Part of "18.3 - Peptides and Protein Vaccines "

The majority of tumor antigens that have been described were derived from melanomas and thus initial experience with peptide vaccination has been in patients with metastatic melanoma. Peptides identified in the MAGE-1 and MAGE-3 tumor antigens (see Chapter 16.1) were used in pilot studies in melanoma patients whose tumors were shown to express MAGE-3 protein as evaluated by reverse transcriptase-polymerase chain reaction analysis. Marchand et al. reported on 12 patients with evaluable melanoma metastases who were treated with an HLA-A1-restricted peptide (EVDPIGHLY) injected at monthly intervals (12). The peptide was injected in saline at a dose of 100 or 300 mg divided between two sites subcutaneously, and 13 to 30 mg given intradermally. Of the 12 melanoma patients included in this study, six were withdrawn from treatment after one or two injections because of rapid progression of disease. Six remaining patients received at least three immunizations, and three of these patients were reported to have some clinical response to the immunizations. One patient had a mixed response but died 1 month after the third treatment. One patient had a partial response of multiple 1- to 3-mm cutaneous metastases, and an additional patient was reported to have a partial response of lung metastases. Also treated in this protocol were two melanoma patients who had no evaluable disease, one patient with non-small-cell lung cancer and one patient with bladder cancer. Neither of the two latter patients showed a clinical response. None of the patients in this study developed evidence of cytotoxic T lymphocyte (CTL) precursors

in the blood, including analysis of patients who appeared to show clinical evidence of tumor regression.

Chakraborty et al. treated 17 patients with melanoma, including 11 with metastatic disease using autologous APCs pulsed with a MAGE-1, HLA-A1-restricted peptide (EADPTGHSY) given intradermally monthly for 4 months (13). Thirteen of these patients completed all four immunizations, and one patient was reported to show a partial regression of a subcutaneous nodule. Monitoring of biologic response using conventional natural killer or CTL assays in these patients revealed no consistent differences between pre- and postimmunization peripheral blood lymphocytes. Nestle et al. reported four patients who received HLA-A1- and HLA-A3-restricted MAGE-3 peptides pulsed to APCs and two additional patients who received MAGE-3 peptides in conjunction with HLA-A2-restricted melanoma differentiation antigen peptides also pulsed on APCs (14). In the Nestle et al. study these cells were injected into lymph nodes, and one of these six patients was reported to have a partial response.

The predominant antigens recognized by tumor-infiltrating lymphocytes (TILs) obtained from patients with metastatic melanoma are the melanoma and melanocyte differentiation antigens (see Chapter 16.2). Pilot studies have been performed in the Surgery Branch, National Cancer Institute (NCI) immunizing patients with evaluable metastatic melanoma using HLA-A2-restricted peptides from the MART-1 and gp100 melanoma antigens (15,16 and 17). In one study, 18 HLA-A0201 patients with metastatic melanoma were immunized with the MART-1:27-35 peptide (AAGIGILTV) in incomplete Freund's adjuvant (IFA) subcutaneously every 3 weeks (15). Evidence of significant immunization to the MART-1 peptide as well as to MART-1-expressing tumors was obtained in most patients, although only one of these patients developed a partial response (ongoing at longer than 4 years). Lymphoid precursors reactive with the MART-1 peptide were detected using *in vitro* assays based on repeated *in vitro* sensitization with autologous peripheral blood mononuclear cells (PBMCs) pulsed with the MART-1:27-35 peptide. In 15 of these patients, postvaccination CTL cultures exhibited more than a threefold increase in specific release of interferon gamma compared with prevaccination samples (Table 18.3-3). No dose response was seen in patients receiving from 0.1 to 10 mg per injection. Because of the low precursor frequency both before and after immunization, it was necessary to perform three *in vitro* stimulations of PBMCs to detect the precursors seen in these patients. This increase in peptide reactivity after immunization was also reflected in increased recognition of MART-1-expressing melanomas (Table 18.3-4). Thus, it appeared that the normal nonmutated MART-1 peptide in IFA was capable of immunizing the majority of patients after immunization, although only one patient in this trial developed a partial response.

Table 18.3-3 HLA-A*0201-Restricted Cytokine Release by Peripheral Blood Mononuclear Cell Cultures Sensitized *In Vitro* with MART-1:27-35

| | IFN-γ Release (pg/5 × 10^5 effectors/24 hr) | |

From Cormier JN, Salgaller ML, Prevette T, et al. Enhancement of cellular immunity in melanoma patients immunized with a peptide from MART-1/Melan A. *Cancer J Sci Am* 1997;3:37, with permission.

A similar study in the Surgery Branch, NCI evaluated the ability to immunize HLA-A2 metastatic melanoma patients

using one of three different immunodominant peptides from the gp100 antigen, gp100:209-217 (ITDQVPFSY), gp100:280-288 (YLEPGPVTA), or the gp100:154-162 peptide (KTWGQYWQV) (16). These peptides were injected in IFA at doses between 1 and 10 mg subcutaneously every 3 weeks. Of the 28 patients immunized with one of these peptides, one patient receiving the gp100:209-217 peptide had a complete response of cutaneous metastases that lasted 4 months. All of the patients receiving the gp100:209-217 or the gp100:280-288 peptide, but none receiving the gp100:154-162 peptide, showed evidence of *in vivo* immunization when multiple *in vitro* sensitizations to compare pre- and postvaccination PBMC samples were performed. Thus, these studies of the nonmutated MART-1 and gp100 peptides revealed that significant increases in circulating precursor levels could be induced by immunization, although clinical responses were rare.

Jager et al. reported on the treatment of patients with metastatic melanoma using combinations of peptides from the MART-1, tyrosinase, and gp100 tumor antigens (18,19). Patients in this trial received 100 µg of each peptide intradermally weekly for 4 weeks. No clinical responses were seen in six treated patients. Several patients showed evidence of precursor development against the MART-1 and tyrosinase peptides, but no reactivity was seen against the gp100 peptides. In a subsequent study, these same investigators reported on three patients who received intradermal injections of these melanoma-associated peptides along with the daily systemic administration of granulocyte-macrophage colony-stimulating factor (GM-CSF) starting 3 days before immunization until 2 days after immunization (20). Delayed-type hypersensitivity responses were seen in each of the patients, and each of these three patients were reported to have experienced clinical regression of disease. There has, however, been no follow-up study of this approach since 1996, and thus the reproducibility of these findings remains to be determined.

A pilot trial has also been conducted using melanoma and melanocyte differentiation antigens from MART-1, gp100, and tyrosinase pulsed onto autologous dendritic cells from HLA-A'0201 patients with metastatic melanoma (14). These peptide-pulsed dendritic cells were injected directly into lymph nodes at weekly intervals, and clinical response was evaluated. Eight patients received immunization with autologous-dendritic cells pulsed with A2 peptides, including two patients who received dendritic cells pulsed with A1 and A2 peptides. One complete response and one partial response were seen in these eight patients, and several developed delayed-type hypersensitivity skin reactions to peptide.

Modification of Melanoma Peptides to Increase Immunogenicity

Part of "18.3 - Peptides and Protein Vaccines "

In contrast to most immunogenic viral peptides that have high binding affinity for their corresponding MHC molecules (21,22 and 23), most of the immunogenic melanoma and melanocyte differentiation antigen peptides have a modest or relatively low affinity for the HLA-A'0201 molecule (24,25). Of the four immunodominant HLA-A'0201–restricted peptides derived from the MART and gp100 antigens, three of the four peptides have a suboptimal amino acid residue at anchor position two and the other peptide has a suboptimal residue at anchor position nine (Table 18.3-5). It is likely that T-cell precursors capable of binding peptides with high affinity for HLA-A'0201 are deleted during lymphocyte maturation in the thymus and that only T cells with relatively weak recognition of peptides survive negative selection (26,27). Thus, although a correlation has been demonstrated between immunogenicity and peptide binding affinity to class I MHC molecules for peptides derived from viral antigens, this appears not to be the case for the immunogenicity of peptides derived from nonmutated self determinants (21,22,23 and 24).

Table 18.3-5 Peptide Binding to HLA-A2

Anchor	2°	1°	2°	—	—	—	—	—	1°
	1	2	3	4	5	6	7	8	9
	—	Leu	—	—	—	—	—	—	Val
Preferred amino acids	—	Met	—	—	—	—	—	—	Leu
MART-1:27-35	Ala	Ala	Gly	Ile	Gly	Ile	Leu	Thr	Val
gp100:154-162	Lys	Thr	Try	Gly	Gln	Tyr	Try	Gln	Val
gp100:209-217	Ile	Thr	Asp	Gln	Val	Pro	Phe	Ser	Val
gp100:280-288	Tyr	Leu	Glu	Pro	Gly	Pro	Val	Thr	Ala

The relatively low binding affinity of the immunodominant self-peptides suggested that amino acid substitutions at anchor residues could increase binding affinity without interfering with peptide recognition and therefore increase the immunogenicity of the peptide (28,29). These modified peptides have been referred to as *heteroclytic peptides.* Parkhurst et al. studied a large number of synthetic peptides with one or two amino acid substitutions of the gp100:209-217 peptide designed to increase binding affinity to the HLA-A'0201 molecule (25). An example is shown in Table 18.3-6 . The relative binding affinity of each synthetic peptide to HLA-A'0201 was evaluated based on the inhibition of binding of a standard radiolabeled peptide to the purified HLA-A'0201 molecule. The relative binding affinity of the leucine modification instead of threonine at the second position resulted in a peptide with a 52-fold higher binding affinity compared to the native peptide and yet was recognized as well as the native peptide by a specific TIL. CTLs induced by *in vitro* sensitization using the modified peptide exhibited superior recognition of the native peptide compared to CTLs raised with the native peptide. Similarly, a peptide with a modification of methionine at the second position was more effective than the native peptide in inducing CTLs reactive with the native peptide *in vitro.*

CTL, cytotoxic T lymphocyte; IFN-γ, interferon-γ; ND, not done; TIL, tumor-infiltrating lymphocyte.

[a]Peptide binding affinity to HLA-A'0201 was evaluated by measuring the concentration of peptide necessary to inhibit the binding of a standard radiolabeled peptide by 50% (ID_{50}). The ratio (R) presented here indicates the relative HLA-A'0201 binding affinity of the modified peptide (mod) compared to the parent peptide (parent):R> indicates the modified peptide bound with greater affinity than the parent peptide. ID_{50} (G9_209 parent) = 172 nM.

[b]IFN-γ release by TIL in the presence of T2 cells preincubated with 1 µM peptide. IFN-γ (T2 cells without exogenous peptide) = 454 pg/mL.

[c]Cytotoxicity or IFN-γ release by CTLs in the presence of T2 cells preincubated with 1 µM peptide.

[d]IFN-γ release by CTLs above the background of T2 cells without exogenous peptide.

[e]Values in parentheses indicate background percent cytolysis of T2 cells without exogenous peptide.

From Parkhurst MR, Salgaller ML, Southwood S, et al. Improved induction of melanoma-reactive CTL with peptides from the melanoma antigen gp100 modified at HLA-A'0201-binding residues. *J Immunol* 1996;157:2539, with permission.

On the basis of these *in vitro* studies, a pilot clinical protocol was performed in the Surgery Branch, NCI in which HLA-A'0201 patients with metastatic melanoma were immunized with the gp100:209-217 (210 M) modified peptide (M substituted for T at the second anchor position, amino acid 210) (17). Using a stringent *in vitro* assay comparing pre- and postimmunization samples after a single *in vitro* exposure to peptide, only two of eight patients immunized with the native peptide showed evidence of successful immunization compared to 10 of 11 patients immunized with the modified peptide. A detailed example of one such assay is shown in Table 18.3-7, and the results of the *in vitro* monitoring of all 11 patients who received the modified peptide is shown in Table 18.3-8 . Increase in precursors was also seen against HLA-A'0201–matched tumors and not against HLA-A'0201–negative tumors (Table 18.3-9). Only mixed responses were seen in patients receiving the modified peptide alone in IFA; however, when interleukin 2 (IL-2) was administered along with the modified peptide in IFA, 42% of 31 patients showed an objective anticancer response (17). This 42% response rate appeared higher than the 17% response rate seen in studies of patients using IL-2 alone (30) or the 15% response rate in 62 melanoma patients receiving the same high-dose IL-2 concurrently at the same institution but not with peptide immunization. A randomized trial is necessary to test whether immunization with the modified peptide can increase the responses seen when IL-2 is administered concurrently with peptide.

The mechanisms by which immunization with the modified peptide in IFA resulted in high circulating levels of cellular immunity against the native peptide as well as against melanoma cells is under intensive study. The emulsification of peptide

in adjuvant is thought to prolong the exposure of the immune system to antigen and to activate nonspecific inflammatory cells with recruitment of APCs to the site of immunization. Of particular interest was the decrease in circulating precursor cells when IL-2 was administered along with peptide, possibly due to redistribution of immune cells out of the circulation to sites of tumor (31). Some studies have identified peptides from the MART-1 tumor antigen that appear to be more immunogenic *in vitro* than is the native MART-1:27-35 peptide (32,33). Modifications of this peptide with a methionine at the second position appear to be more immunogenic *in vitro* than the native nine-mer peptide, and modifications of the MART-1:26-35 ten-mer with a leucine or methionine in the second position appear to be more immunogenic than the native ten-mer peptide. Clinical trials evaluating the ability of modified MART peptides to immunize melanoma patients are under way.

Immunization with Peptides from the ras Oncogene

Part of "18.3 - Peptides and Protein Vaccines "

Increasing efforts are being made to develop peptide immunization for patients with common epithelial tumors. Mutated oncogenes or tumor-suppressor genes are particularly attractive targets for these immunizations (see Chapter 16.4), because the malignant phenotype of the tumor often depends on the expression of these oncogene products, and thus antigen loss variants are unlikely to survive.

Mutations in the ras oncogene have been reported in from 20% to 90% of different human epithelial malignancies (34). Ninety percent of ras mutations occur at codon 12, in which a normal glycine residue is replaced by an aspartic acid, valine, or cysteine. These point mutations lead to the production of aberrant proteins that can affect early events in tumorigenesis. Gjertsen et al. (35) identified the exact ras mutations in five patients with adenocarcinoma of the pancreas using polymerase chain reaction amplification and sequencing and immunized patients with up to 4 × 10⁹ PBMCs pulsed with the synthetic mutated ras peptide (amino acid positions 5 to 21) infused intravenously with booster vaccinations on days 14 and 35 and then every 4 to 6 weeks. In this study, two of five patients were reported to exhibit a transient PBMC proliferative T-cell response to peptide on approximately day 40. One of these responses specifically recognized only the mutated peptide and the other recognized both the mutated and nonmutated peptides. In subsequent reports, specific anti-ras class II-restricted and class I-restricted T-cell responses were described (36). The position 12 valine mutation in one patient was shown to be HLA-B35-restricted and the exact nine amino-acid peptide with the sequence VVVGAVGVG was identified. Of particular interest was the ability of the class I-restricted cells to recognize tumors expressing this K-ras mutation. These studies were encouraging because they demonstrated that peptides arising from these individual point mutations could be presented on the surface of tumor cells and thus potentially serve as targets for immune attack.

Abrams et al. used a similar approach to immunize patients with adenocarcinomas of the colon, lung, or pancreas whose tumors contained point mutations in the K-ras gene at codon 12 (37). Mutant ras peptides, 13 amino acids in length, corresponding to the individual patient's mutation were synthesized and injected subcutaneously admixed with Detox adjuvant (a combination of cell-wall skeletons from *Mycobacterium phlei* and lipid-A from *Salmonella* prepared in oil and water emulsion). Each of the patients received three vaccinations of 0.1 to 1.0 mg peptide separated by 4 weeks. Immunologic responses in these patients were assessed by the generation of cell lines derived from lymphocyte populations incubated *in vitro* and sensitized with autologous APCs, the mutant ras peptides, and IL-2. T-cell lines derived from three of eight patients receiving these vaccinations were reported to recognize the mutated peptide with no detectable crossreactivity against normal ras sequences. A CD8⁺ T-cell line sensitized to a mutant-ras peptide

also exhibited lysis of a tumor-cell line naturally expressing the same endogenous mutation.

Khleif et al. studied 139 tumors and identified 37 (26.6%) that carried K-ras mutations in position 12 of the ras gene (38). Fifteen patients were vaccinated with Detox adjuvant containing 0.1 to 5.0 mg of the specific mutated peptide found in their tumor. Immunologic data was available from 10 of the 11 patients that completed at least three vaccinations, and three of these ten generated either CD4[+] or CD8[+] T-cell responses to the specific mutant ras peptide used for immunization. A CD8[+] CTL line was capable of lysing an HLA-A2 matched tumor-cell line carrying the corresponding mutation.

No clinical antitumor effects were reported in any of the patients immunized with ras peptides.

Immunization with Peptides from the HER-2/*neu* Oncogene

Part of "18.3 - Peptides and Protein Vaccines "

The HER-2/*neu* protein is a member of the tyrosine kinase family of growth factor receptors and is frequently amplified and overexpressed in adenocarcinomas of the breast, ovary, colorectum, and other histologies (39). The expression of HER-2/*neu* correlates with poor prognosis and appears to be involved in the tumorigenic and metastatic phenotype of these tumors.

HER-2/*neu* contains 1,255 amino acids, and multiple potential HLA-binding epitopes exist for most human MHC haplotypes. Several groups have identified peptides that appear to be recognized by human lymphocytes in an HLA-A2-restricted fashion (Table 18.3-10). Fisk et al. identified a nine-amino acid peptide (KIFGSLAFL) at amino acids 369 to 377 (referred to as *p369*) that was recognized by ovarian tumor-associated lymphocytes as well as tumor-reactive clones from four of four patients (40). Independently, Kono et al. reported that two of nine clones derived from ovarian and breast TILs also recognized the p369 epitope (41). Lustgarten immunized HLA-A2.1 transgenic mice with this epitope; splenocytes from these immunized mice recognized HLA-A2[+] HER-2/*neu* overexpressing human tumor lines (42). Additionally, multiple other HLA-A2-binding peptides from HER-2/*neu* have been recognized by PBMCs from HLA-A2[+] patients with ovarian or breast cancer (see Table 18.3-10).

Table 18.3-10 Previous Studies Identifying HLA-A2-Restricted Epitopes from HER-2/neu

Source of CTLs	Method of Induction	Peptides Identified	Tumor Recognition	References
Ovarian TALs, including three derived clones	CD8[+] selection	p369(4/4 lines), P971(2/4 lines)	SKBR-3.A2, OVA-16 HER-2[high]	40
Ovarian TILs and TALs, including nine clones	*In vitro* stimulation with autologous tumor followed by cloning	p369(2/9 clones), p971(1/9 clones)	Autologous and A2[+] HER-2[+] lines	41
HLA-A2.1 huCD8 transgenic mouse	*In vitro* peptide vaccination	p369, p773	Panel of A2[+] HER-2[+] lines	42
Donor PBLs	*In vitro* stimulation with pulsed autologous dendritic cells	p369, p654	A2[+] HER-2[+] breast (MB 231, MCF-7), colon (HCT 116), and RCC (A_498) tumor lines	62
Donor PBLs	*In vitro* stimulation with pulsed autologous dendritic cells	p369, p435, p9	Not shown for p369-reactive cells	59
Ovarian TALs	*In vitro* stimulation with autologous tumor	p971	Autologous	63
Donor PBLs	*In vitro* stimulation with pulsed autologous PBMCs	p968-981, p968-981 611 p971, p971, 9V	Autologous and allogeneic A2[+] HER-2[+] lines	64
Ovarian, breast, and NSCLC TILs	*In vitro* stimulation with autologous tumor, pulsed T2, or pulsed dendritic cells	p654	Autologous and allogenic A2[+] HER-2[high] tumors from ovarian, breast, NSCLC, and pancreatic cancer	65,66 and 67
Donor PBLs	*In vitro* stimulation with pulsed autologous PBMCs	p48, p789	None shown	68

NSCLC, non–small-cell lung cancer; PBLs, peripheral blood leukocytes; PBMCs, peripheral blood mononuclear cells; TALs, tumor-associated lymphocytes; TILs, tumor-infiltrating lymphocytes.

From Zaks TZ, Rosenberg SA. Immunization with a peptide epitope (p369-377) from HER-2/neu leads to peptide-specific cytotoxic T lymphocytes that fail to recognize HER-2/neu+ tumors. *Cancer Res* 1998;58:4902, with permission.

A variety of laboratory studies have also suggested the potential importance of immunologic reactions against HER-2/*neu* in immunotherapy. Disis et al. demonstrated that specific CD4[+] T-cell immunity against HER-2/*neu* could be generated in the rat by vaccination with immunogenic rat peptides but not by immunization with the intact protein (43). No evidence of autoimmunity was seen directed against organs that expressed low basal levels of the HER-2/*neu* protein.

Although several groups have shown that human T cells could be generated *in vitro* that were capable of reacting with HER-2/*neu* peptides, controversy exists concerning the ability of these cells to recognize processed HER-2/*neu* peptides on the surface of tumor cells. Zaks et al. raised highly avid T cells capable of recognizing the p369 peptide but could not detect reactivity against HER-2/*neu*-overexpressing human tumors (44). Four patients were then treated with the HER-2/*neu* p369 peptide administered subcutaneously in IFA every 3 weeks, and PBMCs collected before and after two and four immunizations were analyzed. Strong peptide reactivity was raised in the PBMCs of three of these four patients that could recognize peptide concentrations of 1 ng per mL, yet failed to react with a panel of HLA-A2[+] HER-2/*neu* overexpressing tumors or with HLA-A2[+] cells infected with recombinant *vaccinia virus* encoding the HER-2/*neu* protein. It thus appeared

from these studies that the p369 peptide was not presented on the surface of tumors cells. Further work is necessary to clarify this point.

