is an adjuvant made up of detoxified MPL from *Salmonella minnesota*, cell wall skeletons of *Mycobacterium phlei*, squalane oil, and emulsifier (108). Schultz et al. (109) immunized 19 patients with resected stage III melanoma using a polyvalent melanoma antigen vaccine (40 mg) admixed with DETOX three times weekly for 4 weeks in a dose-escalation trial. A nonrandomized control group of 35 patients were immunized using the vaccine admixed with alum. A significantly greater percentage of patients receiving DETOX developed antibody responses. The DTH responses were similar for the two groups. Nevertheless, median disease-free survival was significantly better for the group receiving alum, thereby showing little treatment benefit for DETOX. Similarly, only two durable responses out of 42 patients were reported in a study of active immunotherapy with ultraviolet B-irradiated autologous whole melanoma cells plus DETOX (110). A randomized phase 2 study of sialyl-Tn and DETOX for 23 patients with breast cancer also demonstrated enhanced humoral immunity but little clinical impact (111). In contrast, Mitchell et al. (112) achieved promising results from several phase 1, 2, and 3 studies of two mechanically disrupted melanoma cell lines (M-1 and M-2 cell lines, also known as *Melacine*) injected subcutaneously along with the adjuvant DETOX. In one phase 1/2 report (108), 25 subjects were given 200 antigenic units (2×10^7 tumor cell equivalents) along with 0.25 mL of DETOX (consisting of 250 μg of cell wall skeletons and 25 μg of MPL) subcutaneously on weeks 1, 2, 3, 4, and 6. Adverse events were minimal and without anaphylactic reactions. Nineteen percent (20 of 106 patients) had objective tumor regression of tumor masses, including five CR. The median duration of response was 46 months. A strong association existed between clinical response and an increase in CTL activity, although antibody production did not correlate with treatment outcome (108). In a phase 3 study in patients with resected stage III melanoma, melacine plus DETOX again showed therapeutic benefit (113). A 66% overall survival rate was attained with a median relapse-free survival time of 36 months. All subjects responded to or failed treatment by 4 months after treatment onset.

Immunogenic Proteins and Peptides

Part of "17.2 - Immune Adjuvants "

Keyhole Limpet Hemocyanin

KLH is a powerful immunostimulatory protein that is produced by the mollusk *Megathura crenulata.* Originally, the capacity of KLH to evoke IgM, IgG, and DTH responses in normal recipients inspired subsequent studies in cancer patients. In earlier cancer investigations, it was used primarily as a carrier molecule for those immunotherapeutic approaches using haptens. More recently, its role has expanded to include acting as a surrogate marker of immunologic memory, providing a nonspecific indication about the effectiveness of the vaccine in enhancing a recipient's tumor antigen-specific immune responses.

Moltro and coworkers showed that KLH augmented NK cell activity in patients with transitional cell carcinoma of the bladder. Most studies have shown that KLH primarily elicits a CD4⁺ T-cell response (82 ,83). Jurincic-Winkler et al. (114) confirmed that KLH administered intravesically enhanced local cellular immunity within the bladder wall of patients with superficial bladder carcinoma. Twelve patients underwent complete tumor resections immediately before six weekly treatments with 20 mg KLH in saline followed by monthly treatments for the balance of 1 year. Using immunohistochemistry, they noted a marked infiltration of immunocompetent cells into the bladder wall 6 weeks into treatment. The majority of the cell infiltrate into the submucosa were CD4⁺ T cells, but CD8⁺ T cells and B cells were also observed to a lesser extent. The immunophenotypic characteristics of the control group (recipients without malignant bladder disease or cystitis) was similar. HLA-DR–positive cells were found in bladder walls with the number of such cells increasing during treatment and persistent up to 9 months of follow-up. NK cells and macrophages were rare, confirming previous findings (115). Several studies with bladder cancer patients demonstrated that KLH given subcutaneously (116) or intravesically (114 ,117 ,118) produced a reduction in tumor burden without major side effects. Yet, no clinical responses were shown. Nestle et al. (119) vaccinated 16 melanoma patients with autologous DCs pulsed with melanoma-derived peptides or tumor lysates combined with KLH. All patients displayed a positive immune response to KLH as demonstrated by a KLH-restricted DTH response. It could then be implied that KLH helped evoke a more vibrant and durable Th-cell response—two patients still had positive DTH reactions more than 6 months after their final treatment. All groups received KLH. Thus, it remains to be conclusively established that KLH administration enhances tumor regression *in vivo*, despite its ability to augment immunity. It certainly is valid to state, however, that KLH acts as a neoantigen of great potency, permitting investigators to monitor the induction of specific immune reactivity (119).

Pan-DR Epitope

The numerous reasons for eliciting Th activity led to the development of artificial Th pan (HLA)-DR epitopes (PADRE). This group of nonnatural peptides has a polyalanine backbone and bind with intermediate or high affinity to nine of ten common HLA-DR specificities (120). The idea for this approach arose from research suggesting that bulk or charged side chains, oriented at angles away from the DR-peptide complex, are frequently recognized as immunodominant regions (121). PADRE peptides were more strongly immunostimulatory to peripheral blood mononuclear cells *in vitro* as compared with the tetanus toxoid peptides previously used to elicit Th cells (120). Several PADRE peptides of various lengths and forms (mono- and multimeric) have been studied. Some variants cross-react with particular murine MHC class II alleles, thereby establishing the ability of PADRE epitopes to provide T-cell help for MHC class I-restricted immune responses (122). From the murine experiments arose studies concerning human cancer and infectious disease. One of the types of cancers investigated involved those containing p53 mutations. p53 is a cellular regulatory molecule, which is overexpressed in approximately 50% of all malignant cells (123 ,124). Moreover, its overexpression frequently is associated with poor prognosis. Yu and coworkers (125) immunized HLA-A2.1 transgenic mice with immunodominant p53 peptide epitopes (p53$_{149-157}$ and p53$_{264-272}$) in conjunction with PADRE peptides in IFA. CTL with strong affinity to the p53 peptides were elicited. CTL were cytolytic against the established breast carcinoma cell line MDA-MB231 (HLA-A2.1⁺ and overexpressing p53), but without concurrent lysis of human HLA-A2.1⁺ cells displaying normal p53 expression. The specific lytic activity confirmed earlier findings that showed vaccination with p53 peptides resulted in potent antitumor efficacy against murine tumors overexpressing mutated murine p53 (126). The precise contribution, however, of PADRE peptides in cancer vaccines targeting p53 or other gene products remains unclear.

Cytokines

Part of "17.2 - Immune Adjuvants "

Interleukin-2

IL-2 is produced principally by Th cells and induces the activation and proliferation of a variety of cells (127), including T cells, NK cells, macrophages, epidermal Langerhans' cells, and oligodendrocytes (4). IL-2 also enhances the secretion of cytokines, such as IFN-γ and TNF-α (128). Initial work using murine tumor models indicated that IL-2 could retard the development of 3-day liver and lung micrometastases in a dose-dependent fashion (129). A phase 1 clinical trial with IL-2 therapy alone was unsatisfactory, as none of 66 metastatic melanoma patients responded to treatment (130). The balance of escalated dose of IL-2 with minimal treatment-related mortality (>1.5%) and acceptable toxicity resulted in a 15% combined CR plus PR against several cancers, including melanoma, renal, colorectal, breast cancer, and non-Hodgkin's lymphoma (131). In a 1998 study, IL-2 adjuvant therapy was combined with immunodominant peptides from the gp100 melanoma-associated antigens and IFA. Based on *in vitro* immune monitoring analysis, 91% of patients were successfully immunized with these synthetic peptides. *In vivo*, 13 of 31 patients (42%) receiving the peptide vaccine plus IL-2 had objective cancer responses, and four additional patients demonstrated mixed or minor responses (43).

Some clinical benefit was observed in 29 patients with stage IV colorectal cancer who received 15 doses of IL-2 and IFN-α with only four partial responses (17%) (132). Even fewer clinical responders resulted from bolus IL-2 administration combined with the adoptive transfer of anti-CD3–stimulated T-killer cells (133). Also, capillary leak syndrome was observed in several of these reports.

The approach of combining IL-2 with lymphokine-activated killer (LAK) cells most commonly harvested from peripheral blood and activated *in vitro* was first studied in a clinical trial of 180 patients treated with IL-2 and LAK cells, which resulted in a CR plus PR rate of 35% and 21% for RCC and melanoma, respectively (134 ,135). Duration of response varied from 1 month to more than 5 years. Histologic analysis of subcutaneous melanoma lesions revealed widespread infiltration of lymphocytes, suggesting that the mechanism of action was enhancement

of local immune reactivity (129). Another report concerned six melanoma patients who had failed previous treatment with chemotherapy and isolated perfusion. They were treated with 7 to 16 × 10⁹ LAK cells plus bolus IL-2. All six responded to some degree with four PR, one CR, and one patient with stable disease (136). Blay et al. (137) gave a continuous infusion of IL-2 (20 to 28 × 10⁶ units per m² per course) in combination with LAK cells (4.8 to 7.5 × 10¹⁰) to 25 patients with metastatic RCC and achieved a 20% overall response rate. A larger follow-up phase 1/2 trial treated 68 evaluable RCC patients with a combination of IL-2, LAK, and IFN-α (138). Four (24%; three CR, one PR) and 19 responders (37%; 6 CR, 13 PR) were obtained in the phase 1 and 2 trials, respectively. No patient was administered only IL-2 and LAK, so it was not possible to assess if the IFN-α accounted for the enhanced clinical efficacy as compared with the previous report (137).

IL-2 has also been used as an adjuvant in tumor-infiltrating lymphocyte (TIL) studies. Abundant IL-2 receptors on the surface of TIL permitted *in vitro* expansion by culturing in the presence of IL-2 (129). After *in vitro* growth with IL-2 and autologous tumor, TIL demonstrated cytolytic activity against autologous and HLA-matched allogeneic tumors of murine, as well as human, origin (139 ,140 ,141 and 142). Most likely, the largest study on the therapeutic benefit of IL-2/TIL immunotherapy reported on a 5-year experience with 86 metastatic melanoma patients treated with autologous TIL and high-dose bolus IL-2 (720,000 IU per kg at 8-hour intervals) (143). Thirty-four percent of patients displayed a partial or complete clinical response, which compared favorably with the 17% overall response rate observed in melanoma or RCC patients receiving only high-dose IL-2 (135).

A combined regimen of TIL, IL-2, and IFN-α was used to treat 11 patients with metastatic RCC. IFN-α alone was given before radical nephrectomy, as well as in conjunction with IL-2 (6 × 10⁶ U per m² per day IFN-α, 2 × 10⁶ U per m² per day IL-2) during the weeks of TIL infusion. 0.14 to 16 × 10¹⁰ TIL were infused, containing mostly (>80%) CD3⁺ T cells and an average ratio of 2:1 CD8⁺:CD4⁺ lymphocytes. The treatment was fairly toxic. Reversible thyroid dysfunction, mild to moderate fever, chills, fatigue, diarrhea, and nausea occurred in at least nine of ten evaluable patients. In this and a second similar investigation, a 32% total response rate was observed (seven CR, three PR) with disease-free survival lasting more than 3 and one-half years (144).

Interleukin-4

IL-4 expression is limited to T cells, mast cells, basophils, and eosinophils, unlike several other cytokines that are expressed by various hematopoietic and nonhematopoietic cell lineages (145). Development of type II T-cell cytokine profiles is strongly affected by IL-4 (146), although the cell source during this process is uncertain (147). IL-4 augments the ontogeny of B lymphocytes by enhancing their activation, proliferation, and differentiation. It upregulates the expression of MHC class II antigens, human leukocyte function-associated antigen-1 (148). It increases CTL cytotoxicity (149) and stimulates lytic activity and expansion of TIL *in vitro* (150). IL-4 also has profound effects on the generation of DCs from precursors of the monocytic lineage pathway (151 ,152 ,153 and 154), in part by downregulating CD14 expression (148). In conjunction with phase 1 clinical testing, IL-4 injections produced moderate eosinophilia in all 17 cancer patients (155). Systemic eosinophil degranulation was noted based on dose-dependent elevations in serum major basic protein and urine major basic protein. Blood samples from eight patients showed enhanced eosinophil survival that could be abrogated by antibodies to IL-3, IL-5, and GM-CSF. Cells previously activated before IL-4 exposure generally exhibited increased proliferation and biologic function. Yet, if already activated before IL-4 exposure, the same cell types could be similarly inhibited (156).

Earlier animal studies focused on the ability of IL-4 to demonstrate antitumor efficacy against a variety of tumors, including chemically induced fibrosarcoma, spontaneous adenocarcinoma, melanoma, and RCC (16). In 1998, Husain and coworkers (157) further expanded the potential clinical benefit of IL-4 by analyzing its activity in the treatment of glioblastoma. It had been previously determined that: (a) glioblastoma cells express IL-4 receptors with high affinity, and (b) a chimeric molecule consisting of IL-4 and *Pseudomonas* exotoxin was highly cytolytic in a dose-dependent fashion (158). Female athymic nude mice were implanted with the U251 human glioblastoma cell line by subcutaneous injection into the flank, generating tumors in less than 6 days. Animals given the IL-4/endotoxin chimeric protein intratumorally on alternate days for 3 to 4 days demonstrated a complete remission of small and large tumors without accompanying toxicity. A marked antitumor response was observed as well with intravenous and intraperitoneal administration of chimeric protein. A phase 1 clinical trial for the treatment of recurrent glioma using intratumoral vaccination with IL-4 toxin is planned.

By 1994, the safety and tolerability of recombinant human IL-4 (rhIL-4) was established in phase 2 and 3 studies in human subjects with several different cancers at doses as high as 5 µg per kg per day (159). A phase 2 clinical trial of rhIL-4 involved 36 patients with malignant melanoma and no previous systemic therapy for metastatic disease (156). Subjects received 5 µg per kg per day subcutaneous injections for 1 to 28 days succeeded by a 7-day rest period, then another cycle. Aggressive supportive care was implemented to try to prevent serious side effects that could force a dose reduction. Although 68% (23/36) of subjects developed at least one grade 3 or 4 toxicity distinct from elevated liver function tests (the most frequent side effect), all but three completed treatment. One durable CR (15+ months) and two cases of stable disease were achieved. The areas of tumor that were eliminated in the lone CR were a large cervical lymph node and several minute lung nodules. The estimated median survival was 6 months. Serum levels of IL-4 were not measured. Therefore, although the clinical responses were minimal, it remained unknown whether the IL-4 levels previously shown to display antitumorigenicity *in vitro* (160) had been reached *in vivo.* Some degree of therapeutic benefit was also observed in a phase 2 clinical trial of rhIL-4 for patients with recurrent or advanced non-small-cell lung cancer (101). Of the 63 subjects enrolled, eleven had stage IIIB disease and 53 had stage IV disease. Patients were randomized to receive low-dose (0.25 µg per kg) or high-dose (1.0 µg per kg) rhIL-4 injected subcutaneously three times per week. The regimen consisted

of at least two cycles of 4 weeks' duration each or until disease progression or severe toxicity occurred. No grade IV toxicity developed in either group. No cardiac toxicity was observed. One patient per group discontinued treatment owing to toxicity. The most common side effects at both dosages were mild to moderate fever and rigors. One PR (1 of 41 patients; 2.5%) and eight cases of stable disease (8 of 41 patients; 20%) were achieved in the high-dose group. Only a single case (1 of 22 patients; 5%) of stable disease was achieved in the low-dose group. No significant difference existed between the dosage groups in median survival time or the percentage of subjects alive after 1 year. The promising percentage of subjects at the higher dose with decreased disease progression combined with the lack of dose-limiting toxicity has led to ongoing clinical testing using rhIL-4 at higher doses in patients with stage IV non-small-cell lung cancer.

Interleukin-12

IL-12, a heterodimeric cytokine first demonstrated as being secreted by phagocytic cells as part of the innate immune repertoire, has lately shown antitumor potency. It is produced by many kinds of immune cells, including macrophages, monocytes, B cells, granulocytes, keratinocytes, mast cells, and DCs. It induces the maturation and proliferation of preactivated T and NK cells and augments T- and NK-mediated cytolytic activity. IL-12 stimulates T and NK cells to make several cytokines, such as IFN-γ, TNF-α, IL-2, IL-3, IL-8, IL-10, and numerous colony-stimulating factors. It also directs the naïve Th cell towards a Th1 (effector cell) phenotype while at the same time promoting its expansion (161 ,162 and 163). IL-12 does not exert its antitumor effects directly (164 ,165), probably because only T cells, NK cells, and DCs express the cognate receptor. The effect of IL-12 on DCs has just been elucidated. DCs contain IL-12 receptors, and signaling via this receptor involves activating members of the NF-κB family for DNA binding (166). Recombinant IL-12 primes purified DCs exogenously pulsed with tumor peptides *in vitro* for potent sensitization *in vivo* (167 ,168).

Brunda and colleagues (169) administered systemic IL-12 five times per week for a total of 4 weeks to mice previously injected with B16F10 melanoma cells. Tumor growth was markedly diminished, even when treatment did not begin until day 28 when tumors were well established. Antitumorigenicity resulted largely from the contribution of CD8$^+$ cells and not as much from CD4$^+$ or NK cells. Studies involving antiangiogenic factors capable of cutting off a tumor's blood supply by preventing new vessel formation or by blocking those already formed suggested an additional role for IL-12 in tumor inhibition. Voest et al. (170) examined the effect of IL-12 in a model of basic fibroblast growth factor–induced corneal neovascularization in normal and immunodeficient mouse strains. In normal, T-cell–deficient and in T- and B-cell–deficient mice, IL-12 injection strongly abolished vessel formation. The effect could be reversed by concurrent administration of antiinterferon monoclonal antibodies, indicating that antiangiogenesis was mediated through this cytokine (170). But, in a previous study, injection of anti-NK cell monoclonal antibody, not anti-IFN-γ monoclonal antibody, abrogated the enhancement of IFN-γ–producing T cells (171). These findings imply that IL-12 may promote an antitumor effect via more than one pathway, including one distinct from that mediated via various immune effector cells. After the observation that tumors in IL-12–treated mice displayed a severely diminished system of blood vessels, it was established that IL-12 promoted production of an antiangiogenic protein, IPO-10, and became the basis of an IL-12–based phase 1 clinical trial for the treatment of kidney cancer (172).

A phase 1 dose-escalation study to assess safety, maximum tolerated dose, pharmacokinetics, and antitumor activity after intravenous injection of rhIL-12 was reported in 1997 (173). Patients received escalating doses (3 to 1,000 ng per kg per day) of rhIL-12 via bolus intravenous infusion. The regimen consisted of one injection followed by a 2-week rest period, and then once daily for 5 days every 3 weeks. Forty patients participated, including 20 with RCC, 12 with melanoma, and five with colon cancer. Routine toxicities included fever, chills, fatigue, nausea, vomiting, and headache. Common laboratory affects included anemia, neutropenia, lymphopenia, hyperglycemia, thrombocytopenia, and hypoalbuminemia. The dose-limiting toxicities included oral stomatitis and abnormal liver function tests. The elimination half-life was between 5.3 and 10.3 hours. One RCC patient achieved a partial tumor regression that was still ongoing after 2 years. One melanoma patient achieved a complete regression of small pleural-based nodules and cervical adenopathy lasting 4 weeks. None of the 14 patients injected at the maximum tolerated dose demonstrated a clinical response. Owing to the low number of patients per dose level and prior immunotherapy, it was not possible to assess the therapeutic benefit of rhIL-12. It should be mentioned that a phase II clinical trial for RCC had to be stopped when two patients died after IL-12 administration and several others experienced severe side effects. The initial investigation theorized that the subjects received multiple doses of IL-12 before the previous dose had time to clear from their systems (174). No such severe toxicities were observed in a phase 1/2 clinical trial of patients with breast cancer, melanoma, and head and neck cancer after direct intratumoral injection of autologous fibroblasts secreting IL-12 (175). Clinical benefit occurred, as shrinkage of the injected lesions and more than one-half the distal lesions was noted in three melanoma patients, two breast cancer patients, and one patient with head and neck cancer.

Interferon-α

IFN-α has been shown to be one of the more effective cytokine adjuvants in the treatment of melanoma and renal carcinoma. The proposed mechanisms of action included activation of intracellular signaling pathways that, in turn, modulate numerous cytokines including IL-1, IL-2, IL-6, IL-8, and TNF-α (176). In 1995, Doveil and associates (177) reported that IFN-α-2b treatment (3 MU intramuscularly three times a week) was well tolerated and increased 5-year survival from 36% to 62% in patients with stage IIIB melanoma (177). A 1996 report from the Eastern Cooperative Oncology group also underscored the potential clinical benefit of IFN-α-2b therapy in the treatment of melanoma (178). Two hundred fifty-two subjects were treated with maximum tolerated doses of 20 MU per m^2 per day intravenously

for 1 month and 10 MU per m^2 three times per week subcutaneously for 48 weeks. A significant increase in relapse-free survival was achieved after periodic examination of tumor burden, as well as regional lymph node metastasis. Despite severe toxicity (67% of all patients demonstrated grade 3 toxicity and two patients died from lethal hepatic toxicity), 5-year survival rates increased from 37% to 46% (178). It should be noted, however, that using a different method of statistical analysis (two-sided instead of one-sided p test) and quality-of-life survival analysis (Q-TwiST), a reinvestigation of the data concluded that the improvement was significant only for those patients who considered toxicity to have a high relative value and relapse to have a low relative value (179). In 1998, a comprehensive summary of adjuvant IFN-α therapy for melanoma reported clinical benefit in several multicenter trials (180). High-dose IFN-α-2b treatment of patients with stage IIB and III melanoma received 20 MU per m^2 intravenously daily for 5 of 7 days per week for 4 weeks, followed by 10 MU per m^2 subcutaneously three times weekly for the remainder of 1 year. Statistically significant improvements in overall and recurrence-free survival (p = .47 and p = .004, respectively) were achieved (181). Severe toxicities prompted the study of low-dose IFN-α (e.g., 3 MU subcutaneously daily three times weekly for 36 months), but, thus far, durable responses have not been obtained.

Because IFN-α is important in priming tumor-specific lymphocytes and IL-2 enhanced lymphocyte expansion, immunotherapy using IFN-α and IL-2 was thought to have synergistic activity. This theory was substantiated in clinical trials of IFN-α and IL-2 in metastatic renal cancer, which achieved a 30% response rate. Combined IFN-α and IL-2 did not seem to significantly benefit patients with metastatic colorectal carcinoma, but this could reflect the failure to show treatment benefit when either cytokine was used singly (132). IFN-α adjuvant therapy has also been combined with other adoptive cellular immunotherapy. In one such study, renal carcinoma patients received IFN-α before nephrectomy. TIL were isolated from autologous tumor, cultivated in IL-2, and returned to the patient along with continuous *in vivo* IL-2 infusion. An overall response rate of 30% was achieved in this regimen. In addition, the responses appeared to be more durable than those observed with TNF-α and IL-2 combination therapy (144). IFN-α has also been used with melanoma patients who were nonresponders to previous treatment with an allogeneic melanoma vaccine (182). Forty percent of patients responded as measured by regression of tumor. Although this response rate is greater than the response to IFN-α or vaccine alone, the study design did not allow comparison of combination therapy with either single therapy. In 1998, Tonini and associates (183) used TNF-α and IL-2 in combination with chemotherapy [cyclophosphamide, methotrexate, and 5-fluorouracil (5-FU)] in a pilot study of ten patients with stage I and II breast carcinoma. The regimen was well tolerated, although transient leukopenia and fever were common. No clinical responses were reported.

The literature indicates that the potential clinical benefit of IFN-α as an adjuvant for cancer treatment is dependent on tumor type. When seven randomized trials for chronic myeloid leukemia were analyzed, it was evident that regimens using IFN-α produced a significant improvement of 5-year overall survival rates (from 42% to 57%), as compared with standard chemotherapy treatments with drugs such as busulfan or hydroxyurea (184). Yet, for patients with advanced colorectal cancer, the addition of IFN-α-2b to standard therapies has not proved beneficial. When used as an adjuvant to single modulation chemotherapy [leucovorin (folinic acid) concurrently with 5-FU], IFN-α-2b (5 MU subcutaneously three times weekly) actually decreased overall survival rates and had more frequent toxicity and contraindications (including neutropenia, anemia, diarrhea, and flulike syndrome) as compared with the group given only leucovorin and 5-FU (185). In a subsequent report, the combination of IFN-α-2b with 5-FU did not provide any benefit over treatment solely with 5-FU (186). In summary, when used alone or in combination with other immunotherapeutic modalities, studies suggest that IFN-α has potential therapeutic benefit for certain cancer types, the durability and frequency of which await long-term follow-up (187).

Interferon-γ

IFN-γ mediates numerous biologic activities. It enhances the expression of MHC class I and II molecules and other surface molecules, such as tumor-associated antigens and IL-2 receptors. IFN-γ modulates lipid metabolism. It displays antiviral and antimicrobial activity (4). NK-produced IFN-γ plays a key role in acute inflammation. During antigen-specific immune response, it modulates antigen presentation, as well as lymphocyte differentiation, in a classic Th1-type reaction (188). It affects the nonspecific and specific arms of the immune system in a myriad of ways, including Ig synthesis by B cells and activation of CTL (4). Although it has been investigated for many years as an immune adjuvant in cancer patients, the number of clinical trials with IFN-γ have been much less frequent as those with IFN-α.

The several clinical trials using IFN-γ for the treatment of RCC achieved disparate results (189 ,190 ,191 ,192 and 193), which is not entirely surprising considering the disparate schedules and doses. Aulitzky et al. (192) performed a dose-escalation phase 1 study using 10, 100, and 500 μg of subcutaneus IFN-γ weekly for a total of three injections. Beta-2-microglobulin and neopterin served as biologic surrogate end points. Patients at the 100 μg dose demonstrated beta-2-microglobulin and neopterin levels comparable to those given 500 μg, yet without the toxicity levels resulting from the highest dosage. A subsequent phase 2 study with 100 μg of rhIL-4 reported a 30% response rate with a duration of from 6 to 24+ months (192). Ellhorst et al. (193) achieved a 15% response rate with a duration of from 2 to 18 months. In one of the largest multicenter studies, 202 RCC patients were evaluated after treatment with 60 μg per m^2 rhIL-4 subcutaneously once every 7 days until disease progression. During the initial year of treatment, subjects were analyzed for therapeutic benefit and adverse events every 57 days. Ninety-two percent of subjects experienced a drug-related adverse event, but only 14% had a grade 3 or 4 toxicity. Clinical responses were disappointing: only 6% of subjects were classified as responders. In addition, the median survival observed (13.4 months from treatment onset) was not an increase over that obtained in other

studies. Bruntsch et al. (190) also obtained minimal clinical responses in a phase 2 study in metastatic RCC.

Granulocyte-Macrophage Colony-Stimulating Factor

GM-CSF is a glycoprotein that modulates the maturation, production, and function of the granulocyte and monocyte-macrophage subpopulations of human white blood cells (194 ,195). It is produced by monocytes, B lymphocytes, neutrophils, eosinophils, mast cells, keratinocytes, fibroblasts, endothelial cells, osteoblasts, and various epithelial cell types. Constitutive expression by resting cells is low, but after stimulation, such as infection by microbes or microbial products, secretion is greatly enhanced (196). GM-CSF has pronounced effects on the immune system, including:

1. Upregulating MHC class II expression
2. Modulating other hematopoietic growth factors
3. Eliciting localized inflammatory responses at the site of antigen deposition
4. Stimulating myeloid precursors in bone marrow
5. Promoting DC migration and development (197 ,198 ,199 and 200)

As far as the effect on DCs is concerned, GM-CSF potentiates several *in vitro* effects that would suggest it being advantageous as an adjuvant in immunotherapeutics. The addition of GM-CSF to peripheral blood DCs has been shown to prolong cell viability beyond 30 days of culture. Such long-lived DCs remain immunostimulatory, as evidenced by their ability to provoke T-cell proliferation in autologous and allogeneic-mixed leukocyte reactions. Total cell number, however, does not increase over time, implying the inability of GM-CSF to induce DC division and proliferation (201).

Clinical trials of GM-CSF as an adjuvant began in earnest after a 1994 report by the American Society of Clinical Oncology recommended further research for adult and pediatric cancers (202). In a 1996 study of GM-CSF's *in vivo* immunomodulatory properties (203), 12 patients with small-cell lung cancer were given a single 2.5, 5.0, or 10.0 μg per kg injection of the cytokine 3 days before ACO (cyclophosphamide, doxorubicin, and vincristine) chemotherapy. After chemotherapy, patients received supportive therapy with recombinant human GM-CSF 5 μg per kg daily for 8 days. GM-CSF enhanced the MHC class II expression on monocytes, confirming earlier *in vitro* findings (204). GM-CSF demonstrated a minor effect on adhesion molecules: only CD44 (a molecule important for the binding of leukocytes to bone marrow stroma and lymphoid organs) levels were markedly induced. An increase in IL-1 receptor α plasma and soluble IL-2 receptor levels were detected as well. To assess whether such immunomodulation could translate into therapeutic benefit, Samanci et al. (205) treated 18 colorectal carcinoma patients with recombinant human carcinoembryonic antigen with or without 80 μg per day of GM-CSF subcutaneously on days 1–4. The regimen was repeated six times over a term of 9 months. The recombinant human carcinoembryonic antigen–specific proliferative activity and IFN-γ secretion levels were higher in the nine GM-CSF recipients compared with the non–GM-CSF group. A smaller percentage of GM-CSF recipients also demonstrated IL-4 secretion via enzyme-linked immunospot assay indicative of a type II response. Those given GM-CSF had an increased humoral response as well, as evidenced by nine out of nine patients developing increasingly higher IgG antibodies against recombinant human carcinoembryonic antigen after each cytokine injection, whereas only three out of nine patients not given GM-CSF displayed no antibodies whatsoever. No evidence of clinical benefit for any subject was indicated.

Two reports involving GM-CSF adjuvant therapy for metastatic prostate cancer (206 ,207) and RCC (208) also showed no treatment benefit. In the first report, a phase 2 trial was performed to determine the efficacy of infusions of DCs exogenously pulsed with two HLA-A2–restricted peptides derived from prostate-specific membrane antigen. Each subject received six infusions of DCs and prostate-specific membrane antigen peptide-1 and prostate-specific membrane antigen peptide-2 peptides (LLHETDSAV and ALFDIESKV, respectively) every 6 weeks. GM-CSF was self-administered by subcutaneous injection at a dose of 75 μg per m^2 per day for 7 days with each of six infusion cycles. Most reported side effects (local reactions at the injection sites, pain, fever, and fatigue) were of mild severity, although 11 patients with such symptoms requested discontinuation of GM-CSF. DTH responses against a panel of highly immunogenic recall antigens improved in five control patients and only three patients receiving GM-CSF. One CR plus eight PRs were obtained among 44 subjects who were given adjuvant therapy compared with 2 CRs plus 17 PRs among 51 subjects who did not receive GM-CSF (209). Thus, no *in vitro* or *in vivo* treatment benefit was observed in this prostate cancer vaccine study. In the second report, 24 patients with metastatic RCC were given 10 mg per kg of GM-CSF per day using a 14-days-on/14-days-off regimen. Toxicity, including nausea, vomiting, fever, pain, skin reactions, fatigue, myalgia, and hyperleukocytosis, often required dose modifications. Three patients demonstrated a slowing in the progress of their cancer, but 21 of 24 subjects died from their respective illnesses. Because 17 of 24 patients had received prior immunotherapy, it is possible that a more definitive assessment of GM-CSF activity could be conducted using untreated patients.

Finally, supportive adjuvant GM-CSF therapy has also been used to try to mitigate the side effects of chemotherapy and increase the maximum tolerated dose. As with its use as an antitumor agent, the results with GM-CSF were mixed. Stoger et al. (210) found that posttreatment administration of GM-CSF allowed for dose intensification of epidoxorubicin and cyclophosphamide in a randomized phase 2/3 study in patients with advanced breast cancer. The ability of GM-CSF to enhance hematologic recovery in a chemotherapy setting was demonstrated in phase 1/2 studies of advanced sarcomas (211 ,212). In a phase 2 study of patients with squamous cell carcinoma of the head and neck, however, GM-CSF adjuvant therapy did not improve antitumor activity for patients receiving cisplatin and 5-FU (213).

Haptens

Part of "17.2 - Immune Adjuvants "

A hapten is a small moiety that is unable to elicit an immune response by itself unless it is linked to a larger moiety, such as a

protein, peptide, or lipid (214). In 1965, Weigle and colleagues (215) initially established that haptens could:

1. Enhance immunogenicity to the hapten-protein (in this instance, thyroglobulin) complex
2. Concurrently increase immunogenicity to the carrier protein itself
3. Induce an immune response to the normal "self-protein," which manifested itself with the development of autoimmunity.

Since then, class I-restricted T-cell responses have been generated against haptenized proteins. Once more, immune responses can be demonstrated against the hapten-carrier complex, as well as to the unmodified carrier. The most commonly used haptens are dinitrophenyl (DNP) and trinitrophenyl.

In the first human clinical trial using a haptenized vaccine, 24 metastatic melanoma patients were immunized with autologous, irradiated tumor cells conjugated to DNP (216). Fourteen subjects (60%) demonstrated intense inflammatory responses using physical examination and immunohistochemistry. Tumor biopsies revealed T-cell and DC infiltration. In a follow-up report, 20 of 46 subjects identically vaccinated developed inflammatory reactions, consisting of erythema, warmth, and tenderness at the site of tumor nodules. Five patients achieved a PR, including one durable response still evident 16 months after the initial immunization. The 2-year overall and disease-free survivals attained, 85% and 59%, respectively, were significantly better than those of participants given the unmodified vaccine (217). Later, Berd et al. (218) showed that melanoma patients vaccinated with DNP-modified autologous tumor cells acquire a hapten-restricted T-cell response, as evidenced by DTH and HLA-specific proliferation and IFN-γ production *in vitro.* The combination of DNP- and melanoma-specific immunity seems to enhance clinically relevant antitumor activity: results of two phase 2 trials attained a median relapse-free survival duration (24-37 months) and rate (45%) superior to those attained with high-dose IFN in an Eastern Cooperative Oncology Group trial (214).

Conclusion

Part of "17.2 - Immune Adjuvants "

The extensive body of research that has accumulated in the field of adjuvants does not paint a clear picture. Some adjuvants are efficacious only in animal tumor model systems, whereas others have shown clinical benefit only with certain human tumors. Many of the most promising agents will soon enter large, multicenter clinical trials in which their use can truly be affirmed or denied. Yet, unless a cohort group is established for each trial in which patients are given all vaccine components save the adjuvant, it will continue to be difficult to gauge their contribution. The added complexity and cost of including such cohort groups certainly contributes to why so few adjuvant-inclusive trials have been performed this way. The reality of medicine today is that cost and ease of manufacture will be increasingly important factors in future adjuvant development (40). In addition, an adjuvant should be stable and readily mass-produced so that it could potentially be used worldwide. It should elicit a wide range of immune events to overcome potential problems with tumor-escape mechanisms, such as downregulation of MHC expression (219 ,220). Ideally, it should be immunostimulatory and safe by several routes of administration. Several candidate adjuvants with many of these parameters are in ongoing phase 1, 2, and 3 clinical trials. Within a few years, it will be possible to draw firm conclusions about the validity of their approach towards enhancing antitumor immunity.

Introduction

Part of "17.3 - Mechanisms of Immune Escape and Immune Tolerance "

A remarkable breakthrough in the understanding of human tumor immunology is the demonstration that the host immune system can mount humoral and cellular responses against antigens expressed by autologous cancer cells (1 ,2 and 3). Serologic analysis of recombinant complementary DNA-expression libraries has identified humoral immune responses directed against autologous cancer-specific proteins. The antitumor role of these antibodies, however, remains unclear because the proteins that

they recognize are expressed in the intracellular compartment where immunoglobulins cannot reach them (3). Cellular immune responses are directed toward intracellular proteins because T cells recognize molecules that have been cleaved into short peptides and presented on target cell surfaces in association with major histocompatibility complex (MHC) class I molecules (called *human leukocyte antigens* or *HLA* in humans) (4). Because tumor antigens consist in large part of intracellular proteins, it is generally assumed that cellular immune responses are the prevalent immunologic defense of the organism against tumors (5). Indeed, most experimental models support a predominant role of the cellular rather than humoral arm of the immune response in cancer (6). Thus, T-cell-based immune interactions with tumor cells have been more extensively studied.

Among human tumors, malignant melanoma has been the most comprehensively studied because of the ease with which tumor-associated antigen (TAA)-specific T cells can be expanded by *in vitro* incubation of tumor-infiltrating lymphocytes (TILs) (7) with T-cell growth factors, such as interleukin-2 (IL-2) (8 ,9). The availability of tumor-specific TILs has led to the identification of several cytotoxic T lymphocyte (CTL)-defined melanoma-associated antigens (MAAs). MAAs fall into distinct categories according to various genetic and physiologic properties. Some MAAs are tissue specific because they are expressed by melanoma cells and normal melanocytes (10). These MAAs are called *tumor differentiation antigens* (TDAs). Other MAAs consist of proteins that are not expressed in normal adult tissues except for the testes (10). In addition, these antigens are expressed by tumors other than melanoma and are called *tumor-specific antigens* (TSAs) or *cancer-testis antigens.* The remaining MAAs are products of genes overexpressed in comparison with normal tissues (oncogenes) or of aberrant transcription of intronic sequences, mutated genes, or alternate open reading frames (10). Characterization of antigen-specific TILs has demonstrated that cellular immune responses are most commonly directed toward nonmutated TDAs or TSAs.

It was previously believed that the immune system could control tumor growth by recognizing foreign "new" molecules expressed by tumor cells (11 ,12). Proteins selectively expressed by tumors are not included in the repertoire of molecules determining negative selection of T cells in the thymus. Therefore, T cells recognizing "neoantigens" are not eliminated, and tumor cells are killed as they originate on the basis of self/nonself discrimination. Accordingly, most cancer cells were thought to have a "nonself" identity and to be eliminated by a vigorous immune reaction. Occasionally, however, under immune selection, tumor cells lacking neoantigens could survive, replicate, and produce clinically detectable tumors. This theory, referred to as *immune surveillance*, postulates a predominant role of escape mechanisms adopted by cancer cells to offset a brisk immune response against them. Immune surveillance is, however, questioned by the modern understanding of the immune biology of melanoma. Obviously, self/nonself discrimination does not apply broadly to tumor immunology because most identifiable immune responses against cancer are directed against self-molecules (1 ,2 and 3) and tolerance of self is the expected default reaction of the host toward them. Yet, the immune system is not totally unaware of cancer cells, as evidenced by the ease with which TAA-specific TILs can be generated from tumors (13 ,14 ,15 and 16). Thus, an indolent, rather than absent, immune response appears to govern the overall balance of tumor/host interactions. This guarantees a relatively pacific coexistence of effector and target cells, as evil and good seen from a distance seem to peacefully coexist in the society. The TAA-specificity of TILs observed *ex vivo* is likely to constitute an exaggeration of the immune reaction existing naturally at tumor site. If a cell suspension from a tumor is expanded *in vitro* without the addition of T-cell growth factors, tumor cells or fibroblasts (or both) take over the culture. TILs expand and tumor cells die only when cytokines stimulating T-cell proliferation are provided, unless resistant tumor cells arise (17). Because *in vivo* such growth factors are not provided, T cells that can kill tumor targets *in vitro* can coexist with the same cells *in vivo.* This view of tumor/host interaction (opposite to the immune/surveillance theory) suggests that tumor growth most often does not represent an escape from an effective immune response, rather an insensitivity to an insufficient immune response. When tumor rejection exceptionally occurs, the balance between tumor cell growth and destruction by T cells is overturned by immune stimulatory conditions similar, perhaps, to those causing autoimmunity. Thus, the term *immune escape* might be misleading because, in most cases, there is nothing to escape from. Therefore, for the rest of the chapter we refer to *tumor escape* when an immune response of sufficient magnitude to cause immune regression is postulated. In this case, the presence of tumor masses is attributed to countermeasures adopted by tumor cells or other cells, or both, within the tumor microenvironment to offset such response. We instead refer to *tumor tolerance* when an absent or insufficient immune response is postulated independently from the ability of tumor cells to escape it.

Expression of shared CTL-defined MAAs in a large percentage of patients with melanoma has stimulated enthusiasm for their use in clinical trials of active specific immunization. Thus, large amounts of information have been accrued on immune and clinical responses in these trials (18 ,19 ,20 ,21 and 22). These studies have shown that immunization with MAAs induces detectable MAA-specific CTL responses (19 ,22 ,23) but does not yield the clinical responses predicted by murine models. In mice, established immunogenic tumors can be cured by innumerable immune treatments. Furthermore, growth of poorly immunogenic tumors can be controlled or prevented in protection experiments in which animals are immunized before implantation of tumor cells. The exciting results obtained in mice are, however, invariably tempered by follow-up clinical studies, which, as noted long ago (24), regularly fail to yield similar results. Protection experiments illustrate the need for immune T cells to face small cell burdens for successful control of tumor growth. Bulky tumors may exhaust the host immune competence by altering its metabolism or producing immune suppression (25). Large cell populations may tolerize immune-reactive CTLs because of lack of costimulation (26) or by overwhelming the immune reaction. It is also possible that the greater number of cell divisions in larger lesions may statistically increase chances for the development of tumor cell variants resistant to treatment.

Human treatments deal with the polymorphic nature of the human immune systems and tumors. Furthermore, the extreme heterogeneity of cancer cells has to be faced. Therefore, tumor escape mechanisms may play a bigger role in human disease than in prefabricated oligoclonal murine models. Thus, a pessimistic interpretation of the discrepant results observed between preclinical and clinical studies is the higher likelihood of human tumors to escape immune recognition.

Multiple Ways to Tumor Tolerance

Part of "17.3 - Mechanisms of Immune Escape and Immune Tolerance "

Immune escape and *immune tolerance* are general terms that include a variety of mechanisms (Table 17.3-1). Inadequate immune responses in patients with cancer and other chronic illness have been attributed to decreased T-cell receptor (TCR) signaling capacity (25 ,27). No convincing evidence exists, however, that cancer patients are immune compromised. Flu-specific CTL reactivity is not different between patients with melanoma and healthy controls (28). Furthermore, MAA-specific CTL reactivity is easier to induce in patients with melanoma than in non-tumor-bearing individuals (28 ,29). Clonal deletion or exhaustion (30 ,31 ,32 ,33 ,34 and 35), replicative senescence (36 ,37), circulating immune-suppressive cytokines (25), soluble HLA molecules (38 ,39), and epitope mimicry (40) have been implicated in the induction of systemic, epitope-specific immune tolerance. Because MAA-specific T cells, however, can be activated and expanded *in vivo* by antigen-specific vaccines (19 ,22 ,23), deletion of tumor-reactive clones may not play in human cancers the role it plays in some preclinical models (30 ,33 ,36 ,37 ,41). We believe that the natural history of tumor growth and its response to immune manipulation is predominantly influenced by local factors. The ease with which MAA-specific CTLs can be detected among peripheral blood mononuclear cells and TILs suggests that the host immune system is sensitized against MAAs. The observation of "mixed responses" also suggests local factors as major modulators of tumor behavior. A mixed response is a relatively frequent (although the actual frequency has never been documented) phenomenon characterized by different behavior of synchronous metastases in response to T-cell-based immunotherapy. Although some metastases decrease in size or disappear, others grow unaffected by therapy. As a patient's immune response at a single time point is a constant, mixed responses reflect the major role played by the interactions between tumor and immune cells at each tumor site. Thus, we focus on local factors that could account for immune escape or peripheral tolerance of tumors, or both.

Table 17.3-1 Multiple Ways to Tumor Tolerance

I. Systemic mechanisms

  A. Immune suppression

    1. Cancer cachexia

    2. Alteration in T-cell receptor signal transduction (ζ-chain downregulation)

    3. Circulating immune-suppressive cytokines (transforming growth factor-ß, interleukin-10, etc.)

  B. Systemic tolerance

    1. Clonal exhaustion

    2. Replicative senescence

    3. Fas/Fas ligand-induced apoptosis

    4. Soluble HLA

    5. Epitope mimicry

II. Local mechanisms

  A. Lack of localization

  B. Inadequate immunogenicity of tumor cells

    1. Lack of danger signal

    2. Insufficient epitope density

  C. Escape mechanisms

    1. Tumor-associated antigen loss or downregulation

    2. Abnormalities in antigen processing

    3. HLA loss or downregulation

  D. Peripheral tolerance

    1. Fas/Fas ligand-induced apoptosis

    2. Soluble HLA

    3. Paracrine secretion of immune suppressive cytokines by tumor cells (transforming growth factor-ß, interleukin-10, etc.)

    4. Epitope mimicry

Methodologic Considerations

Part of "17.3 - Mechanisms of Immune Escape and Immune Tolerance "

Although the clinical results of TAA-specific vaccinations have been disappointing, the use of well-defined immunogens represents an unprecedented human model to test hypotheses suggested by preclinical studies. Epitope-specific vaccines allow for analyses of immune responses confined to a single TAA/HLA allele combination targeted by the vaccination (42). This simplification might be incredibly important considering the complexity of the algorithm governing tumor/host interactions. The difficulty of correlating laboratory findings with clinical outcome is the primary obstacle to the assessment of the role of immune escape or tolerance, or both, in cancer progression. Tumor/host interactions *in situ* have traditionally been studied in excised surgical specimens with immunohistochemistry (IHC) to estimate protein expression, DNA amplification to identify genetic abnormalities, and messenger RNA amplification for the assessment of gene expression. Fixed material, however, is not suitable for the assessment of T-cell function. Freshly isolated tumor cells or lymphocytes are suboptimal for accurate functional studies because of their extensive contamination by various cell types and the altered conditions of cells recently subjected to enzymatic or mechanical treatment. Expansion of TIL/tumor cell pairs from excised tumors has provided elegant models for the characterization *in vitro* of CTL/tumor interactions at a given time point (43). Although it is not clear whether cultured cells are representatives of *in vivo* conditions, experiments performed with cell lines establish important principles of T-cell/epitope interaction, which allow formulation of hypotheses to be tested *in vivo.* Analysis of reagents obtained from excised specimens, however, yields static information about a disease characterized by extreme genetic instability (44). As the natural course of the removed tumor cannot be followed prospectively to take the excised lesion as representative of other lesions left *in vivo,* homogeneity among metastases must be assumed. Even synchronous metastases, however, are quite heterogeneous (i.e., in the expression of MAA and HLA molecules) (45). This limitation could be overcome by serial analysis of identical tumor samples through fine needle aspiration (FNA) biopsies, which provide the opportunity to evaluate dynamically

the expression of relevant markers (46 ,47). Because of the limited amount of material obtainable, however, FNA suffers from its own limitations. FNA could be combined with other techniques, allowing analysis of limited materials. Distinct populations of cells could be sorted by microdissection (48 ,49) or epitope/HLA tetramers (50 ,51), and their status of activation could be tested using accurate and sensitive methodologies, such as Taqman-based real-time polymerase chain reaction (52) or intracellular fluorescence-activated cell sorter analysis (53). This theoretically allows evaluation of the status of activation of CTLs *in vivo.* Collection of complementary DNA libraries from FNA of metastases could profile patterns of expression of thousands of genes in a single experiment (54). This information, combined with knowledge of the natural history of the lesion left *in situ*, might yield clinical material for correlation of laboratory findings with clinical outcome and identification of the algorithm necessary for tumor regression.

T-Cell Localization at Tumor Site

Part of "17.3 - Mechanisms of Immune Escape and Immune Tolerance "

CTLs kill their victims by direct contact. Thus, localization of TAA-specific CTLs at tumor site is expected for their effector function. Adoptive transfer of indium-111–labeled TILs has shown that their localization is necessary for a clinical response to occur (55). In some cases, TILs home within the tumor and no regression is observed, suggesting that other factors within the tumor microenvironment may influence the status of CTL activation or the sensitivity of tumor cells to CTLs.

T Cells as "Lazy" Soldiers

Paradoxically, TILs can routinely be expanded *ex vivo* from growing melanoma metastases and shown to be able to effectively kill tumor cells in *in vitro* assays. Thus, TIL/tumor cell interactions observed *in vitro* do not explain *in vivo* phenomena. The discrepancy may reflect lack of sufficient stimulation *in vivo*, as the expansion *ex vivo* of TILs requires incubation not only with tumor cells but also with IL-2. Indeed, the requirements necessary to induce and sustain a CTL response in target organs are higher than that necessary for the execution of effector responses by the same CTL (26 ,56 ,57). Matzinger's "danger model" (26 ,58) proposes an explanation for the coexistence of effector and target cells in tissues without the development of tumor rejection, suggesting that the default interaction between tumor cells and host immune systems is absent or minimal. This model, in antithesis with self/nonself discrimination, suggests that immune responses start when tissue distress (danger) is detected. T cells require two types of stimulation to become activated, to stay activated, or both: (a) a "first signal" (signal one) provided by specific antigen/TCR interaction and (b) a "second signal" (signal two) bearer of the environmental conditions in which the immune interaction is occurring (59 ,60). The second message can be provided by cytokines ("help") or by costimulatory molecules expressed by specialized antigen-presenting cells (APCs) (61) in condition of tissue distress. Cancer cells do not constitutively express costimulatory molecules and do not secrete immune-stimulatory cytokines. Furthermore, by offering only signal one, tumors might induce tolerance because the interaction of antigen-specific T cells with signal one in the absence of signal two causes their deletion (26). Thus, the majority of tumors do not "escape" immune recognition but simply survive in a favorable environment. In particular circumstances, however, the host immune response is awakened, resulting in spontaneous or therapeutically provoked regression of disease. The nature of the extra stimulation operating in such circumstances is unknown.

CTL requirements for induction of IL-2 or other cytokines promoting their activation and proliferation are relatively high (57), and "help" from HLA class II-restricted CD4+ T cells may be required (5 ,62 ,63 ,64 and 65). Tumors, particularly melanoma, express HLA class II molecules (66) and their expression in metastases correlates with response to T-cell-based therapy (67). Furthermore, HLA class II-associated MAAs have been identified (65 ,68), and evidence exists that malignant cells can present endogenous antigens in the context of HLA class II (69 ,70 ,71 and 72). Thus, it is possible that tumor cells could cross-prime effector and helper T cells; however, this possibility is difficult to accept considering the difficulties in identifying MAA-specific, HLA class II-restricted CD4+ T cells in tumor specimens. Furthermore, tumor cells do not provide signal two necessary for T-cell activation, and it is likely that APCs are required for activation of TAA-specific CTLs. It is assumed that TAAs shed by cancer cells are incorporated into lysosomes by APCs cleaved into peptides and presented on their surface bound to HLA class II molecules (5). Interactions with HLA class II-restricted helper T cells would cause release of cytokines capable of recruiting, expanding, and activating TAA-specific CTLs *in situ.* No direct evidence exists in humans, however, that APCs present TAAs shed by tumor cells *in vivo.* In murine models, APCs can present endocytosed antigens in association with MHC class I and class II molecules, and, if an adequate amount of antigen is provided, APCs induce concomitant activation of CD8+ and CD4+ T cells (73 ,74). High doses of antigen are necessary for efficient cross-presentation. If the amount of antigen incorporated by APCs is not sufficient, no CD4+ T-cell activation occurs, and tolerance is induced. Whether the efficiency of TAA incorporation by APCs in the tumor microenvironment is adequate for cross-presentation to helper and CTL populations or inadequate, leading to tumor tolerance, is not known. Tumor cells die without causing inflammation probably through an apoptotic pathway. Human CD14 (abundantly present on the surface of phagocytes) mediates phagocytosis of apoptotic cells (75) without induction of inflammatory processes. Thus, macrophages infiltrating tumors act as scavengers for senescent cancer cells, which remain "unnoticed" by the immune system. If, however, activated dendritic cells (DCs) incorporate and present antigen to CD8+ T cells, a powerful CTL response is induced (76). Viral models suggest that APCs activated by the viral infection can efficiently present antigens to CD8+ T cells (77). It is possible, therefore, that an activating step is required in tumors to turn macrophages into efficient APCs (78).

The primary interaction between tumor and T cells leads to expansion of APC-activated TAA-specific helper T cells, which, although unable to kill tumor cells, are capable of producing cytokines for the proliferation of TAA-specific, HLA class I-restricted

CTLs. The difficulty encountered in identifying TAA-specific CD4[+] helper cells suggests that tumors may escape immune recognition simply because of the low chances of productive encounters among the various cell populations. It is possible, however, that non-TAA-specific CD4[+] helper cells are all that are needed for induction of TAA-specific CD8[+] T-cell responses. Environmental immunogens coincidentally expressed at the tumor site might suddenly stimulate proliferation of CD4[+] T cells. These helper cells would in turn promote proliferation and activation of dormant TAA-specific CD8[+] T cells (58). The coincidental nature of such events could offer a rationale for rare and serendipitous spontaneous tumor regressions. CD4[+] T cells can also directly activate and mature APCs through CD40/CD40L interactions (79). In this case, no close contact between CD8 and CD4 T cells is necessary. The activated APC then acts as a temporal bridge between a helper and a killer cell (79) and can activate more than one DC, which, in turn, could activate more than one CTL, leading to exponential expansion of the immune response. In this case, the presence of a helper epitope in the tumor microenvironment could be all that is required to initiate effective anticancer responses. Yet, most commonly, tumors might not express such helper molecules.

Tumor Cells as Inadequate Targets

Expression of MHC class I molecules is necessary for tumor recognition by CTLs (15,80,81). The molecular basis of this phenomenon has been well characterized by crystallographic resolution of peptide/HLA class I (82) and peptide/HLA class I/TCR complexes (83). Thus, complete loss of expression of TAA or HLA has, as undisputed consequence, loss of recognition by TAA-specific CTLs. It is, however, still controversial whether decreased expression of TAA or HLA, or both, affects significantly tumor/host interactions *in vivo*. An extensive description of TAA and HLA loss or downregulation has recently been prepared and we refer the reader to this review (10). Here we limit the discussion to the salient points with particular attention to the functional implications.

Loss or Decreased Expression of Tumor-Associated Antigens

Alterations in TAA expression were originally identified in murine tumor models as a cause of tumor escape (84,85,86,87 and 88). In humans, TAA expression is quite heterogeneous. TSAs are variably expressed in tumors (89) in correlation with a genome-wide demethylation process associated with tumor progression (90,91 and 92). Treatment with demethylating agents, such as 5-Aza-2"-deoxycytidine, can induce expression of TSAs and sensitize cell lines to lysis by TAA-specific CTLs (90,93,94). The ability of demethylating agents to restore recognition of tumor cells by CTLs has not been exploited in clinical grounds because of the widespread effects that these agents have on normal cells (90,93). TDAs are more commonly expressed than TSAs. Earlier studies detected MART-1/MelanA messenger RNA in all cell lines and melanoma lesions tested (95). These studies, however, might have underestimated the heterogeneity of TDA protein expression. Idiopathic hemochromatosis (IHC) analysis with monoclonal antibody specific for gp100/Pmel17, MART-1/MelanA, and tyrosinase revealed that their expression is not as ubiquitous as suggested by molecular methods (46,96,97,98,99,100,101,102,103,104 and 105). Furthermore, contrary to TSAs, the frequency of TDA expression decreases with disease progression (45,106,107,108 and 109), probably because TSAs are not related to neoplastic transformation (Table 17.3-2). In particular, gp100/Pmel17 is less frequently expressed than MART-1/MelanA, which is less frequently expressed than tyrosinase (45,102,108,109 and 110).

Table 17.3-2 Hypothesized Behavior of Tumor-Associated Antigen Expression during Disease Progression

Type of Tumor-Associated Antigen	Expression Relationship with Oncogenesis	Relative to Normal	Expected Expression with Disease Progression	Expected Effect on HLA Class I Expression
Tumor differentiation antigens	None	Decreased	Gradual loss	Less powerful
Tumor-specific antigens	Associated	Increased	Increased	Powerful
Oncogenes	Causative	Increased	Stable	Powerful

Approximately 25% of synchronous metastases of patients with melanoma display significant differences in the percent of tumor cells expressing a given TAA (45,108,109). In addition, IHC of metastatic lesions has shown heterogeneity not only in percentage of tumor cells expressing a TAA but also in the level of TAA expression by demonstrating differences in intensity of staining (45,102,106). These findings have been corroborated in cell lines by analysis of TDAs by fluorescence-activated cell sorter analysis (111) and by quantitative real-time polymerase chain reaction (108). *In vitro* studies have also shown a correlation between the variability of expression of TAAs and recognition of tumor cells by CTLs (46,111,112 and 113). Variation in the level of TAA expression may explain the coexistence of TAA-specific TILs in tissues expressing the target TAA. It is possible that productive engagements between TCRs and HLA class I antigen/peptide complexes proceed to a point of balance between avidity for and availability of epitope, which might correspond clinically to a temporary shrinkage of the tumor. At this point, T cells fail to destroy the remaining malignant cells efficiently, and the size of metastases is determined predominantly by the rate of growth of the remaining cancer cells. Yet, MAA-specific CTLs roam the tumor mass because TAAs shed by dying cancer cells may be presented by intratumoral APCs, which, with their superior antigen-presenting capability, can perpetuate the presence of TILs within the tumor.

Decreased expression of MAA or HLA class I molecules, or both, has been noted in residual tumors after immunotherapy (45,108,109,114).

In 1999, an analysis of pooled metastases from HLA-A*0201 melanoma patients showed a significant increase in frequency of gp100-negative lesions (29% of 155 lesions) after immunization against this TDA compared with metastases analyzed before immunization (18% of 175 lesions) (108). Another study has shown a reduced expression of the ErbB-2 protooncogene in HLA-A2-expressing breast cancer lesions compared with HLA-A2-negative lesions (115). Because this antigen has a well-defined HLA-A2-associated epitope, this finding suggests that lesions expressing HLA alleles other than HLA-A2 may experience reduced immune pressure against this TAA.

Loss or Decreased Expression of HLAs

Altered MHC class I antigen expression in tumors was also first observed in murine tumor models (116 ,117 ,118 ,119 ,120 ,121 ,122 and 123) and shown to be a factor determining tumor escape from immune response (124 ,125 ,126 ,127 ,128 ,129 ,130 ,131 ,132 and 133). Surface expression of HLA molecules on human tumor cells has also been extensively studied, mostly with monoclonal antibody-recognizing monomorphic determinants of the HLA class I heavy chain (10). In 1999, however, monoclonal antibodies recognizing determinants restricted to the gene products of HLA-A and HLA-B loci or polymorphic determinant-defining HLA class I alleles were used to analyze malignant cells (10). HLA class I loss or downregulation has been described in several human tumors, including melanoma and carcinomas of the bladder, breast, cervix, colon, head and neck, kidney, lung, pancreas, prostate, and stomach (10 ,134 ,135). The frequency of HLA class I antigen loss and downregulation in various tumor types is presently controversial and has been discussed elsewhere (10).

Characterization of the molecular basis of altered HLA class I expression could be performed by the study of tumor cell lines. Several phenotypes have been identified and classified differently by various authors (134 ,135). They include: (a) total HLA class I loss, (b) selective loss of an HLA haplotype, (c) selective loss of one HLA allele, and (d) locus-specific or allele-specific downregulation (Table 17.3-3). Total HLA class I loss in tumor cells is caused by mutations in the β_2m gene, which results in loss of functional β_2m expression necessary for the stability of the peptide/HLA complex (136 ,137 ,138 ,139 and 140). Loss of β_2m expression has been observed by IHC staining of HLA class I-negative tumor specimens (141 ,142). Abnormalities ranging from point mutations to large deletions within the β_2m gene are responsible in the majority of cases for altered translation of the protein product. These mutation occur most often within a "hot spot" in cell lines with a high mutation rate (44 ,138 ,139 ,143 ,144). Because two identical β_2m genes exist in the human genome, both genes need to be knocked out before HLA class I expression is totally lost. This may account for the relative rarity with which this phenotype is detected and its occurrence in the later stages of tumor progression. β_2m loss and identification of the same molecular abnormalities identified in cell lines have also been described *in situ* in the tumor lesions from which the cell lines were derived (137 ,139 ,145 ,146 and 147). Selective loss of an HLA class I allele has been documented by IHC staining of malignant lesions and by analysis of cell lines (148 ,149 and 150). Loss of an HLA class I heavy chain gene owing to loss of an HLA class I haplotype has been described in malignant melanoma (151), pancreatic (152), cervical (150), and colon carcinoma (*unpublished data,* 1999). This loss is most often caused by a large genomic deletion of the region encoding for HLA class II, III, and I genes (134 ,135 ,151). This relatively common mechanism leads to a 50% reduction in the ability of cells to express antigens in association with HLA molecules and is not reversible by treatment with interferon-γ (IFN-γ). This defect arises through mechanisms of defective chromosomal segregation, nondisjunction, or mitotic recombination that cause loss of variable portions of genomic DNA in the short arm of chromosome 6. In the 1990s, allelic loss was characterized in a melanoma and in cervical cell lines (149 ,150). In the melanoma cell, the loss of the HLA allele is caused by a defect in HLA-A*0201 premessenger RNA splicing (153).

Table 17.3-3 Aberrant HLA Class I Phenotypes

Phenotype	Mechanism
Loss of Expression	
Loss of all HLA class I alleles	Mutations in the β_2m gene
Selective loss of one HLA haplotype	Loss of large genomic unit
Selective allelic loss	Mutation in heavy chain gene
Downregulation	
Locus specific downregulation	Locus linked variability in transcriptional regulation
Allele downregulation	Unknown

Locus-specific abnormalities affect more commonly the HLA-B and -C loci and can be reversed *in vitro* by incubation of cell lines with IFN-γ (151 ,154). The systemic administration of IFN-γ, however, does not achieve a tissue concentration sufficient to achieve the same effect *in vivo* (155). It is likely that a common pathway is responsible for HLA class I locus-specific downregulation in tumor cells, as most HLA class I alleles within the same locus are simultaneously downregulated or upregulated (154). Although a correlation was described between HLA-B downregulation and elevated c-myc expression (156 ,157 ,158 and 159), it is unlikely related to the oncogenic process because HLA-B molecules are downregulated with the same frequency in normal cells (151) and in tumor cells not overexpressing c-myc (160 ,161). The selective downregulation of HLA class I alleles has been less extensively studied. Marked variation in the level of HLA-A2 was identified in clones isolated from a bulk melanoma cell line (149) and confirmed by an analysis in 1999 of a large panel of melanoma cell lines (111). The mechanism(s) underlying the variability of allelic expression noted in cell lines has not been investigated. Furthermore, it is not known whether the naturally occurring variation in HLA class I allele expression noted in cell lines corresponds to similar variability *in vivo.*

Little is known about the expression of nonclassical MHC molecules, such as HLA-E or -G. HLA-G expression has been reported on lymphoma (162) and melanoma (163) cell lines. Furthermore, a higher level of HLA-G expression was found in metastatic melanoma lesions than in normal skin (163). No

conclusive information is available about the expression of HLA-E by solid tumor cells.

Defects in HLA Class I-Dependent Antigen Processing

Correct assembly of HLA class I molecules and efficient presentation of antigenic peptides depends on the generation of peptides by the proteasome complex and transport of these peptides into the endoplasmic reticulum, where they are assembled with HLA class I heavy chains and B_2m. Tumor cells may alter expression of components of the HLA class I antigen-processing pathway, leading to abnormal processing and presentation of TAAs. Several studies have demonstrated defective expression of the proteasome subunits LMP2 and LMP7 or the transporter subunits TAP1 and TAP2, or both, in cell lines derived from various tumor types (10). These defects have been shown to cause defective processing and presentation of antigenic peptides to CTLs (164 ,165 ,166 ,167 and 168). Synchronous loss of LMP and TAP observed in tumor cell lines and restoration of their expression by incubation in IFN-γ suggest that mechanisms of gene regulation are defective in these cells (164 ,168 ,169 and 170). Analysis of tissue specimen expression has identified examples of TAP1 downregulation in head and neck, breast, lung, colon, and cervical carcinomas and in melanomas (10), and noted more frequent losses in metastatic than primary lesions. The role of TAA processing defects in tumor immunology is, however, not clear, as these defects may not cause detectable loss of HLA class I expression because peptides may be generated by alternative proteasome complexes (171) and supplied through TAP-independent mechanisms (172).

Functional Significance of Tumor-Associated Antigens or HLA Loss or Downregulation, or Both

The majority of studies correlating HLA class I expression by tumor cells with their recognition by TAA-specific CTLs has evaluated this relationship in terms of an all-or-none phenomenon. The effect of variability in the surface expression of a specific TAA/HLA epitope on the recognition of tumor cells by cognate CTLs has been investigated only to a limited extent. The scanty information on this topic is likely to reflect at least in part the general assumption that as few as 1-5 peptide/MHC class I complexes on a target cell are sufficient for its recognition by CTLs (173 ,174 ,175 and 176). As a consequence, one may be inclined to dismiss the possibility that downregulation of the restricting HLA class I allele or associated TAA, or both, may provide tumor cells with an escape mechanism from CTL recognition. Intracellular peptides, however, compete with thousands of other peptides for a specific HLA class I allele (177). Therefore, not all possible endogenous epitopes can be presented with a density sufficient for recognition by CTLs (178), especially when the restricting HLA class I allele is downregulated. Furthermore, it has been proposed that high-avidity TCR/ligand interactions in the context of self-recognition are eliminated during thymic selection (179). As a consequence, TCR activation may require a threshold of self-epitope density higher than 1-5 HLA/peptide complexes (174 ,175). Studies in 1999 have shown that the level of HLA class I allele expression may vary considerably among tumor cells (111). Furthermore, level of TAA expression is an independent cofactor determining recognition by CTLs (111). Because of the highly competitive characteristics of MHC/peptide binding (180 ,181), variations in MHC molecule expression may significantly affect recognition of antigenic peptides by MHC-restricted CTLs. This variability may be particularly important for poorly immunogenic human tumors in which a combination of low expression of TAAs, low affinity of the TAA-derived peptide for HLA class I allele, and HLA class I allele downregulation may switch on and off TAA-specific CTLs. When HLA class I allele availability is sufficient to present one or more TAA-derived peptides on the cell surface, a target cell could be lysed through serial TCR engagement as an all-or-none phenomenon (182 ,183). If a cell population rather than a single cell is considered, a proportional relationship is expected to exist between epitope density and extent of CTL-mediated lysis of target cells. A normal distribution predicts that in borderline conditions the epitope density is on some cells below and on others above the threshold level required for recognition of targets by CTLs. Furthermore, the statistical probability of productive encounters between TCRs and epitopes increases with their density. These mechanism(s) account for the statistically significant relationship found between the level of the restricting HLA class I allele and extent of CTL-mediated lysis when the TAA-derived peptide recognized by CTLs is not a limiting variable.

As suggested by the "missing self" hypothesis, HLA class I downregulation on cells renders cells more susceptible to NK cell-mediated lysis (184). NK cell function is inhibited by the interaction of two distinct families of NK cell inhibitory receptors with HLA class I molecules (185). The first family of receptors, referred to as *killer inhibitory receptors*, includes molecules with two (p50, p58) or three (p70) immunoglobulinlike domains in their extracellular region and interacts with specific HLA-A, -B, and -C alleles. The second family of inhibitory receptors includes heterodimers composed of a CD94 glycoprotein and a NKG2 protein specific for the nonclassical HLA-E. The expression of HLA-E is of particular interest because it depends on binding of peptides derived from the signal sequence of most HLA-A, -B, -C, and -G molecules, therefore acting as a gauge for the overall expression HLA class I molecules (186 ,187 and 188). NK cells monitor HLA class I expression on target cells through these inhibitory receptors and eliminate those with low expression. Increased susceptibility of tumor cells with HLA class I downregulation to NK cell-mediated lysis has been demonstrated in several studies (134 ,184 ,189 ,190 ,191 and 192), although examples of tumor cell lines resistant to NK cell lysis despite HLA class I downregulation have been identified (Ferrone S. *unpublished data*, 1997;191 ,193). HLA-G has also been implicated as an inhibitor of NK cell activity and to protect melanoma cells from NK cell lysis (163). It is not clear what NK receptor interacts with HLA-G (194 ,195 ,196 ,197 ,198 and 199). Inhibitory receptors are expressed also on T cells (200 ,201), and the presence of killer-inhibitory receptors on TAA-specific CTL clones may have important implications for recognition of tumor cells with altered HLA class I (202). The frequency of

expression of inhibitory receptors in TAA-specific CTLs, however, is not known.