Immunization with Peptide Vaccines from Human Papillomavirus-Induced Tumors

Part of "18.3 - Peptides and Protein Vaccines "

Cancers known to be induced by viruses represent attractive candidates for the development of cancer vaccines because of the possible presence of foreign virally encoded epitopes presented on the tumor cell surface (see Chapter 16.3). Human papillomavirus (HPV) infection is strongly associated with the presence of cervical cancer; greater than 90% of cervical cancers harbor DNA encoding HPV (45). The HPV genotype 16 is detected in approximately 50% of squamous carcinomas of the cervix. The E6 and E7 genes of HPV16 encode nucleoproteins that are involved in the malignant transformation of cells and have been shown to inactivate the tumor-suppressor protein p53 and retinoblastoma, respectively (46). Continued expression of the E6 and E7 encoded proteins is essential for maintenance of the malignant phenotype. Studies by Ressing et al. using HLA-A*0201 Kb transgenic mice as well as *in vitro* sensitization of human PBMCs have identified a series of E6- and E7-binding peptides that appear to be immunogenic *in vitro* and are capable of giving rise to reactive T cells that recognize not only the peptide but an HLA-A*0201 HPV-positive cervical carcinoma cell line as well (47). Because HPV16 is foreign to both mice and humans, animal models have been particularly valuable in developing immunization protocols capable of preventing the growth of tumors expressing these viral proteins (48).

The HPV16-E7 peptide with amino acids 86 to 93 (TLGIVCPI) has been of particular interest because of its high binding to HLA-A*0201 as well as its ability to mediate the generation of antitumor lymphocytes *in vitro* (47). Clinical studies have been initiated attempting to raise specific CTLs against these peptides in humans (49).

Peptide Vaccines Directed Against Prostate and Colon Cancer-Associated Proteins

Part of "18.3 - Peptides and Protein Vaccines "

Murine monoclonal antibodies have identified a variety of proteins, such as carcinoembryonic antigen (CEA) and prostate-specific antigen (PSA), that exhibit a high degree of selective expression on tumor cells and have been useful in monitoring cancer patients. Because of the selective expression of these proteins in unique organs or their overexpression in tumors, these proteins have been the subjects of study for the development of cancer vaccines. Prostate-specific membrane antigen (PSMA) is a protein found in the prostate gland and is recognized by monoclonal antibody 7E11.C5 (50,51). PSMA is present in seminal fluid, prostate epithelial cells, and low levels are found in normal male sera. By studying allele-specific motifs, two PSMA peptides called *PSMA-P1* (LLHETDSAV) and *PSMA-P2* (ALFDIESKV) were identified that exhibited high binding to HLA-A*0201. Murphy et al. reported on 51 patients with advanced hormone-resistant prostate cancer treated in a phase 1 study with these two PSMA peptides (52). Thirty of these patients were HLA-A2^{+}. Patients received between 0.2 mg and 20.0 mg of either the PSMA-P1 or PSMA-P2 peptides given intravenously or autologous dendritic cells produced *in vitro* using GM-CSF and IL-4 given either alone or pulsed with the PSMA-P1 or PSMA-P2 peptides. Between 10^6 and 2×10^7 dendritic cells were administered at 6- to 8-week intervals for four or five doses. Many of the patients in this study had advanced disease, and 39 of the 51 patients were stage D2 patients. Some impairment of cellular immunity was seen in 39 of these 51 patients based on failure to develop a standard delayed-type hypersensitivity reaction to at least one standard test antigen. In this study, and in follow-up evaluations, an increase in PSMA peptide-specific cellular reactivity was reported in some patients who received dendritic cells plus peptide (53,54). Seven of these patients were reported to have a clinical response based largely on reduction of circulating PSA levels. In more recent studies, this group has added the systemic administration of GM-CSF to the peptide immunizations.

Study of the class I HLA-A*0201 binding motifs of PSA have identified several candidate peptides for use in immunization (55,56). A 30-mer oligopeptide called *PSA-OP* encompassed two HLA-A2 binding epitopes as well as an HLA-A3 binding epitope (57). *In vitro* stimulation for six to seven cycles with this PSA-OP lead to the generation of CTL lines capable of lysing target cells pulsed with these peptides as well as a PSA-positive prostate cancer cell line. The difficulty in generating prostate cancer lines has limited the ability to test T-cell reactivity against naturally processed peptides. The description of techniques to generate prostate cancer lines using transduction with E6- and E7-expressing retroviruses has provided additional lines of value in subsequent studies of PSA (58).

Attempts are under way to identify peptides that may be useful for immunization of patients with a variety of epithelial tumors. Kawashima et al. used peptide-specific motifs to identify several CEA peptides that could give rise to CTL precursors in an HLA-A2-restricted fashion (59). Tsang et al. immunized patients with a recombinant *vaccinia virus* encoding CEA and used these postimmunization PBMCs stimulated with candidate CEA peptides to identify a nine amino-acid peptide called *CAP-1* comprised of amino acids 571 to 579 (YLSGANLNL) (60). *In vitro* immunization with this CAP-1 peptide was capable of generating T-cell lines capable of recognizing the peptide as well as an HLA-A2 CEA expressing colon cancer line. Subsequent studies demonstrated that a substitution with aspartic acid of the asparagine at position six of this peptide led to a peptide that exhibited significantly increased immunogenicity *in vitro* (61). Clinical trials using these peptides for immunization are planned.

Concluding Comments

Part of "18.3 - Peptides and Protein Vaccines "

In preliminary studies, immunization of humans with peptides in adjuvant has been surprisingly effective in generating circulating

lymphocytes with antipeptide and in some instances antitumor recognition. Except in rare cases, these antitumor immune responses have not been sufficient by themselves to mediate tumor regression, and additional manipulations to increase the avidity of the lymphocytes for tumor or to increase lymphocyte number and traffic are required. The modification of native peptides with amino acid substitutions to increase binding to MHC molecules, the systemic administration of cytokines such as IL-2, the use of improved adjuvants, and the simultaneous administration of multiple class I and class II peptides are approaches that may increase the therapeutic effectiveness of peptide immunization.

18.4

DNA Vaccines

Stephen A. White

Robert M. Conry

Introduction

Part of "18.4 - DNA Vaccines "

The term *DNA vaccination* designates a form of active immunization or immunotherapy in which antigen-specific humoral and cellular immune responses are induced by direct introduction of recombinant plasmids encoding immunogens. This process was first described in 1992 by Tang et al., who noted the elicitation of antibody responses against human growth hormone in mice after intramuscular injection of a growth hormone–expressing plasmid construct (1). Subsequently, Ulmer's group reported that inoculation of a DNA vector encoding influenza virus nucleoprotein (NP) into murine muscle generated NP-specific humoral and cytotoxic T lymphocyte (CTL) responses with resultant immunoprotection against intranasal challenge with influenza A virus (2). Since these initial reports, numerous investigators have used the direct injection of antigen-encoding plasmids to induce protective humoral and cellular immune responses against a broad range of microbial proteins and tumor-associated antigens (TAAs) in numerous animal species. Immune responses to DNA vaccines have been described after administration by needle injection into muscle, skin, spleen, and subcutaneous tissue, as well as by particle bombardment–mediated transfer into muscle, skin, and mucosa (3,4,5 and 6). Additionally, several groups have reported induction of immune responses by intranasal administration of lipid-encapsulated DNA vaccines (7,8) and by oral administration of attenuated *Salmonella* carriers transfected with antigen-encoding plasmids (9,10).

Some studies have demonstrated the ability of DNA vaccination to elicit meaningful immune responses in nonhuman primates. For example, Boyer et al. noted the generation of antigen-specific humoral and cellular immunity with resultant protection against challenge with human immunodeficiency virus 1 (HIV-1) in chimpanzees vaccinated with DNA constructs encoding HIV-1 *rev, env*, and *gag/pol* (11). This group has subsequently reported the boosting of anti-*env* antibodies and a decline in viral load in HIV-1–infected chimpanzees after immunization with an HIV-1–*env/rev* DNA vaccine (12). Liu's group has described the utilization of a DNA vaccine construct encoding influenza virus hemagglutinin (HA) in African green monkeys to elicit HA-specific humoral immune responses equal or superior to those induced by commercially available whole inactivated influenza virus vaccines (13). These findings have generated considerable interest in the application of DNA vaccination to human disease.

DNA vaccination provides several advantages over protein or peptide vaccines. First, DNA vaccines possess greater chemical stability and are more easily sequenced and purified than proteins or peptides. Second, plasmid vaccines are inherently immunogenic and generally do not require coadministration of adjuvants. Third, DNA immunization generates antigen expression within the cytosol of transfected cells, permitting direct entry of antigen to intracellular major histocompatibility complex (MHC) class I processing pathways and facilitating the induction of CTL responses. In addition, intracellular synthesis with posttranslational modification generates antigenic proteins with native tertiary structure. Finally, in preclinical studies, DNA vaccines have elicited a broad range of antigen-specific immune responses, including antibodies, lymphoproliferation, CTL activation, and delayed-type hypersensitivity (DTH). Similarly, immunization with plasmid constructs provides certain advantages over recombinant viral vaccination. First, DNA vaccines are easier to construct, produce, and control for quality than viral recombinants. Second, recombinant viral vaccines frequently evoke vector-specific immune responses that preclude their use in multidose immunization schedules. Third, DNA vaccines carry less risk of insertional mutagenesis than viral vectors, particularly retroviral recombinants. Fourth, unlike adenoviral and vaccinia recombinants, DNA vaccines are not known to downregulate MHC class I gene expression in transfected cells (14). Finally, DNA vaccines do not confer a risk of recombinational events leading to the derivation of revertant or recombinant pathogenic viruses.

This chapter describes preclinical advances in DNA vaccination and reviews applications of this form of active immunotherapy

in the prevention and treatment of human infectious disease and cancer.

Cellular Mechanisms of DNA Vaccination

Part of "18.4 - DNA Vaccines "

The cellular mechanisms responsible for T-lymphocyte activation after DNA vaccination have been partially elucidated. Antigen-specific induction of naïve T-helper cells and CTLs involves two discrete processes: antigen synthesis and MHC-restricted antigen presentation. The specific roles of bone marrow-derived antigen-presenting cells (APCs) and locally transfected nonhematopoietic cells (i.e., myocytes or keratinocytes) in these processes are discussed below.

Bone marrow-derived APCs appear to be the predominant cells involved in MHC-restricted antigen presentation after intramuscular or cutaneous DNA immunization. This contention is supported by several observations. Myocytes and keratinocytes lack cell surface costimulatory molecules (B7-1, B7-2) that promote T-cell adhesion and thereby facilitate antigen-specific T-cell induction. Antigen presentation in the absence of these ligands is thought to induce tolerance rather than immunity (15). Furthermore, *in vivo* expression of MHC class II molecules is generally limited to cells of hematopoietic origin. This fact, coupled with the efficient MHC class II-restricted induction of CD4+ T cells after DNA immunization, suggests antigen presentation by bone marrow-derived APCs. In further support of this contention, several investigators have noted the preservation of immune responses to intramuscular DNA vaccination despite excision of the inoculated muscle within 1 minute of immunization (16,17). However, the most compelling evidence of antigen presentation by bone marrow-derived cells after DNA immunization is provided by studies of murine bone marrow transplant chimeras (18,19). In these studies, DNA vaccine-induced CTL responses after intramuscular immunization were restricted to MHC haplotypes expressed by cells of hematopoietic origin.

Two hypotheses have been proposed regarding the source of antigen for bone marrow-derived APC presentation: (a) direct transduction of these APCs at the inoculation site or draining nodes, and (b) antigen synthesis within transduced myocytes or keratinocytes with subsequent transfer to bone marrow-derived APCs. The former hypothesis is supported by several lines of evidence:

1. First, the efficacy of intravenous and intrasplenic DNA vaccination suggests a myocyte- and keratinocyte-independent mechanism of antigen expression sufficient for induction of immunity.
2. Second, the preservation of immune responses to intramuscular DNA immunization despite ablation of the inoculated muscle within minutes of vaccine administration argues for plasmid transduction and antigen synthesis at distant sites. Of note, the excision of inoculated skin within 24 hours of cutaneous DNA vaccination markedly diminishes antigen-specific CTL induction (16,20). This attenuation may reflect the importance of transfected keratinocytes in immunogen expression after DNA vaccination of skin. Alternatively, this finding could be attributable to the removal of transfected, cutaneous dendritic (Langerhans') cells before their migration to regional lymph nodes.
3. Third, some studies have described the detection of plasmid DNA sequences by polymerase chain reaction (PCR) in lymph-node dendritic cells and in epidermal Langerhans' cells after intramuscular and cutaneous DNA vaccination, respectively (21).
4. Finally, the presence of green fluorescent protein (GFP) in rhodamine-positive lymph-node dendritic cells has been observed 24 hours after biolistic delivery of a GFP-encoding plasmid to rhodamine-stained murine epidermis (22). This finding suggests direct transfection of cutaneous dendritic cells with ensuing migration to regional lymph nodes. In a similar study, GFP expression was detectable in bone marrow-derived APCs in lymph nodes, peripheral blood, and the spleen after intramuscular inoculation of mice with a DNA construct encoding GFP (23). GFP signals display a diffuse pattern within the cytoplasm of positive cells consistent with intracellular synthesis, as opposed to a focal distribution that would suggest endocytic uptake of presynthesized GFP.

The second hypothesis regarding DNA vaccine immunogen expression, the synthesis of antigen within myocutaneous cells with subsequent transfer to bone marrow-derived APCs for presentation, is supported by the following observations.

1. First, numerous immunohistochemical studies have demonstrated the presence of plasmid-encoded antigens within myocytes and keratinocytes at sites of DNA immunization (24).
2. Second, some investigations have established the ability of bone marrow-derived APCs to endocytose, process, and present extracellular antigen in association with MHC class I molecules. For example, dendritic cell phagocytosis of apoptotic cells with subsequent stimulation of MHC class I restricted CTLs specific for phagocytosed antigens has been described (25).
3. Third, augmentation of antigen-specific humoral and CTL responses against human immunoglobulin G (IgG) has been reported after fusion of human IgG complementary DNA (cDNA) with cDNA encoding the APC-targeting ligand CTLA4 within a plasmid construct (26). This observation is highly suggestive of APC cross-priming with antigen presynthesized in myocytes, keratinocytes, or other cells after DNA immunization.
4. Finally, two reports have described the induction of antigen-specific CTL immunity after the transplantation of lipid-encapsulated myoblasts stably transduced with antigen-encoding plasmid (27,28). Of note, CTL responses in these studies were restricted to MHC haplotypes absent from transplanted myoblasts, further confirming the contention that antigen presentation after intramuscular DNA vaccination is a function of bone marrow-derived APCs, not myocytes.

Role of CpG Dinucleotide Motifs in DNA Vaccination

Part of "18.4 - DNA Vaccines "

One important advantage of DNA vaccines is the inherent adjuvanticity of the plasmid vector. This immunogenicity results from

the presence of unmethylated CpG-dinucleotide motifs in the six-residue nucleotide sequence 5" Purine-Purine-CpG-Pyrimidine-Pyrimidine 3" (29). CpG dinucleotides occur with a frequency of 1 per 16 base pairs in bacterial DNA versus a frequency of 1 per 50 base pairs in vertebrate DNA (30). Additionally, the incidence of cytosine methylation is much lower in prokaryotic DNA (5%) than in eukaryotic DNA (70% to 90%) (31). Thus, unmethylated CpG motifs are much more common in bacterial DNA (and in DNA from certain nonbacterial species, including yeast, nematodes, mollusks, and insects) than in mammalian genomic DNA (32,33). These immunostimulatory sequences enhance cell-mediated immunity and promote the generation of T helper 1 (Th1) immune responses by inducing macrophages, B cells, and natural killer cells to secrete interferons, tumor necrosis factor alpha (TNF-α), interleukin-6 (IL-6), IL-12, and IL-18 (29,34,35 and 36). Unmethylated CpG motifs promote the maturation and activation of dendritic cells (37). The immunomodulatory effects of plasmid DNA can be abrogated by cytosine residue methylation (38), by reversal of the central dinucleotide within immunostimulatory sequences from CpG to GpC (38), or by the removal of CpG motifs (35). Conversely, in a single report, the addition of immunostimulatory sequences to the plasmid backbone of a DNA vaccine construct has been demonstrated to enhance antigen-specific humoral and cellular immune responses without alteration in the level of antigen synthesis (35).

The immunogenic properties of plasmid DNA and of synthetic oligodeoxynucleotides (ODNs) containing CpG motifs have prompted interest in their use as vaccine adjuvants. Several investigators have reported that coadministration of irrelevant plasmid DNA with DNA vaccines reduces the minimum dose of vaccine required for the elicitation of measurable immune responses (39,40 and 41). However, the use of immunostimulatory ODNs as DNA vaccine adjuvants may be precluded by an ODN dose–dependent reduction in vaccine antigen expression (42). Numerous murine studies have demonstrated augmentation of antigen-specific Th1 immune responses to protein vaccines [e.g., hepatitis B surface antigen (43,44), hen egg lysozyme (45), influenza NP (46), and B-cell lymphoma idiotype (47)] and inactivated viral vaccines [e.g., formalin-inactivated influenza virus (48)] by codelivery of CpG-rich synthetic ODNs.

Potential mechanisms whereby plasmid DNA produces Th1-biased immunostimulation have been elucidated. APC internalization of DNA into endosomes is sequence-independent (29). After DNA uptake, sequence-dependent activation of two separate signal transduction pathways has been described. First, acidification of double-stranded DNA containing immunostimulatory nucleotide sequences induces the generation of reactive oxygen species with resultant expression of specific cellular proto-oncogenes (e.g., c-myc) and cytokines (e.g., IL-12) (49). Second, CpG-rich DNA induces the phosphorylation-mediated activation of two members of the mitogen-activated protein kinase superfamily, leading to lymphokine gene expression (50). *In vitro* studies suggest that inhibitors of endosomal acidification (e.g., quinacrine and chloroquine) block the activation of B lymphocytes and mononuclear cells by DNA-containing immunostimulatory CpG motifs (49,50,51).

Krieg et al. have reported the existence of neutralizing oligonucleotide sequences, which, if present in DNA vaccine constructs, counteract the immunostimulatory sequences (52). These neutralizing motifs, initially described in adenoviral DNA, include CpG dinucleotides in direct repeats, the nucleotide sequence 5"CpCpG3", and the nucleotide sequence 5"CpGpG3". Coadministration of synthetic ODNs containing neutralizing sequences with DNA vaccines containing immunostimulatory motifs markedly inhibits immune induction by the latter. Conversely, elimination of neutralizing sequences from the plasmid backbone of a DNA vaccine construct has been demonstrated to augment the elicitation of antigen-specific Th1 immunity.

Nucleotide sequences flanking immunostimulatory motifs within DNA vaccines may also influence the pattern of cytokine secretion elicited from immune effector cells. As noted above, CpG-rich DNA typically induces the production and release of IL-6, IL-12, and TNF-α. An 18-residue, CpG-rich nucleotide sequence derived from the murine IL-12 p40 gene has been identified that elicits IL-12 secretion without stimulation of IL-6 or TNF-α release (53).

In summary, unmethylated CpG dinucleotide motifs clearly explain many of the inherent adjuvant properties of bacterial plasmid DNA. Furthermore, synthetic ODNs containing CpG motifs appear to represent an important new class of adjuvant molecules to enhance immune responses to protein and inactivated viral vaccines. However, most plasmid DNA vectors contain many immunostimulatory CpG dinucleotide motifs by random chance. Thus, the clinical impact of engineering plasmid DNA vaccines based on the number and potency of CpG motifs remains to be determined.

Modulation of Immune Responses to DNA Vaccination

Part of "18.4 - DNA Vaccines "

The magnitude and character of immune responses to DNA vaccination are influenced by multiple factors, including the site and mode of vaccine administration, the level of expression and cellular localization of the encoded antigen, and the concurrent use of genetic and chemical adjuvants. In preclinical DNA vaccination studies, manipulation of these and other variables has altered the level and orientation of vaccine-induced immunity.

The influence of the site and technique of vaccine administration on immune responses to DNA immunization has been extensively studied in animals. In general, needle inoculation of DNA vaccines into muscle preferentially elicits Th1 immune responses characterized by enhanced CTL immunity, IgG2a antibody production, and interferon-γ (INF-γ) release (54). Biolistic vaccine delivery into skin or muscle typically induces Th2 responses with increased IgG1 antibody production and IL-4 release (6,54). The orientation of immune responses to intradermal needle DNA immunization is variable, with both Th1 and Th2 responses reported (6,54,55). These differences in immune response patterns may be secondary to Th1-biased immunostimulation associated with the high doses of plasmid DNA generally used for needle immunization. In support of this contention, Barry and Johnston noted IgG1 (Th2) humoral responses to minute doses of an α-1 antitrypsin DNA vaccine administered to mice by gene-gun cutaneous inoculation, whereas biolistic delivery of high doses (50 µg) of this construct

induced antigen-specific IgG2a (Th1) production (56). Conversely, in studies of a DNA vaccine encoding influenza virus hemagglutinin, Robinson's group reported dose-independent generation of Th1 antibody responses after needle injection and Th2 antibody responses after biolistic delivery (6).

Several groups have investigated the utilization of plasmid-encoded cytokines as molecular adjuvants for DNA vaccination. In general, coadministration of proinflammatory cytokine genes (e.g., IL-1, TNF-α, TCA3, and INF-γ) or Th1-associated cytokine genes (e.g., IL-2, IL-12, IL-15, and IL-18) with antigen-encoding DNA constructs induces enhanced CTL activity, lymphocyte proliferation, and DTH responses with variable effects on antibody production (57). For example, Xin's group noted increased IgG2a-antibody production, INF-γ secretion, CTL activity, and DTH as well as decreased IgG1 antibody production and IL-4 release after intranasal vaccination of mice with DNA constructs encoding HIV-1 antigens and IL-2 (58). Similarly, codelivery of the murine IL-12 gene with an HIV-1 DNA vaccine has been demonstrated to promote antigen-specific lymphoproliferation and CTL immunity and reduce antibody responses in mice (59). Conversely, coadministration of plasmids encoding Th2-associated cytokines (e.g., IL-4 and IL-10) with DNA vaccines typically augments overall antibody and IgG1 production, reduces IgG2a production, and diminishes CTL and DTH responses (57,60,61). Codelivery of the granulocyte-macrophage colony-stimulating factor gene with DNA constructs encoding antigens generally promotes antibody production, Th1 cytokine (e.g., IL-2) release, lymphoproliferative responses, CTL activity, and DTH (62,63,64 and 65). In two reports, enhanced antigen-specific humoral responses associated with the use of plasmid-encoded granulocyte-macrophage colony-stimulating factor entailed increases in both IgG1 and IgG2a antibody production (64,66).