It is unknown whether TAA or HLA class I expression, or both, gradually decreasing along with advancing stage of disease (203 ,204 ,205 ,206 ,207 ,208 and 209) reflects the progressive dedifferentiation of tumor cells or is the result of immune selection (205 ,208 ,209 and 210). Several *in vivo* observations suggest that MAA loss may lead to tumor escape from host immune recognition. Reports about loss of HLA or MAA owing to a particular treatment have been, however, anecdotal (45 ,47 ,109 ,114 ,166 ,202 ,211). Some larger studies have suggested MAA loss in relation to the specificity of the expected immune response (108 ,115), whereas others did not (111). Thus, circumstantial but not conclusive evidence exists that TAAs during progression of disease is owing to immune selection. Still, independent from its cause, loss, or downregulation of TAA or HLA, or both, MAA loss makes tumor cells unsuitable targets for HLA class I-restricted CTLs. Considering the extreme stringency of the human TCR repertoire for unique epitope/HLA allele combinations (212 ,213), it could be predicted that the HLA phenotype may influence the chance of a patient to respond to T cell-based immunotherapy. Conversely, loss of particular TAAs might be noted more frequently in patients with an HLA phenotype associated with a strong immune response toward that TAA. An extensive analysis of HLA phenotypes in patients undergoing T-cell-based immunotherapy, however, failed to demonstrate any association between HLA phenotype and disease stage or response to therapy, or both (214). The inability to identify a relationship between a particular HLA phenotype and clinical correlates remains an unsolved question going beyond the domains of tumor immunology (215).

Tumor Microenvironment is a Messy Battlefield

Part of "17.3 - Mechanisms of Immune Escape and Immune Tolerance "

Immune Regulatory Cytokines

Within the environment where tumor cells live, immunologic mediators, particularly cytokines (216), may control host defenses. Cytokines can modulate interactions between CTLs and tumor cells by interfering with production and function of other cytokines or by altering the expression of adhesion or costimulatory molecules on various cell types (217 ,218 ,219 and 220). Intracellular adhesion molecule-1, which reinforces CTL/tumor interactions, can be induced or enhanced in normal and malignant cells *in vitro* and *in vivo* by tumor necrosis factor-α (TNF-α) (221 ,222 ,223 ,224 and 225), IFN-γ (224 ,226), and IL-10 (227). Furthermore, TNF-α and IFN-γ have been implicated in the shedding of soluble intracellular adhesion molecule-1 by malignant cells, which may inhibit CTL and NK lytic function (228). The effect of adhesion molecule expression on the cytotoxic activity of CTL and NK cells, however, remains controversial (218 ,219 and 220 ,229 ,230 and 231). Cytokines can also induce maturation and differentiation of APCs (232), or, like IL-10, have direct depressing effects on T-cell function (25). These include suppression of IL-2, IFN-γ, and granulocyte-macrophage colony-stimulating factor production by T helper cells (233 ,234) and inhibition of T-cell proliferation (235). IL-10 has also been described as a growth factor for human melanoma cells (227). IL-10 is produced by immune cells (233), but it can also be secreted by melanoma cells and has been found in tissues from patients with metastatic melanoma (236). Furthermore, elevated serum levels of IL-10 were found in patients with metastatic melanoma, suggesting that this cytokine may have a systemic immune-suppressive effect (237).

Wojtowicz-Praga suggested a predominant role of transforming growth factor-β (TGF-β) as a cause of "tumor-induced immune suppression" (25). *In situ* expression of various isoforms of TGF (TGF-β1, -β2, and -β3) is common in tumors and correlates with progression of melanoma (238 ,239 and 240) and other skin tumors (241). The expression of TGF-β *in situ* is possibly owing to paracrine secretion by tumor cells, which can secrete cytokines *in vitro* (242 ,243). TGF isoforms have similar biologic effects acting as inhibitors or stimulators of cell replication (240 ,244 ,245). In murine models, TGF-β modulates melanoma growth by inducing immunosuppression of the host (246 ,247). It is not clear, however, whether the immunosuppressive effects of TGF-β produced by tumor cells are limited to the tumor microenvironment or affect the entire host immune system. In patients with melanoma, a correlation exists between plasma levels of TGF-β and disease progression (25). This association, however, may simply reflect the higher tumor burden in patients with progressive disease. *In vitro* TGF-β is also a powerful inhibitor of NK (248) and CTL function (246). TGF-β and IL-10 have been shown to act synergistically to induce immune privilege in the eye by inducing downregulation of Th1 immune responses (249). It is not known, however, whether IL-10 produced by melanoma cells plays a similar role by turning tumors into immune-privileged sites. In 1997 and 1998, different expression of lymphoattractant C-X-C chemokines was proposed as a relevant variable for the recruitment of T cells at the site of pathology (250 ,251 ,252 and 253). Evidence that these chemokines may play a significant role in cancer, however, is not available. Cytokines secreted by normal cells or tumor cells, or both, can also facilitate tumor growth. One example is IL-6, which can have a direct effect on tumor growth and progression (254). In addition, some cytokines can act as stimulus for induction of angiogenesis factors required for the supply of blood to tumor cells.

Interactions between the vascular endothelium and tumor cells may also affect the outcome of the antitumor immune response. Swelling, tenderness, and other inflammatory signs precede the disappearance of tumor masses and characterize tumor regression. This extraordinary behavior is difficult to consider the sole effect of CTL-mediated lysis of tumor cells because lysis induces apoptosis, which, per se, is not inflammatory. Alternatively, by selectively recognizing a target tissue, CTLs may trigger *in situ* an inflammatory cascade by producing TNF-α, IFN-γ, and other cytokines. Some tumors might be more sensitive than others to these inflammatory signals. This may explain why tumors respond with similar frequency to different biologic agents (CTLs, bacille Calmette-Guérin, IL-2, IFN, etc.). In all cases, the therapeutic agent might trigger inflammation, but tumor response would depend on the sensitivity of the tumor to the cytotoxic substances produced by the inflammatory process or the ability of the tumor environment

to sustain an inflammatory process. This hypothesis could also explain why melanoma and renal cell cancer, two tumors that are characterized by different immunogenic potential (in melanoma, it is easy to derive MAA-specific CTLs, and multiple MAAs have been identified, the contrary for renal cell cancer), overall have similar sensitivity to biologic manipulation (255 ,256). It is possible that, although immunologically different, these tumor types have the same frequency of lesions sensitive to inflammation. TNF-α could play a significant role by exercising antitumor effects by a direct induction of apoptosis after contact of T cell with the target cell (257) or by indirect effects on tumor vasculature (258). As TNF-α is one of the cytokines secreted by activated CTLs, it is reasonable to postulate that factors modulating its antitumor effects could play a significant role in determining the sensitivity of a tumor to T-cell attack. In 1998, Wu et al. have shown that melanoma cell lines produce a cytokine called *endothelial monocyte-activating polypeptide II*, which increases sensitivity of endothelial cells to TNF-α (259). Melanoma cell lines secreting higher amounts of endothelial monocyte-activating polypeptide II are more sensitive *in vivo* to the antineoplastic effects of TNF-α. The expression of endothelial monocyte-activating polypeptide II in various tumor types, however, is not known, nor has this parameter been correlated with clinical outcome.

Surface Expression of Apoptotic Signals

Fas ligand (FasL) has been reported to be expressed in a high percentage of melanoma lines and melanoma lesions and to be detectable in sera of patients with melanoma (260). These findings suggested a novel mechanism of tumor escape whereby, through interaction with Fas on the surface of TILs, FasL could counter attack CTLs and extinguish anti-TAA CTLs. This model was accepted originally with enthusiasm because it provides a mechanism for the rarity of tumor regressions in spite of the presence of TAA-specific CTLs in malignant lesions. Furthermore, several studies described the detection of FasL in a number of other tumor types, including glioblastoma (261); astrocytoma (262); and lung (263), colon (264 ,265), and esophageal carcinoma (266). On scrutiny, however, it was realized that this model is not supported by the available experimental data. TILs and CTLs can be expanded *ex vivo* by repeated exposure to freshly isolated tumor cells or cell lines. In addition, Rivoltini et al. reported that TILs are insensitive to FasL (267) and, in murine models, the implantation of FasL-transduced tumors does not abrogate antitumor immune responses (268 ,269). In 1997 and 1998, an analysis of a large panel of melanoma cell lines found no evidence of FasL in melanoma (265 ,270). These studies were carried out on extensive control populations and with multiple methods, including real-time polymerase chain reaction, flow cytometry, and functional assays. One study included cell lines established from melanoma metastases, which had not responded to active specific immunotherapy with MAA-derived peptides (108). The conflicting information in the literature is likely to reflect the limited specificity of the anti-FasL antibodies used in IHC and flow cytometry and the contamination of tumor cells with other types of cells in studies, which have used real-time polymerase chain reaction. Thus, the available information indicates that the expression of FasL in malignant lesions is minimal and its role in inducing immune escape limited as recognized by the same group, which had originally proposed this theory (271). Alternatively, tumor tolerance may be explained by Fas/FasL interactions between activated CTLs expressing FasL (272). Therefore, CTLs may not be able to efficiently attack tumor targets because on engagement of the TCR with the appropriate epitope they become activated and express FasL. Fas/FasL interactions occurring within the same T cell (suicide) or between closely proliferating activated T cells could cause their apoptotic death. Such effect would be specific for areas within the tumor microenvironment rich in activated T cells.

Soluble HLA

Soluble HLA (sHLA) class I molecules have been implicated in the induction of peripheral tolerance (39). Multiple mechanisms have been described that could induce secretion of sHLA molecules from cells, including alternative splicing of messenger RNA, proteolytic cleavage of membrane-bound HLA molecules, or secretion of unloaded heavy chains. sHLA molecules have been identified in serum, urine, and other body fluids (273 ,274). Among solid organs, the liver seems to contain the highest amount of sHLA, a curious finding considering the resistance of transplanted livers to rejection compared with other transplanted organs (275 ,276). Possibly, sHLA molecules could tolerize the host immune system by inducing apoptosis of alloreactive CTLs (38). Although sHLA have been implicated in the modulation of immune responses during rejection of HLA-mismatched organs, little evidence exists that these molecules could interfere with TAA-specific CTL function (39 ,277). Only a few studies have measured levels of sHLA molecules in cancer patients (278 ,279) and no studies assessing the effect of sHLA on TAA-specific T cells have been reported. Thus, the relevance of sHLA in the induction of tumor tolerance still needs evaluation.

Downregulation of Cytotoxic T-Lymphocyte Activity by Tumor-Associated Antigen Epitope Mimics

Among various factors that can shape TCR repertoire after birth are repeated encounters with degenerate epitopes from endogenous or exogenous sources. This phenomenon is called *molecular mimicry* (280 ,281 and 282). Molecular mimicry interactions between environmental pathogens or self-antigens and TAA-CTL reactions have also been described (283). A database search for peptides structurally similar to the MART-1 immunodominant epitope MART-1$_{27-35}$ identified multiple mimicry sequences occurring in proteins of viral, bacterial, and human (self) proteins. Some of these mimicry peptides could react with MART-1-specific CTLs. Although an individual TCR can engage different (though biochemically related) peptide sequences, the result of the various TCR/epitope interactions can yield remarkably different outcomes on a particular T cell, ranging from fully agonistic to totally antagonistic reactions (284). In 1998, Loftus et al. identified partial agonists of

MART-1_{27-35}, which could partially tolerize MART-1-specific CTLs (40). These experiments suggested that encounters with partial agonist or antagonist peptides may hamper CTL responses to their natural ligands and, in the case of TAA-specific CTLs, be responsible for impaired antitumor responses. Most of the MART-1_{27-35} analogues so far identified are peptide sequences from proteins produced by human pathogens or expressed by human normal tissues. Therefore, it could be postulated that such analogue peptides could be commonly present in the organism and be responsible for decreased function of TAA-specific CTLs. Evidence is lacking, however, that these analogue peptides are present in the systemic circulation or in the tumor microenvironment in concentrations sufficient to cause the effects described *in vitro.* Thus, future work should demonstrate a tissue distribution of weak agonist or antagonist epitope mimics compatible with induction of tumor tolerance.

Getting to the End of the War

*Part of "*17.3 - Mechanisms of Immune Escape and Immune Tolerance "

For the immunotherapist, cancer is a fratricidal war that leads most often to the demise of the society in which it occurs. Like in most civil wars, the fight is complicated by a (sub)conscious repulsion of brothers to kill brothers (tolerance) and by the ease in which differences can be concealed by similarities (escape mechanisms). Contrary to regular wars, the end of a civil war is rarely achieved by force, as it is difficult to overpower a concealed enemy. This war is more likely ended by understanding its causes and the reasons extending it. Sorting the evil from good might depend on subtleties more likely to be appreciated by the patience of a diplomat than the power of a general. Thus, it is likely that the defeat of cancer will be achieved by crafters of smarter bombs rather than more powerful ones.

The identification of MAAs and their respective CTL epitopes has raised interest in peptide-based vaccinations (2), as clinical studies have shown that MAA-specific vaccines can powerfully enhance TAA-specific CTL reactivity (19 ,22 ,23). Systemic CTL responses to the vaccines, however, most often do not correspond to clinical regression, leaving investigators with the paradoxical observation of identifiable CTL reactivity that is not capable of destroying the targeted tissues. Among the questions raised by this paradox stands the enigma of whether tumors resist immunotherapy because the immune response elicited is insufficient (26) or because tumor cells rapidly adapt to immune pressure by switching into less immunogenic phenotypes (10). As discussed, animal models support either point of view and this dichotomy is far from solved in humans. It is possible that a balance between subliminal immune responses and fading immunogenicity of tumors governs the fine equilibrium, allowing tumor survival in the immune competent host. Epitope-specific vaccinations for the immunotherapy of melanoma, although disappointing in their clinical results, have given us the unique opportunity of comparing systemic T-cell responses with localization and status of activation of the same T cells in the target organ. At the same time, accurate analyses of the molecules targeted by the vaccination (TAA/HLA complex) can be performed. Prospective analyses of large cohorts of patients undergoing these "immunologically simplified" treatments will allow, in the near future, an expedited understanding of the issues raised in this chapter.

- Principles of Measuring Antibody Responses to Cancer Vaccines
- Summary

Introduction

Part of "17.4 - Principles of Immune Monitoring in Cancer Vaccine Trials "

Cancer vaccines are designed to induce or enhance antigen-specific immune responses against cancer cells. On entering clinical trials, selection of an optimum dose and schedule for a vaccine and decisions regarding subsequent clinical development are based in large part on laboratory studies that monitor and measure the vaccine-induced immune response. The laboratory correlative studies also have the potential to provide further insight into host tumor biology and support alternate methods of administration or combination with other agents that may result in more effective immunization strategies.

A major challenge in monitoring cancer vaccine trials is determining which parameters to measure *in vivo.* Cancer vaccines are capable of inducing complex and diverse immune responses, and the quantitative and qualitative aspects of effective antitumor immune responses are not completely understood. Furthermore, patient and tumor-related factors may influence the response to the vaccine, as well as the capacity of the immune response to produce tumor regression. The complex interactions and feedback mechanisms that occur *in vivo* when modulating an immunologic response also complicate the establishment of a direct dose effect. Major advances in molecular biology, immunology, and the biology of cancer have provided the scientific basis to discover and understand some of the basic principles that govern the interactions between the host immune system and cancer cells. In particular, the identification of tumor antigens recognized by T cells and their T-cell epitopes have given the unprecedented opportunity to characterize and follow the development of cancer-specific immune responses *in vivo*, including the interactions between molecularly defined T-cell responses and the relevant antigen in the target tissue (1 ,2).

General Principles

Part of "17.4 - Principles of Immune Monitoring in Cancer Vaccine Trials "

To fully assess and understand the effects of a cancer vaccine in the initial clinical trials, the laboratory studies are generally focused on:

1. Monitoring the method of vaccination, including the parameters of vaccine administration, biologic properties, and local or systemic effects that lead to effective immune responses, as predicted from preclinical data.
2. Measuring the immune response to the vaccine, based on the best available understanding of the type, quality, and magnitude of immune response necessary to mediate antitumor effects.
3. Assessment of patient and tumor-related factors known or suspected to influence the development and evolution of an effective antitumor immune response *in vivo.*

Several general principles of monitoring cancer vaccine trials can be proposed that may be applicable regardless of the vaccine or immunization approach. The immunologic concepts that

underlie the selection and interpretation of the assays are fully covered in other chapters and reviews (3).

Selecting Relevant End Points for Immune Monitoring

Depending on the antigen form and source, relevant immune responses may include CD4[+] helper, CD8[+] cytotoxic T lymphocyte (CTL), and antibody responses. It is essential, but often neglected, to demonstrate that the vaccine induces an immune response that recognizes the antigens as naturally processed and presented by tumor cells or host professional antigen-presenting cells (APCs) because antitumor efficacy could not occur otherwise. Furthermore, assessment of the magnitude and quality of the immune response is likely to be important in determining the potential efficacy of the vaccine in subsequent studies. For example, the number of tumor antigen–specific cells (4), their avidity for the antigen (5), the cytokines they produce (6), and their ability to traffic to tumor may be critical for mediating antitumor effects (7 ,8). Similarly, for antibody responses, the titer, epitope or number of epitopes recognized, class and isotype, and affinity for the antigen as expressed by tumor may influence antitumor efficacy (9). Monitoring of immune responses against tumor antigens not targeted directly by the vaccine may also be relevant to the outcome, as destruction of tumor cells by vaccine-induced effectors may lead to the release of other abundant antigenic molecules in the tumor milieu, and to inflammatory reactions that facilitate the presentation and development of immune responses to the antigenic molecules. The latter phenomenon, which results in broadening the specificity of the host immune response, is referred to as *epitope spreading.*

Issues Related to Selection of Tissue and Timing for Sampling

The immune response to a vaccine can be assessed at the vaccine site, draining lymph nodes, peripheral blood, and the tumor. Theoretically, the tumor is the most relevant tissue because lymphocytes or antibodies must reach the tumor to mediate antitumor effects (except, perhaps, in the situation where the immune response is eliminating circulating malignant cells before implantation). Furthermore, examination of the tumor prevaccination can confirm that the relevant antigen and the major histocompatibility complex (MHC) molecules associated with the presentation of antigen to T cells are expressed. Postvaccination sampling of tumor specimens can provide important information on immune selection, such as the development of antigen loss variants as a result of an effective immune response. For practical purposes, in most circumstances, it is only possible to monitor the relevant antigen-specific response in draining lymph nodes or peripheral blood. The limited data obtained from the latter sites are still considered useful because they verify the ability of the vaccine to produce a systemic immune response, although without the more relevant information on the ability of vaccine-elicited T cells to localize, function, and sustain an immune reaction within tumor.

Another consideration that has scientific and practical implications is the timing of tissue sampling after vaccine administration. Substantial *in vitro* and clinical data support the observation that antibody- and cell-mediated responses to vaccines evolve over time *in vivo;* therefore, the ability to detect the response in any particular site may vary as a function of the time from immunization. Clear data regarding optimal timing of sampling are not available from animal or human trials, particularly for T-lymphocyte responses to cancer vaccines.

Selecting Assays to Monitor the Parameters of Effective Immunization

Where possible and applicable, monitoring the parameters of effective antigen presentation aids in the interpretation of the clinical trial. Several examples are relevant. If the gene for the antigen is delivered by a viral, plasmid DNA or other vector, consideration should be given to confirming the extent and duration of gene expression *in vivo* and comparing the results to effective parameters in the animal models. For cytokine-transduced tumor cells, the levels of cytokine produced by the tumor cells in the vaccine (or gene expression) should be similar to that required for effective immunization and antitumor activity in preclinical experiments (10). Furthermore, the vaccine site can be biopsied and examined histologically to determine whether the local inflammatory response conducive to antigen presentation is similar in quality and magnitude to that observed with analogous vaccines in the animal models (10 ,11). Measurement of immune responses against non-tumor-related antigens in the vaccine may provide important information on the duration of expression of the relevant tumor antigen *in vivo* and the possibility of successful immunization with future application of the same vaccine construct. For example, vaccinia and adenovirus constructs induce potent neutralizing antivirus immune responses. Therefore, in subsequent use of the same viral construct, the infection is cleared rapidly, and the antigen gene insert is not expressed sufficiently to stimulate an effective immune response (12 ,13).

Determination of Assay Performance Characteristics

The usefulness of data generated during the monitoring of a cancer vaccine trial is highly dependent on the quality of the assays and the availability of sufficient numbers of samples to conduct valid analyses. Assays used for immune monitoring should be validated by showing that they are reproducable and specific, and sufficiently sensitive to detect relevant immune responses. If possible, the immune studies should be defined and prioritized prospectively, and levels of response worthy of further study should be clearly stated.

Appropriate controls are essential to the interpretation of any outcome in laboratory monitoring of cancer vaccine trials. Simple measurement of prevaccination versus postvaccination immune responses must be demonstrated to be specific for the immunizing preparation and, where applicable, to a tumor antigen and not a bystander component of the vaccine. For example, in allogeneic or autologous tumor cell vaccines, enzymes used in the preparation and dissociation of tumor samples and components of culture media can be immunogenic and responsible

for positive delayed-type hypersensitivity (DTH) responses or an apparent increase in a T-lymphocyte response postvaccination (14). The results can be interpreted correctly only if appropriate controls are included.

Inclusion of positive and negative controls for *in vivo* immunization and *in vitro* testing can aid in identifying nonspecific effects of the vaccine, as well as potential problems in the patient population being studied, the immunization method, or the assay itself. For example, measurement of immune responses to influenza antigens is commonly included as a positive *in vitro* control because most patients have been immunized to influenza and have strong baseline immune responses that can be readily detected *in vitro* (15). No agreement exists on a standard positive control antigen that reliably induces primary immune responses *in vivo* in most individuals.

Correlation of Laboratory Studies to Clinical Outcome

A common objective of monitoring in early clinical studies is to correlate immune response to clinical outcome. Although this provides some useful information in the context of a single-arm trial, a responder-to-nonresponder analysis, which generally shows that responders fare better than nonresponders, often leads to the incorrect conclusion that treatment and the induced immune response produced clinical benefit. Often, immune responders simply represent a better prognostic group of patients who are therefore better able to generate immune responses to the vaccine. Placement of a control immunogenic antigen together with the cancer antigen may allow more accurate correlation between induced response to the cancer antigen and clinical outcome.

Monitoring of Patient-Related Factors

Induction of an immune response in a patient may depend on several patient-related factors, including prior treatment with cytotoxic agents, type of disease, stage of disease, performance status, and other variables. Some animal studies suggest that growing tumors may induce conditions that affect overall immune status, ability to respond to new antigens, or the type of immune response to an antigen. Several investigators have reported generalized or specific defects in T-cell signaling in animal models and patients with advanced cancer (16 ,17 and 18). Defects in maturation of professional APCs have been reported in animals and patients owing to tumor overproduction of vascular endothelial growth factor and other cytokines (19 ,20). Clearly, it would be desirable to determine the immune competence of a patient before immunization to interpret the results of vaccination, and, perhaps, to select patient populations that are most appropriate to test the vaccine. No reliable tests for immune competence and the ability to respond to new antigens have been developed. Many investigators perform recall-antigen DTH tests or measure CD4/CD8 ratios or lymphocyte responsiveness to mitogens, viral antigens, or alloantigens. The significance of the results from these studies to overall immune status, ability to respond to immunization, and clinical outcome has not been fully defined.

MHC phenotyping has become an important aspect of patient selection for vaccine trials and monitoring of immune response to the vaccine (21). Patients selected for treatment with a particular MHC-restricted peptide antigen must be shown to express that MHC molecule. Such a requirement may not be present when the immunizing preparation is a whole protein or derived from whole tumor cells because the antigens are taken up and processed by host APCs, and the appropriate epitopes are bound to the patient's own MHC molecules. Because of the higher level of difficulty in measuring and characterizing immune responses to proteins or whole tumor cells, monitoring in the latter trials has, in certain settings, been directed to specific MHC-restricted epitopic determinants of the proteins contained in the immunizing preparation (12 ,22 ,23). Precise determination of the MHC phenotype has become increasingly important after demonstration that even one amino acid variant within the MHC molecule may totally alter the ability of an antigen to function as immunogen in a particular patient (24). Knowledge of each patient's MHC phenotype also enables investigators to characterize and identify possible shared antigens recognized by the induced T-lymphocyte response within the context of vaccines composed of proteins or whole cells. Methods for identifying antigens recognized by tumor-specific T lymphocytes are described in another chapter.

Monitoring of Tumor-Related Factors

Events that occur in tumors are the most relevant to the clinical outcome of any anticancer therapeutic approach. Indeed, clinical and preclinical data suggest the possibility of a dissociation between immune responses detected in peripheral blood versus tumor (25). Assessment of the tumor can also be used to guide selection of appropriate patients for treatment with a vaccine or can provide data to explain the biologic basis for treatment failures and successes, which may lead to improved vaccine approaches. Obtaining sufficient tumor tissue for these studies in most patients can be quite difficult, particularly when tumors are not in easily accessible sites. Furthermore, assays conducted on tumor are expensive and labor intensive, and interpretation of the results is complicated by heterogeneity within and between tumor specimens. Compared with full biopsies, fine-needle aspirates of tumors (which, in many cases, can be performed with relative ease and minimal morbidity) can provide sufficient tissue for some correlative studies, give information on antigen expression, and be used to establish lymphocyte cultures and tumor cell lines for *in vitro* immune assays (26). Nevertheless, even fine-needle aspirates can be used only in a subset of patients with minimal morbidity.

Perhaps the primary reason to examine tumor tissue within the context of a vaccine trial is to assess the extent to which tumors express the antigen in the vaccine and, where appropriate, the restricting MHC molecule. This is because lack of appropriate antigen presentation by the tumor precludes therapeutic efficacy (27 ,28). Indeed, *in vitro* data suggest that CTL recognition of tumor cell lines can vary depending on the level, as opposed to just the presence or absence, of antigen and MHC expression (29). It is possible to measure relative expression of

the protein antigen and the restricting MHC molecule for the relevant peptide epitope with various techniques, such as immunohistochemistry or polymerase chain reaction (PCR) (30 ,31), but techniques are not available to accurately assess the number of MHC complexes containing the relevant peptide on the surface of the cell. In the future, it may be possible to raise antibodies that are specific for a single peptide/MHC complex, which can therefore be used to more accurately determine tumor antigen presentation.

A number of other tumor-related factors have been identified that may determine responsiveness to a vaccine, including expression by tumor of immunosuppressive molecules, such as Fas ligand that binds to death receptors on T cells, or the lack of expression of certain adhesion molecules on tumor vasculature that allow penetration by T cells (7). In some settings, interactions between tumor-related products may influence the developing immune response. For example, the combined expression of transforming growth factor-β and Fas ligand by tumor has been shown to markedly inhibit the activation, function, and survival of infiltrating T cells, whereas expression of Fas ligand alone promoted tumor regression (32). Defects in certain tumor cell signaling pathways can also affect immune recognition. For example, disruption of the interferon-γ (IFN-γ) signaling pathway in tumors was associated with resistance to lymphocyte-mediated control of growth in animal models (33). Because of the many factors that appear to impact on the antitumor immune response, newer technologies, such as gene chip arrays that can measure expression of many genes simultaneously within a sample of tumor tissue, may be necessary to fully characterize the tumor phenotype before immunization (34).

Theoretically, lymphocytes, antibodies, or both must reach the tumor to mediate antitumor effects. Tumor can be examined histologically for lymphocytic infiltration and presence of other immune effector cells, as well as the induction of apoptosis in tumor cells and induced changes in tumor vasculature. The interpretation of histologic findings is subject to variations in sampling, observer bias, or error. Therefore, assessment of the slides should be blinded with regard to the treatment received and the time of tissue sampling (pre versus post), and overall conclusions should be based on examination of multiple samples from multiple patients. In addition to visual examination, infiltrating lymphocytes can be assessed directly by staining or PCR measurement of gene expression or indirectly through subsequent *in vitro* culture; the latter may be necessary to expand infiltrating lymphocytes to sufficient numbers for functional studies. Lymphocytes are generally examined for surface expression of markers that determine identity, activation state, ability to home within target organs, and antigen specificity and function (avidity, cytokine production, and cytotoxicity). The data generated by these laboratory assays can confirm that activated antigen-specific T lymphocytes were produced as a result of immunization and reached the tumor site. These types of analyses, although extremely important, cannot be performed routinely. It should be emphasized, however, that the collection of clinically relevant material might be all that is necessary. The availability of an "off the shelf" clinically relevant library of tissue specimens allows eventual selection of the most interesting samples for further study and interpretation of clinical results.

Special Issues Concerning the Monitoring of Vaccines Derived from Autologous or Allogeneic Tumor

Part of "17.4 - Principles of Immune Monitoring in Cancer Vaccine Trials "

A large number of vaccines are derived from autologous or allogeneic tumors in which the specific tumor antigens are not known. For autologous tumor vaccines, an assumption is made that the more relevant antitumor immune responses are generated to unknown unique antigens. Vaccines derived from allogeneic sources of tumor are presumably inducing immune responses to shared tumor antigens, which may or may not be known. In either case, if the tumors are likely to contain known or putative shared defined tumor antigens, it may be possible to monitor the overall immunogenicity of the vaccine by measuring immune responses to the defined shared antigens. Monitoring of immune responses to defined antigens is discussed in the next section.

If the antigens contained in the vaccine are not known, then other monitoring approaches must be considered. The major goal is to determine whether immune responses are induced to antigens expressed by the vaccine preparation. T-lymphocyte and serologic responses can be measured, but instead of a defined antigen, established autologous or HLA-matched allogeneic cell lines from the vaccine preparation are used as targets for *in vitro* assays. Another measure of immune response to the vaccine preparation is development of DTH reaction to a skin test, consisting of the whole or some fraction of the vaccine (35). Appropriate controls should be included because enzymes used in the preparation and dissociation of tumor samples and components of culture media can be immunogenic and can be responsible for positive DTH responses or an apparent increase in a T-lymphocyte response postvaccination.

Vaccine efficacy can also be monitored by assessing and comparing local or tumor site-specific biologic effects to those that correlated with effective immunization in animal models (10 ,11 ,36). Even before the administration of autologous or allogeneic tumor cells transfected with a cytokine gene, production of cytokine by the cells (i.e., measurement of cytokine production per number of cells per unit of time) should be demonstrated to be in the same range as that required for increasing immunogenicity in the animal models. After placement of the vaccine, a biopsy of the site some days later can be examined histologically for infiltration by T lymphocytes, plasma cells, dendritic cells, eosinophils, or other populations, providing some indication that the local effects of the vaccine in humans mimic those conducive to antigen presentation observed in animals. Ultimately, the vaccine is expected to induce an inflammatory response in the tumor. Tumor biopsies can provide an indication of effective immunization if the postvaccine sample shows an increase in the inflammatory infiltrate, which again can be correlated to findings in the preclinical models. T lymphocytes isolated from biopsy sites can be phenotyped for expression of cell surface markers by immunohistochemistry and possibly expanded *in vitro* culture to examine functional properties, such as ability to recognize cell lines from the immunizing preparation. With the inclusion of appropriate controls, the sum of the data could provide convincing evidence of effective immunization against tumor antigens, even if the tumor antigens are not defined.

Measuring T-Lymphocyte Responses to Cancer Vaccines

Part of "17.4 - Principles of Immune Monitoring in Cancer Vaccine Trials "

Many cancer vaccines in development are designed to induce T-lymphocyte responses against tumor antigens based on the prevalent role of T cells in mediating tumor regression in preclinical animal models. Parallel with clinical evaluation of the vaccines, several assays were adapted or developed for measuring the vaccine-induced T-lymphocyte responses (Table 17.4-1). Although each has advantages and disadvantages, none can measure the full spectrum of possible lymphocyte responses. Furthermore, no clear correlations at this time exist between a measured immune response and antitumor activity. For these reasons, the assays must be considered research techniques rather than fully validated instruments that can be routinely used to guide the development of cancer vaccines in the clinic. Selection of the particular assay and the target for measuring the response depends on the form and source of vaccine, its antigen contents, and the expected immune response. Monitoring becomes increasingly more directed as the antigen in the vaccine becomes more defined and restricted. Broad monitoring of immune responses must be considered even in studies of well-defined single antigens because tumor lysis by a specific immune response may promote more effective and broader presentation of tumor antigens *in vivo.*

Table 17.4-1 Various Assays Used for Monitoring of Epitope-Specific CD8+ T-Cell Responses

	Main Characteristic	Sensitivity	Comments
Direct Assays			
HLA tetramers	Requires only engagement of TCR with epitope/MHC complex	1:5,000	Does not yield information about the ability of T cells to respond to stimulation
Intracellular cytokine expression	Requires engagement of TCR with epitope/MHC complex and activation of T cell	1:5,000	Does not identify epitope-specific T cells incapable of responding to the stimulatory conditions applied by the assay
Enzyme-linked immunospot	—	1:10,000	—
Reverse transcriptase polymerase chain reaction	—	1:50,000	—
Indirect Assays			
In vitro sensitization	Requires engagement of TCR with epitope/MHC complex, activation and proliferation of T cell	Undetermined (probably higher than all other assays)	Does not identify epitope-specific T cells incapable of proliferation in response to the stimulatory conditions applied by the assay
Limiting dilution assay	—	1:10,000 to 1:50,000	—
Proliferation assay	—	Undetermined	Nonspecific, does not correlate with antigen-specific reactivity, practically obsolete

MHC, major histocompatibility complex; TCR, T-cell receptor.

The immunology of CD4+ and CD8+ lymphocyte responses on which the monitoring studies are based is described in another chapter. Both cell types may play a role in mediating antitumor responses. In general, cellular responses to antigen recognition include cell activation, changes in expression of surface markers, proliferation, cytokine production, and antigen-specific lysis of target cells. CD4+ cells are primarily nonlytic and produce cytokines, whereas CD8+ lymphocytes can produce cytokines and lyse tumor cells. CD4+ cells are capable of differentiating along separate pathways, leading to different patterns of cytokine production, which may affect their ability to promote versus inhibit an effective antitumor response. CD4+ cells with immune-suppressive properties have also been reported. The significance of CD4+ T-cell responses in tumor immunology has been reviewed (37). For CD4+ and CD8+ immune responses, the magnitude of response (the frequency of antigen-specific T cells), as well as the avidity of the T cells for their respective peptide/MHC complex, may be important factors in determining whether immunization results in tumor regression.

The subsequent sections focus primarily on assessment of CD8+ T-cell responses. Few shared CD4+ antigen epitopes of tumor antigens have been identified, and the majority of CD4+ tumor antigen-specific responses that have been well characterized in humans have been against unique mutations in cellular proteins (38 ,39). Nevertheless, assessment of CD4+ responses is appropriate for vaccines containing long peptides, proteins, or cells.

Assays in Bulk Cultures of Lymphocytes

Immunization against various antigens in animal models and humans has been shown to produce expansion of antigen-specific T-cell precursors in peripheral blood. When the antigen-specific T cells reach a threshold percentage of the overall peripheral blood mononuclear cell (PBMC) population, it becomes possible to detect proliferation and cytokine production in response to or cytotoxicity against target cells bearing the antigen of interest. In some cases (i.e., infection with or immunization against some viral antigens), a large expansion of antigen-specific precursors in peripheral blood occurs, and reactivity against the target antigen can be detected without further expansion of the specific T-cell precursors. With lower numbers of precursors in peripheral blood, detection of T-cell reactivity against a specific antigen in bulk cultures requires expansion of the precursors *in vitro.* Bulk PBMCs or sorted subpopulations from PBMCs (i.e., CD8+ T cells) are exposed to the antigen in combination with interleukin-2 (IL-2) in repeated cycles of approximately 7 days. The conditions of *in vitro* expansion vary depending on the particular assay and may include one or more of the following in various concentrations depending on the optimal conditions established for the assay: IL-7, IL-6, IL-12, other cytokines, antibodies activating CD28, irradiated

feeder cells, and activated mature dendritic cells. The higher the baseline number of precursors in fresh peripheral blood, the fewer the number of *in vitro* sensitization cycles required to expand the precursors to a level where proliferation, cytotoxicity, or cytokine production in response to the relevant target antigen can be demonstrated in the bulk culture (Fig. 17.4-1).
FIGURE 17.4-1. *In vitro* sensitization assay for the evaluation of MART-1–specific immune reactivity in peripheral blood mononuclear cells of a patient who received MART-1 (27-35) peptide vaccine in incomplete Freund's adjuvant. Peripheral blood mononuclear cultures were stimulated *in vitro* repetitively with the MART-1 (27-35) peptide and tested after each restimulation for their ability to lyse cancer cells in a cytotoxicity assay. Immune-reactive cells specific to the vaccine and able to kill cancer cells were developed more efficiently after four vaccinations than after two vaccinations and before vaccination. (E:T, effector:target.) [Data from this trial are reported in Cormier JN, Salgaller ML, Prevette T, et al. Enhancement of cellular immunity in melanoma patients immunized with a peptide from MART-1/Melan A (see comments). *Cancer J Sci Am* 1997;3:37.]

Although lymphocytes can produce several cytokines (IFN-γ, granulocyte-macrophage colony-stimulating factor, IL-2, tumor necrosis factor, IL-4, IL-10), assays for detection of antigen-specific cells in bulk cultures, particularly for CD8$^+$ CTLs, are often designed to measure production of IFN-γ. The choice of IFN-γ is based in part on preclinical studies of adoptively transferred CTLs to treat murine tumors, which demonstrated a correlation between IFN-γ production by CTLs (but not cytotoxicity) and *in vivo* antitumor effects (6). CTL cytotoxicity for target cells generally correlates with IFN-γ production, but the two functions may be dissociated, partly because the different functions of T cells can require different levels of activation (40). Proliferative assays are usually conducted by measuring the incorporation of tritiated thymidine, which is added over the last 24 hours of an *in vitro* culture of PBMCs with antigen and IL-2. The proliferative assays are used less commonly because they provide minimal information on function of the antigen-specific cells.

Assays for lysis or cytokine production are conducted against target cells expressing the relevant antigen and MHC restriction element. If a generic target cell is used, antigen is placed on the target by pulsing with the appropriate peptide or transfecting the cell with the gene coding for the antigen. Autologous tumor cell lines, or, more commonly, allogeneic tumor cells that contain the antigen and the appropriate MHC restriction element matched to the patient, are also used as targets. The assays are conducted at various ratios of T cells:targets for periods ranging from 4 to 24 hours. Cytokine production is generally measured in the supernatant after a 24-hour incubation using commercially available kits. Lysis is measured by release of a chromium-51 or other label from the target cell, usually over a 4-hour period. To determine the specificity of response, cytotoxicity or cytokine-release assays are conducted in parallel against target cells alone (without peptide) or pulsed with irrelevant peptide, antigen-positive cells mismatched at the MHC restriction element, or antigen-negative MHC-matched cells. In certain circumstances, a blocking antibody against the MHC restriction element is added to verify that recognition is through a receptor-peptide-MHC interaction. For lytic assays, unlabeled antigen-negative target cells can be added to determine if any of the observed lysis is caused by non-antigen-specific killer cells. After correction for background release, the percent of target cells lysed at each effector:target ratio is plotted. Various publications present the data as lytic units, defined as the number of effector cells necessary to give *x*% lysis (usually 33%) of *x* target cells (usually 2,500), divided into 1×10^7 effector cells.

The sensitivity of a cytokine release or lytic assay depends on many variables, including the effector:target ratio, amount of antigen/MHC expressed by the target, the avidity of the T cell, and its capacity for specific lysis or cytokine production. Even such factors as the solubility of the peptide may affect the outcome of the *in vitro* assays. For example, a poorly soluble peptide may give falsely low CTL read-out when pulsed on target cells *in vitro*. A reasonable estimate of the sensitivity of a typical cytotoxicity or cytokine release assay has been provided by spiking PBMCs with increasing numbers of cloned high-avidity CTLs recognizing their respective peptide antigen loaded on target cells or expressed by tumor (41). (M. Nishimura, *personal communication*, 1999). Under the prescribed experimental conditions, the cloned cells must comprise approximately 0.2% to 1.0% of the bulk PBMC population to detect IFN-γ production above background in a standard 24-hour cytokine release assay or cytotoxicity against tumor or peptide-pulsed target cells. Thus, unless immunization results in specific precursor frequencies in peripheral blood or other sampled tissue of approximately 1% (for these particular peptides and assays), detecting the antigen-specific cells requires some *in vitro* expansion. Indeed, successful immunization to the MART-1 melanoma peptide, among the first to be studied in the clinic, was demonstrated by showing detection of CTLs with fewer *in vitro* stimulations postimmunization compared with preimmunization (42 ,43). (see Fig. 17.4-1). For peptides capable of inducing potent immune responses, such as the modified gp100:209-217 (210M) melanoma peptide, production of IFN-γ above background against a peptide-pulsed target cell rarely can be detected directly out of peripheral blood and,

in most cases, is detected after a single 7- to 11-day *in vitro* sensitization with peptide and IL-2 (44 ,45).

Characterization of CTL responses in bulk culture can be expanded to examine production of other relevant cytokines and to estimate the avidity of the CTL for the antigen target. For the latter, detection of CTL activity at low effector:target ratios or recognition of peptide-pulsed target cells at low concentrations of peptide suggests that CTLs have high avidity for the antigen-MHC complex. In patients immunized with the modified gp100:209-217 (210M) peptide, Dudley et al. have shown that the avidity of CTLs in bulk culture, as measured by IFN-γ production against peptide-pulsed target cells, correlates with their capacity to recognize tumor cell lines *in vitro* (46) (Fig. 17.4-2). Further characterization of the CTL response in bulk culture can be accomplished by cloning and analyzing antigen-specific T cells. The latter analysis in patients immunized with the modified gp100:209-217 (210M) peptide revealed the diversity of the T-cell response (47). Many of the clones recognized only target cells pulsed with the modified peptide or with the native peptide, but not antigen-positive tumor containing the appropriate MHC restriction element HLA-A*0201. Furthermore, analysis of T-cell receptor (TCR) alpha and beta chain usage among these and other antigen-specific clones has demonstrated the broad variability in TCRs that are capable of recognizing a particular peptide-MHC complex (48).
FIGURE 17.4-2. Recognition of tumor by vaccine-specific T-cell clones derived from a patient vaccinated with gp100-209-2M in incomplete Freund's adjuvant. Recognition of tumor highly correlates with recognition of antigen-pulsed T2 cells. Interferon-γ (IFN-γ) secretion by individual clones for each indicated tumor is plotted as tumor-stimulated release *(y axis)* versus peptide-pulsed T2 cell–stimulated release *(x axis).* The trendline for the population of clones is shown with the regression coefficient indicated (R^2 value). Top graphs: T2 pulsed with 1.0 µm gp100-209 peptide. Bottom graphs: T2 pulsed with 0.03 mm gp100-209 peptide. SK23, 624.38, 1479, and 501 are gp100 and HLA-A*0201–expressing cell lines. [Adapted from Dudley ME, Nishimura MI, Holt AKC, Rosenberg SA. Anti-tumor immunization with a minimal peptide epitope (G90209-2M) leads to a functionally heterogeneous CTL response. *J Immunother* 1999;22(4):288.]

Enzyme-Linked Immunospot Assays

The enzyme-linked immunospot (ELISPOT) assay was developed to increase the quantitative capacity of monitoring T-cell responses (49 ,50 and 51). Plates are coated with antibody to a specific cytokine, most commonly IFN-γ. Target cells pulsed with peptide or target tumor cells are placed onto the plate on which the lymphocytes are added to form a layer one cell thick. The conditions of the assay can be varied. For example, lymphocytes may be sorted to select CD4+ or CD8+ cells before plating, or, if unsorted populations are used, blocking antibodies can be added to decrease background and increase detection specificity (i.e., adding anti-MHC class II antibodies to the plates to block nonspecific CD4+ cell responses and, therefore, increase the specificity for detecting MHC class I-restricted responses) (52). Plates are incubated for approximately 24 to 48 hours in most settings. In each spot that a lymphocyte specific for the target antigen is located, IFN-γ is produced and captured by the bound IFN-γ antibodies on the plate. A second antibody to IFN-γ is added and, after washing, is visualized with a process that forms a colored spot at the site of the second IFN-γ antibody. The spots are counted, each representing a T cell specific for the antigen target. The total number of spots in plates loaded with the relevant target minus the spots formed in the plates with a nonrelevant target divided by the number of PBMCs per plate represents the frequency

of antigen-specific T cells. Spots can be read manually or with special instruments.

ELISPOT assays can be used to detect CD4+ or CD8+ responses. Theoretically, depending on the number of plates used and the extent of background, an ELISPOT assay could allow detection of antigen-specific T cells directly from peripheral blood without any *in vitro* culture and expansion. Similar to the bulk culture techniques, the development of a spot (and, therefore, the assay results) can be affected by several variables, including the amount of antigen/MHC complex presented by the target, the avidity of the T cells for the antigen/MHC complex, their ability to produce the particular cytokine, the length of time required to activate the antigen-specific cells (incubation time), and the sensitivity of detecting the second antibody in the colorimetric reaction.

The published experience using the ELISPOT assay to monitor T-cell responses to cancer antigens is still limited (52 ,53 ,54 and 55). Pass et al. reported results of ELISPOT assays conducted in patients immunized with peptides derived from the melanocyte protein gp100. 10^4 or 10^5 PBMCs were plated with 10^5 target cells, either T2 cells pulsed with peptide or MHC-matched antigen-positive tumor cells. In general, an 8- to 12-day *in vitro* sensitization with peptide and IL-2 was necessary to detect reactivity above background in the ELISPOT assay. After the *in vitro* sensitization, peptide-reactive CTLs could be detected in most patients immunized with the gp100:209-217 (210M) modified peptide or the native gp100:209-217 peptide and in approximately 20% of patients immunized with the gp100:280-288 (288V) peptide. The frequency of CTLs after the 8- to 12-day *in vitro* sensitization was in the range of 0.1% to 1.0%. When tumor was used as the target in the ELISPOT assay, reactive CTLs at a frequency of 0.1% to 1.0% were demonstrated in several patients immunized with the modified gp100 peptide.

Reynolds et al. used the ELISPOT assay in monitoring immune responses in 22 consecutive patients receiving a melanoma vaccine composed of shed antigens of cultured melanoma cell lines (52). The ELISPOT assay was used to measure directly from peripheral blood pre- and postimmunization PBMC reactivity to a large number of HLA-A*0201-binding peptides derived from several antigens known to be expressed by melanoma. The ELISPOT assay was modified by adding anti-MHC class II antibodies (to block CD4+ responses), and the number of peptide-specific T cells were determined by first subtracting the number of spots in wells containing an anti-CD8+ antibody (which would block peptide-specific CTL responses) and further subtracting the number of spots in wells with control nonmelanoma peptide. A value of 5 out of 500,000 PBMCs was considered positive in the assay. Frequencies of peptide-specific CTLs pre- or postvaccination ranged from 1 in 100,000 to as high as approximately 1 in 5,000 although most were less than 1 in 25,000. Substantial heterogeneity was found in positive CTL responses between peptides and between patients. The ability of the CTL to recognize HLA-A*0201 antigen-positive melanoma cell lines was not reported.

Intracellular Cytokine Production

Techniques have been developed to quantify antigen-specific T cells by sorting on the basis of intracellular cytokine production in response to recognition of specific antigen (56 ,57). T-cell membrane permeability is increased using chemical means, which allows penetration and binding by antibodies specific to the cytokine of interest, usually IFN-γ. Multicolor flow cytometry can then be used to quantify and subset the activated T cells among a bulk PBMC population. The technique has not been fully developed or used extensively in monitoring of cancer vaccine trials and is limited in overall sensitivity by the sensitivity of flow cytometry (Fig. 17.4-3) (58 ,41).
FIGURE 17.4-3. Fluorescene-activated cell sorter analysis for intracellular interferon-γ (IFN-γ) expression in pre- and postvaccination peripheral blood mononuclear cells from a patient vaccinated with gp100-209-2M in incomplete Freund's adjuvant. Peripheral blood mononuclear cells were stimulated with unpulsed T2 cells [T2(-)] pulsed with g209 [T2(g209)] or g2092M [T2(g209-2M)] peptides (1 μm). CD3+/CD8+ cells were gated for analysis, and numbers indicate the percentage of cells in the quadrants over the total gated cells. g209 tHLA staining decreased on stimulation because of downregulation of T-cell receptor as previously noted analyzing epitope-specific clonal populations. [Adapted from Lee K-H, Wang E, Nielsen M-B, et al. Enhanced T-cell response to peptide-based vaccination against melanoma correlates with increased vaccine-specific T-cell frequency and susceptibility to stimulation but does not lead to tumor regression. 1999 *(submitted).*]

Limiting Dilution Assays

The limiting dilution assay (LDA) is designed to yield an estimate of T-cell precursor frequency in the circulation and is therefore a relatively quantitative assay. Furthermore, as expansion of T cells is integral to the conduct of this assay, it has the capacity for increased sensitivity compared with assays such as ELISPOT and intracellular cytokine and tetramer analysis, which are often used to enumerate the number of antigen-specific T cells directly from peripheral blood without expansion. Nevertheless, the capabilities of the tetramer technology (described in the section Tetramer Assays) may ultimately surpass the sensitivity of the LDA in certain settings.

LDA is based on the principle that the number of *in vitro* PBMC cultures from which an antigen-specific T-cell population can be expanded is proportional to the frequency of the precursors in fresh PBMCs. In making serial dilutions of the initial PBMC population and plating replicate cultures at each dilution, the number of cultures containing the antigen-specific lymphocytes should decrease. The number of "negative" cultures per dilution of the starting lymphocyte population can be plotted, and statistical methods can be used to determine the frequency of the target antigen-specific lymphocytes in the undiluted lymphocyte population obtained from peripheral blood (59).

Each culture per dilution is set up by adding feeder cells (usually irradiated PBMCs) and then adding the antigen of interest (a peptide in many cases) or a tumor target. A parallel series of control cultures are established with irrelevant targets. The lymphocytes are added at a predetermined effector:target ratio along with IL-2. The *in vitro* stimulation with antigen and IL-2 may be repeated at set intervals. After a sufficient period for the antigen-specific lymphocytes to proliferate, labeled target cells containing the antigen are added to the cultures, and the end point of interest is measured (usually cytotoxicity or cytokine production for detection of CTLs). In some circumstances, cold antigen-negative target cells are added with the labeled relevant targets to negate nonspecific effector cell activity generated by IL-2. Positive cultures are scored when the values are higher than the mean plus three standard deviations.

The results of the LDA depend on several variables, including the type of cellular response that is assayed, the target cells, the frequency of the antigen-specific cells in the starting population, the ability of those cells to expand in culture, the number of cultures established per dilution, and the number of dilutions that are examined. Overall, the sensitivity of LDA appears to be superior to other assays that use a functional end point for detection of antigen-specific lymphocytes with a range of 1 in 30,000 to 1 in 100,000, although some investigators report sensitivity to 1 in 10^6. Even under the most favorable circumstances, measurement of lymphocyte responses with the LDA is labor intensive and not practical for routine monitoring of cancer vaccine trials. Furthermore, comparison of the LDA with the tetramer assays (discussed in the section Tetramer Assays) for detection of T-cell responses in the setting of a viral infection suggests that LDA detects only a fraction (approximately 1.0% to 20%) of T lymphocytes that express a TCR capable of recognizing the antigen of interest.

The LDA has been used to monitor several cancer vaccine studies, including trials of allogeneic melanoma cell lines or lysates (60 ,61), poxvirus vectors containing the carcinoembryonic antigen gene (using an HLA-A2–restricted carcinoembryonic antigen peptide as the *in vitro* target) (22), and peptides derived from MUC-1 and gp100 (62). Although precursor frequencies of CTLs against the immunogen or the selected target increased in some patients for most of the studies, postvaccination CTL frequencies were generally still quite low. Patients treated with the modified gp100:209-217 (210M) peptide, however, were found to have T cells specific for the native gp100 peptide in the range of 0.1% to 0.01% of the bulk PBMC population (S.A. Rosenberg, *personal communication*, 1998).

Tetramer Assays

Theoretically, the most sensitive and specific assay for antigen-specific T cells would permit identification and enumeration of all cells in a population that contained a TCR that bound to a particular peptide-MHC complex. The lymphocyte TCR binds to a single peptide-MHC complex with relatively low affinity followed by rapid dissociation. Single peptide-MHC complexes are therefore poor reagents for use in cell-sorting analyses of T cells. When two to four MHC molecules are linked and the peptide antigen is allowed to bind to the MHC molecules, the dissociation rate of the peptide-MHC complex from the lymphocyte TCR is diminished substantially, allowing for identification and sorting of lymphocytes using a fluorescence-activated cell sorter instrument (63). The sensitivity of peptide-MHC tetramers to detect antigen-specific CTLs is predicted to be greater than the standard limiting dilution assays because the tetramers detect T cells based primarily on the binding properties of the TCR, whereas detection of T cells by LDA depends inherently on the ability of a T cell to proliferate and perform a function, such as cytotoxicity or cytokine release in response to its antigen. The increased sensitivity conferred by tetramer binding is offset partially by the limited sensitivity of the fluorescence-activated cell sorter instrument, which can only reliably detect approximately 1 in 10,000 cells (0.01% to 0.02%). Furthermore, production of high-quality pure peptide-MHC tetramer reagents can be difficult, requiring relatively pure peptide and a refolding of the recombinant-produced heavy chain and beta-2-microglobulin in the presence of peptide. Nevertheless, the peptide-MHC tetramers appear to provide more reliable quantization of antigen-specific T cells than other techniques, and, in certain settings, may allow analysis of CTL responses directly on peripheral blood or tissue. Furthermore, once the antigen-specific cells are sorted, they can be analyzed for functional properties in bulk or after additional cloning.

In animal and human studies of viral infections, tetramers have detected remarkable peripheral blood expansion of CD8[+] cells specific for a viral peptide epitope, in some cases comprising 5% to 10% of the total CD8[+] lymphocyte population (64 ,65 ,66 ,67 and 68). The published experience with tetramers to monitor CTL responses to cancer antigens remains limited (69 ,70). Tetramers have been generated for the melanocyte HLA-A201–restricted peptide epitopes MART-1/Melan-A:27-35 and 26-35 (27L), gp100:209-217, and its 210M modification gp100:154-162 and tyrosinase:368-376 (370D), all of which are in clinical trials for patients with metastatic melanoma. Ogg et al. used the MART-1/Melan-A:26-35 (27L) tetramers to study the frequency of CTLs specific for MART-1 in the PBMCs of HLA-A201 individuals diagnosed with vitiligo compared with a normal HLA-A201 cohort. Individuals with vitiligo had higher frequencies of MART-1–specific CTLs in the range of 0.01% to 0.50% of all CD8[+] lymphocytes. The majority of tetramer-positive CD8[+] lymphocytes also expressed the skin homing receptor cutaneous lymphocyte

antigen. *In vitro* expansion of PBMCs with the corresponding MART-1/Melan-A peptide and cytokines produced greater expansion of tetramer-positive lymphocytes in the vitiligo cohort compared with the control cohort, confirming the observations made directly from peripheral blood. Expanded tetramer-positive cells were also shown to have cytolytic activity against HLA-A201 MART-1–positive melanoma cell lines. Using similar techniques, Romero et al. demonstrated higher frequencies of MART-1/Melan-A CTL in CD8+ lymphocytes obtained from melanoma-involved, resected regional lymph nodes when compared with CD8+ lymphocytes from tumor-involved lymph nodes in patients with other cancers. The tyrosinase peptide tetramer detected antigen-specific CTLs at low frequencies and only in some patients, although higher frequencies could be detected in two of three PBMCs cultured *in vitro* for 2 to 3 weeks in IL-2 and IL-7.

Lee et al. used tetramers to tyrosinase (as above) MART1:27-35, and gp100:154-162 peptides to stain PBMCs from 11 nonvaccinated melanoma patients (71). In four patients, MART-1-specific CTLs were detected at a frequency of 0.014% to 0.160%, whereas tyrosinase-specific CTLs were detected in two separate patients (0.19% and 2.2%). Tetramer-positive cells were characterized for expression of multiple surface markers, as well as cytolytic activity, cytokine production, and expression of the activation marker CD69 in response to peptide-pulsed target cells. CTLs in two of the patients expressed an unusual phenotype with characteristics of naïve and memory cells. In contrast to control populations of cytomegalovirus or Epstein-Barr virus peptide-specific CTLs from the same patients or normal donors, MART-1- and tyrosinase tetramer-positive CTLs isolated directly from peripheral blood were unable to kill or upregulate CD69 expression in response to peptide-pulsed target cells. *In vitro* exposure of CTLs to IL-2 for 48 hours did not restore lytic activity. Furthermore, the CTLs were unable to produce IFN-γ or tumor necrosis factor in response to phorbol ester and a calcium ionophore. The results illustrate the potential of the tetramer assay to identify and characterize function of specific populations of tumor antigen-specific CTLs and compare them within the same patient to CTLs recognizing nontumor antigens. The investigators were also able to demonstrate a decline in the tyrosinase tetramer-positive CTLs over time in response to chemotherapy.

The gp100:209-217 and 209-217 (210M) tetramers have been used to measure PBMC frequencies of CTLs specific to the gp100:209-217 epitope in patients immunized with the 210M modification of this peptide (58). Samples are generally obtained 3 weeks after the second q3w immunization with peptide administered in incomplete Freund's adjuvant. Whereas up to a one-log increase in CTL frequency could be detected postimmunization directly from peripheral blood in some patients, the absolute number of antigen-specific cells was only 1.0% to 1.5% of PBMCs in patients with the best response. When PBMCs were expanded *in vitro* with peptide and IL-2 for several days, however, the tetramer assay showed a marked expansion in the gp100-specific CTLs only in the postimmunization PBMCs.

Molecular Techniques for Monitoring T-Lymphocyte Responses

Direct monitoring of specific T-cell populations using molecular approaches may improve sensitivity and allow examination of small samples of tissue. One potential approach is to monitor the genes used to code for the TCR of the CTL that recognizes a particular peptide-MHC complex. The TCR is composed of an alpha and beta chain, each of which is formed by recombination of DNA sequences from two and three gene families, respectively, within the respective gene locus. Various combinations of TCR alpha and beta chains can form a binding site for a specific peptide/MHC complex. This marked plasticity of the potential T-cell response within and between patients (before the stimulation of an immune response) precludes determining the genes that will be preferentially used to form the TCRs that bind to the peptide-MHC complex. Once a CTL clone specific for a peptide-MHC complex is available, however, the fate of cells expressing the particular genes coding for the TCR alpha and beta chain and a CDR3 region of specific length (the area that forms the specific antigen-binding region) can be monitored *in vitro* or *in vivo.* A competitive reverse transcriptase PCR assay has been described that can quantitatively assess the absolute number and percent of message for a particular gene of the TCR alpha or beta gene family (72). The assay was reported as being capable of detecting one copy per 100,000 of the message of interest. A second PCR technique estimates the percent of cells within a population that express a particular gene of the TCR beta gene family and a specific length (number of amino acids) of the CDR3 region (the area that makes contact with the peptide-MHC complex) (73). The techniques have substantial value in dissecting the evolution of immune responses to specific antigens in animal models (74 ,75). For clinical trials, the techniques appear to be most useful in following adoptive transfer of specific CTL clones *in vivo* or for tracking expansion and localization of a subpopulation of CTLs once an immune response has been induced (76 ,77).

Rather than following the fate of specific clones of T cells, investigators have developed molecular methods to estimate the presence or changes in frequency of T cells in peripheral blood or tumor that have the characteristics of activation in response to antigen recognition. After activation of a T cell, RNA message for several cytokines and other activation-induced genes increases within 2 to 4 hours. Quantitative reverse transcriptase PCRs can measure the absolute amount of messenger RNA (mRNA) for a particular gene and the increase in message related to T-cell activation. Investigators at the Surgery Branch of the National Cancer Institute have used the quantitative reverse transcriptase PCR techniques to detect evidence of immunization to a peptide vaccine directly from peripheral blood. A sample of PBMCs is exposed to peptide antigen for a short period, and quantitative PCR for various genes is performed at several time points after the completion of peptide incubation (78) (Fig. 17.4-4). Among several genes, IFN-γ has been most sensitive for detecting activation of MHC class I–restricted CD8 T cells when normalized to mRNA copies of the CD8 gene. The sensitivity of the assay, determined by adding titrated

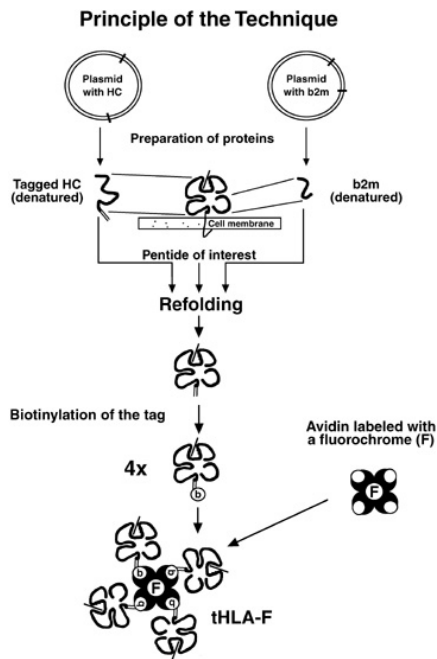
amounts of cloned CTLs to PBMCs, can be in the range of one activated antigen-specific cell among 50,000 PBMCs. In preliminary studies of patients immunized with the gp100:209-217 (210M) peptide, the sensitivity of the quantitative PCR directly from peripheral blood is still below that of bulk *in vitro* culture of PBMCs, because the latter method allows expansion of the antigen-specific CTLs, and the signal can be amplified by secretion of the target cytokine. Nevertheless, the sensitivity of PCR may be sufficient for the purpose of detecting clinically relevant immune responses, and the technique is substantially less labor intensive. Use of PCR in combination with limiting dilution techniques may provide quantitative estimates of specific T-cell precursors in peripheral blood. It may also be possible to assess the avidity of the T-cell response by varying the concentration of peptide used to stimulate the T cells.


FIGURE 17.4-4. Preparation of soluble major histocompatibility complex/peptide complexes for staining of epitope-specific T cells. Both major histocompatibility complex heavy chains tagged with a biotinylation sequence (HC) and beta-2-microglobulin (b2m) are produced in bacteria. Purified molecules are then reconstituted in the presence of a relevant peptide into a trimer, including HC, b2m, and peptide (refolding step). The biotinylation is then performed, and then avidin is added to the biotinylated complexes. Because avidin is a tetravalent molecule, tetramers with four HC/b2m/peptide complexes are obtained.

In Vivo Biologic Measures of T-Lymphocyte Responses

Regardless of the source of antigen or method of immunization, induction of an effective T-lymphocyte response against tumor should result in tumor infiltration by T cells and other inflammatory effector cells drawn to the site by the antigen-specific T-cell response. Therefore, a direct method of monitoring vaccine efficacy is to obtain pre- and postimmunization samples of tumor and assess the tumor inflammatory response. The issues related to monitoring of responses within tumor and interpretation of the results have been discussed in the section Monitoring of Tumor-Related Factors .

Optimally, monitoring of T-cell responses within tumor in response to a particular cancer vaccine would include assessment of the change in number of tumor antigen-specific cells, their activation state, and functional properties. Techniques capable of monitoring all aspects of the T-cell response, however, are not available, and the serial tumor biopsies necessary for these laboratory studies and full histologic examination are difficult to obtain, particularly in patients who have poorly accessible metastatic disease. To address these concerns, investigators at the Surgery Branch of the National Cancer Institute have adapted quantitative PCR techniques (Taq-man) to serially measure absolute amounts of RNA message for genes expressed within samples of tumor obtained by fine-needle aspirates (Fig. 17.4-5). Although not able to ascribe changes to a particular group of antigen-specific T cells, the technique can theoretically provide important information on changes in overall amount of T-cell infiltrate and the activation state and function of those cells. More important, the technique has the capacity to quantitatively measure biologic functions that are activated as part of a presumed common pathway for antigen-specific, T-cell-mediated antitumor response (i.e., amount of IFN-γ produced within the tumor as a result of infiltration and activation of tumor antigen-specific T cells).
FIGURE 17.4-5. Analysis of presence and function of vaccine-specific T cells in peripheral blood mononuclear cells (PBMCs) from a highly reactive patient who had received two vaccinations with the 209-2M peptide. A: Fluorescene-activated cell sorter analysis demonstrates the phenotypic increase of 209-pa/209-2M-specific CD8+ cells in the postvaccination PBMCs. Numbers in the upper right quadrant (URQ) indicate the percentage of tHLA-staining CD8+ T cells calculated according to the formula: URQ/(URQ + lower right quadrant) × 100. B: Kinetics of immune reactivity after direct elicitation of bulk PBMCs with 1 μm of 209-2M and 209-pa. Real-time quantitative polymerase chain reaction performed on PBMCs at time points after peptide incubation. Preimmunized PBMCs (○), + 209-pa (▽), + 209-2M (•), Postimmunized PBMCs (○) +209-pa (▼) +209-2M (□). C: Sensitivity of direct molecular assay; 209-pa-reactive T-cell clone was spiked into preimmunized PBMCs. Elicitation of 209-pa reactivity [interferon-γ (IFN-γ) messenger RNA (mRNA)] could be seen at a spiked dilution of 1 clone in 50,000 PBMCs. Negative control was performed with exposure to irrelevant peptide, MART 27-35. D: Direct reactivity (IFN-γ mRNA production) of pre- and postimmunized PBMCs to HLA-A2+/gp100 + melanomas, 624.38 Mel and 888 Mel (A2+), and HLA-A2-/gp100 + melanomas 624.28 Mel and 888 Mel. (GM-CSF, granulocyte-macrophage colony-stimulating factor.) [Adapted from Kammula U, Lee K-H, Riker AI, et al. Evidence of effective immunization by serial gene expression analysis of tumors. 1999 *(submitted)*.]

Preliminary experiments were conducted retrospectively on cohorts of patients that had received a melanoma peptide vaccine from gp100 [gp100:209-217 (210M)] on Surgery Branch immunotherapy protocols and undergone serial fine-needle aspirates of melanoma lesions (78). Copies of mRNA for IFN-γ were normalized to CD8 messenger RNA, and copies of gp100 messenger RNA were normalized to beta-actin mRNA. In eight of nine patients, posttreatment tumor samples revealed at least a twofold increase in copies of IFN-γ message. Furthermore, the increase in IFN-γ message was correlated strongly to prevaccination tumor expression of gp100. The increase in tumor IFN-γ mRNA was not observed in a cohort of control patients that were treated on other immunotherapy protocols but had no evidence of CTL response against the native gp100:209-217 peptide epitope, as measured in peripheral blood by standard bulk culture techniques. Of substantial interest was the observation that none of the sampled lesions had shown evidence of objective response, suggesting that the immune response was insufficient to mediate tumor regression. The PCR assay is being expanded to measure RNA message for other relevant genes, such as IL-2. If confirmed in larger groups of patients and in prospective trials, the technique will offer a simple and rapid indication of effective

immunization against a tumor antigen because it assesses the integration of events necessary for tumor response (i.e., T-cell activation, migration into tumor, and production of cytokines by the T-cell infiltrate).

Because tumor sampling is not possible in many patients, an alternative to measure effective immunization *in vivo* has been the DTH. The tumor antigen is administered by intradermal injection, and, 24 to 72 hours later, the local inflammatory response, as determined by the diameter of induration, is measured. The reaction is considered positive if induration measures at least 5 mm. The DTH reaction is mediated by an antigen-specific T-cell response. Therefore, a positive DTH test indicates a T-cell response to the antigen placed at the site. The specificity of the reaction is ascertained by placing appropriate controls and further confirmed by biopsy of the site and functional characterization of the T-cell infiltrate (see below).

DTH testing as a monitoring tool has been used primarily for cell-based vaccines (35 ,79 ,80). Typically, the cell line used for vaccination is placed intradermally without adjuvant in successively higher concentrations. For autologous tumor cell vaccines, the best available controls are autologous non–tumor-derived cells that have been prepared using procedures identical to those used in generation of the tumor cell line used for immunization (i.e., normal tissue adjacent to the tumor, peripheral blood lymphocyte, or Epstein-Barr virus-transformed autologous lymphoblastoid cell lines). Comparison of pre- versus postimmunization DTH responses is often insufficient to determine whether the immune response is directed to a tumor-related antigen, because tumor cells may be exposed to highly immunogenic enzymes and fetal calf serum in the preparation procedure (14). Tumor cells that are dissociated mechanically without the use of enzymes and are stored without exposure to foreign proteins, however, may be appropriate for comparison of pre- versus postimmunization DTH responses, although controls are still necessary to increase the certainty that the DTH response is a direct result of immunization. To avoid investigator bias, the skin test results should be read by an independent observer unaware of which site contains the antigen versus the control. In allogeneic cell-based vaccines, skin-test reactivity to tumor antigens is difficult to differentiate from the more likely responses to allogeneic antigens in the vaccine. DTH tests have been performed in studies of defined antigens using the antigen alone or pulsed on dendritic cells, and, in some studies, DTH tests were performed with tumor lysates pulsed on dendritic cells (81).