The utilization of plasmid-encoded costimulatory molecules (e.g., CD80 and CD86) and APC ligands (e.g., CTLA4 and CD40 ligand) as molecular adjuvants for DNA immunization has been investigated. Codelivery of cDNA encoding an immunogen and CD86 (B7-2), either as separate plasmids or within a single bicistronic expression plasmid, is consistently associated with enhanced antigen-specific lymphoproliferative responses and CTL immunity (67,68). However, the effect of coadministration of the CD80 (B7-1) gene with DNA vaccines on T-cell responses is variable (53,67,68 and 69). Boyle's group has reported augmentation of humoral and cellular immune responses to a DNA vaccine encoding human IgG after fusion of the Ig gene to cDNA encoding the costimulatory molecule ligand CTLA4 (26). Another group used codelivery of a plasmid-encoding CD40 ligand, a stimulatory signal for CD40-bearing APCs, to enhance antigen-specific antibody and CTL responses to a DNA vaccine encoding β-galactosidase (70).

Several investigators have attempted to manipulate the cellular localization of antigens encoded by DNA vaccines and thereby influence the magnitude and character of resultant immune responses. In some reports, DNA constructs encoding antigens with secretory signals preferentially enhance antibody (especially IgG1) responses, whereas plasmids expressing nonsecreted immunogens promote CTL immunity and IgG2a humoral responses (71,72). Other groups have investigated the use of DNA constructs containing immunogen cDNA fused in frame with ubiquitin coding sequences (73,74 and 75). In these studies, antigen ubiquitinization is consistently associated with enhanced CTL immunity and abrogation of humoral responses, presumably reflecting antigen targeting for rapid proteosome-dependent degradation and subsequent MHC-restricted epitope presentation.

Other strategies for modulation of responses to DNA vaccination have been proposed and investigated. First, optimization of gene-expression regulatory elements (e.g., promoters) within plasmid constructs may upregulate antigen expression and thereby facilitate immune induction (76). Second, some studies have suggested that the sequential use of DNA vaccines and recombinant viral vaccines (e.g., fowlpox recombinants) may synergistically induce durable and protective immune responses (77,78 and 79). Third, several investigators have reported that fusion of antigen DNA sequences and cDNA encoding highly immunogenic proteins [e.g., fragment C of tetanus toxoid, hepatitis B surface antigen (HBsAg)] within DNA vaccine constructs promotes the generation of immunity against poorly immunogenic antigens (80,81). Finally, chemical adjuvants may modulate the magnitude and character of immune responses induced by DNA vaccination. For example, one report described enhanced antigen-specific IgG2a production, IL-2 and IFN-γ secretion, CTL immunity, and DTH responses to HIV-1 DNA vaccines encoding *env* and *rev* after coadministration of the anticancer immunomodulator Ubenimex into mouse muscle (82). Similar immune modulation was noted after intranasal or intramuscular administration of an HIV-1 *env* DNA vaccine with the saponin adjuvant QS-21 (83). Myolytic agents (e.g., bupivacaine and cardiotoxin), when inoculated into muscle several days before DNA vaccination, promote DNA uptake by myofiber cells and thereby increase the level of antigen synthesis within regional myocytes (84,85). However, the use of these agents as adjuvants in DNA immunization studies has not consistently augmented vaccine-induced immune responses (86).

RNA Vaccination

Part of "18.4 - DNA Vaccines "

To circumvent the risk of vaccine integration into host chromosomal DNA, our group and others have investigated the use of naked RNA constructs encoding antigenic proteins for immunization. We noted priming of an anti-carcinoembryonic antigen (CEA) antibody response in mice after multiple intramuscular injections of messenger RNA (mRNA) transcripts encoding CEA (87). Similarly, biolistic delivery of an mRNA construct encoding human α-1 antitrypsin into mouse epidermis elicited antigen-specific humoral immunity (88). Direct injection of mRNA transcripts is generally associated with a low level and brief duration of transgene expression, an advantageous characteristic for vaccines encoding transformation-associated oncoproteins (e.g., erb-B2). However, such limited antigen expression is frequently inadequate for the induction of immune responses.

To enhance the level and duration of transgene expression from naked RNA vaccine constructs, several investigators have incorporated antigen-encoding sequences into self-replicative vector RNA derived from alphavirus, including Sindbis virus and Semliki Forest virus. The alphavirus genome consists of a

positive-polarity, single-stranded RNA molecule containing coding regions for viral replicase and transcriptase and structural proteins, including basic capsid protein (89). After alphavirus infection of susceptible cells, this genomic RNA serves as a template for translation (by host ribosomal complexes) of viral proteins. Nascent viral transcriptase then uses genomic RNA to synthesize full-length minus-strand RNA, which provides a template for the production of multiple genome-length positive-polarity RNA molecules and subgenomic-positive strand transcripts encoding structural proteins. Our group and others have replaced structural genes from alphavirus genomic RNA with heterologous coding sequences to derive self-replicative, packaging-defective RNA species. We used Sindbis virus RNA to produce a self-replicative transcript encoding luciferase (90). Injection of this construct into mouse muscle generated markedly increased and prolonged reporter-gene expression relative to that obtained with nonreplicative transcripts. The efficiency of heterologous gene expression from alphavirus-based recombinant RNA may be further augmented by the retention within chimeric RNA of a translational enhancer located near the beginning of the open reading frame of basic capsid protein (91).

Several investigators have conducted murine vaccination studies using alphavirus-based constructs with heterologous antigen-encoding sequences. For example, intramuscular injection of recombinant Semliki Forest virus genomic RNA encoding influenza virus HA induced seroconversion against HA and protected against intranasal challenge with influenza virus (92). Other groups have attempted to combine the advantages of DNA vaccines (e.g., stability and ease of production) with the enhanced gene expression of alphavirus-based replicons by the production of plasmid constructs driving expression of self-replicative, antigen-encoding transcripts. Intramuscular injection of a DNA vaccine encoding a Sindbis virus–based replicon containing coding sequences for herpes simplex virus, glycoprotein B elicited, antigen-specific, humoral and cellular immune responses in mice (93). This was a highly efficient vector, requiring 100- to 1,000-fold lower doses of plasmid to induce immunity, as compared to a conventional DNA vaccine encoding the same antigen. This efficiency presumably reflects enhanced transgene expression due to cytoplasmic amplification of self-replicative RNA transcripts.

Preclinical Studies of Antitumor DNA Vaccination

Part of "18.4 - DNA Vaccines "

Several investigators have reported the generation of antigen-specific humoral and cellular immune responses and the rejection of tumor transplants in animals vaccinated with DNA constructs encoding TAAs. Examples of these studies are provided in Table 18.4-1, and our preclinical experience with DNA vaccines encoding CEA is outlined in Table 18.4-2 . In preparation for a phase 1 trial of DNA vaccination against CEA in patients with colorectal carcinoma, we immunized a group of pig-tailed macaques with a single plasmid-encoding CEA and HBsAg by repetitive intramuscular injections (98). Lymphoproliferative and antibody responses to CEA and HBsAg were not consistently observed until 4 months after primary immunization, suggesting the need for a protracted immunization schedule in human trials of DNA vaccines.

Table 18.4-1 Preclinical Trials of DNA Vaccines Encoding Tumor Antigens

Tumor Antigen	Associated Human Cancers	Animal Models	Route	Immune Responses	References
Her-2/*neu*	Breast, ovarian, gastric	Mouse	i.m.	Ab, TP	94,95

Ab, antibody; DTH, delayed-type hypersensitivity; g.g., gene gun (skin); i.s., intrasplenic; LP, lymphoproliferation; ND, not done; TP, tumor protection; +, immune response or protection against tumor challenge; -, absence of immune response or tumor protection.

We have investigated the efficacy of intrasplenic administration of a DNA vaccine encoding CEA (pCEA) (4). In this study, several groups, each containing 15 mice, were immunized with 50-µg doses of pCEA by intrasplenic or intramuscular injection. Six weeks later, sera were collected followed by subcutaneous challenge with syngeneic, CEA-expressing colon carcinoma cells. Intrasplenic administration of pCEA induced anti-CEA antibody responses at a frequency comparable to the intramuscular route. Anti-CEA IgG antibodies were observed in 73% (11 of 15) and 53% (8 of 15) of mice receiving 50-µg doses of pCEA by intrasplenic or intramuscular injection, respectively. Both intrasplenic and intramuscular administration of pCEA elicited CEA-specific IgG1, IgG2a, and IgG2b antibody responses, an isotype pattern consistent with the activation of T helper 1 cells. Additionally, partial immunoprotection against tumor challenge occurred with comparable frequency after either route of immunization. No anti-CEA antibodies or tumor-free survival occurred after intrasplenic or intramuscular injections of a control plasmid lacking CEA coding sequences.

Two antitumor DNA vaccine studies have reported induction of immune responses against tumor-associated self-antigens in animals. First, a DNA construct encoding the human small-cell carcinoma antigen HuD elicited anti-Hu humoral immunity in mice (100). Sera from vaccinated animals were reactive with murine neuron Hu antigens *in vitro*, but seroconversion was not associated with the development of neuropathologic changes. Additionally, immunization with plasmid-encoded human HuD conferred immunoprotection against challenge with syngeneic neuroblastoma cells constitutively expressing native mouse HuD. A second report described the induction of tyrosinase-related protein 1 (TRP-1)-specific autoantibodies with consequent coat depigmentation after the immunization of mice with a plasmid construct encoding homologous human TRP-1 (110). Vaccination with this construct also provided protection against challenge with a syngeneic melanoma cell line expressing native mouse TRP-1. Of note, immunization with a DNA vaccine encoding syngeneic murine TRP-1 produced neither seroconversion against TRP-1 nor tumor protection. Two additional murine studies have described the use of DNA vaccines to break tolerance to self-antigens. One group has noted the induction of anti-HBsAg antibodies in HBsAg-transgenic mice after intramuscular administration of a plasmid encoding HBsAg. Immune response to this vaccine was accompanied by loss of circulating antigen and complete disappearance of hepatitis B virus (HBV) mRNA in the liver (112). In another report, vaccination of mice with DNA encoding the human thyrotropin receptor induced a humoral response against this antigen and produced histologic evidence of murine thyroiditis (113). Collectively, these observations support the use of DNA vaccine constructs encoding TAA homologues from other species to break tolerance to tumor-associated self-antigens in humans.

Safety Considerations in DNA Vaccination

Part of "18.4 - DNA Vaccines "

Potential adverse effects associated with the use of DNA vaccines in the management of human cancer include the elicitation of anti-DNA autoantibodies with resultant induction or exacerbation of systemic autoimmune disease, integration of plasmid into host genomic DNA with consequent insertional mutagenesis, induction of deleterious host immune responses against plasmid-transfected tissues, and provocation of immune responses against host tissues expressing proteins homologous to vaccine-encoded antigens.

The risk of induction or acceleration of systemic autoimmune disease by DNA vaccines has been extensively evaluated in murine studies. For example, multiple intramuscular injections of a plasmid-DNA construct into normal mice was associated with a threefold increase in the number of splenic B cells secreting IgG with anti-DNA specificity and an associated modest increase in serum anti-DNA antibody levels (114). This serologic response was not accompanied by the development of proteinuria or other clinical findings suggestive of glomerulonephritis or systemic autoimmune disease. In subsequent studies, DNA vaccination of lupus-prone mice neither accelerated the development of anti-DNA antibodies nor altered the age of onset or severity of glomerulonephritis (114). Several investigators have reported the induction of anti-DNA antibodies in mice by the administration of bacterial DNA complexed to a charged carrier protein with adjuvant (115,116). Inoculation of *Escherichia coli* DNA complexed to methylated bovine serum albumin in complete Freund's adjuvant into the peritonei of lupus-prone mice accelerated the development of anti-DNA antibodies but appeared to attenuate the clinical manifestations of systemic lupus erythematosus (117). Inoculated mice displayed less proteinuria, less histologic evidence of glomerulonephritis, and a longer life span than controls. Moreover, administration of protein-complexed bacterial DNA in adjuvant to lupus-prone mice after the spontaneous development of DNA autoantibodies stabilized nephritis and prolonged survival (117). These murine studies collectively suggest that the use of DNA vaccines may result in the elicitation of anti-DNA antibodies but is unlikely to induce or accelerate systemic autoimmune disease. This contention is supported by reports describing the presence of anti-DNA antibodies in sera from normal human subjects that target nonconserved epitopes on bacterial DNA, presumably reflecting exposure to bacterial DNA in the setting of colonization or infection (118). These antibodies lack cross-reactivity with host DNA, and their detection does not correlate with the presence or subsequent development of autoimmune disease. Several phase 1 clinical trials of DNA vaccines have specifically looked for development of anti-DNA antibodies but none have been detected (119,120,121 and 122).

Potential mechanisms whereby a DNA vaccine could integrate into host chromosomal DNA include homologous recombination and random insertion. Integration by these means

could be tumorigenic by virtue of host proto-oncogene activation or disruption of expression of a host tumor suppressor gene. Additionally, chromosomal integration of a DNA vaccine encoding a transformation-associated oncoprotein (e.g., erb-B2) could induce cellular transformation independent of the site of plasmid insertion. The risk of DNA vaccine integration to host genomic DNA by homologous recombination is low given the lack of sequence homology between bacterial and mammalian DNA, as well as the general absence of chromosomal replication and cell division in cells transfected with DNA vaccine reagents. Two lines of evidence suggest that the risk of insertional mutagenesis secondary to random plasmid integration is similarly small. First, widespread clinical use of live replicating DNA virus vaccines (e.g., vaccinia) has not been associated with tumorigenesis. Second, PCR-based studies of myocytes transfected with DNA vaccine constructs have suggested an absence of plasmid integration into host chromosomal DNA. In one of these investigations, inoculated mouse quadriceps were harvested at various time points after injection of a large dose of a DNA vaccine (123). After whole DNA extraction, high-molecular-weight host chromosomal DNA was separated from nonintegrated vaccine DNA by agarose gel electrophoresis. Isolated host genomic DNA was then evaluated for the presence of integrated plasmid by PCR using plasmid-specific primers. No plasmid integration was demonstrable at a sensitivity of 1.0 to 7.5 copies of integrated plasmid per 150,000 cell nuclei. Based on these observations, the authors of this study estimate that the risk of insertional mutagenesis of a given gene secondary to random DNA vaccine integration is at least three orders of magnitude lower than the rate of spontaneous mutation. Although the risk of host chromosomal integration appears to be low, some investigators have proposed the inclusion of apoptotic signals within DNA vaccine constructs intended for human use to circumvent any potential risk of plasmid-mediated oncogenesis (124).

A third theoretical adverse effect of DNA vaccination is the provocation of destructive immune responses against plasmid-transfected cells, which has not been reported in preclinical DNA immunization studies. Klinman's group noted no increase in serum antibodies reactive with myosin and no evidence of muscle inflammation following multiple intramuscular DNA immunizations of adult mice (114). Similarly, intradermal and epidermal delivery of DNA vaccines have not been associated with the development of dermatitis. Several phase 1 clinical trials of DNA vaccines have reported the absence of serologic or clinical evidence of myositis despite successful elicitation of immune responses to plasmid-encoded antigens (119,120,121 and 122). Absence of local immunologic sequelae may reflect the relative inefficiency of target-cell transduction by DNA vaccines. Immunohistochemical studies suggest that generally less than 1% of regional myocytes are transfected by intramuscular DNA vaccines (86). Thus, immune-mediated destruction of transfected cells would likely be a subclinical event.

The potential destruction of host tissues expressing proteins identical or homologous to plasmid-encoded antigens is of particular concern with the use of DNA vaccines encoding tumor-associated self-antigens. To investigate this possibility, we administered a DNA vaccine construct encoding human CEA to macaques, a primate species with low-level expression of human CEA homologues on intestinal mucosal cells and neutrophils (CD66) (98). In this study, we noted frequent anti-CEA immune responses among immunized animals without generation of autoimmune colitis or neutropenia. However, as noted in the section Preclinical Studies of Antitumor DNA Vaccination, immunization of mice with a DNA vaccine encoding human TRP-1-elicited antibodies that cross-reacted with the native mouse homologue resulting in autoimmune coat depigmentation (110). If immunologic tolerance to tumor-associated self-antigens can be broken in humans by DNA vaccines, the likelihood and clinical relevance of the resultant autoimmune toxicity depends on several factors, including the expression level and tissue distribution of the antigen as well as the magnitude and character of the vaccine-induced immune response.

Clinical Trials of DNA Vaccines in Infectious Diseases

Part of "18.4 - DNA Vaccines "

Since 1996, phase 1 clinical trials have been conducted with DNA vaccines directed against a variety of viral pathogens and malaria, an intracellular parasitic infection. These trials are summarized in Table 18.4-3 . Only a few DNA vaccine clinical trials have reached phase 2, and no large-scale phase 3 trial has yet begun. Although the safety database is still accumulating, the data obtained from vaccinating approximately 400 human subjects indicate that plasmid DNA vaccination is safe and well tolerated. Clinical trials to date have reported minimal local toxicity consisting of occasional injection-site erythema or tenderness (135). No systemic toxicity has been reported, including no laboratory abnormalities (119,121,125,127,128 and 129). Specifically, no anti-DNA antibodies or muscle enzyme elevations have been reported (119,121,125).

Ab, antibody response; AVEG, AIDS Vaccine Evaluation Group; CEA, carcinoembryonic antigen; CTCL, cutaneous T-cell lymphoma; CTL, cytotoxic T lymphocyte; CR, clinical antitumor response; HBsAg, hepatitis B surface antigen; HIV, human immunodeficiency virus; HSV, herpes simplex virus; LP, lymphoproliferative response; NA, not available; NIH, National Institutes of Health; PfCSP, *Plasmodium falciparum* circumsporozoite protein; TCR, T-cell receptor; Web site, http://dnavaccine.com/.

One of the first DNA vaccine clinical trials to be reported involved immunization of 15 asymptomatic HIV-infected patients with a DNA plasmid containing HIV *env* and *rev* genes (119,120). Successive groups received three intramuscular injections of vaccine (30, 100, or 300 μg) at 10-week intervals in a dose-escalation trial. CD4/CD8-lymphocyte levels and plasma HIV concentration remained relatively unchanged throughout the study. Antibody against the *env* gene product (gp120) increased modestly in a minority of patients in the 100 μg and 300 μg groups, though no consistent effect on cellular responses to HIV was noted (57,119,120). Interpretation of humoral and cellular immune response data was hampered by significant preexisting immunity in these HIV-infected individuals.

In a second clinical trial, nine asymptomatic HIV-infected patients were immunized with one of three DNA constructs encoding the *nef, rev,* or *tat* regulatory genes of HIV-1 (125). Groups of three patients received 100-μg doses of a single DNA construct by intramuscular injection on days 0, 60, and 180. DNA vaccination induced antigen-specific lymphoproliferative and CTL responses. CTLs were MHC class I restricted and primarily CD8 positive (125). More recently, more than 80 HIV seronegative volunteers have been enrolled in clinical trials testing both *env/rev* and *gag/pol* DNA vaccines (121,126,127,130,131,132,133,134 and 135).

One such trial evaluated intramuscular delivery of a DNA vaccine encoding HIV *gag/pol* at 0, 1, 2, and 6 months in 39 healthy subjects (121). The vaccine dose was escalated from 100 to 1,000 μg of DNA. Vaccine-induced lymphoproliferative responses to *gag* occurred. However, no antibody responses were observed to *gag* or *pol*, and only rare CTL responses were induced with plasmid DNA doses up to 1 mg. Knowledgeable sources have expressed doubt that the first generation HIV DNA vaccines, as currently designed, can induce significant CTL responses in uninfected human volunteers (127).

In the largest DNA vaccine trial reported to date, 219 healthy volunteers were randomized to receive up to three doses of a plasmid-encoding influenza hemagglutinin or placebo (129). Doses ranged from 1 to 500 μg of plasmid DNA administered intramuscularly. Virus-neutralizing and hemagglutination-inhibiting antibodies were observed in a minority of subjects. However, the immunogenicity of this first-generation vaccine appears to have been somewhat disappointing.

More encouraging results have emerged from the initial clinical trial of a DNA vaccine against malaria. Twenty healthy malaria-naive adults were randomized into four dosage groups to receive three intramuscular injections of 20, 100, 500, or 2,500 μg of plasmid DNA encoding the *Plasmodium falciparum* circumsporozoite protein (130). Vaccinees developed antigen-specific, CD8+ CTLs restricted by multiple HLA alleles. Immunization with either 500 or 2,500 μg of DNA induced significantly better CTL responses in comparison with either 20 or 100 μg of DNA. Furthermore, a significantly higher frequency of CTL response was induced with 2,500 μg of DNA in comparison to 500 μg of DNA after the second immunization. This trial represents the first demonstration in healthy naive humans of the induction of CD8+ CTLs by a DNA vaccine, providing a foundation for further human testing of this potentially revolutionary vaccine technology (130).

Encouraging results have also emerged from the first clinical trial of a DNA vaccine administered by cutaneous particle bombardment. Twelve healthy naive volunteers received a prime and two boosts of a DNA vaccine encoding the surface antigen of HBV adhered to gold particles and delivered by the Dermal PowderJect System (PowderJect Pharmaceuticals, Madison, WI). Interim analysis showed that all 11 subjects completing the vaccination schedule seroconverted to antibody levels, which are accepted as conferring protection against HBV. Thus, early clinical trials of DNA vaccines against infectious pathogens have provided mixed results. Trials conducted in HIV-infected individuals have been difficult to interpret due to preexisting immunity; and trials of HIV and influenza DNA vaccines in healthy volunteers have been somewhat lackluster. However, DNA vaccine trials against malaria and HBV have provided unequivocal evidence for the induction of antigen-specific CTL and antibody responses, respectively.