Principles of Measuring Antibody Responses to Cancer Vaccines

Part of "17.4 - Principles of Immune Monitoring in Cancer Vaccine Trials "

Depending on the type of cancer vaccine, the method of delivery, and the antigens used for immunization, antibody responses may be elicited in patients. For some vaccines, immunization is intended solely to induce antibody responses to the cancer antigen. Reliable techniques for measuring antibody responses have been available for many years. Studies often use a combination of Western blot and enzyme-linked immunosorbent assay to determine presence or absence of antibody to the antigen and the titer, respectively (82 ,83 ,84 ,85 and 86). The time course of response in serum is usually determined, as well as the immunoglobulin M (IgM) and IgG component and the subclass of the IgG response. The antibody response is sometimes further characterized to assess complement fixation in the presence of the antigen target and ability to mediate antibody-dependent cellular cytotoxicity. As with vaccines that induce cell-mediated responses, it is critical to demonstrate that the antibody response recognizes tumor cells because the conformation or composition of purified antigen may be quite different than that found on tumor. Although not a common feature of vaccine trials, obtaining tumor tissue to demonstrate saturation of antibody binding sites after immunization may provide useful information.

Summary

Part of "17.4 - Principles of Immune Monitoring in Cancer Vaccine Trials "

Substantial progress has been made in the development and application of techniques to immune monitoring of cancer vaccine studies. Ongoing studies dissecting the type, quality, magnitude, and targets of effective antitumor immune responses in more sophisticated and predictive preclinical models will lead to even more rapid progress and focus in the development of immune-monitoring assays for early clinical trials. Current assays are able to detect evidence of T-cell responses and antibody responses to immunization with reasonable sensitivity and specificity; however, full characterization of the complex immune response *in vivo* is still beyond the resources and technical capabilities of most investigators. New molecular techniques that assess expression of many genes within tumor before and after treatment offer great hope for more fully characterizing the events necessary for tumor regression, and, most important, reasons for failure and means to improve the efficacy of cancer vaccines in future trials.

Introduction

Part of "18.1 - Whole Cell and Lysate Vaccines "

The concept of host immunity against tumor was developed by Ehrlich (1) nearly one century ago and was later reinforced in the early 1900s by several laboratories that studied transplantable tumor cell lines in mice. In 1910, Cantamin (2) demonstrated the development of protective immunity against transplantable tumor in mice immunized with the same irradiated tumor cells. Furthermore, in 1935, Besredka and Gross (3) showed that some animals inoculated with tumor cell homogenate experienced tumor regression, as well as protection to tumor reinoculation challenges. These studies, however, were inconclusive because the distinction between immunity against histocompatibility antigens and tumor antigens was not entirely understood.

After the development of inbred mouse strains with stringent criteria, tumor-specific immunity was clearly demonstrated in murine tumor models. In 1943, Gross (4) showed that C3H inbred mice immunized with methylcholanthrene-induced sarcoma were protected against the same tumor, whereas the nonimmunized inbred mice experienced tumor development. Subsequently, in 1954, Foley (5) and Donaldson (6) also demonstrated the induction of specific protective immunity in mice against sarcoma and Ehrlich's ascites tumor, respectively.

Because these experimental tumor models suggested that tumors could indeed generate host immunity, a search for tumor-specific antibodies was initiated using serologic techniques. Antisera prepared against murine tumor tissue were formerly studied in an immunodiffusion approach; the resultant precipitation reaction indicated the presence of antibodies in the sera reacting to tumor antigens (7). Based on this evidence, antisera for human cancers were prepared in various animals and then tested for reactivity to human cancer. For example, human tumor tissue was used to develop antisera in horses, which was then shown to lyse tumor cells from that particular human tumor (8). The specificity of these antisera to tumor was demonstrated by preventing tumor cell lysis with antisera absorbed in tumor while retaining tumor cell lysis with antisera absorbed in normal tissues (8). These humoral responses to tumor antigens encouraged investigators to identify tumor-specific antigens.

Tumor-Associated Antigens

Part of "18.1 - Whole Cell and Lysate Vaccines "

Several tumor-associated antigens (TAAs) were initially defined in mouse tumors based on components from oncogenic viruses, such as polyoma virus, SV-40, and Friend leukemia virus. These antigens, however, could not be identified on human tumor cells. After the development of monoclonal antibody technology, several TAAs identified previously were confirmed unequivocally and many new TAAs were detected on human tumor cells.

These TAAs are unique to individual tumor or shared between tumors of the same histiotype. The unique tumor antigens are characterized by restricted expression on autochthonous human tumor cells. They are derived from mutated cellular gene products, such as p53, ras, cyclin-dependent kinase, and p21, often secondary to chemical or radiation-induced carcinogenesis. These unique antigens are not detected in normal tissue of the same histologic type. The shared tumor antigens, such as common acute lymphocytic leukemia antigen, carcinoembryonic antigen, fetal-associated antigen, gp100 (melanocyte lineage antigens), MUC-1 (mucin glycoprotein), prostate-specific antigen, carcinoma antigen-125, and GD3 and GM2 (glycolipid antigens of tumors originated from neuro crest), are normal cellular antigens that are overexpressed in tumor. These antigens also include the neonatal antigens (fetal-associated antigen and carcinoembryonic antigen) that are overexpressed on cancer cells of different origin. In addition, antigens of oncogenic viruses, such as human T-cell leukemia virus, Epstein-Barr virus, human papilloma virus, and hepatitis B virus, are expressed on leukemia/lymphoma, cervical cancer, nasopharyngeal cancer, and liver cancer, respectively.

Although TAAs were shown to induce host antibody responses, immunologists remained puzzled for many years thereafter in search of TAAs that can induce T-cell responses. Boon (9) performed elegant work in identifying cytolytic T lymphocyte (CTL)–recognizing tumor antigens using variants of p815 plasmacytoma tumor cell lines. They extended this undertaking to identify human TAAs that can induce a CTL response. Consequently, the CTL-inducing melanoma antigen encoding gene–1 (MAGE-1) antigen was recognized using a melanoma-specific CTL clone that had HLA-A1 restriction properties. Subsequently, several other CTL-inducing cytoplasmic tumor antigens, such as MAGE-3, MART-1, and gp100, were identified for human cancers from numerous laboratories (10,11). Some antibody-inducing antigens, such as carcinoembryonic antigen, gp100, and NYESO-1, have also been shown to contain peptide epitopes that induce CTLs (11,12). Moreover, these antigens were expressed on a majority of tumor cells of the same histiotype and could thus stimulate antigen-specific CTLs in most patients, provided that an HLA compatibility exists. In addition to the above-described antigens, several novel tumor antigens that induce antibody responses were identified using serologic analysis of recombinant expression libraries (13). These antigens are also shared between tumor cell lines.

The heterogeneity in the expression of TAAs has been documented in several types of tumor (14,15) and clearly plays a role in the escape of tumor cells from immune surveillance (16). Therefore, the development of tumor cell lysate vaccines (TCLVs) or whole tumor cell vaccines (WCVs) should embody a polyvalent antigen approach. This method incorporates two or more cell lines of the same tumor histiotype and thus offsets any potentially lost antigens.

TCLVs and WCVs from autologous tumor cells target unique antigens and shared antigens as vaccine components. TCLVs and WCVs derived from allogeneic tumor cell targets, however, only shared antigens as vaccine components and rarely contain unique antigens. Unlike cancer vaccines derived from purified proteins, glycoproteins, glycolipids, carbohydrates, and synthetic peptides, TCLVs and WCVs derived from allogeneic tumor cells have several advantages. Most important, the polyvalent nature of TCLVs and WCVs covers most of the identified TAAs, such that an immunization with these vaccines neutralizes the tumor's escape mechanisms from host immune surveillance. Other advantages include the ease in preparing, storing, and transporting the actual vaccine. Notwithstanding, TCLVs and WCVs prepared from autologous or allogeneic tumor cells have demonstrated induction of cellular and humoral immune responses in cancer patients (17,18,19 and 20).

Expression of shared tumor antigens and the induction of host immune responses by these antigens form the basis for using TCLVs and WCVs in the active specific immunotherapy of cancer patients. Clinical trials with TCLVs and WCVs have been shown to increase the survival of patients, and, in some cases, even induce clinical remission. The clinical application of WCVs and TCLVs is detailed in this chapter. Because Chapter 18.2 discusses cancer vaccines using gene-modified tumor cells, this review does not consider this subject matter.

Preparing Tumor Cell Lysate Vaccines and Whole Tumor Cell Vaccines

Part of "18.1 - Whole Cell and Lysate Vaccines "

Autologous or allogeneic tumor cells are the major components of TCLVs and WCVs. Chemical or biologic adjuvants are often used as additional vaccine components, although a few clinical trials have used tumor vaccines without any adjuvants.

Selection of tumor tissue or cells is a critical step in the preparation of a tumor vaccine. Tumor tissue isolated from different sites on a patient is the most appropriate method of preparing autologous TCLVs and WCVs. Several autologous TCLVs and WCVs have been used in clinical trials of cancer patients. The major advantage to these vaccines is that they do not contain any allogeneic tissue–specific antigens that induce undesired immune responses when administered. Nevertheless, several reasons exist as to why it is difficult to use autologous tumor tissue or cells in the preparation of TCLVs and WCVs. First, the patient's own tumor cells are not usually available during early stage of disease. Second, several arduous steps are involved in the preparation and standardization of TCLVs and WCVs, such that batch-to-batch consistency would be difficult to maintain. This is particularly true of TCLVs made from different cell lines and in various laboratories. For example, one laboratory reported that 60% of autologous colon WCVs were contaminated with normal microflora (21).

To avoid such problems, several investigators have decided to use allogeneic tumor cells for the preparation of TCLVs (19,22,23,24,25 and 26) and WCVs (27,28,29,30,31,32,33,34 and 35). When selecting an appropriate allogeneic tumor cell line, it should be screened for the highest expression of TAAs that can induce humoral or cellular responses, or both. Moreover, the expression of HLA class I and class II antigens on these tumor cells should be analyzed and correspond to a profile consistent with most patients. Morton et al. (26) illustrated this point by preparing a second-generation whole-cell melanoma vaccine using three melanoma cell lines that express high levels of six melanoma antigens and cover more than 95% of melanoma patients' HLA type. Similar characterization was applied to tumor cell lines that were used in the preparation of our laboratory's melanoma vaccine (17). In light of studies reporting TAA expression heterogeneity on different tumor cell lines despite identical histiotype (14,15), cell lines inclusive of all shared TAAs and HLAs are to be selected for preparing TCLVs and WCVs. We and others have used fluorescent-activated cell sorter–aided immunofluorescence assays to characterize the expression of TAAs and measure the density of TAAs on tumor cells. Furthermore, we have used reverse transcriptase polymerase chain reaction to characterize the cytoplasmic peptide antigens of the tumor cells. More than one cell line (17,26,35), and, in some cases, even seven cell lines (24) are used to prepare TCLVs or WCVs to incorporate as many TAAs as possible. These cell lines should be subjected to rigorous quality control inquiries, such as optimal tissue culture conditions, karyotyping, and freedom from bacterial or viral (including human immunodeficiency virus) contamination. These screening methods establish the stability and sterility of a tumor cell line and can then render it appropriate for use in the preparation of TCLVs. Finally, a manufacturer's working cell bank should be instituted for all cell lines used in vaccine preparation.

This cell bank system would allow one to expand the production of these vaccines to an industrial level without sacrificing quality. Although some clinical trials with TCLVs and WCVs have used plain tumor cell lysates without any adjuvants (36,37), the majority have indeed used adjuvants. They include bacterial (19,21,26,29), viral (24,25,38), chemical (39,40), and cytokine (41,42) adjuvants. Haptens, such as dinitrophenyl, and enzymes, including neuraminidase, have also been used to modify tumor cell vaccines (20).

Bacterial adjuvants, such as bacille Calmette-Guérin (BCG) and *Corynebacterium parvum*, have been used as cancer vaccine adjuvants. BCG is the most commonly used bacterial adjuvant in preparing TCLVs and WCVs (19,26,31). These ancillary components are mixed with the tumor vaccine before injection or given separately, even at an entirely different site.

Several pathogenic and nonpathogenic viruses have also been used as adjuvants in the preparation of cell lysate and whole cell vaccines. Nonpathogenic viruses, including influenza and vaccinia, have demonstrated tumor cell lytic activity (25,38,43). Other nonlytic viruses used as adjuvants are the budding viruses, including Newcastle disease virus (NDV), RNA C-type virus, and vesicular stomatitis virus (23,24,44,45).

In our laboratory's TCLV preparation, vaccinia virus was used as a vaccine adjuvant for multiple reasons. It can modify membrane-associated tumor antigens using neuraminidase, as well as reexpress tumor antigens (46). Moreover, it can enhance expression of antigen chaperone heat-shock proteins (47,48) and nonspecifically help the induction of tumor-specific CTLs (49). Most importantly, it was documented to be safe in the mass immunizations against smallpox. Killed pathogenic viruses, such as influenza virus and vesicular stomatitis virus, have also been used as adjuvants in tumor cell vaccines.

Carefully tailored synthetic products, such as detoxified endotoxin (DETOX) and QS21, are yet another group of adjuvants that have been used in tumor cell vaccines (42). The DETOX adjuvant contains bacterial cell wall skeleton derived from *Mycobacterium phlei*, monophosphoryl lipid-A from the *Salmonella minnesota* squalane, egg phosphatidyl choline, and α-tocopherol. Chemical adjuvants to cancer vaccines include muramy dipeptide, cholesteryl hemisuccinate, and monophosphoryl lipid-A. Moreover, the cytokines interferon-α (INF-α), INF-γ, granulocyte-macrophage colony-stimulating factor, interleukin-2 (IL-2), and IL-12 have been studied as adjuvants in cancer vaccine therapy.

WCVs contain autologous or allogeneic tumor cells, γ-irradiated with 50 to 200 Gy, and adjuvants that are added before or after irradiation. The irradiation itself is often performed before freezing or just before injection. Until that point, these cells are maintained in appropriate medium and then frozen at a controlled rate. The frozen tumor cells are ultimately stored in the vapor phase immersed in liquid nitrogen. Before injecting patients, they must be thawed quickly and washed.

TCLVs contain mechanically lysed autologous or allogeneic tumor cells. Similarly, adjuvants are added before or after cell lysis. The tumor cell lysates are then reconstituted in a buffer and stored at -70°C until use. Alternately, tumor cell lysates can be freeze-dried and stored at refrigeration temperatures if antigenic quality is maintained. Dried tumor cell lysates are reconstituted with a diluent just before injection.

All final TCLVs and WCVs should be subjected to quality control screening, such as freedom from bacterial, fungal, mycoplasma, and other human pathogenic viral (cytomegalovirus, Epstein-Barr virus, hepatitis B virus, human papillomavirus, human immunodeficiency syndrome, and human T-cell leukemia virus) contamination. Likewise, the antigenic quality of TCLVs should also be tested by measuring representative tumor antigens.

Clinical Trials with Whole Cell and Cell Lysate Vaccines

Part of "18.1 - Whole Cell and Lysate Vaccines "

Almost all tumor vaccine studies have initially tested their vaccine approach in a "feasibility clinical trial" in which a small number of advanced-stage patients are treated with one dose of vaccine. The prototype trial to test vaccination against tumors was attempted by Leyden and Blumenthal (50) in 1902; however, details of this trial are not documented. Later, in 1909, Coca and Gilman (51) reported a feasibility clinical trial using autologous TCLVs for the treatment of fourteen patients with early and advanced stages of carcinomas, including buccal cavity, bladder, breast, cervix, cheek, pelvic, neck, and rectum, and one of Hodgkin's lymphoma. Although problems with vaccine sterility were addressed in this trial, a standard had not been established for the preparation of these vaccines. Patients were injected subcutaneously with 10 to 25 g of tumor lysates. Sterilization of the vaccine was performed by chemical treatments that would have altered the nature of tumor antigens. Furthermore, only some patients received a booster injection 3 weeks after the first vaccine injection, whereas others received just one injection. The follow-up of patients was likewise not uniform. Despite these problems, four patients with carcinomas displayed softening and disappearance of some tumor mass, three patients with inoperable cancers showed stable growth, and seven patients were disease-free for 6 months.

Finney et al. (52) performed immunotherapy studies in nine patients with melanoma, sarcoma, or carcinoma to evaluate the induction of tumor-specific antibodies. They used intratumoral injection of autologous tumor tissue lysates mixed with Freund's adjuvant. The first three vaccine injections were given to patients on alternative days. An additional vaccine injection was given 2 to 4 weeks after the peak antibody response in these patients' sera. All nine patients immunized with this vaccine showed increased titers of antibodies in their postimmune sera when compared with their preimmune sera. All patients exhibited uniform erythema, swelling, edema, and tenderness at the tumor site 15 to 25 days after initial injection, which then persisted for 2 to 7 days thereafter. Moreover, to document humoral antitumor cytotoxicity, purified immunoglobulins from these patients' sera were injected into tumor nodules. Sixty-three percent of injected tumor nodules were rendered nonpalpable in 10 days, suggesting the specificity of antibodies to tumor. This study clearly demonstrated the induction of tumor-specific cytotoxic antibodies by tumor cell lysate vaccination.

Czajkowski et al. (53) used intact, irradiated autologous tumor cells modified with bisdiazobenzidine and rabbit γ-globulin in 14 patients with squamous cell carcinoma of cervix and skin, adenocarcinoma of the breast, ovary, pancreas, colon, and prostate, melanoma, hepatoma, or chronic lymphocytic leukemia. Patients received a vaccine injection every 2 to 3 weeks for a total of 4 to 11 injections. One patient with squamous cell carcinoma and another with adenocarcinoma of the breast lived tumor free for 4 years longer than the expected survival. Four patients also revealed stabilization or slowed progression of tumor. Sera from 13 patients contained a high titer of antibodies that were reactive to melanoma antigens from their own melanoma cells.

McCune et al. (30) performed a phase 1 clinical trial using autologous tumor cells mixed with *C. parvum* in 15 patients with renal, melanoma, breast, lung, or colon cancer. Patients were treated with irradiated 10^6 to 10^8 tumor cells weekly for a minimum of three injections. Minimal toxicity was noted, such as fever, chills, tiredness, and pain at the site of injection. Only one patient had actual regression of tumor, whereas seven patients had stable disease that lasted for 1 to 13 months; seven other patients, however, did experience disease progression.

Wallack et al. (54) studied viral oncolysate vaccines in 29 patients with different types of advanced-stage cancers, including colon, melanoma, breast, thyroid, ovarian, cervical, and gastric carcinoma; hypernephroma; hepatoma; and fibrosarcoma. Patients were immunized intradermally with vaccinia virus-modified autologous tumor cell lysate vaccines. The majority of patients who participated in this trial had melanoma (9 of 29 patients) or colon carcinoma (10 of 29 patients). None of the patients experienced untoward responses during the trial. It was concluded that vaccinia oncolysate vaccine treatment is safe and produces only minimal side effects, such as fever, chills, malaise, headache, nausea, and inflammation with minimal pain at the injection site. Nine of the 29 patients experienced controlled tumor growth. Three of the nine patients who showed lack of progression of disease were melanoma patients, perhaps owing to the highly immunogenic nature of melanoma.

Pattillo (27) conducted an active specific immunotherapy (ASI) trial using autologous and allogeneic tumor cell-derived antigens mixed with BCG for patients with melanoma and cervical, ovarian, and breast cancers. Patients with advanced stages of cancer were treated with this vaccine preparation. Clinical responses included regression, as well as stabilization of tumor growth. Imperato et al. (55) conducted a similar immunotherapy study for a patient with advanced-stage ovarian carcinoma. This patient was primed with two intradermal injections of BCG followed by immunization with 2×10^8 autologous tumor cells. The patient also received a booster vaccine containing the same amount of tumor cells mixed with BCG. Only a partial clinical response was noted.

To avoid problems with the isolation of tumor cells from patients for the preparation of TCLVs or WCVs, several investigators studied ASI via intratumoral injection of adjuvants. Biologic adjuvants, such as vaccinia virus and BCG, were used in this approach. Hunter-Craig et al. (56) and Roenigk Jr et al. (57) used intratumoral injection of vaccinia virus for patients with melanoma. Their studies yielded some clinical responses, including regression of tumor and increased survival. Morton (58) also studied intratumoral injection of BCG for patients with melanoma and sarcoma and demonstrated tumor regression in some patients.

All of these aforementioned clinical studies were preliminary trials that tested the feasibility of their respective vaccine approach. None of the described vaccines produced significant toxicity. Collectively, these trials demonstrated minimal clinical responses. Possible reasons include a lack of standardized vaccine production and the fact that multiple kinds of cancers with variable immunogenic properties were studied concurrently. Accordingly, cancer vaccine preparation adopted standardized techniques and approaches, including standard amounts of antigen(s) and adjuvant(s). These changes have assured vaccine quality for future clinical trials.

Several clinical trials have put to use whole cell vaccines or cell lysate vaccines prepared under these new standards. Patients in these trials generally fall into one of the following categories: (a) minimal disease (early stage of disease) or (b) free of tumor via surgery but with advanced stage of disease. Most important, these clinical trials studied patients with only one distinct type of cancer. Testing methods were also organized incorporating phase 1 through phase 3 clinical protocols (summarized in Table 18.1-1 and Table 18.1-2).

Table 18.1-1 Clinical Trials Performed with Whole Cell Vaccines

Cancer	Vaccine Therapy	Patient Characteristics (n)	Responses	Reference
Breast cancer	Irra. auto. tumor cells; i.d.	Stage II (131)	No clinical benefit	61
	randomized trial; irra. allo. tumor cells + BCG and CT		No clinical benefit	62
Colorectal cancer	Randomized trial; auto. tumor cell + BCG; i.d.	B2 and B1 colon C1 and C2 rectal (98)	No significant difference in DFI or OS; patients with positive DTH showed improved survival	64
	Phase 2 trial; NDV-modified irra. auto. tumor cells	Advanced stage (48)	Survival rate at 2-yr time point was 97.9%	66
Colon cancer	Randomized trial; auto. tumor cell + BCG; i.d.	Stages II and III (254)	Significant DFI in all patients with stage II disease at median follow-up of 5.3 yrs	21
Glioblastoma	Randomized trial; irra. auto. tumor cells	Grades III and IV (62)	No survival difference	67
	Phase 1 trial; irra. auto. tumor cells + BCG	Advanced stage (19)	One patient showed response	33
Gynecologic cancer	Irra. allo. tumor cells + BCG and CT	Advanced or recurrent ovarian cancer (10)	A better DFI and OS with vaccine compared with matched controls	68
Leukemia	Irra. allo. tumor cells. BCG and *Corynebacterium parvum*, i.d.; CT and radiation therapy	All stages (100)	33% DFI in all patients; 43% DFI in patients <15 yrs of age	34
	Irra. allo. tumor cells mixed with BCG	Patients with AML in remission (8)	6/8 DFI for 1 yr	69
	Randomized trial; irra. and nonirra. allo. tumor cells mixed with BCG, s.c.; CT	Patients with AML in remission or with disease (100)	Significantly longer survival with immunotherapy	70
Lung cancer	Irra. allo. tumor cells + BCG, i.d.	Stages I and II (13)	No significant DFI	71
	Irra. auto. tumor cells mixed with BCG, i.d.	Stages I-IV (18)	13/18 positive to DTH. Seven of these 13 had relapse	72
Melanoma	Phase 2, irra. allo. tumor cells with BCG, i.d. CY, cimetidine, or indomethacin	Stages III and IV (136)	Significant survival when compared with controls; significant IgM type antibody to melanoma	74
	Phase 2, irra. allo. tumor cells mixed with BCG, i.d.	Stage III (30)	33.3% DFI at 20-mo interval	75
	Phase 2, irra. auto. melanoma modified with DNP, i.d. Initially sensitized with DNFB, i.v., plus CY.	Stage III (62); stage IV (15)	At 5-yr point, DFI 45% and OS 58% for stage III; at 5-yr point, OS of stage IV >50 yrs, 71% and >50 yrs, 41%	76
Renal cancer	Irra. auto. tumor cells and *C. Parvum*, s.c.;	All stages (14)	Four patients had CR; one had stable disease	77
	Irra. auto. tumor cells mixed with BCG, i.d. and i.l., plus hormonal therapy	Stages I-III (24)	At 3-yr point, DFI 54% and OS 65% on vaccine + hormone vs. DFI 34% and OS 52% on hormone	78
	Irra. auto./allo. cells mixed with *Candida* antigens	Stages III and IV (35)	No significant improvement in survival	32
Sarcoma	Irra. auto. tumor cells, i.d.	All stages (12)	No clinical response	79
	Irra. allo. tumor cells mixed with BCG, i.d., plus RT	Stages I-III (18)	11/18 were disease free	80

allo., vaccine derived from allogeneic tumor cells; auto., vaccine derived from autologous tumor cells; BCG, bacillus Calmette-Guérin; CT, chemotherapy; CR, complete response; CY, cyclophosphamide; DFI, disease-free interval; DNFB, dinitroflurobenzene; DNP, dinitrophenyl; irra., irradiated; DTH, delayed-type hypersensitivity; IgM, immunoglobulin M; NDV, Newcastle disease virus; OS, overall survival; RT, radiotherapy.

Table 18.1-2 Clinical Trials Performed with Cell Lysate Vaccines

Cancer	Vaccine Therapy	Patient Characteristics (n)	Responses	Reference
Breast cancer	Auto./allo. tumor cells lysate; i.d.	Stages I and II (5)	At 5 yrs, 83% stage I survived, 53% stage II survived	37
Colon cancer	Phase 1 allo. lysate with Freund's adjuvant; i.d.	Dukes' B2, C, and D (28)	At 21 mos, 82% OS; DTH response in all patients	82
Gynecologic cancer	Allo. ovarian tumor cells modified with influenza; i.p. and intrapleural	Advanced or ovarian cancer (40)	9/40 PR	83
Leukemia	Allo. cell lysate modified with fowl plaque virus + CT	Patients in remission (27)	No significant improvement in survival	85
Melanoma	Vaccinia virus-augmented allo. cell lysate, i.d. Phase 1	Stages I and II (48)	24/48 NED	87
	Phase 2	Stage III (39)	21/39 NED	88
	Phase 3	Stage III (217)	No significant DFI or OS	38
	Allo./auto. cells modified with VSV, i.d.	Stages II-IV (24)	1/24 SR	23
	Allo. cells modified with vaccinia, i.d., some with CY phase 2	Early stage (62)	A significant survival with vaccine	91
	Allo. cells lysate modified with influenza A, i.m. and s.c., plus BCG + CT	Stage III (13)	6/13 PR	90
	Phase 1			
	Phase 2	Stages II and III (32)	28/32 DFS at 3 yr	91
	Allo. cell lysate mixed with DETOX + CY	Stages III and IV		
	Phase 1/2	(109)	5 CR, 17 PR	42
	Phase 3	Stages II and III	In progress	42
	Phase 3	Stage IV (56)	No significant difference	42
	Allo. tumor lysate	Stages I and II (190)	Stage I did not show significant OS; stage II showed significant survival	36
Renal cancer	Auto./allo. cell lysate mixed with BCG, i.d.	Stage IV (30)	7% CR, 7% PR, 37% SD	92
Lung cancer	Allo. cell lysate, s.c.	Advanced stage (8)	Two had increased survival	93
Sarcoma	Allo. cells lysate modified with influenza A, s.c., plus CT	All stages (19)	4/19 CR, 9/19 PR	94
	Auto. tumor cell lysate	All stages (15)	Seven survived disease free	79

allo., vaccine derived from allogeneic tumor cells; auto., vaccine derived from autologous tumor cells; BCG, bacillus Calmette-Guérin; CR, complete response; CT, chemotherapy; CY, cyclophosphamide; DETOX, detoxified endotoxin; DFI, disease-free interval; DFS, disease-free survival; DTH, delayed-type hypersensitivity; NED, no evidence of disease; OS, overall survival; PR, partial response; SD, stable deisease; SR, serologic response; VSV, vesicular stomatitis virus.

Whole Cell Vaccine

*Part of "*18.1 - Whole Cell and Lysate Vaccines "

Breast Cancer

Although the immunogenic nature of breast cancer is controversial (59,60), a few studies have evaluated the use of cell vaccine therapy. Anderson et al. (61) treated breast cancer patients with an autologous tumor cell vaccine after radical mastectomy but were not able to demonstrate any clinical benefit. Giuliano et al. (62) used allogeneic breast cancer cells with BCG in stage II breast cancer patients, and they, too, did not show any significant clinical response.

Colorectal Cancer

Hoover and his coworkers (63) initiated a pilot ASI study in five patients with colorectal cancer. They initially demonstrated ASI using tumor cells mixed with BCG to induce antitumor responses in guinea pig hepatocarcinoma models. The clinical trial had patients treated intradermally with irradiated autologous colon cancer cells mixed with BCG. Patients experienced minimal toxicity. After the preliminary trial, they performed a prospective randomized clinical trial to determine the efficacy of ASI with this type of vaccine (64). Their objective was to test vaccine efficacy in terms of increased disease-free interval (DFI) and overall survival (OS) of patients with lymph node metastases (stage B2 and B3 colon cancer or stage C1 and C2 rectal cancer). Ninety-eight patients were randomized between vaccine (treatment) and observation (control) groups. Autologous tumor cells from patients' tumor tissues were prepared using standardized procedures. Patients were then immunized intradermally with 10 million viable, irradiated tumor cells mixed with 10 million viable BCG organisms. The first vaccine injection was performed approximately 4 weeks after surgical removal of tumor. Three consecutive weekly vaccines then followed, the third vaccine consisting of irradiated tumor cells only. Patients were monitored at 3-month intervals for the first 2 years, every 4 to 6 months for the next 3 years, and once a year after 5 years. Data from 80 eligible patients were analyzed with a median follow-up of 83 months for patients with colon cancer and 57 months for patients with rectal cancer. When compared with the controls, patients treated with the vaccine did not show a significant DFI or OS. Patients with colon cancer, however, did reveal an increased survival trend with vaccine therapy when compared with controls. Moreover, the induction of immunity by this ASI was determined by a delayed-type cutaneous hypersensitivity (DTH) response.

The Eastern Cooperative Oncology Group subsequently sponsored another randomized trial in patients with Dukes' B2, B3, or C stage colorectal cancer (65). Four hundred and twelve patients were randomized between the observation and vaccine groups; the latter group was immunized intradermally with irradiated autologous tumor cells mixed with BCG. Survival analysis of patients in this trial did not yield any significant treatment differences with respect to OS or DFI. A subset analysis of patients with DTH response greater than 5 mm, however, did indeed demonstrate improved survival with respect to vaccine therapy. These results suggested that an additional immunization would be required to induce enhanced immunity against colon cancer.

Accordingly, a third prospective randomized vaccine trial was performed in patients with stage II and III colon cancer (21). Three months after the third injection, patients received a booster vaccine containing 10 million irradiated tumor cells. Median follow-up was 5.3 years. The results of this trial showed a significant DFI with vaccine therapy when compared with controls, as well as a trend toward improved OS in the treatment

group. Subset analysis of stage III disease did not produce significant DFI or OS in patients treated with vaccine when compared with appropriate controls. A significant DFI, however, occurred in the vaccine-treated group of patients with stage II disease when compared with controls, as well as a trend toward improved survival. Clearly, this data confirms that vaccine therapy was indeed effective in patients with stage II disease but not stage III disease.

In another series, a phase 2 clinical trial using 10^7 autologous colon tumor cells modified with NDV was performed in 48 patients with colorectal cancer (66). Patients were immunized intradermally at 2-week intervals for three injections. The survival rate at 2 years was 97.9% with the vaccine when compared with historical controls (73.8%). These results, however, should be verified in a randomized trial.

Glioblastoma

Bloom et al. (67) investigated the use of ASI for patients with glioblastoma multiforme using irradiated autologous tumor cells in a randomized prospective trial. Sixty-two patients randomized into two groups with grade III or IV glioblastoma were initially treated with radical surgery and postoperative radiation. One group with 27 patients received a subcutaneous injection of crude irradiated autologous tumor cell suspension. Only nine patients received three vaccine injections, one patient received two injections of vaccine, and 17 patients received only one vaccine injection within 2 hours after surgery. Thirty-five patients comprised the control group. No standards were followed regarding vaccine quality or quantity per patient, or both. Moreover, no adjuvant was used with this vaccine. Results were analyzed at a 30-month follow-up time point during which all 27 vaccine-treated patients had expired. No survival difference existed between the vaccine-treated group and the control group. Marked skin reactions at the vaccine injected sites, however, were observed in two of six patients who received only one vaccine injection and four of four patients who received three vaccine injections.

In 1983, Mahaley et al. (33) conducted a phase 1 clinical trial using cells from two allogeneic glioblastoma tumor lines with BCG adjuvant for patients with gliomas. Nineteen patients were immunized with this vaccine. Sera from these patients were analyzed for the presence of antibodies binding to glioblastoma cell lines. Only one of the patient's serum contained tumor-specific antibodies.

Gynecologic Cancers

Hudson et al. (68) performed ASI trials using irradiated allogeneic tumor cells mixed with BCG for patients with advanced or

recurrent ovarian cancer having completed chemotherapy. At 24-month follow-up, DFI and OS of these patients were better than the matched controls of chemotherapy alone.

Leukemia

The feasibility of ASI trials in patients with leukemia were based on preliminary studies using murine models. The first tumor cell vaccine therapy for patients with leukemia was performed by Mathe et al. (34). This trial used irradiated, pooled allogeneic tumor cells isolated from leukemia patients. Patients were immunized intradermally with 4×10^7 irradiated leukemia cells every week for 3 months and then once every 3 months. Patients also received intradermal immunizations with adjuvants such as BCG, *C. parvum*, and polyinosinic-polycytidylic acid at 20 different sites on every fourth and seventh day thereafter. At 5-years follow-up, 33% of all patients who received immunotherapy survived disease free. Moreover, 43% of patients younger than 15 years of age survived disease free with immunotherapy. It is difficult to draw conclusions about the efficacy of this vaccine because patients in this trial received chemotherapy and radiotherapy, both of which could have suppressed host immunity.

Freeman et al. (69) studied ASI for patients with acute myeloid leukemia (AML). Eight patients who showed complete remission with chemotherapy were immunized with 10^9 irradiated allogeneic tumor cells with BCG as an adjuvant at weekly intervals. Six of the eight patients survived without disease for more than 1 year. Because this trial was performed in only a few patients and without a chemotherapy-alone control, it is also difficult to conclude on the efficacy of this vaccine therapy.

A controlled ASI trial was conducted by Powles (70) in 100 patients with AML who were in remission or failed to achieve remission with chemotherapy. These patients were divided into five treatment groups:

1. Patients in remission receiving chemotherapy
2. Patients in remission receiving chemotherapy plus vaccine therapy with irradiated 10^9 allogeneic AML cells
3. Patients in remission receiving chemotherapy plus vaccine therapy with nonirradiated 10^9 allogeneic AML cells
4. Patients who failed to achieve remission receiving chemotherapy
5. Patients who failed to achieve remission receiving a combination of chemotherapy and vaccine therapy with irradiated 10^9 allogeneic AML cells. BCG was also used as a vaccine adjuvant.

Survival data showed that patients given the vaccine therapy survived significantly longer than those receiving chemotherapy alone. A prospective randomized trial is under way to confirm these findings.

Lung Cancer

The first vaccine therapy trial for patients with stages I and II non-small-cell lung cancer was performed by Perlin et al. (71) in 1980. This trial used 5×10^7 allogeneic irradiated tumor cells mixed with 3 to 5×10^8 BCG organisms as a vaccine. Patients were administered the vaccine twice monthly for 24 months. Fifty-one patients were divided into three groups: (a) a control group of 18 patients who had lobectomy, (b) a nonspecific immunotherapy group of 13 patients who had BCG alone, and (c) a vaccine group of 13 patients. No statistically significant DFI differences were noted between the three groups. On the other hand, a remarkable and significant difference was found in the DFI of stage I patients treated with vaccine therapy alone when compared with matched controls. Another interesting finding concerns the lack of statistically significant differences observed between the nonspecific BCG therapy and the vaccine therapy. Regardless, the results would be inconclusive because the number of patients in each group was insufficient to yield meaningful statistical analysis.

Schulof et al. (72) performed a nonrandomized vaccine trial using 10^7 irradiated autologous tumor cells mixed with 10^7 BCG organisms as a vaccine for 20 patients with stages I to IV non-small-cell lung cancer. Vaccine therapy was initiated 1 to 3 months after surgery. Patients received three consecutive weekly vaccinations intradermally. Moreover, patients were tested before and after vaccine therapy for DTH responses to tumor cells alone and purified protein derivatives of BCG. DTH responses greater than 5 mm were scored as positive. Ten of 18 patients immunized with this vaccine experienced disease relapse with a median follow-up of 17 months. Thirteen patients showed a DTH response to purified protein derivatives before the initiation of the vaccine therapy. Only 5 of 18 patients showed a DTH response to tumor cells before vaccine therapy. Eight patients, however, converted to a positive DTH response after the vaccine therapy. Seven of the 13 patients who showed an initial positive DTH response had relapsed and two DTH negative patients survived without relapsing. Therefore, it was concluded that little correlation of patients' DTH response existed between their actual clinical responses.

Melanoma

Melanoma is perhaps the best-studied cancer in various tumor vaccine approaches. Reasons include the presence of melanoma-specific antibodies and T cells within the sera and peripheral blood lymphocytes (PBLs) of melanoma patients, respectively. Furthermore, reported spontaneous regression of melanoma provides sound evidence in favor of vaccine therapy for this highly immunogenic cancer.

After the demonstration of approximately 90% antibody response to tumor with intratumoral BCG injections, Morton (58) performed a preliminary clinical trial using allogeneic melanoma cells mixed with BCG. Only 35% of patients, however, developed high levels of antimelanoma antibodies. Hence, a new polyvalent allogeneic melanoma cell vaccine was constructed using three melanoma cell lines that contain high concentrations of six representative melanoma antigens (73). They conducted a clinical trial with this new vaccine using 24 million irradiated allogeneic melanoma cells mixed with BCG. This vaccine induced antimelanoma humoral responses that correlated with increased survival. A phase 2 clinical trial was subsequently performed using this vaccine for patients with stage III and IV melanoma (74). One hundred thirty-six melanoma patients were

immunized (intradermally) as follows: every 2 weeks for 4 weeks, then monthly for 1 year, every 3 months for the following year (4 injections), and every 6 months thereafter. Only the first two vaccine injections contained irradiated melanoma cells mixed with BCG, whereas subsequent injections contained only irradiated melanoma cells. Some patients also received biologic-response modifiers, such as cimetidine, indomethacin, and cyclophosphamide. Minor toxicity, such as local erythema, induration, and ulceration at the injection sites, as well as mild fever with occasional myalgia, arthralgia, and chills, were again experienced. Patients were followed at 3-month intervals with pre- and postimmune sera analyses for the presence of antibodies to melanoma antigens. Furthermore, DTH responses against melanoma cells were also measured. Stage III and IV patients receiving vaccine therapy survived significantly longer than those patients treated with other methods. Moreover, those patients with a median survival of 30 months had a significantly higher immunoglobulin M (IgM) antibody response to melanoma antigens and a significantly higher DTH response (>10 mm) to melanoma cells. These results led to a phase 3 multicenter randomized clinical trial to elucidate the efficacy of this melanoma cell vaccine. Results of this trial are awaited.

A nonrandomized phase 2 melanoma vaccine trial was performed by Mordoh et al. (75) for patients with stage III melanoma. This trial used 5 million irradiated allogeneic melanoma cells mixed with 5 million BCG organisms. Thirty patients were immunized intradermally as follows: one vaccine injection every 3 weeks (four injections) every 2 months for the rest of the first year, every 3 months in the second year, and then once every 6 months until the fifth year. Patients received cyclophosphamide 3 days before each vaccination. DTH and antibody responses were analyzed. Twenty-four patients with the same stage of disease served as controls in this study. A significant DFI was noted at 20 months with 33.3% survival with vaccine therapy when compared with only 4.1% survival in the control group. Moreover, a large portion of patients who experienced the induction of antibody response also had positive DTH responses. The efficacy of this vaccine, nevertheless, needs to be confirmed in a randomized trial with a larger number of patients.

Berd et al. (76) used dinitrophenyl as a hapten to modify autologous melanoma cells and used it as a vaccine for patients with stage III or IV melanoma (palpable masses in two lymph node sites). A recent publication in 1997 of their nonrandomized trial reviews results from 62 patients with stage III melanoma and 15 patients with stage IV melanoma, all treated with this vaccine. Each dose of the vaccine contained 5 to 25 million autologous tumor cells. All patients were initially sensitized with 1% of dinitroflurobenzine in acetone corn oil on 2 consecutive days and intravenous cyclophosphamide (300 mg per kg) 2 days before the dinitroflurobenzine to reduce suppressor T-cell activity. These patients were subjected to two different vaccine schedules. In the first schedule, the dinitrophenyl-modified tumor cells were mixed with BCG and administered intradermally every 4 weeks for eight doses. Cyclophosphamide was given only for the first two doses. In the second schedule, six weekly vaccine injections were performed. Only the first three vaccines were modified with dinitrophenyl. Patients were then followed every 2 months for 2 years and tested for DTH responses. With a median follow-up of 55 months, DFI of stage III patients treated with vaccine was 45% at 5 years, and OS was 58% at that point. In contrast, with a median follow-up of 73 months, OS of stage IV patients older than 50 years of age and younger than 50 years of age were 71% and 41%, respectively, at a 5-year time point. These survival rates were better than the survival rates of patients with no treatment. Moreover, a significant survival rate was detected in patients who showed a positive DTH response when compared with negative DTH responders; 71% versus 49% at 5 years. A phase 3 clinical trial with this vaccine is in progress.

Dillman et al. (41) conducted a clinical trial with cultured autologous melanoma cells for patients with metastatic melanoma. Fifty-seven patients were immunized subcutaneously with 10 million irradiated cultured autologous tumor cells 3 consecutive weeks and then once a month for 6 months. Adjuvants included BCG, INF-α, INF-γ, and granulocyte-macrophage colony-stimulating factor. DTH responses in 27 patients with no evidence of metastases were higher than those in 25 patients with metastases.

Renal Cancer

Similar to melanoma, renal cancer also demonstrated immunogenicity, such as spontaneous regression of metastases, tumor infiltration of lymphocytes, and *in vitro* demonstration of T-cell proliferation against renal tumor cells. McCune et al. (77) performed a vaccine trial for patients with renal carcinoma in 1981. They used 3 to 20×10^7 irradiated autologous renal cancer cells mixed with *C. parvum* at a concentration of 37.5 μg per 10^7 tumor cells. Fourteen patients were immunized weekly intracutaneously with this vaccine. The number of doses varied with the availability of tumor cells. Four patients had complete or partial responses, or both. One patient had stable disease for 27+ months. Patients who received vaccines with more than 20×10^7 tumor cells per dose had a higher rate of clinical response than those who received smaller doses. Nevertheless, the important conclusion from this study was that vaccine therapy could induce clinical responses in renal cancer patients.

Adler et al. (78) performed a randomized trial combining a renal cancer cell vaccine and hormonal therapy for patients with all stages of renal cell carcinoma. They used 3×10^6 irradiated autologous tumor cells mixed with BCG as a vaccine. The vaccine was given intradermally for 5 to 6 consecutive weeks, then monthly for 24 months or until recurrence. Patients were also immunized intralymphatically via endolymphatic instillation and lymphangiography. For this procedure, 80 to 100 million irradiated autologous tumor cells in 2 to 3 mL of saline was mixed with 0.1 mL of BCG and slowly injected into lymph vessels. At least one lymphatic immunization was performed in each patient (5 to 6 weeks after the intradermal immunization), as well as an additional two injections (excluding three patients). Patients received hormonal therapy with intramuscular primostat (200 mg per day) five times per week for 1 month, followed by vaccine twice per week for 2 months, and then weekly for 24 months. Forty-three patients with stage I to III renal cell carcinoma were randomized between the hormonal therapy alone (19 patients) and hormonal plus vaccine therapy with 24 patients.

Patients in the vaccine therapy group were evaluated for DTH responses against autologous tumor cells. Although DFI and OS with a median follow-up of 30 months were in favor of immunotherapy over hormonal therapy alone, their respective differences were not statistically significant. At a 3-year time point, DFI was 54% with vaccine therapy and 34% with hormonal therapy. Likewise, OS was 65% in the former and 52% in the latter. Both DFI and OS were also better in positive (i.e., >8 mm) rather than negative DTH responders in the immunotherapy group. These positive DTH responders also demonstrated a significantly higher DFI and OS when compared with hormone-treated controls. A lymphocyte migration inhibition test was also used to evaluate the induction of immunity in patients treated with this vaccine. Accordingly, a higher number of patients in the vaccine therapy group experienced positive lymphocyte migration inhibition to autologous tumor extract. These findings, collectively, strongly suggest that ASI induces clinical and immunologic responses in renal cancer patients.

Rauschmeier (32) conducted a renal cancer vaccine trial using irradiated autologous/allogeneic tumor cells for patients with advanced stage (III and IV) renal cancer patients. Thirty-five patients were treated with 2 million irradiated renal cancer cells mixed with Candida antigen. Two different testing modalities characterized this trial to address vaccine therapy efficacy. The first modality initiated the therapy immediately after surgery, whereas the second initiated the therapy when metastases were diagnosed. Moreover, two different schemas were tested in the vaccination protocol to determine the most effective method of immunization. In the first schema, two cycles of vaccines were given as follows: four weekly primary vaccine injections with booster vaccine injections at monthly intervals for 1 year or four injections, each 1 month apart after 1 year. In the latter protocol schema, the first booster injection was given 2 weeks after the primary vaccination and 24 consecutive months thereafter. Neither stage III or IV patients (median follow-up of 3 years) experienced a significant improvement in survival with vaccine therapy when compared with age-matched controls.

Sarcoma

Vaccine therapy for patients with sarcoma was initially studied in the early 1960s. Marcove et al. (79) performed a clinical trial with a γ-irradiated autologous tumor cell vaccine for 12 sarcoma patients but could not elicit any clinical responses. Townsend et al. (80) also performed a preliminary clinical trial in 15 patients with skeletal and soft tissue sarcomas. Their patients were immunized with 50 to 75 million irradiated tumor cells mixed with BCG. Nine of the 12 patients' postimmune sera yielded increased antisarcoma antibody titers. A positive DTH reaction to autologous tumor cells also developed in seven of 15 patients. Although no significant clinical responses were observed, some patients did experience prolonged survival. Subsequently, these investigators performed a clinical trial in 18 patients with stage I, II, and III skeletal and soft tissue sarcoma using irradiated allogeneic sarcoma tumor cells (10 × 10^7) mixed with BCG. The vaccine was injected intradermally in five separate sites. Patients received the vaccine weekly for 3 months and then biweekly for 2 years or until recurrence. Although 11 of 18 patients with localized soft tissue sarcoma who had received immunotherapy were free of disease, these results were not significant against appropriate controls.

Tumor Cell Lysate Vaccines

Part of "18.1 - Whole Cell and Lysate Vaccines "

The preparation, storage, and transportation of WCVs are difficult because their use emphasizes the preservation of cell viability. Moreover, WCVs with irradiated autologous tumor cells are at risk of radioresistant viable tumor cells that can proliferate at the injection sites. Therefore, TCLVs derived from autologous tumors or allogeneic tumors have also been studied in various cancer patients, including breast, gynecologic, leukemia, lung, melanoma, and sarcoma. The following sections summarize the clinical application of TCLVs in these cancer patients.

Breast Cancer

Surgical adjuvant ASI trials for patients with breast cancer were performed by Humphrey et al. (81) using breast cancer tissue lysates as vaccines. The vaccine was prepared by homogenizing tumor tissues in 0.25 mol/L sucrose solution and removing the cell nucleus and debris by ultracentrifugation. Patients with stage I and II breast cancer were treated with this vaccine weekly for eight injections and then every 3 months for 1 year. The vaccine was administered in two portions, one intradermally and another subcutaneously. Survival results from 95 patients treated with this vaccine were reviewed by Lytle et al. (37). The 5-year survival rate was 83% for those with stage I disease and 53% for those with stage II disease. This data was then compared with survival rates of control patients who underwent standard adjuvant chemotherapy or radiotherapy in studies conducted by the American College of Surgeons and The National Surgical Adjuvant Breast and Bowel Project. At a 5-year interval, vaccine therapy patients with stage II breast cancer demonstrated a survival rate comparable to those of control American College of Surgeons and The National Surgical Adjuvant Breast and Bowel Project patients (53% vs. 51% vs. 59%, respectively). The authors, therefore, suggested that the addition of this adjuvant immunotherapy to other proven adjuvant modalities would further enhance the survival of breast cancer patients.

Colon Cancer

Hollinshead et al. (82) conducted a phase 1 clinical trial with vaccine therapy using allogeneic colon tumor lysate mixed with Freund's adjuvant in patients with colon adenocarcinoma. Twenty-eight patients with Dukes' B2, C, and D stages of colon cancer were treated intradermally for 3 consecutive months. With a median follow-up of 21 months, 82% of immunized patients survived with a mean survival rate of 21 months. A strong DTH response was also observed in these patients.

Gynecologic Cancers

Freedman et al. (83) reported the use of influenza-modified allogeneic ovarian cell lysate vaccines for patients with ovarian

cancer. The vaccine was prepared from two cultured ovarian cell lines. Forty patients with advanced ovarian cancer were given intrapleural and intraperitoneal vaccine injections. All patients had previously received cisplatin and 31 patients received two or more systemic treatments. During the first month of vaccine therapy, 28 patients received a single injection, six received biweekly injections, and six received weekly injections. After the first month, all patients received a monthly booster vaccination. Observed clinical responses included complete or partial regression of ascites and stabilization of a pelvic mass.

Similarly, Freedman et al. (84) used influenza A virus-augmented vulva carcinoma cell lysate from an established squamous vulvar carcinoma cell line in combination with radiotherapy for patients with vulvar carcinoma. Sixteen patients were immunized intradermally weekly for 3 weeks and then biweekly for 2 years. The median DFI was 26+ months for the vaccine therapy patients, considerably longer when compared with controls (e.g., received either surgery alone or surgery plus radiotherapy).

Leukemia

Schuepbach and Sauter (85) performed a clinical trial with avian virus-augmented cell lysate vaccine therapy in combination with chemotherapy for AML patients in remission. The vaccine was prepared using fowl plague virus-infected formalin-treated allogeneic leukemia cells. Twenty-seven patients received the vaccine monthly along with chemotherapy. No significant improvement occurred in survival between those treated with the vaccine plus chemotherapy versus chemotherapy alone. Nevertheless, most patients did develop antiviral antibodies. This trial, however, did not measure antitumor immune responses. In addition, immunized patients may not have induced antitumor immunity because the viral oncolysate was initially treated with formaldehyde, which may have denatured tumor antigens. Chemotherapy may have suppressed host antitumor immunity as well.

Melanoma

Our laboratory has investigated the use of vaccinia virus-modified tumor cell lysate vaccines in various cancer patients. The preliminary clinical trial, described in the section Clinical Trials with Whole Cell and Cell Lysate Vaccines, did not yield significant toxicity with vaccine therapy. Because three of nine patients with melanoma experienced a lack of disease progression in that preliminary clinical trial, the ensuing trial was initiated exclusively for patients with melanoma (86). An allogeneic vaccinia vaccine virus-augmented melanoma cell lysate (VMO) vaccine was prepared from four established melanoma cell lines expressing the identified melanoma antigens. The objective of this preliminary trial was to determine the toxicity and feasibility of VMO therapy. The 12 patients with advanced-stage melanoma who received VMO experienced minimal toxicity, similar to that observed in the previous trial. Moreover, four of 12 patients had improved survival when matched to disease stage.

These encouraging results suggested that this therapy would be even more beneficial to patients with earlier stages of disease. Advanced melanoma patients may be somewhat more immunosuppressed, and, thus, at a disadvantage. Subsequently, a phase 1 trial was designed using patients with stage I and II melanoma. The objective was to establish the most effective dose of VMO in terms of induction of antimelanoma serologic response (87). Forty-eight patients with melanoma were treated with VMO at six different dose levels (0.05 to 2.00 mg protein). Patients' serum at the highest dose produced the most antimelanoma activity, and, therefore, was chosen to be used in future trials. In addition, patients having a high antibody titer showed significant clinical responses, such as stabilization of tumor growth and increased disease-free survival.

After this trial, a phase 2 trial was performed in patients with high-risk stage I and II melanoma in a surgical adjuvant setting (88). Patients were treated with 2.0 mg of VMO, the most active dose established from the previous phase 1 trial. Again, toxicity was minimal. Statistical comparison of VMO-treated patients with 39 matched controls (patients treated with BCG or *C. parvum*) revealed a significant ($p = .04$) increase in the disease-free survival.

A phase 3 randomized, double-blinded, multiinstitutional trial followed the efficacy of the VMO vaccine in patients with high-risk stage III melanoma. The VMO vaccine was used with patients in the treatment group, and live vaccinia virus (V), a component of the VMO, was used in the control group. The objective of this trial was to evaluate the clinical efficacy of VMO versus V to increase the DFI and OS of stage III melanoma patients. The Institute of Mariuex (known as *Pasteur Mariuex and Connaught Laboratories*, Lyon, France) prepared one lot of VMO (#17) and one lot of V (#1) for this trial; 250 patients were accrued from 11 U.S. Medical Centers. Informed consent was obtained from all patients at the individual institutions. All patients registered in this study underwent a central pathology review of the preregistration biopsy and the subsequent wide excision and lymph node dissection. Furthermore, all patients registered in this study underwent a surgical review to confirm that the surgery was performed according to criteria specified in the protocol. Patients in group I (VMO) and group II (V) were treated weekly for 13 weeks and then biweekly for 39 weeks or until recurrence. A total of 33 injections were administered to the patients unless any patient was withdrawn from the study. All patients received a smallpox booster, supplied by Mariuex, at least 48 hours before the first injection of VMO or V. One mL of VMO or V was equally divided among 4 to 6 injections and administered at different sites near several nodal groups. Dates of recurrence documented radiographically or pathologically were used to determine the disease-free intervals.

The first interim survival analysis was performed with a mean follow-up time of 30.38 months after prerandomization surgery (38). Thirty-three patients were deemed ineligible and excluded from the trial. The toxicity of VMO or V was minimal. Data from this trial demonstrated that no significant difference was detected in DFI or OS between the VMO and the V arms. This analysis did show, however, that approximately a 10% difference was detected in the OS at a 4-year time point in favor of VMO-treated patients. Moreover, a retrospective subset analysis was performed to determine any groups of patients that did benefit from VMO treatment. Based on sex, age, positive

node status, depth of invasion, and location of primary tumor, the following populations were identified as having improved survival on VMO: (a) males, (b) males younger than 57 years with 1 to 5 positive nodes, and (c) patients with clinical stage I but pathologic stage II disease. The final analysis of data with a median follow-up of 46.3 months revealed that the surgical adjuvant ASI with VMO did not increase the DFI or OS of patients with stage III melanoma (89). Notwithstanding, VMO continued to show survival advantages in a subset of males between the ages of 44 and 57 years with 1 to 5 positive nodes.

Other laboratories also reported the use of virus-augmented melanoma cell lysate vaccines for patients with melanoma. Sinkovics (25) used influenza A-modified allogeneic melanoma cell lysate in combination with BCG and chemotherapy for patients with stage III melanoma. In this 5-year follow-up study, no evidence of disease was observed in 36% (n = 30) of patients compared with 29% with chemotherapy and BCG alone. Cassel et al. (90) used a NDV-modified allogeneic melanoma cell lysate vaccine for patients with melanoma and observed clinical responses, such as complete remission and lack of progression of tumor, in 6 of 13 patients. Hershey et al. (91), in Australia, also reported an improved survival in patients treated with vaccinia melanoma cell lysate (VMCL) vaccine, a viral oncolysate similar to VMO but containing viral melanoma cell lysates from two allogeneic melanoma tumor cell lines.

Livingston et al. (23) used vesicular stomatitis virus–modified autologous or allogeneic melanoma cell lysate vaccine for melanoma patients. No clinical responses were observed in patients from this trial using this type of vaccine. Furthermore, they reported that most of these patients' sera contained only antibodies to fetal calf serum components rather than antibodies to melanoma antigens. This viral oncolysate vaccine was exposed to ultraviolet irradiation before its administration into patients. This procedure may have provided the minimal clinical responses observed in patients treated with this viral oncolysate vaccine.

Cassel et al. (24) and Hersey et al. (22) also performed independent phase 2 trials with cell lysate vaccines in early stage melanoma patients. They reported a significant increase in disease-free survival. The latter investigators also performed a phase 3 randomized trial with their VMCL vaccine to evaluate its efficacy in patients with stage 3 melanoma. An interim analysis of data from this trial showed survival advantage with VMCL when compared with observation controls. The survival with VMCL, however, has not reached statistical significance.

Mitchell et al. (19,42) performed phase 1 and 2 clinical trials with a melanoma cell lysate vaccine plus the adjuvant DETOX for advanced-stage melanoma patients. The phase 1 trial and the earlier part of the phase 2 trial used frozen melanoma cell lysate suspended in a buffer. The latter part of the phase 2 trial also used a lyophilized melanoma cell lysate vaccine. Some patients in the phase 2 trial also received cyclophosphamide. A review of the results from these trials of 109 patients, collectively, rendered five complete responses, 17 partial responses, and nine minor responses. Subsequently, a randomized clinical trial with a combination of vaccine mixed with DETOX and cyclophosphamide was performed in patients with resected stage II and III melanoma. The final analysis of data from this trial will be presented over the next few years. Results from this trial, however, would not clearly define the efficacy of this vaccine because patients in the observation arm received experimental therapies from other institutions.

Mitchell et al. (42) have also performed a phase 3 randomized clinical trial with the TCLV melacine, using the adjuvant DETOX and low-dose cyclophosphamide in patients with stage IV melanoma. The TCLV arm was compared with the control chemotherapy arm; however, the objective responses between these treatments were not statistically significant. The median survival of patients treated with TCLV is 9.4 versus 12.1 months with chemotherapy alone. The toxicity of TCLV therapy was far less than that observed with chemotherapy.

A tumor tissue lysate vaccine without any bacterial or viral adjuvants for patients with melanoma was studied by McGee et al. (36). This vaccine therapy was conducted in a nonrandomized clinical trial for 129 patients with stage I melanoma and 61 patients with stage II melanoma. Immunizations were given weekly for 8 weeks and then every 3 months for 24 months. The vaccine was administered in two portions, one intradermally and another subcutaneously. At 5-years follow-up, patients with stage I melanoma did not show any significant survival when compared with their historical controls. Patients with stage II melanoma, however, demonstrated a significant increase in survival rate when compared with historical controls (64% vs. 40%, respectively).

Renal Cancer

Neidhart et al. (92) studied ASI using TAAs derived from homogenized renal cancer tissues admixed with BCG or phytohemagglutinin in patients with stage IV renal carcinoma. Autologous and allogeneic tumor tissues were used in preparation of the cell lysate vaccine. Thirty patients were treated intradermally biweekly until disease progression. Seven percent, 7%, and 37% of patients had complete, partial, and stable disease, respectively.

Lung Cancer

Specific immunotherapy trials for patients with advanced lung cancer were conducted by Alth et al. (93). The vaccine was derived from six bronchogenic carcinoma cell lines of various histologic types. A group of eight patients with advanced stage bronchogenic carcinoma was immunized subcutaneously twice weekly throughout the study time. Two of the eight patients had longer survival with 19 and 22 months, respectively.

Sarcoma

Marcove et al. (79) reported a study with 15 patients with osteogenic sarcoma. These patients were treated with autologous tumor cell lysate containing tumor cell membranes. Fifteen patients were treated with this vaccine subcutaneously at 3-week intervals for 30 injections. Seven patients were free of disease and 46% of patients in the treatment group survived with good performance, whereas only 17% survived in the control group.

Greene et al. (94) used influenza virus–augmented cell lysate vaccines for patients with osteosarcoma. Toxicity was related to

the influenza virus itself present in their TCLVs. Only a minimal clinical response was observed in patients treated with this type of TCLVs. Sinkovics (95) used influenza A virus-modified allogeneic sarcoma cell lysate in combination with BCG and chemotherapy for patients with metastatic sarcoma but observed complete response in four of 19 patients and partial response in nine of 19 patients.

Immune Responses in Patients Treated with Cancer Vaccines

Part of "18.1 - Whole Cell and Lysate Vaccines "

In addition to evaluating the antitumor efficacy of tumor vaccines in cancer patients, analyzing their induction of immune responsiveness is as equally important. Results of immune response data could further be used to demonstrate a correlation with the observed clinical response(s). Finally, the induction of humoral and cellular responses could be used to evaluate vaccine potency, as well as provide prognostic information.

In T-cell–immunocompromised patients and studies in CTL-depleted animal tumor models clearly suggest the importance of the cellular immune response. The CTL response arm is regarded as the most important aspect of antitumor immunity. The relative importance of cellular immune responses over antibody responses to tumors, however, has not been elucidated in humans. The following sections summarize studies that assessed *in vitro* cellular and humoral responses using PBLs and sera from vaccine-treated patients, respectively, as well as *in vivo* DTH responses in the same patients.

Antibody Response

Humoral immune responses in vaccine-treated patients were well documented in most of the above clinical trials (29,33,40,73,86). Tumor-reacting antibodies of IgG and IgM classes were observed in patients treated with TCLV or WCV using enzyme-linked immunosorbent assay (73,88). In a dose-response phase 1 trial with VMO vaccine, IgG and IgM antibody responses were found to be proportional to the increasing doses of VMO vaccine (86). Additionally, antibodies induced by allogeneic TCLVs and WCVs were found to be reacting to tumor-specific antigens (29) and HLA antigens, although some trials reported that the reactivity was directed to fetal calf serum components (23). The specificity of antibodies to tumor antigens was further characterized by Western blot analysis that revealed the recognition of different tumor antigens present in tumor cells of the same histiotype (17). These antibodies have demonstrated tumor cell lysis via antibody-dependent cellular cytotoxicity assays. Antibody responses correlated with patients' clinical responses; increased concentration of antibodies to melanoma antigens corresponded to increased survival of vaccine-treated patients (73).

Cellular Response

In addition to the induction of humoral immune responses, cellular immune responses have been demonstrated in patients treated with cancer vaccines (19,40). Vaccine-treated patients' postimmune PBLs showed an enhanced proliferative response. Likewise, PBLs from vaccine-treated patients lysed proper tumor target cells in a 4-hour chromium-release assay (19,31,40), suggesting that these patients developed tumor-specific cytolytic cellular immunity. The induction of cytolytic cellular response by tumor vaccines was also confirmed by analyzing the frequency of tumor-specific precursor cytolytic T cells (CTLp) before and after tumor vaccine therapy using a microcytotoxicity assay. An increased amount of CTLp was detected in the postimmune PBLs when compared with the preimmune PBLs of patients immunized with vaccines. The increase in CTLp frequency also correlated to patients' increased survival time. In some studies with a peptide vaccine, patients' improved clinical status could not be demonstrated with an increase in the CTLp in their postimmune PBLs (96). One speculation is that all the CTLp in the circulation may be homed to the tumor site, which could have resulted in an undetectable level of CTLp in the PBLs. For this reason, CTLp analysis is performed from biopsies taken in regressing tumors. Alternately, CTLp analysis could be performed in the vaccine-injected sites. In fact, a 1998 study measured the CTLp in the vaccine-injected site and showed a higher preference of tumor antigen-specific CTLp when compared with a control site that was not presented with the same antigen (97).

The microcytotoxicity assay to determine the CTLp frequency is cumbersome to perform. The enzyme-linked immunospot assay simplifies the CTLp frequency analysis. Clinical trials have shown that the enzyme-linked immunospot assay can be used to measure CTLp in PBLs, and, thus, determine the induction of immunity in patients treated with a cancer vaccine (98). Moreover, a novel technique of staining antigen-specific T cells with a tetramer complex could further simplify the CTLp frequency analysis. This future staining method will undoubtedly be used to measure the induction of CTLp by cancer vaccines (99).

Enhancement of natural killer cell and lymphokine-activated killer cell responses can improve the antitumor potency of a given vaccine therapy. Hence, these responses have been analyzed in patients treated with TCLVs. Some tumor vaccine studies have shown an increase in the natural killer cell and lymphokine-activated killer cell responses, probably owing to the presence of adjuvants.

Helper T cells are known to augment the induction of tumor-specific CTL responses. Only a few helper T-cell-stimulating tumor antigens have been identified. The role of these antigens in the induction of tumor-specific CTLs and antibody responses has been the endeavor of many laboratories. Furthermore, the role of adjuvant vaccine components in the induction of antitumor responses (via stimulation of helper T cells) has been widely studied. In a virus-augmented tumor cell lysate-treated host, an increased immunoglobulin production was correlated with virus-stimulated T-cell helper activity (100). We (19) and others (101) have demonstrated that virus-specific helper T cells enhanced antimelanoma cytolytic activity in patients treated with vaccinia virus-augmented melanoma cell lysate vaccine.

In addition to the above *in vitro* assays, DTH responses have been used to measure *in vivo* induction of antitumor immunity by a vaccine. Many clinical trials performed this DTH test in

patients undergoing the vaccine therapy (20,21,102). Although the nature of the DTH response to T cell, B cell, or other infiltrating mononuclear cells is not known, patients' DTH responses have correlated well to clinical responses. Ongoing problems include the lack of standard positive responses, although wheels of 5 to 10 mm have been considered positive in previous studies.

Mechanism of the Induction of Immunity by a Tumor Cell Lysate Vaccine or a Whole Tumor Cell Vaccine

Part of "18.1 - Whole Cell and Lysate Vaccines "

The mechanisms of the induction of helper T cell and antibody responses by a TCLV are not different than those of viral or bacterial antigen. Mechanisms for the induction of CTL responses by soluble antigens from a TCLV, however, are not clear. These antigens are known to be generally processed by endosomal pathways for class II major histocompatibility complex (MHC) binding only. Nevertheless, several reports suggested new pathways for processing soluble antigens through the MHC class I pathways for the stimulation of CTLs (103,104). Several studies demonstrated that tumor cell lysate-pulsed dendritic cells (DCs), efficient antigen processing and presenting cells, induced *in vitro* and *in vivo* CTL responses.

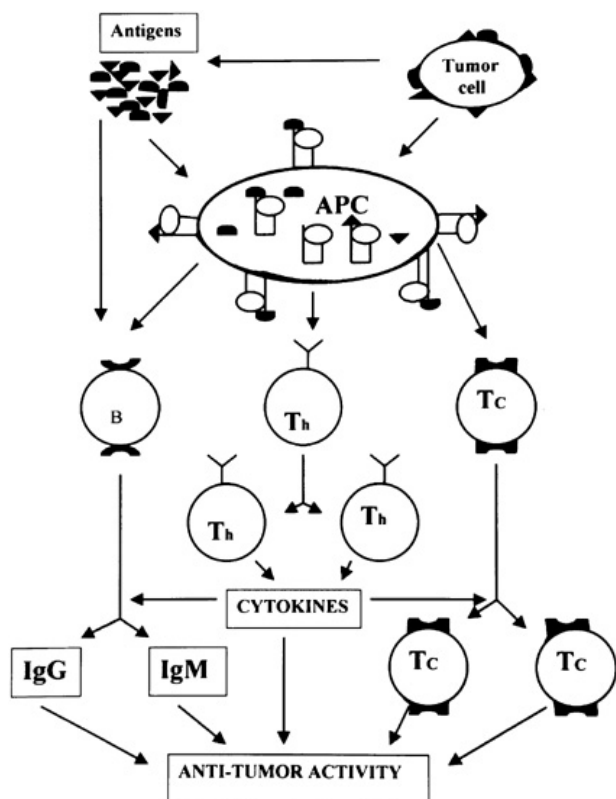
Although an intact whole tumor cell can present CTL-inducing peptide antigens in context with MHC, these cells are poor stimulators of CTL because of the absence of T-cell costimulatory factors, such as B7.1 and B7.1, on their membranes. Moreover, a study by Huang et al. (104) clearly showed in a murine tumor model that bone marrow-derived cells, perhaps of DC lineage, were essential for an effective immune response. These bone marrow-derived cells are rich in costimulatory factors and MHC molecules, and they are presumably involved in the processing of soluble antigen from the necrotic tumor cells and effectively priming CTLs. Hence, the suggested mechanism for induction of antitumor immune responses by TCLVs and WCVs is represented in Figure 18.1-1 . Tumor antigens present in a lysate or WCV are captured by antigen processing and presenting cells by simple pinocytosis or by receptor-mediated uptake using Fc and mannose receptors. These cells then process these antigens into peptides, assembled with MHC class I and class II molecules, and transport them to the membrane. The helper and the cytolytic T cells specific for these antigens are then stimulated. Cytokines produced from helper T cells help in the proliferation and expansion of the T and B cells. Furthermore, tumor vaccines contain antigens that can stimulate B cells to produce antibodies; IgA, IgG, and IgM type antibodies, TAA-specific, have been produced by tumor vaccines. Because both arms of the immune system are induced by the TCLV and WCV, an effective and potent antitumor immune response can clearly be generated with cancer vaccines.