Clinical Trials of DNA Vaccines for Cancer Therapy

Part of "18.4 - DNA Vaccines "

Our group at the University of Alabama at Birmingham has completed a dose-escalation clinical trial of a dual-expression plasmid encoding CEA and HBsAg in 17 patients with metastatic colorectal carcinoma (122,131). This represents the first completed clinical trial of a DNA vaccine in patients with cancer. The HBsAg cDNA was included as a positive control for immune response to the DNA vaccine without relying on breaking immunologic tolerance to the tumor-associated self-antigen, CEA. Groups of three patients each received the DNA vaccine by intramuscular injection at 3-week intervals in a dose-escalation format as follows: group one, 100-μg single dose; group two, 300-μg single dose; group three, 1-mg single dose; group four, 300 μg × three doses; group five, 1 mg × three doses; and group six, 2 mg × three doses. No significant toxicity occurred, including no autoimmune toxicity (122). All five patients receiving repetitive 1- to 2-mg doses of the DNA vaccine seroconverted to antibodies against HBsAg, and three of these five patients achieved antibody levels that are accepted as

conferring protection against HBV (Fig. 18.4-1). Antibody responses to HBsAg occurred less frequently at lower doses and among patients receiving only a single vaccination. Notably, anti-HBsAg seroconversion was achieved within 9 weeks after primary immunization, a constraint imposed by vaccination of patients with limited life expectancy due to metastatic colorectal carcinoma. We have previously reported immunization of three pig-tailed macaques by intramuscular injection of the same DNA vaccine (98). Only one of three animals developed anti-HBsAg antibodies within 19 weeks after primary immunization, whereas all three seroconverted to protective levels of antibody by week 28. Thus, a more protracted vaccination schedule may increase the frequency of seroconversion to protective levels of anti-HBsAg antibodies, particularly when lower doses of DNA are used. No anti-CEA antibodies or lymphoproliferative response to CEA or HBsAg occurred. Analysis of CTL response to CEA and HBsAg is ongoing.
FIGURE 18.4-1. Antibody response to hepatitis B surface antigen (HBsAg) after intramuscular DNA vaccination. Colorectal carcinoma patients received three repetitive doses of a DNA vaccine encoding both carcinoembryonic antigen and HBsAg at 3-week intervals in a dose-escalation trial. Anti-HBsAg antibodies were quantitated by commercial enzyme-linked immunosorbent assay (Abbott Laboratories, Abbott Park, IL). Prevaccination values were zero for all patients, and the dashed line at 10 mIU per mL indicates the accepted threshold conferring protection against hepatitis B virus.

Additional phase 1 and phase 2 trials of DNA vaccines for cancer therapy are summarized in Table 18.4-3 . A trial initiated in 1997 at the University of Pennsylvania is evaluating a DNA vaccine encoding the idiotypic T-cell receptor VΒ in patients with CTL (106,128). Similarly, a British trial initiated in 1998 is examining a DNA vaccine encoding a fusion protein consisting of fragment C of tetanus toxin and a tumor-derived single-chain idiotypic antibody-variable region in patients with B-cell lymphoma in first remission (80). Phase 1 and phase 2 trials of DNA vaccines are also ongoing in patients with prostate cancer, renal cell carcinoma, and melanoma (135).

The first clinical trial of a plasmid DNA vaccine in patients with melanoma was conducted at the University of Michigan in the early 1990s (132,133 and 134). In this trial, five HLA-B7-negative patients with metastatic melanoma and subcutaneous tumor nodules received intralesional injections of a plasmid DNA vaccine encoding a foreign human MHC class I gene, HLA-B7, complexed with liposomes (134). This strategy was designed to enhance the immunogenicity of tumor cells through immune activation by the foreign MHC antigen. Recombinant HLA-B7 protein was demonstrated in tumor biopsy tissue from all five patients, and circulating tumor-specific CTLs were detected in three of five patients after vaccination. One patient demonstrated regression of injected nodules and regression at distant sites. No harmful side effects occurred. More recently, the Surgical Oncology Branch of the National Cancer Institute initiated a trial of a DNA vaccine encoding gp100 in patients with metastatic melanoma in late 1988. Approximately 24 patients have received 1 mg of plasmid DNA by intramuscular or intradermal needle injection every 4 weeks for four doses with or without systemic IL-2. One partial clinical response is ongoing, as is the analysis of immune response to gp100 immunodominant peptides (James Yang, *personal communication*, 1999).

Our group at the University of Alabama at Birmingham is conducting a phase 1 dose-escalation trial of a DNA vaccine encoding MART-1, melanoma antigen recognized by T cells-1, in patients with resected melanoma at significant risk for relapse. A separate DNA vaccine encoding HBsAg is administered into the contralateral deltoid as a positive control for immune response. Because this trial is in the adjuvant setting, we have selected a more protracted vaccination schedule consisting of DNA vaccine injections (100, 300, or 1,000 μg of each plasmid) every 6 weeks for four doses.

In summary, a trial in a small number of patients has demonstrated the ability of plasmid DNA complexed with liposomes to direct expression of a foreign MHC antigen within subcutaneous melanoma nodules with resultant tumor-specific immune responses. Our phase 1 trial in colorectal cancer has not yet demonstrated immune responses to the tumor-associated antigen. However, protective levels of anti-HBsAg antibodies were induced in the majority of patients receiving repetitive 1- to 2-mg doses of DNA vaccine. This information, together with the phase 1 malaria DNA vaccine trial (130), suggests enhanced frequency and magnitude of immune responses to DNA vaccines when 1.0- to 2.5-mg doses are used in humans. Furthermore, data from our group and others in nonhuman primate models suggest that a protracted vaccination schedule over 4 to 6 months may enhance the immune response to DNA vaccines. Otherwise, clinical trials of DNA vaccines have been initiated in a wide range of malignancies; whether this new technology represents hope or hype for patients with cancer remains to be seen.

Conclusion

Part of "18.4 - DNA Vaccines "

Data obtained from first-generation clinical trials indicate that DNA vaccination is safe and well tolerated. DNA vaccine clinical trials have also unequivocally elicited antigen-specific CTL and antibody responses against malaria and HBV, respectively. Furthermore, humoral and cellular immune responses against TAAs have been induced in numerous preclinical models with resultant antitumor effects. This has led to the initiation of clinical DNA vaccine trials in six human malignancies. Second-generation clinical trials examine exciting augmentation strategies

for preferential induction of Th1 and CTL immunity. The next half-decade promises to provide much insight into the clinical utility of this revolutionary vaccine technology in the fields of infectious disease and cancer.

Poxvirus Family

Part of "18.5 - Recombinant Poxvirus Vaccines "

Poxviruses are not strangers to the world of vaccines. In 1796, Edward Jenner administered the first vaccine containing a cowpox virus, which subsequently demonstrated resistance to smallpox (variola) infection. This milestone eventually led to the worldwide eradication of smallpox, a disease that had plagued humankind for thousands of years. To date, vaccinia virus has been administered to more than 1 billion people. The last endemic case of smallpox occurred in 1977 (1).

The *Poxviridae* family consists of two major genera of large DNA viruses that are being used in cancer vaccine development. The *Orthopoxvirus* group includes the replication-competent vaccinia virus, originally derived from cowpox, and the replication-defective modified vaccinia virus Ankara (MVA). The *Avipoxvirus* group consists of fowlpox and canarypox (ALVAC); both are replication-defective. Excellent review articles have been written on poxviruses and on the use of genetically engineered poxviruses (1,2,3,4 and 5).

Potential Advantages and Disadvantages of Recombinant Poxvirus Vaccines

Part of "18.5 - Recombinant Poxvirus Vaccines "

Recombinant poxviruses have been used in a wide range of vaccines in experimental and clinical studies. Most of these vaccines have been directed against viral antigens such as rabies and human immunodeficiency virus (HIV) (6,7,8,9,10 and 11). Thus, both rodent models and clinical studies have revealed many of the advantages and disadvantages of recombinant poxvirus vectors.

Vaccination with a live recombinant vaccinia (rV) virus allows expression of foreign antigens encoded by a transgene directly in various cells of the host, including professional antigen-presenting cells (APCs). This method of vaccination enables antigen processing and presentation of antigenic peptides along with host histocompatibility antigens and other necessary cofactors found on the APC. These foreign antigens are presented to the immune system with the large number of proteins produced by the vector itself, which likely is responsible for the significant inflammatory response to the poxvirus vector. In turn, this inflammatory process could lead to an environment of cytokine production and T-cell proliferation, which may act to further amplify the immune response to the foreign antigen. This process favors induction of a cell-mediated immune response and humoral responses to the foreign antigen. Because vaccinia actively replicates in the host, it can present high levels of antigen to the immune system over a period of 1 to 2 weeks, substantially increasing the potential for immune stimulation. The immune response to the vaccinia vector then eliminates the virus.

Thus, one of the main advantages of using rV viruses to develop cancer vaccines is that when a gene for a weakly immunogenic protein is inserted into rV and used as an immunogen, the expressed recombinant protein is much more immunogenic as a vaccine than the use of that protein with adjuvant (12,13 and 14).

A striking example of this is seen in Figure 18.5-1, which shows that two injections of carcinoembryonic antigen (CEA) protein in adjuvant generated little, if any, of an immune response to CEA in a CEA-transgenic mouse. This would be expected because the host is seeing CEA as a self-antigen. However, when the rV virus containing the CEA transgene (designated rV-CEA) is administered one or two times, a strong CEA-specific T-cell response is elicited (13). The likely reason for this is that a strong inflammatory response is generated by the host against vaccinia proteins, which leads to an environment of cytokine production and T-cell proliferation. Although this situation is excellent for inducing immune responses to bystander transgene products, this same phenomenon leads to a limitation in the use of rV vectors. After one or two administrations of rV, the host mounts potent antivaccinia antibody and T-cell responses (15,16). This leads to a reduction in the ability of vaccinia to replicate in subsequent booster vaccines and, hence, to limited transgene expression. However, some clinical studies have shown that the administration of one or two vaccinations of an rV virus can elicit T-cell responses to the inserted transgene even in patients who previously received the smallpox vaccine (17,18). Several experimental studies and some clinical studies have demonstrated that rV viruses are best used for priming the immune response (19,20,21 and 22). Subsequent vaccinations can use proteins, peptides, or replication-defective poxviruses, as well as other recombinant vectors (19,20,21,22,23,24 and 25).
FIGURE 18.5-1. Carcinoembryonic antigen (CEA)–specific splenic $CD4^+$ proliferative responses from CEA. Tg mice vaccinated with rV-CEA (1 to 2×) or CEA protein. CEA.Tg mice (H-2D) (2 to 3/group) were administered 10^7 plaque-forming units rV-CEA 1× (open triangles) or 2× (closed triangles) by tail scarification. Another group of CEA.Tg mice (4/group) was administered 100 µg CEA in 100 µL adjuvant (R7BT Superdetox) by tail scarification (solid circles). Fourteen days later, mice were sacrificed, splenic T cells were isolated, and the proliferative responses to soluble CEA were measured by a T-cell lymphoproliferative assay. The assay included splenic T cells, isolated and purified from the different groups of immune CEA.Tg mice, that were co-cultured with irradiated (2,000 rad) syngeneic CEA.Tg mouse splenocytes and soluble CEA (100–3.125 µg/mL). Proliferation was measured by ^{3}H-thymidine incorporation after 5 days of incubation at 37°C. Stimulation indices were calculated as follows: [cpm (antigen-stimulated cells)]/[cpm (unstimulated cells)]. Stimulation indices of splenic T cells isolated from untreated and control vaccinia virus (Wyeth)–vaccinated mice were approximately 1.0.

MVA is a replication-defective poxvirus derived from vaccinia after 500 passages in chicken embryo cells. It has been used in many experimental studies and has been administered to more than 120,000 humans without apparent side effects (1). This virus has been molecularly characterized and has been found to have lost several genes involved in host-range determination and possible immune system suppression. Although MVA efficiently infects human cells and expresses both early and late genes, it is replication-defective and incapable of producing infectious progeny in mammalian cells. MVA-recombinant viruses have been shown to be highly immunogenic in both rodents and primates. To date, only a few experimental studies have used recombinant MVA as anticancer vaccines (26,27).

The avipoxviruses represent potentially attractive vectors for use in cancer vaccines. Although the immunogenicity of the inserted transgene may not be as potent as that of vaccinia virus, avipoxviruses such as fowlpox and canarypox can be administered numerous times to enhance immunogenicity (6,19,28). Because they are replication-defective, induction of any host immune responses should be inconsequential. Avipoxviruses are also distinguished from vaccinia in that the inserted transgene is expressed in infected cells for 14 to 21 days before the death of the cell. In a vaccinia-infected cell, the transgene is expressed for 1 to 2 days until cell lysis, and for approximately 1 week in the host until virus replication is arrested by host immune responses.

One of the advantages in using recombinant poxviruses as anticancer vaccines is the ability to insert large amounts of foreign DNA and multiple genes. To date, as many as seven genes have been inserted into vaccinia virus (29). Generally, poxvirus-based vaccines have been shown to be cost-effective, safe, easy to administer, and stable for long periods without special storage conditions. Other advantages include the following:

1. A wide host and cell-type range
2. Stability
3. Accurate replication
4. Efficient posttranslational processing of the inserted transgene
5. The tendency of recombinant gene products to be more immunogenic

Recombinant poxviruses can be used in several modalities in the development of cancer vaccines. The first modality involves the insertion of one or more tumor-associated antigen (TAA) genes into the vector, which can then be administered as conventional vaccine subcutaneously, by skin scarification, intramuscularly or, potentially, by the intravenous route. In addition to containing one or more TAAs, a recombinant poxvirus vector can also contain one or more costimulatory molecule genes or cytokine genes. Recombinant poxviruses can also be injected directly into the tumor containing TAA, cytokine, chemokine, or T-cell costimulatory genes. Another application of the use of recombinant poxviruses as anticancer vaccines is the infection *in vitro* of tumor cells that can subsequently be x-irradiated and administered to patients. It has also been demonstrated that one can infect professional APCs, such as dendritic cells, with

recombinant poxviruses containing either tumor-antigen genes or costimulatory genes to sensitize tumor antigen-specific T lymphocytes *in vitro* (30,31).

Experimental Studies

Part of "18.5 - Recombinant Poxvirus Vaccines "

The unique biologic properties of recombinant poxviruses have enabled development of two related strategies for designing cancer vaccines capable of inducing antitumor immunity. In an antigen-specific approach, one or more TAA-encoding genes that are associated with a certain cancer and that are known to elicit or are suspected of invoking immune responses in cancer patients are specifically engineered into the vector. The intent of this approach is to present these selected antigens to the immune system in a manner capable of inducing tumor-specific cellular responses.

Diversified Prime and Boost Protocols

A number of investigators have demonstrated the advantage of priming with vaccinia recombinants and boosting with immunogens such as recombinant protein, peptide, DNA, or recombinant avipoxvirus vectors to enhance immune responses in cancer vaccine models (19,20,23,32). The experimental studies that involved priming with rV and boosting with recombinant avipoxvirus also demonstrated that the host immune response to the transgene increased with continued booster vaccinations (19).

Delivery of Cytokines

Several studies have shown that recombinant poxviruses can efficiently deliver a wide range of cytokines and chemokines via traditional vaccination and tumor cell infection (33,34,35,36,37 and 38). Interleukin-12 (IL-12) has been expressed by rV virus and Avipoxviruses and found to be effective in the generation of antitumor immunity in two animal models (33,34 and 35). Additionally, the use of granulocyte-macrophage colony-stimulating factor (GM-CSF) as the transgene in tumors, which are used as a vaccine, has demonstrated that these modified tumor cells can enhance antitumor activity in several models (37,38 and 39).

Delivery of Costimulatory Molecules

T-cell activation has been shown to require at least two signals. The first signal is antigen-specific, is delivered through the T-cell receptor via the peptide/major histocompatibility complex, and causes the T cell to enter the cell cycle. The second, costimulatory signal is required for cytokine production and proliferation, and is mediated through ligand interaction on the surface of the T cell. Several molecules normally found on the surface of professional APC have been shown to be capable of providing the second signal critical for T-cell activation. These molecules include B7-1 (CD80), B7-2 (CD86), intercellular adhesion molecule-1 (ICAM-1, CD54), and leukocyte function–associated antigen-3 (LFA-3, human CD58/murine CD48) (40). Each of these molecules has been inserted into poxvirus vectors, and each has been shown to efficiently mediate T-cell costimulation (40). Initial studies involved the use of B7-1 inserted into rV-B7-1 that was admixed before vaccination with rV-CEA (41). Although the single administration of rV-CEA inhibited tumor development to some extent, a more dramatic antitumor effect and CEA-specific T-cell response was seen when using the admixture. The power of the use of admixtures for replication-competent viruses, such as vaccinia, was also demonstrated in a tumor therapy model. In these studies, the admixture of rV-B7-1 and rV-MUC-1, when compared to the use of rV-MUC-1 alone, was shown to be extremely efficient in eliminating experimental lung metastases expressing the MUC-1 tumor antigen (42). Some studies have demonstrated that as long as the plaque-forming unit (pfu) levels in the admixture are sufficient to coinfect cells with both recombinants and the appropriate route is used, this methodology is just as efficient as using a vector containing both the tumor-antigen gene and the costimulatory molecule gene (43). Studies have also revealed enhanced antitumor effects using rV-B7-1, rV-B7-2, rV-ICAM-1, rV-LFA-3, and rV-CD70 in anticancer vaccines (44,45,46 and 47). The use of a costimulatory molecule and a TAA in replication-defective viruses most likely requires that both genes be in the same vector to guarantee coexpression of the TAA and costimulatory molecule on the same cell (40).

One of the major advantages in the use of recombinant poxvirus vaccines is the ability to insert multiple transgenes. Using retroviral vector infection of tumor cells and multiple drug selections, it has been shown that the insertion of two costimulatory molecule genes into tumors can produce additive or synergistic activation of T cells (48,49,50 and 51). Newly designed and developed poxvirus constructs are capable of expressing a *tri*ad of *co*stimulatory *m*olecules (B7-1, ICAM-1, and LFA-3, designated TRICOM) (40). Within 5 hours of infection, tumor cells infected with either recombinant fowlpox (rF)-TRICOM or rV-TRICOM were shown to express all three costimulatory molecules on the cell surface. Using Concanavalin A as a generic signal 1, a panel of tumor cells was created that expressed each of the three costimulatory molecules alone and together (as the TRICOM construct) to provide costimulatory signals. Both CD4$^+$ and CD8$^+$ T cells were isolated, and their ability to be stimulated was analyzed. The stratification of stimulator cell effects on proliferation was similar for both CD4$^+$ and CD8$^+$ T cells (Fig. 18.5-2). As can be seen, the TRICOM vector provided the most potent stimulation of both CD4$^+$ and CD8$^+$ T cells. Moreover, these effects were clearly synergistic, not additive. Tumor cells stimulated with rV-B7-1, rV-ICAM-1, or rV-LFA-3 to provide signal 2 were compared with TRICOM-stimulated cells. An evaluation of cytokine secretion by those cells revealed that IL-2 and interferon-γ production in CD4$^+$ and CD8$^+$ cells, respectively, was much higher for the TRICOM vector than for the single costimulatory molecule vectors. These studies demonstrated that poxviruses containing as many as three costimulatory molecules as transgenes can rapidly and efficiently activate T-cell populations to levels far greater than those achieved when any one or two of these costimulatory molecules are used. Previous toxicology studies analyzing the effects of multiple administrations of rV-B7-1 in mice revealed no toxicity, including no

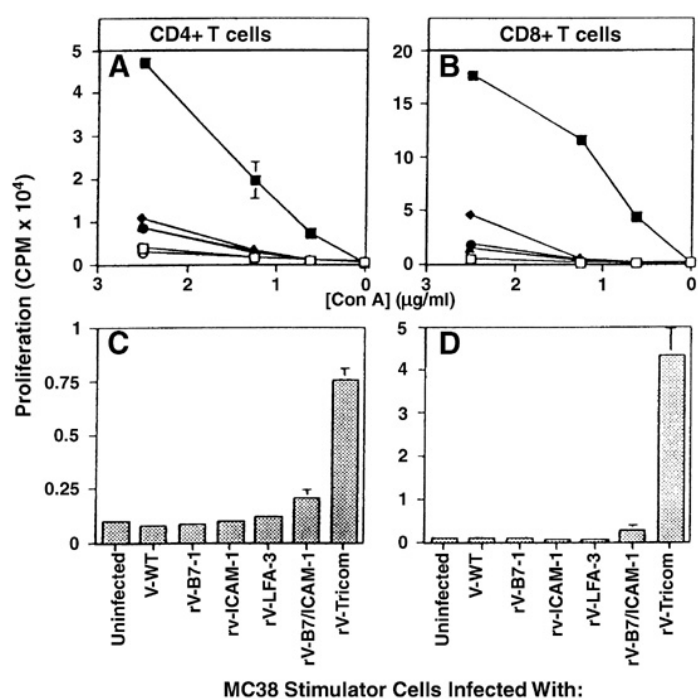
evidence of autoimmunity (52). Similar studies are ongoing using recombinant TRICOM-poxvirus vectors. The ability to achieve this new threshold of T-cell activation using vectors containing multiple costimulatory molecules has broad implications in the design and development of anticancer vaccines because there is overwhelming evidence that the vast majority of TAAs are weakly immunogenic.


FIGURE 18.5-2. Effect of costimulation on specific T-cell populations. Murine CD4+ (panel A) or CD8+ T cells (panel B) were co-cultured with uninfected MC38 cells (open circle), or cells infected with wild-type vaccinia (V-WT) (open squares), recombinant vaccinia leukocyte function–associated antigen (rV-LFA-3) (closed triangles), rV-intercellular adhesion molecule-1 (rV-ICAM-1) (closed circles), rV-B7-1 (closed diamonds) or rV-TRICOM (*triad of costimulatory molecules*) (closed squares) at a 10:1 ratio for 48 hours in the presence of various concentrations of Con A. Panels C and D show the proliferative responses of purified CD4+ and CD8+ cells, respectively, when co-cultured in the presence of vector-infected MC38 stimulator cells at a low Con A concentration (0.625 µg/mL).

Whole Tumor Cell Vaccines

Another strategy uses recombinant poxviruses in encoding and expressing one or more immunomodulating proteins (e.g., costimulatory molecules, cytokines, or chemokines) to stereotypically modify tumor cells *in vivo* or *ex vivo.* Although tumor cells may display TAAs on their surface, they usually do not elicit immune responses. One explanation is that, unlike APCs, tumor cells do not naturally express costimulatory molecules and, therefore, are unable to activate the immune system. To address this deficiency, recombinant poxviruses that express one or more costimulatory molecules can be used to infect tumor cells by direct injection into the tumor itself. Infection results in short-term, or transient, expression of the costimulatory molecules. In preclinical models, such expression has proven sufficient to activate immune responses directed against the antigens naturally present on the surface of tumor cells. Once activated, these immune responses may be capable of recognizing all tumor cells of the same type, whether or not these tumor cells also express costimulatory molecules.

Many studies have revealed the efficacy of whole tumor cell vaccines to enhance antitumor activity in experimental models (37,38 and 39,44,45,46 and 47,53,54,55 and 56). Because this approach is not dependent on the identification of specific tumor antigens, it can be used for the treatment of multiple cancers, including those for which TAAs have not been identified. Advantages of this approach include

1. Efficient delivery of genes to the tumor cells by recombinant poxviruses.
2. Ability to phenotypically modify tumor cells *in vivo*, rather than only after surgical removal.
3. Capability of rapid, efficient *ex vivo* infection of tumor cells by recombinant poxviruses; cells can subsequently be x-irradiated and administered back to the patient.
4. The transient nature of the tumor modification. This is naturally limited by the immune system's eventual destruction of infected cells and by the fact that poxviruses do not insert their genetic material into the genome of the cells they infect.

In some cases, the vaccines consisted of live or x-irradiated tumor cells that were highly or moderately immunogenic (56). In other studies, tumor cells were shown to be weakly immunogenic or not immunogenic at all (i.e., the tumor cells would grow readily in the host, and vaccines consisting of x-irradiated tumor cells were not capable of inducing antitumor immunity). It is in these cases that the insertion and expression of transgenes such as cytokine genes and costimulatory molecule genes may make tumors more immunogenic. Insertion of costimulatory molecule genes is extremely attractive in the case of tumor vaccines because the vast majority of nonhematopoietic tumors do not express T-cell costimulatory molecules. To date, most whole tumor cell vaccines expressing a transgene via a vector have used retroviral vectors. Several studies have used poxvirus vectors to infect whole tumor cell vaccines. One study has compared for the first time the use of a poxvirus vector versus a retroviral vector to express the B7-1 costimulatory molecule transgene in both live and x-irradiated whole tumor cell vaccines (57). Both the recombinant retrovirus (R-B7) and the rV-B7 induced equivalent expression of B7 on the surface of the MC38 murine carcinoma cells slated to be used as a vaccine. Wild-type retrovirus (R-WT) and vaccinia virus (V-WT) were used as controls. Using live whole tumor cells as vaccine, cells transduced via recombinant retrovirus or rV virus expressing B7-1 equally induced protection against challenge with native MC38 tumor cells. On rechallenge with native tumor cells 40 days later, however, the R-B7 vaccine was shown to be less effective than the rV-B7 vaccine whole tumor cell. These experiments were also conducted using x-irradiated tumor cells as vaccine. Again, the rV-B7 vector-infected x-irradiated tumor cells were superior to the vaccine prepared with R-B7. Comparative studies have also been conducted in which x-irradiated tumor cell vaccines were administered to mice containing experimental lung metastases. In these therapy studies, all mice receiving x-irradiated native tumor cells developed more than 200 metastatic nodules in the lung, similar to

the result seen in nonvaccinated mice. All mice receiving vaccine consisting of x-irradiated tumor cells infected with V-WT or R-WT also developed lung metastases. Mice receiving the x-irradiated rV-B7 tumor-cell vaccine experienced a statistically significant reduction in lung metastases compared to those receiving vaccine infected with R-WT. Similarly, mice receiving the x-irradiated rV-B7 tumor vaccine had a statistically significant reduction in the development of lung metastases compared to those receiving x-irradiated V-WT vaccine. Mice receiving the x-irradiated rV-B7 vaccine experienced a statistically significant reduction in lung metastases compared to mice receiving the x-irradiated vaccine infected with R-B7.

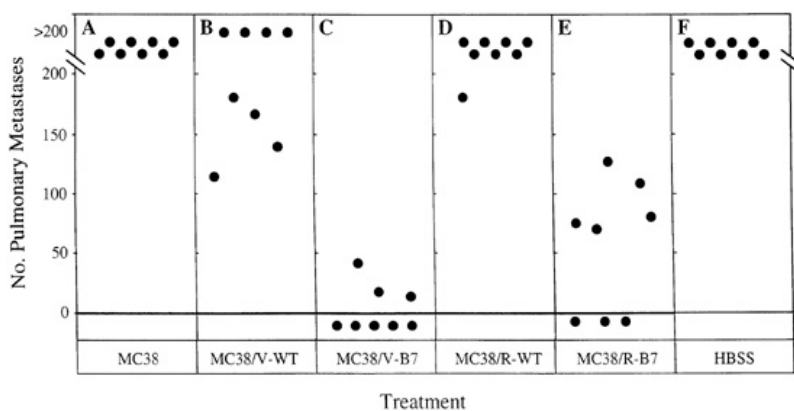
One of the concerns inherent in using an rV-based vaccine is that previous immunity—via the smallpox vaccine or poxvirus vaccinations, for example—would inhibit its effectiveness (15,19). To determine if earlier exposure to vaccinia would inhibit the antitumor efficacy of x-irradiated whole tumor cell vaccines with the rV-B7 vector, these studies were performed in mice that had received 10^7 pfu V-WT 17 days before vaccination. This dose and interval had been shown to lead to the development of substantial antivaccinia immune responses. As seen in Figure 18.5-3, the x-irradiated R-B7 tumor-cell vaccine was still statistically significant in its therapeutic effectiveness as compared to the retroviral vaccine. Indeed, in these types of whole tumor cell vaccines, there is no need for virus replication; therefore, there should be no inhibition of antitumor efficacy by antipoxvirus immune responses. Moreover, such immune responses may actually enhance the antitumor effect in this setting. This phenomenon formed the basis for the use of oncolysate, using extracts of vaccinia as vaccines (58). As previously pointed out, such preparations may have been less than optimal because no costimulatory molecules were present to provide the required second signal for enhanced T-cell activation. Studies have been reported in which anti-cytotoxic T lymphocyte A4 (CTLA4) monoclonal antibodies were used to inhibit growth of tumors in some murine models but not in others, particularly those tumors that are poorly immunogenic (59,60 and 61). The use of anti-CTLA4 monoclonal antibodies was shown to be ineffectual in the tumor model used in the studies (62).


FIGURE 18.5-3. Treatment of lung metastases using x-irradiated whole tumor cell vaccines in mice that had been administered wild-type vaccinia (V-WT). On day 14, all mice received 1 × 10^7 plaque-forming units V-WT. Groups of eight mice were then inoculated intravenously with 1 × 10^6 native MC38 cells on day 0. On days 3, 10, and 17, mice received as vaccine x-irradiated MC38 tumor cells (panel A), or x-irradiated tumor cells previously infected with V-WT (panel B), V-B7 (panel C), R-WT (panel D), or R-B7 (panel E), or no tumor cells (HBSS buffer; panel F). On day 28, mice were sacrificed and lung metastases were counted.

Pros and cons exist in the use of any vector for anticancer vaccine applications. Advantages of using a retroviral vector in whole tumor cell vaccines include the following:

1. Stable integration
2. Transgene expression by all cells, if the cells are drug-selected and cloned
3. Proposed lack of immunogenicity

Most studies have used murine retroviruses in murine systems. It is not clear at this point if antiretroviral immunity in humans develops after administration of tumor cell vaccines containing retroviruses. There are several potential disadvantages in using a retroviral vector that do not exist when using poxvirus vectors in whole tumor cell vaccines. Poxviruses do not require a lengthy drug-selection or cloning process, because it has been shown that they can express the transgene efficiently in greater than 95% of cells within 5 hours (40,44). Moreover, unlike retroviruses, poxviruses do not require cell division to express transgenes. Although the use of retrovirus vectors is efficient for established tumor-cell lines that rapidly divide *in vitro* and *in vivo*, this is not the case for cells derived from human tumor biopsies or for human tumors *in situ.* For example, it is extremely difficult to propagate tumor cells from biopsies in cases of breast and colon carcinoma, and cells do not divide rapidly *in situ.* Perhaps the main advantage in using poxviruses in whole tumor cell vaccines is that one can insert multiple genes into a poxvirus vector, which is not possible for most other types of vectors. Vectors containing three or more costimulatory molecules possess great potential for this approach and clearly merit further investigation.

Clinical Studies

Part of "18.5 - Recombinant Poxvirus Vaccines "

Poxviruses have been widely used as human vaccines. Vaccinia has been used in the worldwide eradication of smallpox. Recombinant avipoxviruses and rV viruses have also been used clinically to induce immunity to a range of viruses and other pathogens. These vaccines include: rV-HIV (11,21,24,25); ALVAC-HIV (7,8,9 and 10,63,64); rV-Japanese encephalitis virus (65); ALVAC-Japanese encephalitis virus (65); rV-malaria (29); rV-Epstein-Barr virus (66); and ALVAC-rabies (6). To date, few or no serious adverse effects stemming from the use of these vaccines have been reported. The use of recombinant poxviruses as anticancer vaccines is in a relatively early stage. Anticancer

recombinant poxvirus vaccines that are being evaluated clinically are listed in Table 18.5-1 .

Table 18.5-1 Recombinant Poxvirus Anticancer Vaccines: Clinical Studies

Immunogen	Immune Response
rV-CEA	CTL
ALVAC-CEA	CTL
rV-MUC-1	CTL
rV-MUC-1/IL-2	Studies ongoing
rV-PSA	Ab, Studies ongoing
rF-PSA	Studies ongoing
rV-HPV	CTL, Ab
rV-MART	Studies ongoing
rF-MART	Studies ongoing
rF-gp100	Studies ongoing
rV-CEA→ALVAC-CEA (3X)	CTL
ALVAC-CEA (3X)→rV-CEA	CTL
ALVAC-CEA-B7-1	Studies ongoing
ALVAC-B7-1	Studies ongoing
ALVAC-IL-12	Studies ongoing

Ab, antibody; ALVAC, *Avipoxvirus* group; CEA, carcinoembryonic antigen; CTL, cytotoxic T lymphocyte; HPV, human papillomavirus; IL, interleukin; PSA, prostate-specific antigen; rV, recombinant vaccinia.

A phase 1 rV virus trial in cancer patients focused on the use of rV-CEA (67). Three dose levels were given to different cohorts, and each patient received three vaccinations. Peripheral blood mononuclear cells (PBMCs) from the advanced cancer patients who had received this vaccine yielded T cells that were analyzed for their ability to respond to a range of potential immunodominant epitopes of CEA. These studies identified a peptide (YLSGANLNL) designated CAP-1, which could be used to generate CEA-specific T cells from the PBMCs of vaccinated patients. No such T-cell lines could be generated using PBMCs from the same patients before vaccination. These studies elucidated the ability to generate a T-cell response to a self-antigen, such as CEA, using a recombinant poxvirus vector. The T-cell lines were shown to be capable of lysing (a) CEA peptide-pulsed targets, (b) autologous B cells that had been transduced with the CEA gene, and (c) colon cancer cells, as long as the tumor was expressing CEA and the appropriate major histocompatibility complex allele.

Phase 1 studies have also been carried out using the replication-defective ALVAC-CEA recombinant in advanced cancer patients (68). These studies also showed the generation of CEA-specific CTLs obtained from patients postvaccination. No such CTLs could be obtained before vaccination. These CTLs were shown to be capable of lysing allogeneic and autologous tumor cells. CTL responses were determined by classical precursor frequency studies. Ongoing studies involve the administration of ALVAC-CEA with recombinant GM-CSF at the injection site, as well as with low-dose IL-2 given postvaccination.

Studies were then carried out using diversified prime and boost protocols. In these studies, cohort A received a primary vaccination with rV-CEA followed by three vaccinations with ALVAC-CEA, and cohort B received three vaccinations of ALVAC-CEA followed by a single vaccination of rV-CEA. T-cell responses in both cohorts were measured using the enzyme-linked immunospot (ELISPOT) assay for interferon-γ production in response to a CEA peptide. The CEA-specific T-cell responses of cohort A, in which rV-CEA was given as the primary vaccination, were shown to be statistically superior to those of cohort B. These clinical results were in agreement with preclinical studies showing the advantage of diversified prime and boost protocols. Studies have also been conducted using an rV virus containing sequences of the MUC-1 carcinoma-associated mucin and IL-2 in the same vector. These ongoing studies have resulted in the induction of anti-MUC-1 T-cell responses in vaccinated breast cancer patients with some early indications of antitumor effects (69). Another phase 1 trial focusing on a different portion of the MUC-1 gene in an rV virus has just been initiated in breast cancer patients (70).

Several studies using rV and avipoxviruses have been completed, and others are in progress in patients with melanoma. To date, however, these studies have not been as successful as those using modified melanoma peptides. Research is ongoing to insert modified melanoma-associated and carcinoma-associated genes into recombinant poxviruses (71,72 and 73).

Clinical studies are also ongoing with rV viruses containing the genes for human papillomavirus (HPV) (types 16 and 18), E6 and 27 genes (rV-HPV) (74,75). These vectors are being administered to patients with late-stage cervical carcinoma. Initial analysis indicated that HPV-specific antibody responses and CTL responses were being elicited by this vaccine. Clinical trials have also been conducted in which the human prostate-specific antigen (PSA) has been inserted into an rV virus (18). These studies have revealed that prostate cancer patients can generate a PSA-specific antibody responses after vaccination with rV-PSA, and PSA-specific T-cell responses (18,76).

Two clinical trials using ALVAC-CEA/B7-1 as a vaccine in patients with advanced cancer have been completed (77,78 and 79). These were the first clinical trials to use a recombinant poxvirus vector containing a costimulatory molecule gene and a TAA gene. Using the ELISPOT assay for interferon-γ production and analyzing PBMCs after less than 24 hours in culture, substantial increases in CEA-specific T cells were observed postvaccination compared to prevaccination. As a control, no changes in T-cell responses were observed to a Flu peptide from PBMCs obtained pre- and postvaccination. Clinical trials testing the direct administration of ALVAC-B7-1 or ALVAC-IL-12 into tumor lesions have just begun.

The phase 1 clinical results described previously in this section clearly demonstrate that recombinant poxviruses containing tumor-associated genes can be used to generate specific immune responses to a range of tumor antigens in a safe manner. Some phase 2 clinical studies using some of the modalities described (see under Experimental Studies) are just beginning; planning is under way for others.

Future Development of Recombinant Poxvirus Vaccines

Part of "18.5 - Recombinant Poxvirus Vaccines "

Considerable potential exists in the future development of recombinant poxvirus vaccines for cancer management. Virtually all of the clinical studies described have been carried out in patients with rather advanced cancers. These patients most

likely have subtle but depressed immune responses, which have been exhibited two ways: (a) via downregulation of the ζ chain of the T-cell receptor and (b) in the cytokine profile of T cells obtained from advanced cancer patients (type 2 profile) compared to a type 1 profile from healthy individuals. Thus, the full potential of these vaccines has yet to be defined. The advantage of diversified prime and boost protocols using poxvirus recombinants has been demonstrated preclinically and in the clinic. It is not known, however, how many boosts using replication-defective avipoxviruses or MVAs are optimal.

Modification of tumor-associated immunodominant epitopes, such as those of gp100 and CEA, has been shown to enhance immune responses *in vitro* (72) and in patients (71,73,80). The use of recombinant poxviruses containing these modifications in tumor-antigen genes may enhance immune responses in patients. The use of cytokine genes as transgenes in recombinant poxviruses either alone or with tumor-antigen genes is currently being explored, as is the administration of recombinant cytokines such as GM-CSF and IL-2 in vaccine protocols containing recombinant poxviruses.

Perhaps the most intriguing advantage of using recombinant poxvirus vectors in anticancer vaccines is the ability to insert multiple transgenes; this can include the use of multiple tumor-antigen genes, cytokine genes, and/or T-cell costimulatory molecule genes. The belief that the vast majority of tumor-associated genes are weak immunogens supports this approach. Underscoring these vectors' significant potential as vaccines is the demonstration that recombinant poxviruses can efficiently express three T-cell costimulatory molecules in the same APC and activate T cells to levels not previously achievable with the use of any one or two of these molecules. Modes of application of pox vector-based vaccines potentially include direct administration into patients as a classical vaccine, infection of whole tumor cells either *in vitro* or *in situ*, or the *in vitro* infection of APCs such as dendritic cells to enhance the effectiveness of this approach.

Introduction

Part of "18.6 - Adenovirus and Other Viral Vaccines "

The identification of tumor-associated antigens (TAAs) that are targets for cancer patient–derived immune effector cells has revolutionized the field of cancer immunotherapy. Clinicians are attempting to focus the immune system on these specific molecular targets in the hope that anti-TAA immune responses are sufficient to cause tumor cell elimination. Two strategies that use adenoviral vectors have been pursued to elicit anti-TAAs, and, thus, antitumor cell immune responses (Fig. 18.6-1). In one approach, tumor cells are used as the source of antigens, and adenoviral vectors are used to deliver immunomodulatory genes to tumors cells to enhance their immunogenicity. The use of tumor cells as the source of antigens favors the presentation of the full repertoire of TAAs to the immune system. Tumor cells, however, can elaborate immunosuppressive factors that can thwart one's efforts to use them to provoke immunity, and they may possess defects in antigen presentation that render them defective for the generation of immune responses. In an alternative approach, tumor antigen genes are delivered via adenoviral vectors to professional antigen-presenting cells (APCs), such as dendritic cells (DCs), to maximize presentation to the immune system. The efficiency of gene transfer to patients' APCs (as opposed to tumor cells) can be more predictable, and targeting of APCs favors optimal presentation of tumor antigens to the immune system. Drawbacks of this approach include the

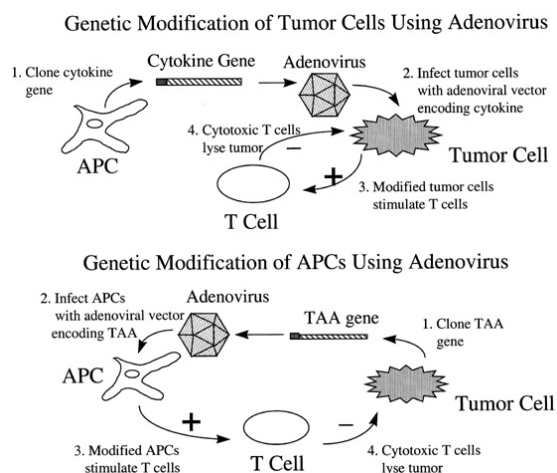
requirement for cloned antigens, of which few are available, and the limitations associated with generating a narrow, highly restricted immune response against a handful of TAAs.


FIGURE 18.6-1. Adenovirus cancer vaccines. Adenoviral vectors encoding immunomodulatory genes can be used to enhance the immunogenicity of tumor cells, as shown in the top panel, whereas adenoviral vectors encoding tumor-associated antigens (TAAs) can be used to provoke anti-TAA immune reactivity, as shown in the bottom panel. (APC, antigen-presenting cell.)

This chapter reviews the properties and attributes of adenoviral vectors as they pertain to their use in immunotherapy. Comprehensive reviews of adenovirus and adenoviral vectors have appeared previously (1,2).

Adenovirus Family

Part of "18.6 - Adenovirus and Other Viral Vaccines "

Adenoviruses are nonenveloped icosahedral nucleocapsid particles of 70 nm in diameter, containing a linear double-stranded DNA genome of approximately 35 to 36 kilobase (kb) (1). Forty-one different human adenovirus serotypes have been classified into seven subgroups (A through G) based on a variety of criteria. Adenoviruses of subgroup C (serotypes 1, 2, 5, and 6) cause mild infections of the respiratory tract, whereas subgroups B and E viruses are associated with acute respiratory disease and subgroup D viruses are associated with keratoconjunctivitis. The majority of adenoviral vectors are based on the serotypes 5 and 2 viruses. Although one might imagine adenoviruses might exhibit a preferential tropism for epithelial cells based on the observed clinical symptoms in humans, adenoviral vectors can infect a variety of cell types.

The proteinaceous outer capsid of adenovirus consists of predominantly three structural proteins: a 120-kd hexon protein (720 copies per viral particle), a 85-kd penton base protein (60 copies per particle), and a 62-kd fiber protein (36 copies per particle). Of these structural proteins, the fiber and penton base proteins (Fig. 18.6-2) participate in the infection of target cells via a two-step process. The fiber protein, which extends from the corners of the icosahedral particle like an aerial, is thought to interact first with a cellular fiber receptor, allowing the pentose base protein of the viral particle to engage a second cellular receptor (the $\alpha_v\beta_3$ or $\alpha_v\beta_5$ integrins). A cellular receptor (CAR) for the fiber protein, which also serves as a receptor for coxsackie virus, has been identified (3); however, the fact that target cells lacking CAR can be infected with adeovirus suggests other means of entry may exist.
FIGURE 18.6-2. Adenoviral particle structure. This diagram illustrates the fiber and penton base proteins of the adenoviral particle that participate in the two-step infection of target cells via specific cellular receptors.

Internalization of the adenoviral particle occurs via receptor-mediated endocytosis. Once inside a cell, a series of modifications of the outer capsid occurs, enabling the virus to escape from the endosome and gain entry to the nucleus. This feature of adenovirus enables it to infect dividing and nondividing cells, an attribute that makes adenovirus ideal for gene transfer. Once established within the nucleus, the double-stranded DNA of the adenoviral genome remains as a linear extrachromosomal element. The fact that adenovirus does not integrate into the host genome has been exploited as an important safety feature for gene therapy applications. As with other viruses, the genome is divided into early and late transcription units (1). The E1a and E1b protein products encoded by the first of the four early transcription regions are master control proteins that participate in a number of regulatory functions, including transactivation of gene transcription within the other three early regions, as well as the late region. The E1 proteins also enable replication of the adenoviral genome in infected cells in part by the ability of E1a to bind the Rb tumor suppressor and E1b to bind p53. As a consequence of these interactions, the combination of the E1a and E1b genes can be oncogenic in rodent but not human cell lines.

The majority of adenoviral vectors generated for gene transfer purposes are deleted for the E1a and E1b products (2) for the following purposes:

1. To render the vectors' replication deficient
2. To eliminate the adenoviral genes associated with transformation of rodent cells
3. To eliminate the activation of late gene expression and the potential cytotoxicity of viral proteins

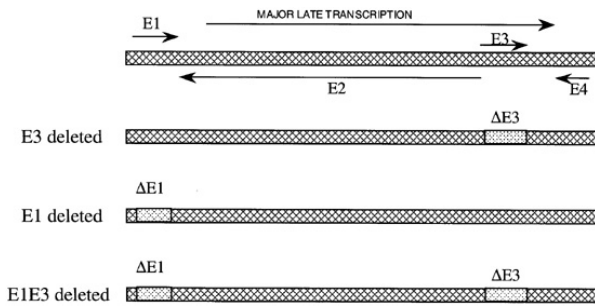
4. To provide cloning space for the insertion of transgenes into the genome (Fig. 18.6-3).