FIGURE 18.1-1. Mechanisms of the induction of antitumor responses by tumor cell lysate vaccines and whole cell vaccines. Tumor-associated antigens present in tumor cell lysate vaccines or whole cell vaccines are captured by antigen-processing cells (APC). These cells then process antigens into peptides assembled with major histocompatibility complex class I and class II molecules and transport them to the cell membrane. These peptide-major histocompatibility complexes stimulate helper T cells (Th) and cytolytic T cells (Tc) specific for these antigens. Simultaneously, cytokines produced from Th are used in the proliferation and expansion of Th and Tc. Furthermore, soluble tumor-associated antigens from tumor cell lysate vaccines and whole cell vaccines stimulate B cells to produce antibodies [immunoglobulin A (IgA), IgG, and IgM] using the cytokines from Th. Collectively, tumor-specific Tc cytotoxic cytokines form Th, and tumor-specific antibodies mount an effective antitumor response.

Future of the Whole Cell and Cell Lysate Vaccines

Part of "18.1 - Whole Cell and Lysate Vaccines "

Several areas of interest exist regarding the improvement of TCLVs and WCVs. The first one is to combine immunomodulating cytokines with cancer vaccines to augment their efficacy. Several murine model experiments suggest that the addition of cytokines and chemotherapeutic drugs, including antiangiogenic factors or radiotherapy to cancer vaccine therapy, improve their efficacy. In fact, Mitchell et al. (42) and Dillman et al. (41) have used combinations of cytokines and cancer vaccines for patients with melanoma and demonstrated significant clinical responses. Immunomodulating cytokines, such as IL-2, IL-12, granulocyte-macrophage colony-stimulating factor and tumor necrosis factor, are candidates for such combination therapy. Cytokine gene-encoded bacterial and viral adjuvants can also be used to augment the efficacy of TCLVs. Our laboratory has studied the IL-2 gene-encoded recombinant vaccinia virus to augment the efficacy of a cell lysate vaccine in a murine colon cancer model. An enhanced antitumor effect was observed with a TCLV containing IL-2 gene-encoded vaccinia virus in comparison with a TCLV containing plain vaccinia virus (105). Antiviral immunity is a major problem, however, regarding repeated boosters with this approach. In addition, several

WCVs with cytokine gene-transduced tumor cells have been tested as potential vaccines in clinical trials; these are discussed in Chapter 18.2 .

Finally, the use of DCs to augment TCLV therapy is being explored. DCs are the most potent antigen processing and presenting cells because they express surface markers (e.g., mannose receptors, Fc receptors, etc.) that are involved in capturing and retaining antigens. They also express a high level of HLA class I and class II antigens and T-cell costimulatory molecules CD80, CD86, intracellular adhesion molecule-1, and lymphocyte function-associated antigen-3 that are involved in the effective stimulation of cytotoxic and helper T cells. Moreover, DCs secrete immunomodulating cytokines, such as IL-12, IL-15, and INF-γ, which are involved in expanding the cellular response. DCs have demonstrated migration to lymph nodes, where they can effectively prime T cells.

DC-pulsed tumor cell lysates have demonstrated antitumor immunity in patients with melanoma (106). We have studied vaccinia virus-augmented tumor cell lysate vaccine-pulsed DCs in the ASI of mice with CC-36 colon tumor and demonstrated enhanced survival when compared with no treatment control (107). Melanoma patients immunized with unfractionated melanoma tumor cell lysate-pulsed DC therapies experienced the induction of melanoma-specific CTLs, as well as clinical responses. DC-aided TCLV therapies, hence, represent the next generation of cancer vaccines.

Introduction

Part of "18.2 - Genetically Modified Tumor Vaccines "

The concept of cancer vaccination, also referred to as *active immunotherapy*, is based on the notion that exposure of a cancer patient's immune system to tumor antigens expressed by their cancer in an "immunogenic" fashion activates therapeutically useful antitumor immunity. For a limited number of tumors, such as melanoma and virus-associated tumors, candidate immunodominant

tumor-associated antigens have been identified, providing the basis for antigen-specific vaccines in the form of adjuvanted peptide, protein or recombinant DNA, or virus or bacterium. For the majority of cancers, however, we have essentially no information regarding the identity of the most relevant tumor-associated antigens. Therefore, cancer vaccines for these tumors necessitate the use of tumor cells as the source of antigens.

Earlier approaches to enhance the immunogenicity of tumor cells have involved mixing them with bacterial adjuvants, such as bacillus Calmette-Guérin or *Corynebacterium parvum* (1,2,3 and 4). With the cloning of gene-encoding immune system regulatory molecules, a new generation of cell-based cancer vaccine strategies has arisen through transduction of tumor cells with genes encoding immunologically active molecules. The evaluation of antitumor immunity induced by vaccination with genetically modified tumor cells has been extensively studied in preclinical (mostly murine) models, and results of early-stage clinical trials applying this vaccine approach have been reported in a number of centers. In general, the types of immunologically active genes that have been introduced into tumors can be divided into three categories: (a) major histocompatibility complex (MHC) genes, (b) genes encoding membrane-associated costimulatory molecules (i.e., B7), and (c) cytokine genes. Although it is impossible to completely review all of the published information on genetically modified tumor vaccines, this chapter summarizes general principles and concepts and highlights concordant themes derived from multiple studies in different tumor models.

Central Role of the Antigen-Presenting Cell in Cancer Vaccination

Part of "18.2 - Genetically Modified Tumor Vaccines "

One of the most important principles emerging from mechanistic studies of immunologic priming, as well as tolerance induction to tissue and tumor antigens, is that the response of the immune system to a particular antigen is largely determined by the characteristics of the antigen-presenting cell (APC), which presents that antigen to cognate T cells *in vivo.* Increasing evidence supports the idea that tolerance and activation of immune responses depends on antigen presentation by different subsets or differentiation states of bone marrow-derived APCs.

The original notion that most tumors arising *in vivo* are efficiently eliminated by immune surveillance (5,6) has been replaced by an increasing appreciation that tumors can induce tolerance to their tumor-associated antigens through pathways that reflect natural mechanisms of tolerance induction to self tissue antigens expressed in the periphery (7,8,9,10,11 and 12). The application of transgenic mouse models and bone marrow chimera approaches, which allow the distinction of *in vivo* antigen presentation by bone marrow-derived versus parenchymal or tumor cells, has demonstrated a critical role for the "cross tolerance" pathway in which tissue and tumor antigens are transferred to a specialized class of "tolerizing" bone marrow-derived APCs, which, in turn, present them to T cells in a tolerogenic fashion (13). Hence, therapeutic vaccines for cancer of any type must overcome this tolerant state of the immune system to activate clinically useful immune responses. Strategies to break tolerance with vaccination must not only provide a high density of peptide-MHC complexes on APCs but also cause the activation of APCs to states in which they activate T cells most efficiently. APCs in this "activated" differentiation state are generally referred to as *dendritic cells* (DCs) (14). Taking into account the central role of the APC in vaccine efficacy, genetically modified vaccines seek to convert the tumor cell itself into an APC or to attract APC progenitors to the site of the vaccine, which can then differentiate *in situ* to DCs.

History of Genetically Modified Tumor Vaccines

Part of "18.2 - Genetically Modified Tumor Vaccines "

The first studies demonstrating enhanced immunogenicity of genetically altered tumors were performed in the late 1960s, starting with Lindenmann and Klein (15), who showed that vaccination with influenza virus-infected tumor cell lysates generated enhanced systemic immune responses against a challenge with the original wild-type tumor cells. Furthermore, these early studies showed that nonvirally infected tumor cell lysates or tumor cell lysates mixed with the same virus are not immunogenic and cannot elicit a systemic immune response against challenge with the parental tumor cells. The process of introducing strong foreign antigens into tumors (by infection or gene transfer) to enhance their immunogenicity has been referred to as *xenogenization.* Because adequate immunization against the tumor required that the tumor cells be infected with the virus, Lindenman and Klein hypothesized that weak antigens derived from the tumor cells might become associated with or incorporated into the virus and subsequently become potent immunogens. Based on what we have learned since, the enhanced immune response generated by the virally infected tumor cells probably occurred as a consequence of the inflammatory responses induced by viral infection together with "bystander help." As described earlier, these inflammatory responses are critical to the *in situ* differentiation of bone marrow-derived progenitors into activated APCs that can present antigens in an immunogenic rather than tolerogenic fashion. Once this is achieved, CD4 T-cell responses against the strong foreign antigens can provide increased help for the amplification of weaker responses against the endogenous tumor antigens.

The next generation of genetically altered tumor cell vaccines involved the use of mutagenesis to generate immunogenic variants of nonimmunogenic tumor cells, which on immunization could generate enhanced immune responses against the original nonimmunogenic variants. As newer techniques of gene transfer have been developed, infection with virus and mutagenesis was replaced with specific gene transfer in an attempt to more carefully regulate the nature of the genetic alteration within the tumor. The first studies of genetic modification of tumors to enhance immunogenicity involved transfer of the influenza hemagglutinin (HA) gene into a murine colon tumor (16). This approach met with limited success because the majority of HA transfectants failed to be rejected or demonstrated increased immunogenicity. Based on the more recent appreciation of the capacity of tumors to tolerize immune responses specific for their antigens (see above), this result is not surprising in retrospect. Subcutaneous injection of clones selected to express

extremely high levels of HA, however, resulted in some immune response induction to the parental tumor akin to that which was achieved earlier with viral infection. The limited success of these approaches to introduce foreign genes encoding "strong" antigens into tumors to enhance their immunogenicity can be attributed to the inflammatory responses produced by the mechanical trauma of subcutaneous injection together with the bystander help effect, just as was produced with virally infected tumors.

Preclinical Evaluation of Genetically Modified Tumor Vaccines

Part of "18.2 - Genetically Modified Tumor Vaccines "

Despite limited success, the xenogenization experiments described earlier encouraged increasing efforts aimed at directly altering the tumor cell's genetic material to enhance immune responses generated against endogenous tumor antigens. The enhancement of immune responses in the vaccine setting can be divided mechanistically into three categories (Fig. 18.2-1):

1. Enhancement of the presentation of antigens to T cells. This mechanism implies an increase in peptide-MHC density at the site of activation of T cells.
2. Enhancement of costimulation. This mechanism takes into account the fact that T cells require extra costimulatory signals in addition to engagement of the T-cell receptor to become efficiently activated. Costimulatory signals may be membrane-bound ligands, such as B7, that are critical for T-cell activation, or soluble mediators, such as cytokines.
3. Local elaboration of cytokines that attract and locally activate bone marrow-derived APCs, which process and present tumor antigens to T cells.
FIGURE 18.2-1. Potential mechanisms by which gene-transduced tumor cells may enhance the activation of tumor-specific T cells. Shown are examples of different classes of gene products that attract and activate antigen-presenting cells (APCs) for more efficient presentation of tumor antigens to T cells or allow for enhanced direct presentation of antigens by the transduced tumor cell. (GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; MHC, major histocompatibility complex.)

Genetic Modification of Tumors with Major histocompatibility Genes

Part of "18.2 - Genetically Modified Tumor Vaccines "

Introduction of MHC genes into tumors was one of the first approaches for enhancing the immunogenicity of tumors by gene transfer. A number of studies in the 1980s suggested that increasing MHC class I expression by gene transfection typically results in decreased tumorigenic capacity in murine tumor models (17). The decreased tumorigenicity was felt to be caused by enhanced presentation of tumor-specific antigens to CD8+ cytotoxic T lymphocytes (CTLs) *in vivo*. Enhanced expression of self-MHC class I molecules, however, does not always increase the immunologic potency of a tumor, and, in certain circumstances, has been shown to inhibit natural killer (NK) cells, thereby resulting in paradoxically increased tumorigenicity (18). Tumor immunogenicity has also been enhanced by the transfer of allogeneic MHC class I genes (19,20). In certain cases, the rejection of tumors expressing allogeneic MHC class I molecules may result in enhanced systemic immune responses against subsequent challenge with the unmodified parental tumor. This represents an example of the general phenomenon of enhancing tumor vaccine potency by introducing genes encoding any foreign antigen, as in the case of viral infection or introduction of the viral genes. The mechanism by which tumors "xenogenized" with allo-MHC genes enhance systemic immune responses against challenge is likely identical to the original virus infected or foreign antigen-transduced tumor vaccines, namely bystander effects caused by the high frequency of allo-MHC-reactive T cells.

In some murine tumors, introduction of MHC class II genes into tumor cells decreases their immunogenicity and can result in generation of enhanced systemic immune responses against parental MHC class II–negative tumor (21). Further enhancement of vaccine potency has been achieved by cointroduction of MHC class II and B7 genes (22) (see Genetic Modification with Genes Encoding B7 and Other Costimulatory Molecules). It was postulated that the expression of MHC class II molecules on tumor cells allowed for the presentation of MHC class II–restricted tumor-specific antigen CD4 helper T cells, which ultimately could provide enhanced *in vivo* help for action of cytotoxic T cells and possibly other CD4-dependent effector pathways. In one study, evidence was provided that MHC class II molecules introduced into tumors would preferentially present endogenous tumor antigens in the absence of expression of invariant chain (Ii), presumably because of the failure of Ii to block access

of peptides to the MHC class II groove in the endoplasmic reticulum (23). Because Ii is also important in the trafficking of MHC class II molecules to MIIC compartments in which proteases, a low pH environment, and H2M are necessary for efficient peptide loading of MHC class II molecules, the exact nature of antigens expressed by MHC class II molecules in Ii-negative tumors remains to be determined.

Genetic Modification with Genes Encoding B7 and Other Costimulatory Molecules

The original basis for the introduction of the B7 gene into tumors stems from the critical role of B7-CD28 interactions in costimulating T-cell activation. CD28 is well characterized as a critical costimulatory receptor for activation of CD4 and CD8 T cells (24). Cross-linking of CD28 has been shown to enhance the level of lymphokine production by CD4⁺ T cells subsequent to antigen recognition. This enhanced lymphokine production appears to be caused by enhanced transcription, as well as enhanced messenger RNA stability (25,26). Engagement of CD28 also decreases the number of T-cell receptors necessary to be engaged by peptide-MHC complexes for maximum T-cell stimulation (27). Blocking the interaction between B7 and CD28 not only decreases lymphokine production, but it can also result in a functional anergy to subsequent antigen stimulation (28). These important roles of the B7-CD28 interaction in T-cell activation made B7 a promising gene candidate to introduce into tumor cells to enhance their immunogenicity. Indeed, certain tumors are rejected in their syngeneic host subsequent to transfection with the B7 gene, and systemic immune responses capable of generating protection against challenges from the wild-type tumor at a distant site were noted (29,30,31,32,33,34,35,36,37,38 and 39). One study comparing vaccination with tumors expressing B7.1 versus B7.2 suggested that B7.1-transduced tumors elicited superior antitumor immunity to B7.2-transduced tumors (37). Subsequent analyses of B7-transduced tumor vaccines have suggested that the systemic immunity is only generated with immunogenic tumors and not with poor or nonimmunogenic tumors, such as B16-F10. In some cases, it was necessary to introduce an additional "strong" tumor antigen into the tumors to see the B7 effect (39).

The original postulated mechanism for enhanced immunogenicity of B7-transduced tumors was that expression of B7 by the tumor cell itself was converted into a more potent activating APC. This notion was further enhanced by the findings that the cointroduction of B7 and MHC class II genes synergized in enhancing T-cell dependent antitumor immunity (22). Other studies, however, have suggested a different mechanism for the B7 effect. B7 can represent a target antigen for killing by NK cells. Thus, B7-transduced tumors are efficiently killed *in vivo* by an NK-dependent mechanism. Hence, it is possible that enhanced immunogenicity of B7-transduced tumors results from enhanced antigen release to bone marrow-derived APCs mediated by increased killing of the B7-transduced tumor cells by NK cells (35). Evidence for this "cross-priming" pathway was derived through the application of bone marrow chimera experiments, which demonstrated that, although B7 expression could indeed confer some *de novo* capacity of tumor cells to directly present antigens to T cells, the majority of antigen presentation with B7-transduced tumor vaccines was via bone marrow-derived APCs (36,38).

Expression of other cell membrane-bound costimulatory molecules in tumor cells has also been explored, although to a much lesser extent than B7. In particular, members of the tumor necrosis factor (TNF) family, including 4-1BBL, FasL, CD70, CD153, and CD154 genes, have been introduced into tumor cells (40,41). In one study, introduction of FasL into tumor cells induced local tumor regression rather than the expected protection from immunologic attack reported by previous investigators. This effect was shown to be caused by a FasL-Fas dependent activation of neutrophils with resultant local inflammatory destruction (40). In another study, tumor cells expressing CD70 and CD154 were able to induce antitumor immunity at higher frequency than nontransduced irradiated cells when tested in vaccination and therapy models (41). As signaling through the TNF-TNF receptor pathways between T cells and APCs can travel in both directions (and, in some cases, bidirectionally), it is possible that enhanced immunogenicity of tumor vaccines transduced with TNF (or corresponding TNF receptor) family members could work through costimulation of T cells by the transduced tumor or by providing a ligand for the activation of APCs or other inflammatory cells local to the environment of the tumor that are in the process of ingesting released tumor antigens. As agonist antibodies have been produced against a number of the TNF receptor family members, it remains to be determined whether *in vivo* treatment with agonist antibodies or transduction of the gene encoding the ligand will be most effective. In one study, the combination of B7-transduced tumors with agonist antibodies to 4-1BB resulted in synergistic enhancement of antitumor immunity (34).

Genetic Modification with Cytokine Genes

The most actively investigated approach to genetically modified tumor vaccination involves introduction of cytokine genes into tumors. This approach seeks to locally alter the immunologic environment of the tumor cell so as to enhance antigen presentation of tumor-specific antigens to the immune system or enhance the activation of tumor-specific lymphocytes. One of the most important concepts underlying the use of cytokine gene-transduced tumor cells is that the cytokine is produced at high concentrations local to the tumor. Systemic concentrations are generally quite low. Conversely, systematic administration of the cytokine such that blood concentrations are much higher than after injection of the corresponding genetically modified tumor fails to produce the same biologic effects. This paracrine physiology much more closely mimics the natural biology of cytokine action than does the systemic administration of recombinant cytokines. Furthermore, gene transduction allows for a sustained local cytokine release at the vaccine site. Thus, although coinjection of free cytokine at the vaccine site can produce similar effects as gene transfer, they are generally weaker (42).

Many cytokine genes have been introduced into tumor cells with varying effects on tumorigenicity and immunogenicity. When produced by tumors, some of these cytokines induce a local inflammatory response that results in elimination of the

injected tumor. This local inflammatory response is often predominantly dependent on leukocytes or NK cells as opposed to classic T cells. These systems have been used to uncover *in vivo* effects of cytokines that result in activation of tumoricidal potential by various types of leukocytes. In addition to rejecting the genetically modified tumor cells, vaccinated animals may develop a T-cell–dependent systemic immunity, which, in some cases, can cure micrometastases established before treatment with the genetically altered tumor cells. In all cases in which systemic immunity against wild-type tumor challenge has been analyzed, it is mediated by T cells. Given the number of studies done with cytokine-transduced tumor cells, it is not surprising that variable results have been observed when different tumor systems are analyzed. Additional variables to the cytokines used include cell dose, level of cytokine expression, location of immunization and challenge sites, and vaccination schedule. Summarized in Table 18.2-1 and in following sections are results of murine studies using some of the more commonly analyzed cytokine genes.

Table 18.2-1 Biologic Activities of Commonly Investigated Cytokine Gene-Transduced Tumor Vaccines

Cytokine	*In Vivo* Effects of Cytokine Gene-Transduced Tumors
IL-2	Expression of high levels of IL-2 results in regression of transduced tumors. Transduced tumors are characterized by massive infiltrate of lymphocytic cells. In some tumor models, a systemic immune response is generated against challenge with parental tumor. Rejection of the IL-2-transduced tumor cells is dependent on CD8+ and natural killer cells but not on CD4+ cells, suggesting that helper T cells are rendered irrelevant in the rejection response. A correlation exists between increased levels of local IL-2 production and systemic, as well as local, antitumor responses.
IL-4	Expression of high levels of IL-4 results in regression of transduced tumors, characterized by massive infiltrate of macrophages and eosinophils. In some tumor models, a systemic immune response is generated against challenge with parental tumor that is greater than those generated by irradiated nontransduced tumor cells. Systemic antitumor responses are dependent on CD8+ cells and partially on CD4+ cells, suggesting enhanced presentation of tumor antigens by influxing macrophages to CD4+ helper T cells is an important event in the ultimate stimulation of tumor-specific CD8+ cytotoxic lymphocytes.
IFN-γ	Introduction of the IFN-γ gene into tumor cells generally induces or upregulates MHC class I and II gene products. In some tumors, IFN-γ expression results in rejection of transduced tumors and induction of systemic immunity. The effects of IFN-γ are quite tumor system dependent, and, in certain cases, the cotransduction of IFN-γ with other cytokine genes actually reveals an inhibitory effect of IFN-γ in the generation of systemic immune responses.
TNF	TNF-transduced tumor cells typically grow more slowly *in vitro* and are sometimes rejected when injected into syngeneic animals. It is unclear whether the rejection phenomenon is simply owing to the direct effects of TNF on the tumor cells or whether additional effects of TNF occur on inflammatory cells, such as macrophages. Immunization with TNF-transduced tumor cells does not generate enhanced systemic immunity relative to irradiated nontransduced tumor cells.
IL-7	Systemic antitumor immune responses have been reported with an MHC class II + myelocytoma line by immunization with tumor cells engineered to secrete IL-7. Immunity was independent of CD8+ T cells, but dependent on CD4+ T cells (presumably macrophages).
IL-12	IL-12-transduced tumors are vigorously rejected *in vivo* via NK and T-cell-dependent mechanisms. IL-12-transduced tumors variably induce systemic antitumor immunity.
GM-CSF	GM-CSF –transduced cells induce long-lived systemic antitumor immunity relative to irradiated nontransduced tumors in a number of different tumor models. Potency of GM-CSF's effect locally may relate to its unique ability in promoting the differentiation of hematopoietic precursors to dendritic cells. Immunity is dependent on CD4+ and CD8+ T cells, even when tumors are MHC class II-dependent. Effector mechanisms include activation of macrophages to produce reactive nitrogen and oxygen species, as well as recruitment of eosinophils to metastatic sites.

GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; MHC, major histocompatibility complex; NK, natural killer; TNF, tumor necrosis factor.

Interleukin-2

In several murine tumor systems, injection of autologous tumor cells transfected with the interleukin-2 (IL-2) gene (43,44,45,46,47,48,49,50 and 51) leads to IL-2 secretion and MHC class I-restricted CTL activity against transduced and parental tumor. IL-2-transduced tumor vaccines are characterized by a predominantly lymphocytic infiltrate that includes NK cells. All IL-2-transduced tumors are rejected as long as secretion levels of the transductants are sufficiently high. Rejection is dependent on CD8+ T cells and NK cells. Vaccination with IL-2-transduced tumors can also induce systemic antitumor immunity, although not as potently as other cytokine genes. In a number of IL-2 transduction studies that analyzed T-cell subsets, systemic immunity required CD8+ but not CD4+ cells, suggesting that IL-2 was truly bypassing the helper T-cell arm. In one case (47), CD4+ and CD8+ cells were required, indicating that IL-2 can also induce a local inflammatory response, leading to activation of helper and cytotoxic T cells. Cotransduction of tumors with the IL-2 and B7 genes has been reported to synergistically enhance vaccine potency, although the mechanism of synergy has not been specifically determined (52).

Interleukin-4

IL-4 has broad immunoregulatory properties, affecting MHC class II antigens and immunoglobulin isotype switching in B cells, T-cell growth and development, and the secretion or action of IL-1, IL-2, granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor, and granulocyte-macrophage colony-stimulating factor (GM-CSF). The prominent acute inflammatory reaction and rejection of the transduced tumors occurs even in nude mice and is mediated primarily by macrophages and eosinophils. This contrasts with the predominantly lymphocytic infiltrates seen in IL-2–mediated tumor rejection and suggests an important role for the recruitment and enhancement of APCs in antitumor immune responses. In several murine tumor systems, IL-4 gene–transduced vaccines produce

systemic antitumor immunity (53,54,55 and 56). In these cases, immune responses were systemic, tumor antigen–dependent and specific, IL-4 level–dependent, mediated by CD4+ and CD8+ T cells, and they exhibited immunologic memory. As determined by cellular depletion studies, T cells appear to be more critical than B cells, particularly for long-lasting systemic immunity.

Interferon-γ

Interferon-γ (IFN-γ) has direct antitumor properties, as well as several immunoregulatory properties. It induces MHC class I antigens on several tumor cells and class II antigens on macrophages and DCs. It also upregulates lymphotoxin, TNF-α, intracellular adhesion molecule-1, and lymphocyte function antigen-1. IFN-γ can stimulate CTL activity, NK and B cells, and the phagocytic activity of macrophages and monocytes by upregulating Fc receptors and increasing superoxide production.

Transduction of the IFN-γ gene into some murine tumors can induce specific and persistent antitumor immunity that is probably related to MHC class I expression on tumor cells and T-cell activation (57,58 and 59). In other murine models, MHC class I antigen induction and T-cell activity are not needed, and a strong nonspecific antitumor effect is seen.

Tumor Necrosis Factor-α

TNF-α has pleiotropic biologic properties, including the ability to cause hemorrhagic necrosis of established tumors, and the ability to induce multiple cytokines, including IL-6, IL-8, GM-CSF, and G-CSF. Systemic TNF-α shows antitumor effects in mice but minimal activity in humans, where severe dose-limiting toxicity arises at doses one-fortieth of those tolerated by mice on a milligram per kilogram basis. Responses in several human malignancies are reported with intralesional TNF-α injections, which permit high local concentrations. Transduction of the gene provides a technique for delivering similar levels of this active antitumor and immune modulatory agent directly to the tumor site. Gene transfer experiments in preclinical models have demonstrated considerable antitumor activity for TNF-α (60,61 and 62). This activity can be specific and long lasting; it is dependent on CD4+ and CD8+ cells, and its acute inflammatory infiltrate is composed primarily of macrophages. Relatively modest systemic vaccine effects have been observed, however, particularly with poorly immunogenic tumors.

Interleukin-7

Similar generation of antitumor immune responses has been reported by immunization with tumor cells engineered to secrete IL-7 (63). Of interest, the systemic immunity in one system of IL-7–transduced cells was independent of CD8+ T cells but dependent on CD4+ T cells. Furthermore, CR3+ cells, presumably macrophages, were also required for tumor rejection. As the tumor used in this study was an MHC class II plus plasmacytoma line, it is possible that the antitumor response generated by CD4 cells was in response to MHC class II–restricted tumor antigens. The CD4 cells responding to MHC class II–restricted tumor-specific antigens may have subsequently secreted cytokines, which acted as macrophage-activating factors, thereby recruiting tumoricidal macrophages responsible for the ultimate tumor destruction. In a study conducted in 1997, an IL-7–transduced alveolar cell carcinoma vaccine was shown to be much more potent when admixed with *ex vivo*-generated DCs (64).

Interleukin-12

Interest in IL-12–transduced tumor vaccines stems from its extremely potent biologic activity in activating innate immune responses, NK cells, and Th1-type T-cell responses (48,55,56,65,66,67 and 68). Systemic administration of IL-12 in mice generates potent antitumor responses, although increased sensitivity in humans led to prohibitive toxicity (akin to TNF), which has diminished enthusiasm for systemically administered IL-12 as a viable cancer therapy. IL-12–transduced tumors are potently rejected by NK and T-cell infiltrates similarly to IL-2 transductants. Although induction of systemic immunity has been reported, it is not as potent as with other cytokine transductants. Synergy between IL-12 and B7 gene transduction has been reported by a number of groups.

Granulocyte-Macrophage Colony-Stimulating Factor

Since the study by Dranoff et al. (69), which compared multiple cytokine, adhesion molecules, and costimulatory genes introduced into a number of different murine tumor lines, GM-CSF gene–transduced tumors have become the most actively studied genetically modified vaccines at the mechanistic level, as well as clinically. In the original study, each of the genes were introduced into the poorly immunogenic B16-F10 tumor using a replication-defective retroviral vector that produced consistent high levels of expression of each of the transgenes in the absence of selection, thereby eliminating variability caused by different levels of gene expression and resultant cytokine expression. Animals were vaccinated with irradiated transductants, followed by challenge with unirradiated wild-type B16-F10 cells at doses 3 to 4 logs higher than the minimal tumoricidal dose. Although a number of cytokine genes in this study, such as IL-4 and IL-6, induced some measure of systemic antitumor immunity, the most potent systemic antitumor immunity was produced by GM-CSF–transduced tumor cells. Subsequent studies in other tumor models have validated the potent systemic immunity induced by GM-CSF–transduced tumor vaccines (31,33,55,70,71,72,73,74,75,76,77,78,79,80,81,82,83 and 84).

In most, but not all, subsequent studies comparing vaccine potency of tumors transduced with various cytokine and costimulatory genes, GM-CSF–transduced tumor vaccines have proved to be the most potent, as long as a sufficiently high level of GM-CSF production is achieved. A careful analysis of immunity induction as a function of gene transduction and expression demonstrated a steep dose-response curve. Maximal systemic immunity was achieved with vaccines producing 40 ng per 10^6 cells or more per 24 hours (84). Once this dose response between GM-CSF production levels by the transduced vaccine and systemic immunity was established, it became apparent that previous studies, which failed to detect a significant vaccination

effect by GM-CSF–transduced tumors, had not achieved high enough levels of GM-CSF expression by the vaccines.

Antitumor immunity induced by GM-CSF–transduced vaccines has been shown to depend on CD4[+] and CD8[+] T cells. In addition to the classic MHC class-I restricted CTLs, other effector arms mediated by CD4 cells have been shown to participate in the generation of maximal antitumor immunity. Th1 and Th2 effector arms have been delineated. The Th1 effector arm depends on IFN-γ and involves the activation of macrophages at sites of metastases to produce reactive nitrogen species (NO), as well as reactive oxygen species (superoxides). These effectors have been demonstrated to be critically based on the diminished antitumor responses of GM-CSF–transduced vaccines in NOS-2 (inducible nitric oxide synthase) and gp91 (subunit of the reduced nicotinamide adenine dinucleotide phosphate oxidase complex) knockout mice. Eosinophils appear to be important Th2 effectors that are dependent on the production of cytokines, such as IL-4 and IL-5, by tumor-specific CD4 cells (81). The presence of the eosinophils at delayed-type hypersensitivity (DTH) sites and in tumor metastases subsequent to vaccination with GM-CSF–transduced tumors is not only observed in mouse models, but also has been a consistent observation in clinical trials with different tumor types (see the section Clinical Experience with Granulocyte-Macrophage Colony-Stimulating Factor-Transduced Vaccines).

GM-CSF–transduced vaccines represent a prototypical example of paracrine cytokine adjuvants in which local production of a cytokine induces the differentiation of bone marrow–derived progenitors into activated APCs (Fig. 18.2-2). In particular, numerous *in vitro* studies have demonstrated that, at high enough doses, GM-CSF is an extremely potent differentiation factor for DCs. The three following findings all underscore the likely mechanism of action of these vaccines as working through the differentiation of bone marrow–derived progenitors into DCs *in situ* at the vaccine site followed by antigen uptake, processing, and traffic to draining lymph nodes:

1. Higher doses of GM-CSF lead to DC differentiation *in vitro.*
2. Maximal systemic immunity is only found with vaccines that produce high quantities of GM-CSF.
3. Increased DCs are found in lymph nodes draining GM-CSF–transduced vaccines.
FIGURE 18.2-2. Summary of cellular and molecular components of the priming phase and effector phase of systemic antitumor immunity induced by granulocyte-macrophage colony-stimulating factor (GM-CSF) gene-modified vaccines. This diagram represents a synthesis of multiple studies into the mechanism of immunity generation by GM-CSF gene–modified tumor vaccines. At the site of vaccination, high concentrations of local GM-CSF secreted by the transduced tumors attract bone marrow–derived cells and induce their differentiation into early-stage dendritic cells capable of efficiently ingesting antigens released over a 2- to 4-day period by the dying tumor cells. These early-stage dendritic cells then begin to migrate to draining lymph nodes, during which time they process tumor antigens into the major histocompatibility complex (MHC) class I and II pathways. In the draining lymph nodes, dendritic cells present MHC class II–restricted peptides to CD4 cells, which further activates dendritic cell differentiation via CD40, CD40 ligand interactions, and other signals. Mature dendritic cells efficiently process and present ingested tumor antigens to MHC class I-restricted CD8 cells. In the effector stage, CD4-mediated and CD8-mediated antitumor responses collaborate to generate maximal killing at the site of metastases. CD8[+] T cells directly recognize peptide MHC complexes expressed on tumor cells in metastatic phosphides. CD4 cells recognize MHC class II–restricted tumor peptides that have been processed and presented by macrophages within the metastatic tumor mass. The CD4 cells produce Th1 cytokine, such as interferon-γ, which, in turn, activates the macrophages to produce tumoricidal products, such as nitric oxide and superoxides. Th2 CD4 cells produce cytokines, such as IL-4 and IL-5, which attract and activate the eosinophils, thereby inducing them to discharge their cytocidal granule contents. (CTL, cytotoxic T lymphocyte.)

Formal evidence that presentation of the tumor antigens to T cells is mediated by bone marrow–derived APCs for MHC class I- and MHC class II-restricted antigens has been obtained through direct analysis of infiltrating DCs, as well as bone marrow chimera models (82). Similar results have been demonstrated for IL-3-transduced tumor vaccines, which have a potency and mechanism of action similar to GM-CSF (85). Indeed, IL-3 and GM-CSF have similar biologic activities, and their receptors share common subunits. Recent evidence that GM-CSF and IL-3 induced the differentiation of different types of DCs capable of inducing different functional responses in T cells suggests that GM-CSF and IL-3-transduced tumor vaccines should be more carefully compared.