FIGURE 18.6-3. Adenoviral vector design. E1-, E3- or E1E3 deleted adenoviral vectors have been generated to create sufficient cloning capacity for the insertion of therapeutic genes. (Adapted from Graham FL, Prevec L. Manipulation of adenovirus vectors. In: Murray EJ, ed. *Methods in molecular biology.* Clifton, NJ: Humana, 1991:109–128.)

The availability of the 293 helper cell line harboring the E1 genes and able to provide in trans the E1 proteins, which are required for viral replication, enables the preparation of high-titer stocks of adenoviral vectors ($\sim$2 × 10^{11} infectious units per mL, equivalent to 2 × 10^{12} particle per mL). An exception to this general design is one in which the E3 region of the genome is deleted and the transgene of interest cloned into the space created by the deletion (2). Because the E1 region can be retained, vectors can be replication competent. Thus, spread of vector from transduced cells to neighboring cells is possible.

An issue associated with first-generation adenoviral vectors is the generation of replication-competent adenovirus caused by the recombination of DNA sequences flanking the deleted E1 region with homologous DNA sequences contained within 293 cells. Thus, second-generation adenoviral vectors have been designed to remedy this problem. Because the protein IX gene, which lies immediately 3′ of the E1b region, is a potential site for recombination, vectors deleted for this region have been constructed. Because the protein IX gene is required for stabilization and packaging of adenoviral genomes in excess of 100% of the size of the wild-type genome, protein IX-deleted vectors are restricted in terms of their cloning capacity, unless the protein IX product is provided in trans by a suitable helper cell line. An alternative solution involves translocation of the protein IX gene from its normal site to a novel site at the right-hand end of the genome within space created by deletion of the E4 region (4). The latter solution permits use of the existing 293 helper cell lines for vector production. In 1998, an alternative helper cell line was described, which contains the minimal sequences of the E1 region required for replication under the control of a phosphoglycerate kinase promoter. Thus, the possibility of homologous recombination between vector sequences and E1 sequences harbored by the helper cells is negligible (5).

The E3 region of the adenoviral genome encodes proteins whose normal role is to enable virus-infected cells to evade immune surveillance (1). Thus, the E3 19K protein binds to major histocompatibility complex (MHC) class I molecules and inhibits the presentation of MHC molecules on the cell surface, whereas the E3 14.7K protein is antagonistic to the actions of tumor necrosis factor-α. The expression of these genes is greatly diminished in E1-deleted vectors owing to the fact that the E1 products are required to transactivate E3 gene expression. Adenoviral vectors completely deleted for E3 genes have been constructed (2).

A variety of methodologies have been described to construct recombinant adenoviral vectors. In one approach, a linearized shuttle plasmid containing the transgene of interest is cotransfected with a restriction enzyme–digested viral DNA onto a suitable helper cell line (2). As arising viral plaques can be the desired recombinant or parental viral vectors, several rounds of time-consuming plaque purification may be required to obtain the desired recombinant. Using an alternative strategy, the entire viral genome is first assembled in a suitable host, such as *Escherichia coli*, and the complete viral DNA is then transfected onto helper cells to generate viral plaques. Theoretically, any plaques that arise should correspond to the desired recombinant, thus eliminating the need for plaque purification. The development of rapid cloning methods in the late 1990s involving the use of homologous recombination in bacteria to generate plasmids containing complete adenoviral genomes (6,7) has accelerated the process of obtaining clonally pure adenoviral preparations ready for large-scale production.

Genetic Modification of Antigen-Presenting Cells Using Adenoviral Vectors

Genetic modification of APCs affords several advantages when compared with other modes of TAA delivery for the following reasons:

1. The potential exists for a continuous supply of tumor antigen–derived peptides for presentation.
2. Intracellular expression of the tumor antigen gene favors entry of TAA-derived peptides into the class I pathway.
3. The potential exists for CD4 and CD8 T-cell epitopes of the same TAA to be presented by the same APC.
4. Coexpression of a TAA gene with accessory molecules that might enhance an immune response within an APC is possible.

An ideal vector for the delivery of tumor antigen genes should fulfill a number of criteria, including:

1. An ability to mediate efficient gene transfer to target cells without adversely affecting APC function or viability
2. Ease of manipulation of the vector genome
3. An ability to induce antigen-specific immune responses with minimal generation of immune responses directed toward the vector itself.

Adenoviral vectors have been found to meet the above criteria.

Adenoviral vectors can be potentially used to transduce a variety of APCs, but investigators have paid particular attention to DCs because they are considered to be the most potent APCs in the body (8). Gene transfer to human DCs via adenoviral vectors is of 2 to 3 orders of magnitude more efficient than electroporation

or lipofection (9). Typically, at a multiplicity of infection (MOI) of 100 to 250, one can achieve as much as a 90% to 100% transduction of human (9,10) or murine (11,12 and 13) DCs *in vitro*, as judged by marker gene expression. A variety of factors may account for variations in reported efficiencies, including the quality of the adenoviral preparations, the culture conditions used to derive DCs, the source of the DCs, and the sensitivity of the assay used to assess the extent of gene transfer (14).

Monocyte-derived DCs are susceptible to adenovirus-mediated gene transfer and so are monocytes themselves (11,15). Adenoviral vector-transduced monocytes, however, have been reported to be inferior to transduced monocyte–derived DCs in their ability to induce a cytotoxic T lymphocyte (CTL) response and confer protective immunity (11). This observation is consistent with the observation that monocytes lack important costimulatory and adhesion molecules and are inferior to DCs as professional APCs (8).

No data is available regarding the efficiency of gene transfer to APCs *in vivo.* As subcutaneous (s.c.), intraperitoneal (i.p.), intravenous (i.v.), and intradermal (i.d.) administration of adenoviral vectors encoding antigens can induce potent antiantigen immune responses (Table 18.6-1), it is inferred that APCs of one sort or another can be transduced with adenoviral vectors *in vivo.* On the other hand, it is well documented that i.m., i.v., and s.c. injection of adenoviral vectors can achieve high degrees of gene transfer to muscle, liver, and fibroblasts *in vivo.* Thus, the potential for direct or indirect antigen presentation by these tissues exists.

Table 18.6-1 Summary of Preclinical Studies Demonstrating the Efficacy of *In Vivo* Injection of Adenovirus

Transgene	Dose of Virus Administered	Route of Administration	Animal Model (Tumor Cell Type:Mouse Strain)	References
Polyoma middle T	10^7–10^9 PFU	i.m., i.p., s.c., i.v.	MMTV/Middle T transgenic mice (FVB/N)	13

MMTV, mouse mammary tumor virus; PFU, plaque-forming units;TRP-1, tyrosinase-related protein.

Adenovirus-transduced cells have been shown to be able to present individual T-cell epitopes encoded by mini genes (14,16) or complete tumor antigen genes (17), and multiple epitopes encoded by complete tumor antigen genes (18) or concatamers of minigenes (19) to established T-cell lines *in vitro* in an MHC-restricted fashion. Transgene expression, and, thus, presentation have been shown to persist in adenovirus-transduced human DCs for at least 8 days *in vitro* with no signs of cytopathic effects (17).

As most adenoviral vectors used as cancer vaccines have been replication deficient, no provision exists for amplification of transgene copy number within virus-transduced target cells; however, chemical treatments can be used to augment gene expression, and, hence, antigen presentation. Tumor necrosis factor–α and sodium butyrate treatments have been reported to enhance tumor antigen gene expression in virus-transduced cells, as judged by Northern or fluorescence-activated cell sorter analysis when transgene expression is regulated by a cytomegalovirus promoter (18). Furthermore, the susceptibility of adenovirus-transduced cells to lysis by established antigen-specific T cells can be enhanced by tumor necrosis factor–α or sodium butyrate treatment (18).

Adenoviral cancer vaccines have used the cytomegalovirus promoter to control tumor antigen gene expression, and no systematic examination of the effect of different promoters on the level or duration of TAA presentation has been undertaken. In the context of adenoviral vectors, however, the cytomegalovirus promoter has been shown to be active in APCs and capable of directing high levels of tumor antigen gene expression (17,18). The adenovirus E3 19K protein can potentially downregulate cell surface presentation of MHC class I molecules in vector-transduced cells (1). Transactivation of gene expression within the E3 region by adenoviral E1 proteins greatly enhances the production of E3 proteins, but as adenoviral vectors used for cancer vaccines are deleted for E1 genes, expression of E3 gene products should be minimal. Although the E3 19K protein product can be detected in vector-transduced cells, levels are not sufficient to cause a detectable decrease in class I presentation (18), and a separate study has shown only modest reductions in total class I and HLA-A2 levels in adenovector-transduced DCs (17).

Adenovirus types 2 and 5 contain sequence motifs that block immune activation by stimulatory CpG motifs (20). Replication-deficient types 2 and 5 vectors, however, are deleted for the E1 region, which coincidentally harbors these immunosuppressive DNA sequences. Replication-competent adenoviral vectors, which retain E1 functions, have been generated (2) as antiviral vaccines. It remains to be determined to what degree these immunosuppressive sequences impinge on their ability to induce immune responses. Adenoviral transduction appears to have little effect on the morphology or viability of DCs (10). Furthermore, adenoviral transduction does not appear to alter the levels of characteristic cell surface markers on human (9) or murine (11,13) DCs, as judged by fluorescence-activated cell sorter analysis. The function of DCs does not appear to be impaired as a consequence of exposure to adenoviral vectors, as transduced human (9) and murine (11,13) DCs are equivalent to nontransduced cells in a mixed lymphocyte reaction. Adenovirus-transduced murine DCs have been reported to exhibit reduced viability and

impaired activity in a mixed lymphocyte reaction when MOIs of 200 or 500 are used (11). This report of adenovirus-induced cytotoxicity on murine DCs is at variance with a report that no loss in viability occurs when MOIs of as many as 10,000 are used to transduce human DCs (9). Differences in the quality of adenoviral preparations may account for this apparent discrepancy. Finally, transduced DCs have been shown to migrate to the spleen after i.v. injection (13), suggesting adenoviral infection does not alter the capacity of DCs to translocate from a site of injection to T-cell-rich regions.

The ability of adenoviral-transduced DCs to induce immune responses has been examined *in vitro.* DCs transduced with a wild-type adenovirus or a replication-deficient mutant deleted for the E1a protein induce proliferation of antiadenovirus CD4 and CD8 T-cell responses (21). Characterization of expanded T-cell populations supports the conclusion that class I and class II molecules of transduced DCs present adenoviral antigens to T cells (21). Human donor–derived DCs transduced with an adenovirus encoding human melan-A/MART-1 can be used to generate T cells reactive to the encoded TAA *in vitro* (17). A subsequent report has shown that human DCs transduced with the same adenoviral vector can stimulate CD4$^+$ and CD8$^+$ antigen-specific T cells from melanoma patients' peripheral blood mononuclear cells (PBMCs) *in vitro* (22). This observation suggests that antigen presentation via class I and class II pathways can occur in transduced DCs in accordance with earlier observations (21).

Little data is available regarding the relative potency of adenoviral vector-transduced DCs as compared with peptide-pulsed, RNA-pulsed, or protein-pulsed DCs in an instance in which immune responses are induced to a "standard" TAA. It has been reported, however, that DCs transduced with an adenovirus encoding a specific CTL epitope are more potent than peptide-pulsed cells in inducing peptide-specific T-cell reactivity *in vitro* and *in vivo* (14), whereas DCs transduced with an adenovirus encoding β-galactosidase are more potent than DCs pulsed with β-galactosidase protein in inducing CTLs *in vivo* (23). This may be owing to the fact that genetically modified DCs are predicted to have a continuous supply of TAAs. Thus, sustained presentation of TAA-derived peptides may be possible.

An ideal cancer vaccine should induce immune responses directed towards the encoded TAA and not towards the vector itself. Little antiadenoviral CTL reactivity is generated when transduced DCs are used to stimulate T cells *in vitro* (17,22) in spite of the fact that adenoviral proteins would be present in transduced DCs. CTL reactivity to adenoviral proteins, however, can be generated if DCs, transduced with an empty adenoviral vector devoid of a tumor antigen gene, are used as stimulators (17,21). Furthermore, it has been demonstrated that *de novo* gene expression is not required for the presentation of adenoviral antigens by transduced DCs (21). Little advantage may exist in using high MOIs to transduce DCs, as excess viral particles are available for uptake by DCs, and immune responses may be skewed in favor of an antiadenoviral response at the expense of a desired antitumor antigen response. In addition, these observations suggest competition for presentation may occur in adenovirus-transduced DCs. Provided that TAA transgene expression is driven by a strong promoter within the vector, anti-TAA immune responses may be preferentially induced.

The ability of DCs to induce immune responses has been deliberately altered by transduction with an adenovirus encoding the T-cell attractant chemokine lymphotactin (24). The transduced DCs are more potent than unmodified DCs in inducing T-cell responses and conferring protective immunity when pulsed with a T-cell epitope peptide and administered subcutaneously. As most first-generation adenoviral vectors have a 6- to 8-kb cloning capacity (2), tumor antigen and immunomodulatory genes could be incorporated into the design of adenoviral vectors to create superior cancer vaccines.

Adenoviral vaccines have been administered via a variety of routes (see Table 18.6-1). Viruses administered intravenously (18,25), intramuscularly (25), intradermally (16,26), intranasally (25), or intraperitoneally (27) have been shown to induce protective immunity. Differences in vector design and choice of antigen prohibit attempts to deduce whether an optimum route of administration exists. In comparative studies using a single vector, however, investigators have reported variable levels of efficacy depending on the route of administration. Thus, i.m. delivery of an adenoviral vector encoding the model antigen polyoma middle T has been reported to be superior to i.p., s.c., or i.v. delivery, and whereas a dose of 10^7 plaque-forming units (PFU) given intramuscularly is sufficient to induce protective immune responses, higher doses are required to achieve comparable levels of protective immunity when other routes are used (13). i.d. injection of an adenoviral vector encoding a CTL epitope can induce antigen-specific T cells. i.p., s.c., intranasal or intratrachial administrations of vector are also effective in inducing immune responses (16). i.p. delivery of an adenoviral vector encoding multiple CTL epitopes in a string-of-beads fashion is as effective as s.c. or i.m. administration of the vector (19). Thus, it would appear that a variety of routes of administration may be suitable for direct *in vivo* immunization.

Direct injection of adenoviral vectors encoding TAAs or CTL epitopes has been shown to be an efficient means of inducing antigen-specific immunity. i.d. administration of an adenovirus encoding the minimal P1A epitope is sufficient to induce anti-P815A CTL reactivity (16). i.v. administration of an adenoviral vector encoding a model tumor antigen (β-galactosidase) has been shown to induce antigen-specific CTL activity in splenocytes of immunized animals (25). i.v. administration of an adenoviral vector encoding human gp100 stimulates the generation of B16-reactive CTLs (18) cross-reactive with the endogenous gp100 of the murine cells (28). Depletion of T-cell populations by administration of antibodies after adenovirus injection revealed that CD8$^+$ T cells are predominantly associated with the induced antitumor cell reactivity (18). i.p. delivery of an adenovirus encoding multiple epitopes can induce MHC-restricted epitope-specific T-cell reactivity in splenocytes (19). Anti-CD4 and anti-CD8 antibodies can impair the ability of an adenovector encoding murine tyrosinase-related protein-1 to confer protection from tumor cell challenge when given intradermally, suggesting that CD4 and CD8 T cells play important roles in adenovirus vector-induced immunity (26).

The ability of adenoviral vectors encoding tumor antigens to induce antigen-specific reactivity correlates with their ability to confer protection from tumor cell challenge. i.v. administration of an adenovirus encoding a model antigen can confer protection from an i.v. challenge with tumor cells engineered to express the model antigen (25). i.v. injection of an adenovirus encoding human gp100 can provide partial protection from s.c. (18) or i.v. (28) challenge with B16 tumor cells. Similarly, it has been reported that i.p. injection of an adenovirus encoding multiple defined epitopes can confer protection from subsequent challenge with tumor cells (19). Finally, i.d. administration of an adenoviral vector encoding murine tyrosinase–related protein-1 is able to reduce the number of lung metastases that develop after subsequent i.v. challenge with tumor cells (26).

The administration of APCs genetically modified *ex vivo* by adenoviral vectors intravenously (11,13,29) or subcutaneously (12) has been shown to confer protective immunity (Table 18.6-2). Administration of Ad/ß-galactosidase–transduced murine DCs intravenously (11) or subcutaneously (12) can induce CTL reactivity in splenocytes and confer protective immunity from subsequent challenge with a tumor cell engineered to express ß-galactosidase. In models that are perhaps more clinically relevant as they use human TAAs, murine DCs transduced with adenoviral vectors encoding the human tumor antigens MART-1 (29) or mucin 1 (11) can induce antigen-specific CTLs when given intravenously and confer protective immunity from subsequent challenge with tumor cell lines engineered to express the respective human tumor antigens.

Table 18.6-2 Summary of Preclinical Studies Demonstrating the Efficacy of Adenovirus-Transduced Dendritic Cells

CTL, cytotoxic T lymphocyte; MMTV, mouse mammary tumor virus; MUC-1, mucin1.

In vitro antibody depletion studies have shown that CD4 and CD8 antigen-specific T cells are generated by adenovirus-transduced DCs (11). Administration of an established murine DC line transduced with an adenovirus encoding a minimal CTL epitope can confer protection from subsequent tumor cell challenge (14) in normal but not CD8 knockout mice, stressing the important role played by CD8 T cells. As stimulation of CD4 T responses may provide important "help" for CD8 T-cell responses, the fact that adenovirus–transduced DCs can present antigen via class I and class II pathways may have important implications for the induction of anticancer cell immune responses.

The majority of animal studies conducted have used models of prophylactic immunization to evaluate the efficacy of adenoviral vaccines. As patients with established disease are most likely to be the recipients of adenoviral vaccines, it is surprising, perhaps, that little has been reported regarding the efficacy of adenoviral vaccines in active treatment models of cancer. Immunization with an adenoviral vector encoding a model antigen provides only partial protection from the development of lung metastases in an active treatment model; however, concurrent interleukin-2 (IL-2) treatment appears to greatly improve efficacy (25). i.v. administration of adenovirus-tranduced DCs 3 days after s.c. challenge with tumor cells can confer partial protection from tumor growth (29). The reduced efficacy of adenoviral vaccines in active treatment as compared with prophylactic models may be owing to a variety of factors, including the aggressive growth kinetics of the tumor cells used. One potential means to improve efficacy is to repeat dose. Weekly administrations of transduced DCs for 3 weeks has been shown to enhance the magnitude of the CTL response induced, but such is not the case when vector alone is administered intraperitoneally three times a week (14). In addition, dosing of transduced DCs at two separate time points post-tumor cell challenge is superior to providing a single dose in an active treatment model (29). Thus, repeat dosing and boosting of antigen-specific immune responses may be an essential component in the clinical application of adenoviral vaccines.

Adenoviral vectors have also been reported to induce antigen-specific humoral responses. i.p. delivery of an adenovirus encoding the CO17-1A/GA733 antigen can induce antigen-specific antibodies, as well as antigen-specific cytotoxic T cells (27) in a pretreatment model, and can confer protection from subsequent or concurrent challenge with tumor cells engineered to express the cognate antigen. i.m. injection of an adenovirus encoding the single-chain Fv of a B-cell lymphoma idiotypic (Id) protein can induce an anti-Id antibody response (30). Although the overall titer of the antibody response was lower than that induced by vaccination with recombinant Id protein alone, the type of response induced is qualitatively different in that immunoglobulin G_{2a} (IgG_{2a}) predominates over immunoglobulin G1 (IgG_1) (30). IgG_{2a} is associated with Th1 responses, whereas IgG_1 is associated with Th2 responses. Th1-directed immune responses have been associated with favorable antitumor effects, and adenoviral cancer vaccines may provide a useful means of inducing antitumor cell IgG_{2a} responses to complement CTL responses (30).

The types of immune responses induced by adenoviral vaccines are likely to be dependent on the nature of the tumor antigen gene used, but the route of viral vector administration may play a significant role, too. Although studies have reported that protective immunity can be induced by the administration of adenoviral vectors via a variety of routes, a systematic study of the types of immune responses induced (humoral versus cellular,

CD4 versus CD8) as a function of route of administration has not been undertaken.

An exhaustive study of dose response has not been conducted for direct injection of virus or immunization with transduced DCs. i.d. administration of 10^8 or 10^9 PFU of an adenovirus encoding a minimal epitope is sufficient to induce CTLs; however, a dose of 10^7 PFU is ineffective (16). As few as 10^5 transduced DCs are sufficient to induce protective immunity (11,13). A dose in humans of 2.5×10^7 transduced DCs would be equivalent to 10^5 transduced DCs in the mouse (based on surface area), whereas a dose of 2.5×10^{10} PFU of virus for patients would be equivalent to 10^8 PFU in the mouse. Given that 5×10^8 DCs can be prepared from the apheresis product of one patient and doses of as many as 1×10^{11} PFU of an adenoviral vaccine have been administered to patients (31), it is technically possible to administer doses of adenovirus or adenoviral-transduced DCs that are predicted to be efficacious based on mouse model data to patients. Although *in vivo* and *ex vivo* application of adenoviral vaccines is feasible, it should be noted that transduced DCs have been reported to be more potent than injected virus in inducing protective immunity (13,14).

Ideally, one would like to use a gene transfer vector in a manner to minimize the induction of an antivector antibody response that might preclude repeat dosing, and an antivector T-cell response that might be counterproductive to the induction of the desired anti-TAA immune response. *In vivo* administration of adenoviral vectors can induce antiadenoviral antibodies and CTLs, but the degree to which these immune responses impinge on the ability of vector to act as a cancer vaccine has not been evaluated in a systematic manner. Weekly i.p. administrations of an adenoviral vector (but not of transduced DCs) can induce a strong antiadenoviral neutralizing antibody response (14). Although a preexisting antiadenovirus antibody response is sufficient to block the ability of vector to confer protective immunity when given intraperitoneally, it does not impair the ability of adenovirus-transduced DCs to induce immune responses (14). Prior exposure to adenovirus under conditions that are likely to induce antiadenovirus antibodies does not impinge on the ability of an adenoviral vector encoding a model tumor antigen to induce protective immunity when given intravenously, although the serum titers were not reported (25). Two i.p. injections of adenovirus induce an antiadenovirus antibody response that is sufficient to restrict the ability of an adenoviral vector encoding a minimal epitope to induce immunity when given intraperitoneally (16). Although the presence of antiadenovirus antibodies can apparently restrict or even eliminate the ability of adenoviral vectors encoding tumor or model antigens to elicit immune responses when given intraperitonally or intravenously, it is not clear to what degree preexisting immunity impairs adenovirus-mediated gene transfer in patients.

A variety of strategies could be adopted to circumvent the potential limiting issue of neutralizing antiadenoviral antibodies. Investigators have shown that gene transfer can be achieved in the face of an antiadenoviral humoral response by sequential administration of human adenoviral vectors of different serotypes. Thus, efficient gene transfer via subgroup C adenoviral vector is possible in spite of prior exposure to subgroups E or D adenoviruses (32) or to a different subgroup C adenovirus (33), but not to the same subgroup C adenovirus (32,33). Although proof of principle has been demonstrated for this strategy in murine models, it may be impractical economically to produce multiple clinical grade adenoviral vectors of different serotypes encoding common tumor antigens to induce and boost antitumor immune responses in patients.

Little information is available regarding the *in vivo* generation of antiadenoviral CTLs after administration of adenoviral cancer vaccines. Numerous reports, however, have shown that the i.m., i.v., s.c., or i.p. administration of adenoviral vectors can induce antiadenoviral CTLs that can restrict the duration of transgene expression in transduced target tissues. Circumstances have been reported in which long-term expression of a transgene was achieved in spite of the presence of antiadenoviral CTLs. This may be in part owing to the site of gene expression or the nature of the transgene product, or both. DCs transduced with adenoviral vectors fail to induce significant antiadenovirus CTL reactivity *in vivo* (11,13) in accordance with *in vitro* observations (17). This suggests that little presentation exists of adenoviral antigens by transduced DCs when expression of the TAA gene within the adenoviral vector is controlled by a strong promoter.

Only two clinical trials have been conducted using adenoviral vectors encoding tumor antigens or epitopes (Table 18.6-3). In both instances, the recombinant vectors were administered subcutaneously or intramuscularly at least twice with or without concurrent high-dose IL-2 to stage IV, HLA-A2-positive melanoma patients (31). Doses up to 10^{11} IU (or approximately 10^{12} viral particles) were administered, and no signs of article-related toxicity were detected, including inflammation at the injection site or changes in blood chemistry parameters or liver enzymes. One of 16 patients receiving an adenoviral vector encoding human melan-A/MART-1 (Ad2/MART-1) alone experienced an objective clinical response, whereas 4 of 20 patients receiving the virus plus high-dose IL-2 experienced objective clinical responses. In a second study, none of six patients injected intramuscularly with an adenovirus encoding human gp100 (Ad2/gp100) alone experienced an objective clinical response, whereas 1 of 12 patients receiving the gp100 virus plus high-dose IL-2 had a response.

Table 18.6-3 Summary of Phase 1 Clinical Trials with Adenoviral Vaccines

Indication	Transgene	Number of Patients	Dose	Route of Administration	References
Melanoma	Human MART-1	16 without IL-2; 20 with IL-2	10^7-10^{11} IU	i.m., s.c.	31
Melanoma	Human gp100	Six without IL-2; 12 with IL-2	10^9-6×10^{10} IU	i.m.	31
Melanoma and breast cancer	IL-2	15 melanoma; eight breast cancer	10^7-10^{10} PFU	Intratumoral	56
Neuroblastoma	IL-2	Ten	10^4-10^7 transduced tumor cells/kg body weight	s.c.	55

IL-2, interleukin-2; PFU, plaque-forming units.

As a biopsy was not performed on the site of vector administration, it is not possible to assess the degree of transgene transfer to these patients after i.m. or s.c. injection of virus. Of 36 patients who received the Ad2/MART-1, 25 patients were evaluated for HLA-A2-restricted reactivity in PBMCs to an immunodominant MART-1 peptide (residues 27-35). Five of the 25 evaluable patients showed enhanced MART-1 peptide reactivity postimmunization. It was not possible to determine whether those patients who experienced an objective clinical response also had enhanced MART-1 peptide reactivity in PBMCs postimmunization. Of the 18 patients injected intramuscularly with the Ad2/gp100 virus, none showed enhanced HLA-A2-restricted reactivity in PBMCs to any of the three immunodominant gp100 peptides. As patients were injected with adenoviruses encoding the entire MART-1 or gp100 proteins, it is conceivable that immunity could have been generated to TAA-derived peptides other than those tested or via HLA molecules other than A2. This was not investigated because of technical limitations.

Serum titers of total and neutralizing antiadenoviral antibodies were investigated. Three general observations can be made:

1. No apparent correlation existed between the dose or route of adenovirus administration and the titers of antiadenoviral antibodies induced, although patients who received greater than or equal to 10^{10} IU of virus tended to have higher serum titers.
2. No apparent correlation existed between the level of total antiadenoviral antibodies and neutralizing antiadenoviral antibodies.
3. No apparent correlation existed between the serum titers of antiadenoviral antibodies and clinical responses.

Thus, all patients, including those who experienced clinical responses, exhibited serum antiadenoviral antibodies before s.c. or i.m. injection of vector. Serum neutralizing antibody titers remained unchanged from baseline levels in most patients when low doses (up to 10^9 IU) were administered, suggesting a therapeutic window may exist for the administration of adenoviral vectors that provokes a minimal antiadenovirus immune response.

Genetic Modification of Tumor Cells Using Adenoviral Vectors

The ideal features of a vector for genetic modification of tumor cells are largely the same as those cited in the previous section for modification of APCs with the exception that, although vector-induced cytopathic effects might jeopardize the use of genetically modified APCs, such effects are less of an issue for genetically modified tumor cells and could, in fact, be an asset. Because of the heterogeneity of tumor cells, variable efficiencies of adenovirus-mediated gene transfer have been reported, but, in general, a variety of human tumor types can be transduced. In the clinic, one could transduce tumor cells *ex vivo* at high multiplicities of infection to favor gene transfer. For *in vivo* administration, multiple intratumoral injections of accessible lesions on a repeated basis would favor the genetic modification of a high proportion of cells within a tumor.

A variety of transgenes, including cytokines, costimulatory molecules, and combinations thereof have been delivered to tumor cells in an attempt to enhance their immunogenicity (Table 18.6-4). More than any other cytokine, IL-2 has been evaluated for its ability to stimulate antitumor cell immune reactivity after adenoviral vector–mediated delivery of the gene to tumor cells. Tumor cells transduced *ex vivo* (34,35) or *in vivo* via intratumoral injection (35,36,37,38 and 39) with Ad/IL-2 are impaired in their ability to form tumors. Instances of regression of established tumors have been reported, but results are variable depending on the model, size of tumor, and dose of vector administered (35,36,37 and 38). IL-2 gene expression at the tumor site appears to be required, as delivery of the IL-2 gene to distal sites provides no benefit (35). Rejection of transduced tumor cells can lead to protection from subsequent challenge with unmodified parental tumor cells (35,36 and 37). Histologic evaluation of regressing tumors producing IL-2 indicates the presence of a cellular infiltrate predominated by T cells (35,36 and 37). Local expression of IL-2 in adeno-transduced tumor tissue, however, is not without its problems, as it has been reported to cause liver toxicity not unlike that seen with recombinant IL-2 protein. Thus, the therapeutic window may be narrow (38).

Table 18.6-4 Summary of Preclinical Model Studies Demonstrating the Efficacy after Genetic Modification of Tumor Cells Using Adenoviral Vectors

Transgene	Gene Transfer Mode	Animal Model (Tumor Cell Type:Mouse Strain)	References

GM-CSF, granulocyte-macrophage colony-stimulating factor; HSV, herpes simplex virus; IL, interleukin; M-MSV, mouse murine sarcoma virus; MMTV, mouse mammary tumor virus.

In an attempt to enhance the immunogenicity of tumor cells, investigators have transduced tumor cells with adenoviral vectors encoding the costimulatory molecule B7.1. This approach is supported by *in vitro* (40) data showing that human ovarian and cervical tumor cells transduced with an adenovirus encoding B7.1 are superior to unmodified tumor cells in their ability to stimulate the proliferation of PBMC-derived T cells. Intratumoral injection of Ad/B7.1 has been reported to be ineffective or partially effective in reducing established tumors (39,41,42). Thus, gene transfer of B7 in conjunction with cytokines has been explored. An adenoviral vector encoding both subunits of IL-12, as well as B7, is more effective than adenoviral vectors encoding IL-12 or B7 alone in causing regression of established tumors (41). Similarly, an adenovirus encoding B7 and IL-2 is more effective than adenoviral vectors encoding IL-2 or B7 alone, as judged by induction of tumor regression and tumor-reactive T cells (42).

After a seminal report that tumor cells genetically modified to express GM-CSF can induce protective immunity (43), investigators have used adenoviral vectors as an efficient means to deliver this particular cytokine to tumor cells *ex vivo* (44), as well as *in vivo* (45). The administration of Ad/GM-CSF–transduced tumor cells induces systemic immunity as characterized by antitumor cell CTL reactivity in splenocytes and confers protection from challenge with unmodified tumor cells (44). Histologic evaluation has indicated DC recruitment to the site of injected tumor cells (44). Intratumoral injection of Ad/GM-CSF can retard tumor formation; however, the coinjection of Ad/GM-CSF and an adenovirus encoding the 5FC-activating enzyme cytosine deaminase (CD) in conjunction with 5FC treatment can be synergistic (45). DC infiltrates have been observed whether Ad/GM-CSF or Ad/GM-CSF plus Ad/CD are injected into tumors, whereas antitumor CTL reactivity is more pronounced after combination therapy.

Some of the most promising results obtained involving adenoviral-transduced tumor cells as cancer vaccines involves the use of IL-12. IL-12 is a master control cytokine that is expressed by activated APCs, can induce interferon-γ levels, and can enhance Th1-type immune responses in conjunction with IL-2. Intratumoral injection of an adenovirus encoding both subunits of IL-12 (Ad/mIL-12) can inhibit tumor growth (46,47), and, in some cases, cause tumor regression, whereas injection of virus at a site distal to the tumor retards tumor growth but does not induce regression (48,49), suggesting that local delivery of IL-12 at the tumor site is essential for regression. A dose response has been reported in which intratumoral delivery of 10^9 PFU has been shown to be optimal, whereas 10^8 PFU induces only partial, transient regression, and 10^7 PFU is largely ineffective (48). Animals that have rejected injected tumors demonstrate antitumor cell reactivity characterized predominantly by CD8 T cells in the spleen (49), whereas *in vivo* administration of anti-CD4 or anti-CD8 antibodies has been shown to abrogate immune responses induced by intratumoral injection of Ad/IL-12 (48). Animals that reject injected tumors are protected from subsequent challenge with tumor cells (47,48 and 49), suggesting that systemic immunity is induced. Intratumoral injection of Ad/IL-12 has also been shown to cause concurrent regression of distal lung metastases (48). Histologic examination of injected tumors reveals a CD4 and CD8 T-cell infiltrate post injection (49), and injected animals can exhibit elevated levels of IL-12 and interferon-γ at the tumor site (47), as well as in the blood (48,49). Transient expression of the IL-12 transgene has been reported such that baseline levels of cytokine are detected 7 to 14 days post tumor injection (48).

Tumor cells transduced *ex vivo* with an adeno vector encoding IL-4 are impaired in their ability to cause tumors in mice (50), and histologic evaluation reveals the presence of an eosinophil infiltrate in tumor cells expressing IL-4. Intratumoral injection of Ad/IL-4 slows the growth of s.c. tumors or induces complete tumor regression, and "cured" animals are protected from subsequent challenge with unmodified tumor cells. Similarly, multiple intratumoral injections of an adenovirus encoding interferon-α2b has been reported to induce regression of s.c. tumors (51). As these experiments were conducted in athymic nude mice, no assessment of immunologic memory to the tumor was investigated.

Given the variable levels of efficacy achieved by adenovirus-mediated delivery of a single transgene to tumor cells, investigators have explored combination gene therapy. In a model in which an adenovirus encoding IL-2 had little benefit and an adenovirus encoding the ganciclovir prodrug-activating enzyme herpes simplex virus thymidine kinase had partial benefit. The intratumoral administration of both adenoviruses caused significant tumor destruction, induced potent antitumor cell reactivity as characterized by tumor reactive CD8+ T cells, and conferred protective immunity from subsequent tumor cell challenge (52). In other models, however, combination therapy with Ad/TK plus Ad/IL-2 has been reported to be no better than Ad/TK alone (39). Intratumoral coinjection of adenoviral vectors encoding IL-12 and IL-2 is superior to either vector alone, as judged by the frequency of observed complete regression of injected, as well as distal, tumors (53).

Preexisting immunity to an adenoviral vector could potentially reduce the efficiency of gene transfer to tumor cells after

intratumoral injection of virus. Intratumoral gene transfer efficiency is reduced 2.4-fold in animals exhibiting preexisting antiadenoviral antibodies (54). This reduction in gene transfer efficiency, however, is insufficient to inhibit the ability of an adenovirus encoding IL-12 to cause regression of injected tumors and, thus, the induction of antitumor T-cell reactivity. No change in antiadenovirus antibody titers has been detected in patients receiving an s.c. injection of tumor cells previously transduced *ex vivo* with adenovirus, suggesting that an insufficient presentation of viral antigen exists in the transduced tumor cell vaccine (55). Thus, antiadenovirus antibodies may not be a limiting issue in the clinical application of adenoviral vectors for genetic modification of tumors *in vivo.*

A potential concern associated with using adenoviral vectors to deliver cytokine genes to tumor cells is that the induction of an antiadenovirus CTL response might detract from the desired antitumor cell immune response. It is well documented that the *in vivo* administration of adenovirus can induce CTLs; however, control experiments involving the intratumoral injection of adenoviral vectors encoding a marker gene, such as β-galactosidase, have shown that (a) the generation of antitumor cell CTL reactivity is not impaired by the introduction of adenovirus, and (b) the regression of injected tumors cannot be attributed to the action of antiadenovirus CTLs.

Clinical experiences with adenovirus vector–transduced tumor cells is limited. A study involving the intratumoral administration of a replication-deficient adenoviral vector encoding IL-2 into metastatic breast cancer or melanoma has been conducted (56), and an account of gene transfer to cutaneous plasmacytoma in one patient enrolled in this trial has appeared (57). A total of 23 patients (15 melanoma, 8 breast cancer) received intratumoral injections of 10^7 to 10^{10} PFU of the Ad/IL-2 virus with 18 patients receiving a single injection, four receiving two injections, and one patient receiving five injections. No grade 3 or 4 toxicities were noted in any of the patients; however, injection site–localized inflammation that resolved in 5 to 7 days was noted at all doses. Six patients experienced localized regression of injected tumors, but no partial or complete responses were noted. Eighteen of 22 injected tumor biopsies were positive for Ad/IL-2 vector, as judged by polymerase chain reaction 7 days after injection, whereas 62% of the samples were positive for IL-2 messenger RNA as judged by real-time polymerase chain reaction. Seventeen of 21 injected tumor samples showed an increase in lymphocyte infiltration predominated by CD8-positive T cells post injection. Serum titers of antiadenoviral antibodies increased in 16 patients evaluated, with more consistent and marked increases noted for viral doses of 5×10^9 PFU and higher. Nine of these 16 patients exhibited no neutralizing antiadenoviral antibodies in serum preinjection, and no change occurred for three of the nine patients post injection. Nine of the 16 patients demonstrated a significant increase in serum titers of antiadenoviral neutralizing antibodies, and, as above, more consistent increases were noted for viral doses of 5×10^9 PFU and higher. This study demonstrated the Ad/IL-2 vector is safe and relatively nontoxic, and extensive analysis of clinical samples revealed that no evidence existed for significant vector dissemination to organs or virus shedding, thus addressing potential safety concerns.

The s.c. administration of unirradiated autologous tumor cells transduced with an adenovirus encoding IL-2 to patients with advanced neuroblastoma has been reported (55). Of ten patients treated, five clinical responses were observed, including one complete response, one partial response, and three instances of stable disease. An evaluation of injection sites revealed the presence of a T-cell infiltrate, which varied from patient to patient, but was predominated by CD4+ T cells. All of the five patients who experienced a clinical response exhibited enhanced antineuroblastoma CTL reactivity.

Other Viral Vectors

Viral vectors based on herpes simplex virus and adenovirus-associated virus (AAV) have also been explored for immunotherapy of cancer in a limited number of studies. A replication-deficient herpes simplex viral vector encoding IL-2 can efficiently transduce tumor cells *in vitro*, and mice injected with irradiated, transduced tumor cells develop protective immunity and exhibit antitumor CTL activity (58). A replication-competent herpes simplex virus can inhibit tumor growth when injected intratumorally by cytotoxic viral replication, but inclusion of IL-12 within the vector enhances its antitumor effects and the generation of antitumor CTLs (59). Inhibition of tumor growth has been observed in immunocompetent but not immunodeficient animals. An AAV vector encoding an IL-12 fusion protein has been used to transduce acute myeloid leukemic blasts *in vitro* (60), whereas AAV vectors have been used to deliver IL-12 and the costimulatory molecule B7-2 to tumor cells *in vitro* (61), but no reports exist of *in vivo* efficacy. The observation that little information is available regarding the potential use of herpes simplex and AAV viral vectors for immunotherapy of cancer may be in part owing to the fact that production of sufficient quantities of replication-deficient forms of these vectors to support preclinical studies remains a challenge.

Summary

Part of "18.6 - Adenovirus and Other Viral Vaccines "

Encouraging preclinical data has been obtained, suggesting that DCs genetically modified by adenoviral vectors encoding TAAs and intratumoral injection of adenoviral vectors encoding immunomodulatory factors can be efficacious. Although clinical experience with adenoviral vector vaccines is limited, new immunotherapy studies are planned using autologous DCs transduced with adenoviral vectors encoding melanoma antigens and intratumoral injection of adenoviral vectors encoding potent cytokines, such as IL-12. Combination gene therapy has been shown to be synergistic in the induction of antitumor cell immunoreactivity in preclinical studies; therefore, it is not unreasonable to imagine that future clinical trials will involve the concurrent genetic modification of APCs and of tumor cells to dampen immune evasion by tumor cells, thereby enabling more effective destruction by antitumor immune effector cells. As adenoviral vectors constitute an efficient means to genetically modify APCs and tumor cells, the clinical application of adenoviral vaccines holds great promise.

Introduction

Part of "18.7 - Dendritic Cell Vaccines "

"In addition to granulocytes, lymphocytes, and mononuclear phagocytes, there is a fourth variety of adherent nucleated cell whose morphological features are quite distinct.… The cytoplasm of this large cell is arranged in pseudopods of varying length with form and number resulting in a variety of cell shapes ranging from bipolar elongate cells to elaborate stellate or dendritic ones. Most pseudopods

are long, uniform in width, and have blunt terminations, but smaller spinous processes are also evident. The cytoplasm contains many large circular phase-dense granules as well as infrequent refractile granules, probably lipid. There is no morphological evidence of active endocytosis even if the cells are cultivated for several hours in high concentrations (40% volume/volume) of serum, conditions known to stimulate endocytosis in macrophages *in vitro.*"

—Zanvil A. Cohn and Ralph M. Steinman (1973)

Identified in the early 1970s by Cohn and Steinman, dendritic cells (DCs) were named for their curious morphology with long dendritic processes. DCs were difficult to study and define until the development of modern culture techniques in the 1990s using recombinant cytokines. These strategies have been used to define the DCs' central role in antigen processing and presentation (1). In the mid-1990s, we have seen substantial refinement in our understanding of what is a family of cells and their potential application in treating disease in preclinical models, as well as in clinical protocols. We are beginning to understand the role of DCs, not only as antigen-presenting cells (APCs) capable of monitoring the internal milieu, but also as regulators of tissue repair, transplant rejection, and the initiation and maintenance of the inflammatory response (2,3). In addition to playing a role in regulating the initiation of the immune response (4), DCs appear to play a role in the maintenance of the immune response, providing signals for effector T-cell survival. Nonimmune roles as well are suggested by the finding that they produce proangiogeneic and antiangiogeneic hormones. The DC truly has a central role as the pacemaker of the immune system.

DCs not only serve in antigen presentation; they provide costimulation and cytokines to prevent apoptotic death for recruited effector T cells. A number of tumor types, including colorectal cancer and hepatoma and lung cancer (5,6,7 and 8), express Fas ligand (FasL). FasL, a molecule on the cell surface and counterreceptor for the Fas receptor, is expressed on virtually all mammalian cells, including activated T cells, and causes the induction of apoptosis in susceptible T cells. Thus, we have the seemingly paradoxic situation of tumors killing T cells instead of T cells killing tumors. For that reason, one goal of the tumor immunologist is the prevention of premature T-cell apoptotic death and the engagement of so-called T-cell futile cycles. DCs, by virtue of their expression of so-called costimulatory molecules, such as CD80 (B7.1) and CD86 (B7.2), and several "dendrikines," including interferon-α (IFN-α), interleukin-12 (IL-12), and IL-18, may be uniquely capable of preventing premature T-cell death, and, thus, becoming the mediators of T-cell survival.

The biologic therapist has five goals when seeking to treat cancer:

1. The induction of an effective cell-mediated T-cell response
2. The promotion of T-cell survival in the inhibitory milieu of the tumor microenvironment
3. The development of long-lived memory
4. Designing strategies to deliver T cells across the endothelial barrier
5. Regulating angiogenesis (9)

Just as chronic responses to microbial pathogens are maintained in part by retention of antigens in follicular, and, perhaps, other DCs, a durable T-cell response may require DC provision of survival factors, and, possibly, antigens at the site of tumor, as well as regulating the local vascular blood supply.