It is important to note that, although irradiated GM-CSF–transduced vaccines can induce potent T-cell-dependent immunity against challenge at a distant site, nonirradiated GM-CSF–transduced tumors are not always rejected themselves. This is because GM-CSF induces differentiation of bone marrow–derived progenitors into potent APCs (e.g., DCs) but does not induce tumoricidal properties of bone marrow–derived cells

nearly as much as other cytokines. In fact, rejection of nonirradiated tumor cells expressing GM-CSF at modest levels has been shown to preferentially induce differentiation of macrophages capable of suppressing immune responses *in vitro* (86). It has also been shown that IL-10 production by some tumor cells can interfere with *in situ* APC differentiation and subsequent generation of antitumor immunity. In one study, GM-CSF transduction failed to significantly enhance vaccine potency of an IL-10–producing B-cell lymphoma; however, cointroduction of the GM-CSF gene and an IL-10 antisense gene restored immunogenicity (76). These studies underscore the importance of careful attention to parameters, such as gene expression level, expression of interfering genes, and preparation of the transduced vaccines, in determining the ultimate potency of any genetically modified vaccine.

Other Cytokine Genes

Additional cytokines, such as G-CSF (87), macrophage chemotactic protein-1 (88), IL-6 (89), and IL-3 (85), have been shown in isolated reports to be associated with local inflammatory-mediated rejection of tumors engineered to secrete these cytokines locally. In the case of G-CSF, the local inflammatory infiltrate was characterized by large numbers of granulocytes. In the case of macrophage chemotactic protein-1, the local inflammatory infiltrate was characterized by large numbers of macrophages. In neither of these cases was a systemic immune response demonstrated. IL-3- and IL-6–transduced vaccines did produce systemic immunity dependent on CD4$^+$ and CD8$^+$ T cells.

Given the large number of potential immunologically active genes in the armamentarium and the technical difficulties in transducing human tumor cells to make vaccines, it is critical that they be compared for efficacy. Also, given that most mouse tumors show significant immunogenicity when simply irradiated, identification of genes that truly enhance a tumor's immunogenicity above that of irradiated wild-type cells is important.

Vectors Used for Transduction of Tumors

Part of "18.2 - Genetically Modified Tumor Vaccines "

A variety of gene transfer vectors has been used to create genetically modified tumor vaccines. For the creation of autologous gene–modified tumor vaccines, high-efficiency gene transfer, as well as consistent high levels of gene expression in transduced cells, are critical parameters because numerous preclinical studies have verified the importance of levels of gene expression (particularly in the case of cytokine genes) in determining the potency of immunologic priming. In addition, primary human tumor explants are difficult to passage in culture for extended periods, thereby limiting the feasibility of drug-selecting transduced cells *in vitro.*

Initially, replication-defective retroviral vectors constituted the major gene transfer vehicle (69,90). The properties of retroviral vectors, however, are poorly suited for creating genetically modified tumor vaccines. Limitations in achievable virion titers (10^6 plaque-forming units per mL) limit efficiency of gene transfer, and retroviruses have severe limitations in the amount of foreign genetic material they can carry. Also, transduction requires replication of the target cell. Indeed, the major advantage of retroviral gene transfer systems, namely stabile gene expression based on their ability to integrate into the host genome, is, in fact, unnecessary for genetically modified tumor vaccines, as the vaccine cells themselves are ultimately destroyed within the first week after immunization. For these reasons, other gene transfer systems have supplanted retroviruses for the production of genetically modified tumor vaccines.

Replication-defective adenoviral vectors (77,91) represent a more attractive gene transfer system that is being extensively used for tumor transduction *ex vivo*, as well as *in vivo*, because they can be produced at much higher titer (up to 10^{12} plaque-forming units per mL). The limited duration of expression of adenoviruses (which do not integrate into the host genome) does not represent a disadvantage for this particular application, as discussed earlier. Adenoviruses have another advantage in that their larger genome allows for the introduction of larger sized, as well as larger numbers, of inserted genes than is possible with conventional retroviruses. As more experience has developed with adenoviral vectors, a tremendous variability in transduction efficiency and gene expression levels have been observed for different tumors, even from within the same histologic category. Some of this variability in transduction efficiency is accounted for by the variable levels of expression of the primary adenoviral receptor, coxsackievirus and adenovirus receptor, to which the fiber protein binds in the initial adsorption step, and integrins, to which the penton protein binds to effect cell entry (92,93 and 94). Other unidentified factors additionally contribute to the variability of transduction and gene expression, which represents a major barrier to consistent transduction for purposes of autologous vaccine production.

A number of other viral and nonviral vectors, including herpesvirus amplicon vectors (49), adeno-associated virus vectors (95), avipox vectors (96), ballistically delivered gold particles (75), and liposomal DNA carriers (50), are being explored as gene transfer systems for *ex vivo* and *in vivo* transduction of tumors. In addition, replication-competent vectors, such as vaccinia virus, are also being used (71,73). The application of replication-competent viral vectors carries potential advantages and potential disadvantages. Advantages include the ability to locally expand the level of production of cytokine (or other costimulatory molecules) via multiple rounds of infection and replication at the injection site. Also, inflammatory or "danger" signals generated by local viral replication can potentially enhance the priming to tumor antigens released at the vaccine site. Potential disadvantages of cell vaccines transduced with replication-competent viral vectors include the potential danger of systemic infections by the virus after vaccine injection, as well as potential limitations in transgene expression by infected cells, resulting from the cytolytic properties of the particular virus. New generations of attenuated replication-competent viruses that are slow to lyse infected cells and present little danger from systemic infection may represent ideal vector systems that maintain the advantages but diminish the disadvantages of replication-competent viral vectors (52).

Replacement of Direct Tumor Transduction with Bystander Cells

Despite the continued improvement in vector delivery systems, rapid, efficient, and consistent transduction of autologous tumors

continues to represent a major barrier to the broad application of genetically modified autologous tumor vaccines. For cytokine gene-transduced vaccines in which immune response induction depends on the paracrine biology of cytokine production local to the injected vaccine cells, increasing attention has been paid to the idea of replacing direct gene transfer into the tumor with admixture of bystander depots of cytokine. Indeed, a number of studies using bystander-transduced cells or cytokine-containing biodegradable polymer microspheres have demonstrated equivalent vaccine potency to directly transduced tumor cells (54,97). As discussed in the section Clinical Evaluation of Genetically Modified Vaccines, a number of clinical trials have used autologous or allogeneic fibroblast lines as the transduced cell admixed with nongenetically modified tumor cells. An MHC-negative K562 line transduced with the GM-CSF gene and selected to secrete extremely high levels of GM-CSF has been developed as a standardized bystander for human clinical trials (97).

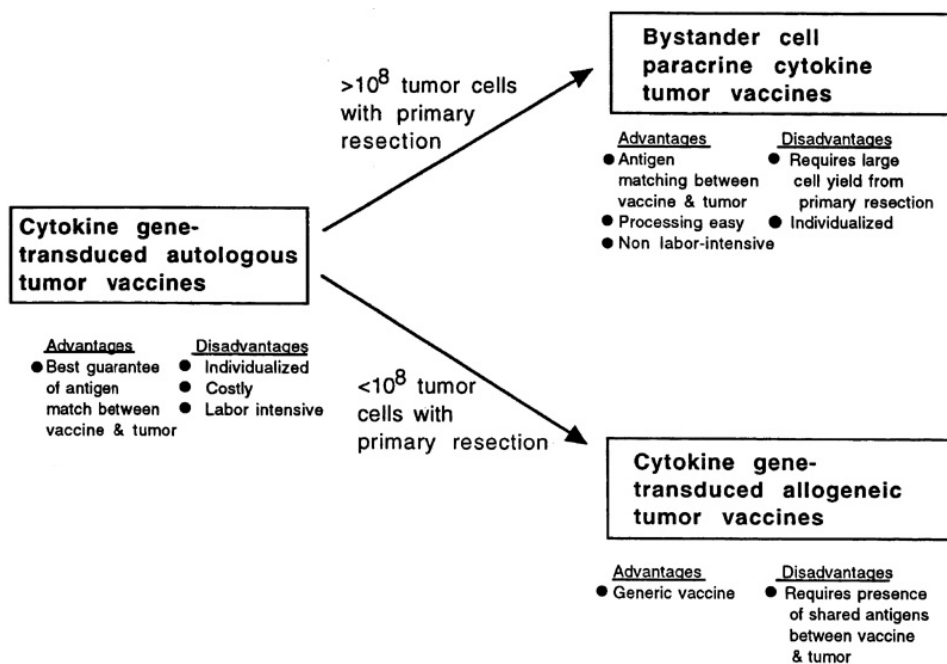
The use of generic transduced bystander lines completely obviates the need for culture or transduction of autologous tumor cells, as long as enough cells can be harvested from the patient to produce the vaccine. Therefore, this approach is most suitable for the treatment of cancers in which a large number of relatively pure tumor cells can be collected through pheresis (in the case of hematologic tumors) or surgical excision of the tumor masses (Fig. 18.2-3). Examples of tumors that commonly fit these criteria include leukemia, lymphoma, multiple myeloma, colon cancer, renal cancer, and ovarian cancer.


FIGURE 18.2-3. Clinical development of cytokine cancer vaccines. For some tumors (cancers of colon, kidney, ovary; leukemias, and lymphomas) from which large numbers of tumor cells can be obtained, vaccines are produced by admixture of patient cells with bystander cells that have been transduced with cytokine genes or with biopolymer microspheres containing cytokines. When autologous tumor is not available, patients can be immunized with allogeneic tumor cells (derived from cell lines of the same type as the patient's tumor) that have been transduced with cytokine genes. This strategy depends on the existence of appropriate antigens shared by the patient's tumor and the tumor cells in the vaccine.

Genetically Modified Allogeneic Vaccines

Even through the application of genetically modified bystander cells, the production of autologous tumor vaccines by necessity includes some degree of individualized cell processing. Two discoveries that have occurred since the early 1990s in the cancer immunology field provide a rationale for the development of generic genetically modified allogeneic cancer vaccines. First and foremost, the finding that some relevant immunologic targets are shared antigens (tissue specific or tumor associated) indicates that established cell lines of a particular tumor type may indeed contain "cross-reactive" antigens associated with that tumor type. Second, the finding that antigen presentation with cell-based vaccines occurs predominantly, if not exclusively, through the cross-priming pathway by host bone marrow–derived APCs indicates that matching of HLA alleles between the vaccine cells and the host is unnecessary. A number of preclinical models have verified that as long as immunorelevant antigens are shared between vaccine and challenge tumor, complete MHC mismatching between the vaccine and the host does not interfere with priming of host-restricted immune responses capable of recognizing the challenge tumor (98). As discussed in the section Clinical Evaluation of Genetically Modified Tumor Vaccines, genetically modified allogeneic vaccines are being actively investigated clinically in a number of cancer types (see Fig. 18.2-3).

In Vivo Introduction of Cytokine Genes into Tumor Cells

Part of "18.2 - Genetically Modified Tumor Vaccines "

Interest exists in the use of viral and other gene delivery vehicles to introduce immunologically active genes into tumor deposits *in vivo* that cannot be easily surgically removed (68,79,99,100). Such approaches have two distinct goals, each of which would be most appropriately achieved by different genes. One goal is to increase the local production of cytokine within a metastatic tumor mass, so as to induce a tumoricidal inflammatory infiltrate. Lymphokine genes, such as IL-2 and IL-12, which induce strong NK and NK target responses, in addition to enhancing CD8 T-cell responses, would likely be the most potent for this purpose. In addition to destruction of the tumor itself, it would

also be advantageous to enhance T-cell-dependent systemic immunity at the same time. Such an outcome might be best achieved through transfer of the GM-CSF gene, thereby enhancing local DC differentiation within the *in vivo*-transduced metastatic tumor mass. Thus, it is not surprising that some of the most potent antitumor effects generated by *in vivo* gene transfer approaches have used IL-2, IL-12, and GM-CSF. Using direct injection of recombinant replication-defective adenoviral vectors, Chen and colleagues have demonstrated that combined gene transfer of the herpes simplex virus thymidine kinase suicide gene, the GM-CSF gene, and the IL-2 gene resulted in the most potent antitumor responses in a murine model of liver metastases (100).

The first clinical evaluation of direct *in vivo* injection of genetic material into tumor masses used a gene encoding an allo-MHC antigen, HLA-B7 (101). As with the *ex vivo* gene transfer experiments with allogenic MHC genes, it is postulated that expression of a foreign HLA antigen by the tumor cells would generate a strong allogeneic immune response, resulting in the bystander stimulation of immunity against the bystander tumor antigens in the transduced mass. A DNA-liposome complex was used to accomplish the *in vivo* gene transfer. Five patients were treated with direct injections into accessible lymph nodes containing melanoma metastases. Analysis of needle biopsy specimens taken from the injected masses revealed that the HLA-B7 gene was expressed in 1% to 10% of the tumor cells near the injection site. No apparent toxicity was associated with this therapy and regression of the treated lesion, as well as several distant metastases, was observed in one patient. CTL precursor frequencies against the HLA-B7 alloantigen were detected, as well as an increase in bulk CTL activity against the autologous melanoma.

One of the great limitations of *in vivo* gene transfer for immunologic, as well as other purposes, is the relatively poor *in vivo* gene transfer efficiency of replication-defective viruses. Approaches that may improve *in vivo* gene transfer, resulting in enhanced immunologic effects, involve the development of targeted vectors, as well as the use of replication-competent recombinant viruses, which are capable of propagating a temporary infection and subsequent amplification within the injected or targeted tumor site. Along these lines, a number of groups are exploring the use of recombinant vaccinia to carry the GM-CSF gene into tumor masses *in vivo*.

Combination of Genetically Modified Tumor Vaccines and Adoptive Immunotherapy

A number of groups have explored combination strategies of vaccination with genetically modified vaccines, followed by *ex vivo* expansion of draining lymph node cells, followed by adoptive transfer back into the tumor-bearing animal (102,103). The rationale behind this approach is that the initial stages of activation and expansion of T cells specific for tumor antigens in the vaccine occurs in the draining lymph node subsequent to traffic of APCs from the vaccine site via afferent lymphatics. Studies using tumor vaccines transduced with allogeneic MHC genes, the IL-2 gene, and the GM-CSF gene have indeed indicated that prevaccination with certain genetically modified vaccines can enhance the ultimate number and potency of T cells cultured *ex vivo* from draining lymph nodes. In one study, adoptive transfer of T cells grown from lymph nodes draining GM-CSF-transduced vaccines provided enhanced immunity relative to vaccination alone (103). These sorts of studies indeed highlight the potential value for approaches that combine multiple immunologic manipulations.

Amplification of Vaccine Potency Through Blockade of Immunologic Checkpoints

As more is learned about the molecular regulation of immune responses, additional strategies to block inhibitory pathways of T-cell activation, so called immunologic checkpoints, have been explored as approaches to amplify the potency of cancer vaccines. One of the most extensively studied examples has been the blockade of cytoxic T lymphocyte antigen-4 (CTLA-4) pathway. CTLA-4 binds B7 with roughly a tenfold higher affinity than CD28. Occupancy of CTLA-4 appears to directly counter the effects of CD28 on T-cell activation and lymphokine induction (104,105). The importance of the CTLA-4 pathway as an immunologic checkpoint *in vivo* is most dramatically exemplified in CTLA-4 knockout mice, which develop a severe lymphoproliferative disease with immunologically mediated organ destruction (106,107). If CTLA-4 could be transiently blocked *in vivo*, it might be possible to enhance vaccine potency while limiting the collateral damage seen in the constitutive genetic knockouts.

Indeed, anti-CTLA-4 infusions produced an enhanced antitumor effect in a number of murine cancer models without overt toxicity in the treated animals (108). The CTLA-4 blockade was found to be most effective when given together with a genetically modified cancer vaccine (109). In initial synergy studies, anti-CTLA-4 treatment was shown to synergize with a B7-transduced prostate cancer vaccine. Subsequently, a number of studies have demonstrated dramatic synergy between anti-CTLA-4 treatment with GM-CSF-transduced vaccines in treating established cancer in two poorly immunogenic tumor models—B16 melanoma (110) and breast cancer (111). In a third model of spontaneously arising prostate cancer in probasin-SV40 Tag transgenic mice (the TRAMP model), neither GM-CSF-transduced vaccines nor CTLA-4 blockade alone significantly affected the rate of spontaneous tumor outgrowth, whereas the combination significantly reduced the rate of tumor growth (112). Further evidence of potent synergy came from the findings that vaccination with B16-GM-CSF plus CTLA-4 blockade induced vitiligo in B6 mice, whereas vaccination with TRAMP-GM-CSF plus CTLA-4 blockade induced autoimmune prostatitis. A report regarding the role of the CD30 pathway as a later immunologic checkpoint in autoimmunity models (113) suggests that multiple opportunities may exist to combine tumor vaccination with blockade of immunologic checkpoints.

Clinical Evaluation of Genetically Modified Tumor Vaccines

Part of "18.2 - Genetically Modified Tumor Vaccines "

The majority of activity in the clinical evaluation of genetically modified tumor vaccines involves cytokine genes. Results of the

early-stage clinical trials have been reported for vaccines transduced with IL-2 (114,115,116 and 117), IL-4 (118), IL-7 (119), IFN-γ (120), IL-12 (121), and GM-CSF (122,123,124,125 and 126). We have used different gene transfer approaches, including retroviruses, adenoviruses, lipofectant, and ballistically delivered gold particles. Although the majority of clinical trials have been performed in melanoma, genetically modified vaccines are also being evaluated in neuroblastoma, lung cancer, pancreatic cancer, prostate cancer, sarcoma, renal cancer, ovarian cancer, and hematologic malignancies. Autologous and allogeneic genetically modified vaccines have been tested, and, in some cases, tumor cells have been admixed with genetically modified autologous fibroblasts.

In addition to the cancer type and the particular cytokine gene transferred, four additional parameters that preclinical models predict would dramatically affect the outcome of vaccination are as follows:

1. Total number of tumor cells expressing antigen needed for generating an effective antitumor immune response: In all preclinical models in which vaccine cell number has been evaluated, increasing the number of vaccinating cells seems to increase the potency of systemic immunity. Importantly, widening the distribution of vaccine injections to involve more lymph node groups at the priming stage also enhances systemic immunity.

2. Expression level of cytokine required for generating an effective antitumor immune response: The importance of concentration of cytokine expression appears to depend on particular cytokines. In the case of IL-2 and IL-4, increasing amounts seem to correlate with increased systemic immunity. In the case of GM-CSF, maximal immunity plateaus at a secretion rate of 40 to 50 ng per 10^6 cells per 24 hours.

3. Route of administration of vaccine most effective at generating an effective antitumor immune response: It is difficult to completely analyze routes of injection in preclinical models because the dermis of rodents is too thin to place large numbers of cells. Studies using soluble GM-CSF to treat cutaneous leprosy, however, suggest that the dermal route of injection is superior. This may be owing to the presence of Langerhans' cells, which are induced by GM-CSF to differentiate into potent APCs. The optimal route of administration, however, may differ for different histologic types of tumors; therefore, this question should be adequately addressed in preclinical models and clinical trials.

4. Methods of pretreatment of reintroduced tumor cells: As described earlier, many of the gene products of the transduced tumor vaccines, particularly the cytokines, generate a local inflammatory response that eventually destroys the transduced tumor. This result is highly variable, however, and depends on levels of cytokine, tumor type, and cell dose. Also, for different cytokines, relative efficiency of elimination of the transduced tumor does not correlate with relative potency of the systemic immunity against distant sites of tumor—the only clinically relevant feature. For the ultimate use of genetically modified tumor vaccines in low tumor-burden patients, additional safeguards must be used. The most feasible and reliable method of inactivating the vaccine cells is radiation. For essentially all tumors, it is possible to find a window of γ irradiation dose that maintains metabolic activity and immunogenicity of the tumor for a few days while inhibiting replication.

Because variability exists in transduced genes, as well as these other critical parameters, it is difficult to derive much consistent information from the outcomes of the reported clinical trials, most of which have involved relatively small numbers of patients from diverse clinical settings; however, a few concordant themes, however, have emerged. First and foremost, the vaccines have not shown any significant systemic toxicity in any of the diverse clinical trials reported. Local inflammatory toxicities at the vaccine site have been reported in a number of trials, consistent with the bioactivity of locally secreted cytokines after injection of the transduced tumor cells. In a number of the studies, increased postvaccination proliferative and cytolytic responses from peripheral blood lymphocytes against the vaccine or autologous tumor cells have been reported. In the absence of information regarding which specific antigens are the targets of induced immune responses, it has been difficult to reliably measure increases in tumor antigen-specific T-cell precursor frequencies or activity. In some cases, increases in titers of serum antibodies reactive with tumor-associated antigens have been identified postvaccination. In the case of an IFN-γ–transduced autologous melanoma vaccine and a GM-CSF–transduced allogeneic prostate cancer vaccine trial, specific species appear to be selectively recognized on serum Western blots by postvaccine but not preimmune serum.

At the clinical level, anecdotal partial responses, mixed responses, and disease stabilization have been reported in a number of clinical trials, although the small patient numbers preclude any statistically significant evaluation of efficacy at this time.

The greatest clinical experience with cytokine gene–modified tumor vaccines has been with the IL-2 and GM-CSF genes.

Clinical Experience with Interleukin-2–Transduced Vaccines

A number of early-stage clinical trials using autologous and allogeneic vaccines have been performed using IL-2 gene transfer. A small trial in patients with metastatic renal cancer and melanoma used autologous untransduced tumor cells admixed with an immortalized fibroblast line stably transduced with the IL-2 gene introduced through cationic lipofection (116). Significant transient inflammatory responses developed at vaccine sites, as well as at DTH sites, where only irradiated tumor cells were injected. Infiltrates consisted of CD4+ and CD8+ T cells, which, on culture, demonstrated a suggestion of specific lytic activity against the autologous tumor cells. Clinical trials using directly IL-2–transduced tumor vaccines have been reported (115,116 and 117). Two of the vaccine trials involved patients with metastatic melanoma. Evidence of immune response induction was found in both cases; however, in neither case were responses against specific melanoma antigens assessed. In one of the trials, disease stabilization was noted in four of 12 patients treated, and mixed responses were observed in two of the 12 patients. Results of a clinical trial using an allogeneic neuroblastoma line transduced with the IL-2 gene were reported in children with relapsed stage IV neuroblastoma (117). As with other clinical IL-2–transduced

vaccine trials, a strong lymphocytic infiltrate was observed at vaccine sites. One of the 12 children demonstrated more than a 90% tumor response (partial response), seven had stable disease, and four had progressive disease in response to vaccine administration as a single agent. The authors concluded that this outcome was indicative of immune response induction to shared antigens, but noted that these results were somewhat less dramatic than with their previous trials using autologous IL-2-transduced neuroblastoma vaccines. It is thus possible that allogeneic vaccination may miss the opportunity to activate responses against relevant unique tumor antigens.

Clinical Experience with Granulocyte-Macrophage Colony-Stimulating Factor–Transduced Vaccines

The results of autologous GM-CSF-transduced vaccine trials in melanoma and renal cell cancer have been reported. In both of the original clinical trials, retroviral vectors were used for gene transfer of cells cultured *ex vivo.* In the renal cancer trial, patients were randomly assigned to be vaccinated with autologous nontransduced tumor cells or with GM-CSF gene-transduced tumor cells (123). Evaluation on the GM-CSF gene transduction arm was only done in cases in which vaccine cells secreted equal or more than 40 ng per 10^6 cells per 24 hours of GM-CSF posttransduction (based on preclinical studies, which demonstrated that this level produced maximal systemic antitumor immunity). This has been the only clinical trial that evaluated genetically modified vaccines that directly compared transduced versus nontransduced vaccines. The results of the trial demonstrated that GM-CSF-transduced vaccines induced a strong infiltration of mononuclear cells (including cells expressing "DC-specific" markers) at the vaccine site relative to nontransduced vaccines. Evaluation of immune response generation indicated that, at the highest dose tier (4×10^7 cells per vaccine dose), a greater magnitude of DTH response to irradiated autologous nongenetically modified cells was detected. Biopsy analysis of the DTH site revealed a significant qualitative difference between patients receiving GM-CSF-transduced vaccines versus patients receiving nontransduced vaccines. In particular, patients receiving GM-CSF-transduced vaccines demonstrated significant eosinophil infiltration at DTH sites reminiscent of the Th2-dependent eosinophil infiltration observed at challenge sites in murine tumor models of GM-CSF-transduced vaccination. One of four patients receiving the highest dose of GM-CSF-transduced autologous vaccine cells achieved more than a 90% regression (partial response) in metastases that lasted 1 year. This patient mounted the greatest DTH response of all the patients in the trial.

In a similar trial using the same retroviral vector to introduce the GM-CSF gene into autologous melanoma cells, dramatic postvaccination responses were observed (124). Increases in melanoma-reactive serum antibody titers were detected, as well as DTH responses. Biopsy of cutaneous melanoma lesions postvaccination revealed strong infiltrates, which included eosinophils (largely perivascular), T cells, macrophages, and quite a large number of plasma cells. A number of the patients demonstrated near complete destruction of tumor cells on biopsy of cutaneous lesions. Although no classic partial responses or complete responses occurred in terms of regression of metastatic lesions, a number of the patients who demonstrated tumor destruction in biopsy specimens achieved long-term stabilization of disease.

Two new directions exist for GM-CSF gene-transduced vaccine development—the application of allogeneic vaccines and the treatment of patients with minimal residual disease. The rationale for the application of these vaccines in the minimal residual disease setting is twofold. First, preclinical evidence indicates that they are significantly more effective with minimal tumor burdens. Second, as multiple clinical trials have verified the lack of toxicity, essentially no risk appears to exist in the vaccination process itself. An allogeneic GM-CSF-transduced prostate vaccine is entering a phase 2 clinical trial and has used two well-characterized prostate-specific antigen (PSA) + prostate cancer lines, LNCAP and PC3 (125). This vaccine was tested in a phase 1/2 trial in patients with postradical prostatectomy with no clinical evidence of metastatic disease but with rising PSA levels. In this clinical trial, 15 of 21 (71%) patients demonstrated a statistically significant decrease in the rate of rise of PSA with approximately one-half of patients demonstrating PSA stabilization. Two patients showed a decrease in PSA levels of more than 50% of their maximal prevaccine levels. Serologic analysis suggested a correlation between the development of antibodies specific for certain protein species (as yet unidentified) in the vaccinating tumors and PSA response. In an allogeneic GM-CSF-transduced pancreatic cancer vaccine trial, patients postradical pancreaticoduodenectomy (Whipple procedure) were vaccinated with two pancreatic cancer cell lines transduced with the GM-CSF gene using the pc-DNA-3 plasmid followed by drug selection of lines secreting approximately 100 ng per 10^6 cells per 24 hours (122). A number of patients at the highest dose tier demonstrated positive DTH responses to autologous tumor postvaccination and some patients demonstrated recurrent inflammatory responses at old vaccine sites. Biopsy in these cases was characterized by a strong eosinophil component to the inflammatory infiltrate, further suggesting that the Th2 response originally identified in murine models may in fact translate to patients with a variety of cancer types.

Conclusion

Part of "18.2 - Genetically Modified Tumor Vaccines "

Major advances in gene transfer technology together with the understanding of immune recognition and regulation have provided the basis for an expanding effort in the development of genetically modified tumor vaccines. Particularly with cytokine gene-transduced vaccines, the concept of paracrine cytokine adjuvants and their role in local activation of APCs has been established. Many decades may pass before the critical shared immunodominant antigens are identified for most cancers. Thus, clinical development of genetically modified vaccines plays a major role in human cancer immunotherapy as clinical and scientific tools. Carefully designed clinical studies together with appropriate immunologic evaluation of vaccinated patients are the critical steps to take to successfully define the most effective application of this approach in the treatment of cancer patients.

Peptide Presentation on Major Histocompatibility Complex Molecules

Part of "18.3 - Peptides and Protein Vaccines "

The T-cell receptor on lymphocytes with antitumor activity recognize a unique conformation on the tumor cell surface comprised of a peptide nestled in the groove of a surface major histocompatibility complex (MHC) molecule (1,2). CD8+ T cells recognize peptides attached to class I molecules, and CD4 cells recognize peptides attached to class II molecules. Class I MHC molecules consist of a heavy chain of 45,000 d and a noncovalently attached beta-2-microglobulin of 12,000 d. There are three major HLA class I alleles called *HLA-A, -B*, and *-C.* Class II molecules are heterodimers consisting of an alpha and beta chain of approximately 30,000 d each, and the three class II alleles are called *HLA-DR, -DQ*, and *-DP.* X-ray diffraction crystallography has characterized the three-dimensional structure of class I and II molecules and their peptide-binding sites.

The cellular processes resulting in the binding of peptides to class I and II molecules are different. The great majority of class I-presented peptides result from the degradation of cytosolic proteins by a multi-unit structure in the cytoplasm called the *proteosome.* Cleaved peptides are transported into the lumen of the endoplasmic reticulum (ER) by the transporter associated with processing molecule, possibly protected from complete degradation by chaperone heat-shock proteins before entering the ER. The trimmed peptides are bound to the groove of the assembled class I molecule in the ER, and the complex is transported to the cell surface.

Most peptides that are loaded onto class II molecules are derived from proteins that are endocytosed into the cell and are degraded in intracellular compartments in endosomal or lysosomal structures. The alpha and beta chains of class II molecules are assembled in the ER and are bound to a chaperone-like molecule called *invariant chain.* A stretch of the invariant chain called the *CLIP peptide* binds in the groove of the class II molecule to prevent premature peptide binding. A targeting sequence in the cytoplasmic tail of the invariant chain also appears to be responsible for transport of class II molecules from the ER to endosomal or lysosomal intracellular compartments where they can bind peptides and are then transported to the cell surface. Although the great majority of class I molecules are bound to peptides from endogenous cellular proteins and the great majority of class II peptides are derived from endogenous endocytosed proteins, there are examples of endogenous proteins entering the class II pathway and exogenous proteins entering the class I pathway.

Thus, a variety of steps can affect which peptides are found on the cell surface, including (a) the presence of endogenous and exogenous proteins, (b) the appropriate degradation of these proteins in intracellular compartments, (c) the ability of the degraded peptides to bind in the groove of the particular HLA class I or II molecules present in that patient, and (d) the successful transport of these molecules to the cell surface. Absence or dysfunction of any of these steps can lead to defective peptide presentation on the tumor cell surface.

The interaction of the three-dimensional structure of the peptide-binding groove of the class I and II molecules with the conformation of the associated peptide determines which peptides can bind to particular HLA molecules as well as the affinity of this interaction. Particular sites in the groove of HLA molecules (called *anchor sites*) play a major role in determining binding of the peptide to the MHC molecule. Other amino acid residues are more involved in interacting with the T-cell receptor, leading to recognition of this peptide and MHC complex. Analysis of known peptides recognized by T cells as well as the analysis of sequences of pooled peptides eluted from MHC molecules have helped to determine the characteristics of peptides associated with particular MHC molecules (3,4 and 5). The relatively uniform length of these peptides (e.g., eight to ten amino acids for most class I molecules and slightly longer peptides for class II molecules) has enabled the definition of these allele-specific motifs for most of the common class I and II specificities. An example of one such peptide-binding analysis derived from studies by Rammensee and colleagues (3) is shown in Table 18.3-1 . Examples of the peptide ligands derived from pooled sequences and from known T-cell antigenic epitopes are shown. From these and other studies, it was determined that position 2 was an anchor residue favoring a leucine or methionine, and position 9 was a second anchor residue favoring binding of a valine or leucine to the HLA-A0201 molecule. Other residues with a lesser degree of preferred binding to HLA-A2 were also found. Examples of predominant anchor-binding residues for HLA-A1, -A3, and -A24 are shown in Table 18.3-2 . Knowledge of these allele-specific motifs has facilitated the identification of the immunogenic peptides of tumor antigens.

Identification of Immunogenic Peptides from Tumor Antigens

Part of "18.3 - Peptides and Protein Vaccines "

Three main techniques have been used to identify peptides derived from tumor antigens. The most common method has been the analysis of synthetic peptides based on the known amino acid sequence of tumor antigens detected by T cells. Most tumor antigens that have been characterized were identified by cloning the genes that encode proteins recognized by T cells with antitumor activity (see Chapter 16.1). The amino acid sequences of these proteins are analyzed, and peptides conforming to the allele-specific motifs of the particular HLA-restriction molecules used by these antigens can then be synthesized and pulsed onto antigen-presenting cells (APCs) and tested for recognition by the antitumor T cells. Estimates of the avidity of T cells for these peptide antigens were determined by pulsing differing concentrations of peptides to APCs and determining the minimal concentrations required for recognition. Algorithms developed to predict the peptides most likely to bind to individual MHC molecules have been useful in facilitating peptide identification (6). Alternatively, it has been possible to use exonuclease digestion to produce fragments that can narrow the areas within the amino acid sequence that contain the immunogenic peptides (7).

A second technique also dependent on the availability of T cells capable of recognizing tumor antigens, but that does not depend on knowing the identity of the antigen, uses the direct elution and identification of peptides from tumor cells. In this approach, class I or II molecules are purified from tumor cells by affinity chromatography, peptides are released from the MHC molecules by acid elution and are fractionated by high-performance liquid chromatography (HPLC) (8,9). These HPLC fractions are pulsed to APCs containing the appropriate MHC molecule, and T cells that recognize tumor antigens can be used to identify the fractions containing the immunogenic peptides. Further fractionation of the peptides by microcapillary HPLC with direct elution into a triple quadruple mass spectrometer can be used to further identify fractions containing immunogenic peptides. Automated Edman degradation or collision-activated dissociation analysis can then be used to identify the amino acid sequence of the peptides. Finally, the ability of these peptides to be recognized by antitumor T cells after pulsing onto APCs can confirm the identity of the appropriate tumor peptide. A peptide at amino acid positions 280 to 288 of the gp100 molecule was identified as a melanoma antigen using this technique (9).

A third approach to the identification of immunogenic tumor peptides uses what has been called *reverse immunology* and does not depend on the availability of T cells capable of recognizing tumor antigens. In this approach, candidate proteins thought to have a high probability of representing tumor antigens because of their overexpression or unique distribution on tumor cells are identified and their amino acid sequence analyzed for the presence of peptides with motifs capable of binding to HLA molecules. Based on these allele-specific motifs, multiple peptides are synthesized and *in vitro* sensitization techniques can be used to generate T cells capable of recognizing the particular peptide. The critical step of this process is the test of whether cloned T cells raised *in vitro* against this synthetic peptide can recognize tumor cells in an MHC-restricted fashion. Using this reverse immunology approach, immunogenic peptides derived from the melanocyte-stimulating hormone receptor as well as tyrosinase-related protein-2 (TRP-2) have been identified as human melanoma antigens restricted by HLA-A2 (10,11).

Peptide Vaccines in Patients with Melanoma