DC biology was initially related to cancer with the observation that DC numbers correlated with prognosis in numerous tumor types, including (a) various cancers from the lung, head, and neck; (b) breast, cervical, endometrial, esophageal, gastric, pancreatic, colon, and prostate cancer; and (c) Hodgkin's disease and mycosis fungoides (10,11,12,13,14,15 and 16) (Fig. 18.7-1, Table 18.7-1). These findings legitimize DC-based immunotherapy, for reversing DC dysfunction and paucity in cancer patients by genetic engineering, cytokine treatment, or the adoptive transfer of DCs may prove therapeutic. The use of DCs in cancer patients may lead to a long-lasting tumor response through efficient activation of specific T cells and the prevention of tumor-induced T-cell death (TICD). Our clinical immunotherapy regimes have combined receptor IL-2 therapy with the adoptive transfer of tumor-infiltrating lymphocytes or lymphokine-activated killer cells with mediocre results (17). Newer strategies involve the adoptive transfer of DCs primed with tumor antigens to elicit a specific, cell-mediated response (18). Promising murine results from our group and others have been brought to intriguing human trials, many of which are reporting responses. Furthermore, the administration of the dendropoietic cytokines FLT-3 ligand (FL), IL-12, or granulocyte-macrophage colony-stimulating factors (GM-CSF) may enhance *in vivo* DC production, and, thereby, specifically enhance T-cell activation (19,20 and 21).

Table 18.7-1 Relationship between Dendritic Cell Infiltration and Prognosis in Malignancy

Tumor	Author (Year)	Dendritic Cell Infiltration
Arsenical skin	Yu (1992)	Less compared with normal skin
Basal cell	Bergfelt (1994)	Less in tumors
Basal cell	Bergfelt (1992)	? Improved
Breast	Wilson (1991)	? Improved prognosis
Bronchoalveolar	Tosi (1992)	No effect
Cervix	Morelli (1993)	Less in human papilloma virus + tumors
Cervix	Nakano (1992)	Improved
Cervix, stage III	Nakano (1993)	Marked improved prognosis
Cervix/penile	Morelli (1992)	Less with human papilloma virus infection
Cervix/human immunodeficiency virus	Spinillo (1993)	Less in acquired immunodeficiency syndrome
Endometrial	Coppola (1998)	Langerhans' infiltration favorable
Esophageal	Furihata (1992)	Marked improved prognosis
Esophageal	Imai (1993)	Direct relationship to grade
Gastric	Tsujitani (1992)	Marked improved prognosis
Gastric	Tsujitani (1995)	More in tumor draining lymph nodes
Gastric, stage III	Tsujitani (1993)	Marked improved prognosis
Hodgkin's disease	Alavaikko (1994)	Follicular dendritic dells improve prognosis
Lung	Zeid (1993)	Marked improved prognosis
Lung	Tazi (1993)	Related granulocyte-macrophage colony-stimulating factor production
Melanoma	Toriyama (1993)	Inverse with tumor thickness
Mycosis fungoides/SS	Meissner (1993)	Marked improved prognosis
Prostate	Bigotti (1991)	Improved prognosis
Pancreatic adenocarcinoma	Dallal et al., manuscript in prep.	Virtually no dendritic cells found
Skin tumors	Schreiner (1995)	Less in tumors
Tongue cancer	Goldman (1998)	Increased dendritic cells improved prognosis
Thyroid (papillary)	Willgeroth (1992)	No effect
FIGURE 18.7-1. Pancreatic adenocarcinoma specimen demonstrates extensive infiltration of S100+ dendritic cells. Only 3 of 47 patients exhibited this degree of S100+ DC infiltration and lived 50, 34, and 3 months (group average, 18 months). (Dallal RM et al. *Unpublished data.*)

Dendritic Cells

Part of "18.7 - Dendritic Cell Vaccines "

DCs appear to be central to the regulation, maturation, and maintenance of a cellular immune response to cancer. They are characterized by the presence of veils and long processes that are quite active, continually extending and retracting, which allows them to be highly mobile. DCs are the most potent APCs in humans; they express high levels of class I and class II major histocompatibility complex (MHC) costimulatory molecules and produce a variety of cytokines, including IL-1, IL-12, IL-18, and IFN-α (22,23). These cytokines stimulate T-helper type 1 (Th1) cells, thus promoting the cellular immune response. DCs are up to 100-fold more efficient in stimulating an allogeneic mixed lymphocyte reaction than other APCs. MHC products are 10 to 100 times higher on DCs than on monocytes or B cells, and DCs contain far more signal two–signaling molecules and T-cell adhesion molecules than other APCs. DCs take up antigen through a variety of pathways, including Fc receptors, mannose receptors, and fluid-phase macropinocytosis. So-called immature DCs take up apoptotic and necrotic cells, microbes, particulate antigens, and soluble proteins. After antigen capture and maturation, DCs apparently promote T-cell survival and selection. After encounter with the appropriate T cells and their subsequent expansion, DCs undergo an apoptotic death in the lymph node and can become targets for T cells or be engulfed by resident macrophages or DCs (24,25 and 26).

Dendritic Cell Origins

DCs constitute a rare but heterogeneous population phenotypically distinct from macrophages (CD14⁻) and represent less than 1% of the entire circulating leukocyte population. They are lineage-negative cells that are distinct from T cells, B cells, natural killer (NK) cells, and monocytes. They include:

1. Langerhans' cells (LCs), located primarily in the skin and epithelial tissues
2. Interdigitating cells, located within T-cell–rich areas within secondary follicles
3. Lymphoid DCs, located in the germinal centers of lymphoid follicles (27)
4. Thymic DCs, a subtype of lymphoid-derived DCs located in the thymic medulla, where they are involved in T-cell selection
5. Veiled cells found in peripheral blood

Various surface markers can be used to identify and distinguish DCs (Table 18.7-2) from other cell types.

Table 18.7-2 Chart of Relevant Surface Markers Related to Dendritic Cells

Surface Marker	Cell Expressing	Comments
CD1a,b,c,d	Cortical thymocytes, Langerhans' cells, some DCs, B cells (CD1c), intestinal epithelium (CD1d)	MHC class I-like molecules associated with beta-2-microglobulin. Presents glycolipids to γδ T-cell receptor
CD4	Helper T cells, weakly positive in lymphoid DC subsets	Coreceptor for MHC class II molecules. Binds lck on cytoplasmic face of membrane.
CD8	Lymphoid DCs express α chain, cytotoxic T cells	Found in DCs with lymphoid origin. Coreceptor of MHC class I molecules
CD11b	Lymphoid DCs	αM subunit of integrin
CD11c	Myeloid DC cells	αX subunit of integrin CR4 (associated with CD18); binds fibrinogen
CD13	Myelomonocytic cells	Zinc metalloproteinase. cleaves N-terminal amino acids from MHC class II-bound peptides
CD14	Myelomonocytic cells	Receptor for complex of LPS and LPS binding protein
CD25	Activated T cells, B cells, monocytes	Interleukin-2 receptor α, marker for terminally differentiated DCs
CD32	Monocytes, granulocytes, B cells, eosinophils	Low affinity Fc receptor for aggregated Ig/immune complexes
CD33	Myeloid progenitor cells, monocytes	Involved in cell-cell adhesion
CD34	Hematopoietic precursors, capillary endothelium	Ligand for CD62 (L-selectin)
CD40	Mature B cells, DCs, activated monocytes	Receptor for CD40L on T cells
CD45	All hematopoietic cells except erythrocytes	Necessary for signaling through T-cell receptor
CD54	Numerous cell types, DCs	Enhances interaction between T cells and antigen-presenting cells
CD58	Numerous cell types	LFA-3 binds CD2, adhesion molecule
CD64	Monocytes, macrophages	High-affinity receptor for IgG
CD80	Resting monocytes, DCs	Interacts with CD28 to provide signal 2
CD83	Activated B cells, activated T cells, circulating DCs (veil cells)	Maturation marker DC; unknown function
CD86	B-cell subset	Interacts with CD28 to provide signal 2
CD102	Numerous	Intercellular adhesion molecule. binds CD11a/CD18 (LFA-1) and CD11b/CD18 (Mac-1) integrins
CDw116	Monocytes, eosinophils, endothelium	GM-CSFR α chain GM-CSF cytokine receptor superfamily

DC, dendritic cell; GM-CSFR, granulocyte-macrophage colony-stimulating factor receptor; Ig, immunoglobulin; LFA, leukocyte function-associated antigen-3; LPS, lipopolysaccharide; MHC, major histocompatibility complex.

DCs are derived primarily from the bone marrow, as revealed by their expression of the common leukocyte antigen CD45 (28). Irradiated mice transplanted with allogeneic bone marrow demonstrate donor MHC on DCs located from the spleen and epidermis (29). These cells express CD13, CD33, and CD11, which are markers of myeloid derivation. The myeloid origin of DCs, however, is confusing. In Ikaros mutants, where all lymphoid precursors are lacking, only the LCs and DCs remain (30). Furthermore, nonprimitive progenitors for lymphoid cells and DCs can be distinct from those of myeloid, megakaryocytic, and erythroid cells, implying that the DC lineage may be more related to the lymphoid lineage than to the myeloid lineage (31).

LCs are located in the basal and suprabasal layers of the epidermis. LCs are myeloid progenitors from CD34⁺ cells, which express the skin-homing cutaneous lymphocyte-associated antigen (CLA) (32). LCs express high amounts of CD1a and are associated with Birbeck granules. CD1a, an MHC-like molecule that associates with beta-2-microglobulin, presents mycobacterial lipids and glycolipids to T cells and some NK-T cells (33,34). LC precursors can differentiate into macrophages under the response

of macrophage colony-stimulating factor (35). Interstitial DCs and CD34-derived cells differ from LCs by lacking CLA, demonstrating higher antigen capture efficiency, and associating with germinal centers. Interstitial DCs are CD1a+ and FXIIIa+ (36). LCs and other DCs express E cadherin (37), α-6/ß-1 integrin, chemokine receptors CCR 1, 2, 5, and 6, as well as the CXCR1 (38).

GM-CSF and tumor necrosis factor (TNF) stimulate growth and differentiation of DC progenitors into DC precursors (39). This differentiation can be enhanced by multiple cytokines, including c-kit, Flt-3 ligand (FL), tumor growth factor-ß (TGF-ß), IL-4, IL-13, and, in particular, TNF-α. Protein kinase C and nuclear factor κB (NFκB) activation seem central in this process (40). IκB phosphorylation releases NFκB in DCs and supports the survival and maturation of these cells. Although numerous agents, including TNF, IL-1, IL-17, lipopolysaccharide, various viruses, phorbol myristate acetate, oxidative agents, and mitogens, cause phosphorylation of IκB, which releases NFκB, the kinase responsible for this in DCs had been elusive. A potent dendropoietic cytokine, FL, induces massive (up to 300-fold) increases in the numbers of DCs in mice and humans. These DCs are functionally and phenotypically indistinct from IL-4/GM-CSF-derived DCs when tested *in vitro.*

When cultured with IL-4 and GM-CSF, peripheral blood monocytes can be induced without proliferation to differentiate into immature DCs (i.e., veiled cells high in costimulatory molecules, class II, CD40, and capable of stimulating a T-cell response at low concentrations) from CD14+ monocytes (41). DCs also can be derived from CD34+ hematopoietic progenitor cells isolated from specific cell columns. Once incubated with IL-4, supercritical fluid (SCF), TNF-α, and GM-CSF, these CD34+ cells proliferate 6 to 8 times and have the phenotype and function of immature DCs (42). Many debate the differences between the myeloid DCs derived directly from CD34+ cells and CD14+ cells. CD34+ DCs may have a preferential capacity to activate CD8+ T cells (43), and CD14-derived DCs elicit enhanced immunoglobulin M (IgM) production from B cells after coculture and addition of soluble CD40L and IL-2. Only the CD14-derived DCs secreted IL-10 after CD40 activation (44). In our early murine studies, we demonstrated that GM-CSF plus IL-4-cultured DCs were superior in their antitumor effects when compared with those derived from CD34 precursors cultured in GM-CSF alone or GM-CSF and TNF-α (45).

The understanding of the ontogeny and phylogeny of DCs has advanced considerably. It appears that the so-called myeloid DCs, those best defined in the early 1970s as separate and distinguishable from macrophages, are directly descended from a CD34+, CD45RA+, or CD10- progenitor or indirectly through a monocyte/macrophage-type cell. A second type of DC, a "lymphoid"-related DC first identified in the thymus and then in peripheral nodal tissue and peripheral blood, is believed to be most closely related to T cells, B cells, and NK cells. The individual roles of myeloid and lymphoid DCs have not been delineated. Lymphoid DCs might be involved in the maintenance of tolerance. Liu et al. propose two distinct DC phenotypes, DC1 and DC2. The human DC1, the conventional "myeloid" DC, plays a role in driving maturation of naïve CD4+ cells into Th1-type cells. When maintained in IL-3 and soluble CD40L, DC2, the "lymphoid" DC, promotes Th2 differentiation (39). Conversely, some groups suggest that lymphoid DCs (which, in their model, produce IL-12) induce Th1 phenotype based on adoptive transfer of DCs in murine models (46). Both models suffer from somewhat protracted culture and isolation of cells; their legitimate role in negative and positive selection or generation of Th1 or Th2 cells requires additional study.

Thymic DCs presumably collect and present self antigen to developing T cells and initiate apoptosis (i.e., mediate negative selection) and the induction of self tolerance (47,48). They express many of the characteristic markers of DCs; in mice they are CD8α+ and in humans they are CD4+ (49,50). Thymic DCs (also known as *lymphoid* or *plasmacytoid DCs*) are bone marrow derived but have a relatively short life span, unlike follicular DCs. In the mouse, these cells are initially unresponsive to GM-CSF but respond to IL-3, FL, CD40L, TNF-α, IL-1, IL-7, and SCF (51). Thus, one classifies them as *lymphoid DCs* (52).

Thymic DCs, lymphoid DCs, and liver DCs differ from myeloid DCs in their appearance and function. By electron microscopy, these plasmacytoid cells have abundant endoplasmic reticulum but die rapidly in culture unless placed in culture with IL-3 and CD40 ligand. The major distinguishing characteristics of the DC2 from so-called DC1 or myeloid DCs is a failure to express CD1a, b, and c and a somewhat higher expression of CD1d. They express CD4 compared with only low-level expression on DC1s and fail to express high levels of CD11b, CD11c, CD13, or CD33. Their DC1s are CD45RO+, whereas DC2s are CD45RA+. DC1s express the GM-CSF receptor α chain, whereas DC2s express the IL-3 receptor α chain and produce a paucity of cytokines, including IL-8 (53). DC1s produce IL-1α, IL-1ß, IL-6, IL-7, IL-12 (p35 and p40), IL-15, IL-18, TNF-α, TGF-ß, macrophage colony-stimulating factor, and GM-CSF (54). Naïve T cells cocultured with DC1s produce INF-γ, whereas DC2s induce production of IL-4, IL-5, and IL-10 (55). Although one observes IFN-γ induction from naïve cells by DC2s, it is attenuated, especially in proportion to the amount of IL-4 produced (56).

NK T cells with characteristic T-cell receptor rearrangement (mouse, Vα14 and Vß8; human, Vα24 and Vß11) respond to myeloid DCs depending on IL-12 availability. When IL-12 is available, they become predominantly Th1-like and make IFN-γ and induce cytotoxic T lymphocytes (CTLs). In the absence of IL-12, NK-T cells become more Th2-like and produce IFN-γ and IL-4 (57).

Follicular DCs are found in the B-cell region of all secondary lymphoid tissue and exhibit typical dendritic morphology (58). Germinal centers contain rapidly proliferating B cells undergoing affinity maturation. They are involved in antigen presentation to B cells and memory B-cell development and lack phagocytic activity (59). They are particularly long lived and have the ability to capture antigen and present antigen for prolonged periods. Controversy exists as to whether follicular DCs have marked differences from other DCs (60).

Some have even suggested that neutrophils could also give rise to DCs by culturing CML blasts, which were CD65+, MPO+, and lactoferrin+, and in 9 days of culture with GM-CSF, IL-4, and TNF-α. The blasts (class II+, CD1a, b, c+, CD40+, MPO-, lactoferrin-) are consistent   with   a   DC   (61).

Murine CD19+ pro-B cells develop into DCs with T-cell stimulatory properties when cultured in IL-1ß, IL-3, IL-7, TNF-α, SCF, and FL. These pro-B cells acquired the DC-related markers CD11c and NLDC145/DEC-205, along with CD80, CD86, and a high density of MHC class II molecules. These marrow-derived DCs do not express CD4 or CD8α, markers related to thymic DCs (62).

Dendritic Cell Maturation

The concept of a stable and rigid DC phenotype oversimplifies the complex biology of DC maturation. DCs have multiple roles and dynamically shift phenotypes relative to their environment. The immature DC is an avidly phagocytic cell with moderate cytoplasmic veil formations. Typically, immature DCs are obtained by culturing the adherent layer of mononuclear cells with IL-4 and GM-CSF. IL-13, and, perhaps, IFN-α (Egawa S., *unpublished data*) can substitute for IL-4 in inducing DC formation (63,64). The mature DC is induced after interaction with bacterial products, such as lipopolysaccharide or saccharin, activated T cells expressing CD40L, apoptotic body uptake, monocyte-conditioned media (macrophage supernatant), and cytokines, including TNF-α or IL-1 (65,66 and 67). Mature DCs most notably express CD83, as well as the p55 actin-budling protein fascin (68,69). They develop extensive cytoplasmic veils, lack antigen-uptake capacity, express different cytokine genes, and display even higher levels of costimulatory molecules, as well as higher levels of class II MHC and CD40 (70). Antigen uptake promotes immature DCs to maturity and allows them to migrate into the lymph node and most efficiently activate a specific T-cell response. A terminally differentiated DC induced by a cytokine cocktail of prostaglandin E$_2$ (1 μg per mL), IL-1ß (10 ng per mL), TNF-α (10 ng per mL), and IL-6 (1,000 U per mL) also exists, which displays even higher amounts of costimulatory molecules, as well as the IL-2 receptor α chain CD25 (Fig. 18.7-2, Fig. 18.7-3, Fig. 18.7-4, Fig. 18.7-5, and Fig. 18.7-6) (71). These cells become unresponsive to CD40 ligation and do not produce IL-12 (72). Monocyte differentiation is reversible, as immature monocyte-derived DCs can reverse into a macrophage after cytokine withdrawal. Mature DCs cannot undergo this reversion. One reason some groups support adoptive transfer of mature DCs is that immature DCs may lose their efficiency for T-cell stimulation once removed from exogenously supplied cytokines.

Flow cytometry of 7-day granulocyte-macrophage colony-stimulating factor/interleukin-4–derived DC, after 48 hours macrophage supernatant and cytokine cocktail of prostaglandin E_2 (1 μg per mL), interleukin-1ß (10 ng per mL), tumor necrosis factor–α (10 ng per mL), and interleukin-6 (1,000 U per mL).

Antigen Capture

Immature DCs are efficient at antigen uptake through several mechanisms, such as the engulfment of apoptotic bodies, macropinocytosis, and receptor-mediated endocytosis via mannose and Fc receptors (CD32 and CD64) (73,74 and 75). These antigens are then processed and complexed with MHC class II and can stimulate a T-helper response. Apoptotic bodies are internalized via binding to $α_vβ_5$, $α_vβ_3$, and CD36 (76). Macrophages are unable to efficiently present antigen from apoptotic cells in part because of the lack of $α_vβ_5$ associated with more rapid degradation of ingested material (77). Maturation also induces downregulation in all of these receptors. $α_vβ_5$ is associated with a 180-kd protein downstream of CrK, DOCK180, which is a homologue of the *C. elegens* protein CED5, which confers slower degradation of antigen than $α_vβ_3$ (78,79).

The captured antigen is engulfed into the MHC class II compartments and relocalized to the cell surface, where the peptide-MHC complex can present to CD4+ cells. How a CD8+ cell is activated in an MHC class I–restricted manner from exogenous antigens is unclear; however, the occurrence of this *in vivo* cross-priming, especially when the antigen is an apoptotic body, is unique to DCs (80,81 and 82).

Dendritic Cell Migration

DCs traffic from the blood to the tissue, where they capture antigens and mature. They then migrate to the lymph nodes to present antigen to T and B cells. Complex regulation of chemokines and their receptors allow this process to proceed. *In vitro*–generated, monocyte-derived DCs express the chemokine receptors C5aR, CCR1, CCR2, CCR5, CCR6, CXCR1, CXCR2, and CXCR4. They migrate in response to the CC chemokines MCP-3, MCP-4, RANTES, MIP-1α, MIP-1ß, and MIP-5 and to the CXC chemokines SDF-1 (83,84). Several adhesion molecules also participate in DC trafficking, such as CLA, CD44, and E-cadherin (85). DCs also possess metalloproteinases involved in matrix degradation, allowing for migration through basement membranes (86). Studies have shown that immature and mature DCs are not recruited by the same chemokines.

Immature DCs respond to many CC- and CXC-chemokines (MIP-1α, MIP-1ß, MIP-5, MCP-3, MCP-4, RANTES, TECK, and SDF-1), and, in particular, to MIP-3α/LARC, which acts through CCR6, a receptor expressed predominantly on immature DCs and memory T cells (87). MIP-3α is inducible by several inflammatory stimuli like most other chemokines acting on immature DCs. In contrast, mature DCs have lost their responsiveness to most of these chemokines through receptor downregulation or desensitization, but acquired responsiveness to MIP-3ß/ELC and 6Ckine/SLC as a consequence of CCR7 upregulation. The CCR7 ligands 6Ckine and macrophage inflammatory protein MIP-3ß are selective chemoattractants for bone marrow–derived DCs at a potency 1,000-fold higher than their known activity on naïve T cells and play an important role the homing of DCs to lymphoid tissues (88).

Migration of DCs to draining lymph nodes occurs as a result of the downregulation of inflammatory chemokine receptors (89,90). Mature DCs cluster with T cells through various intercellular adhesion molecules that are upregulated on maturation as well, including CD102 (intracellular adhesion molecule-3), CD58 (leukocyte function–associated antigen-3), and CD54 (intracellular adhesion molecule-1) (91). The CX3C chemokine fractalkine is associated with DCs, and CD40 ligation increases expression by 2.5-fold. This molecule may also play a role in the interaction of mature DCs and T cells (92).

Perhaps the most facile means to contrast CD34-derived DCs and CD14 monocyte–derived DCs is by their chemokine

receptor expression and response to individual chemokines. CD34-derived DCs appear to respond preferentially to MIP-3α and not to MIP-1α or RANTES and conversely for monocyte-derived DCs. The CCR6 chemokine receptor appears to be on immature DCs, as well as memory T cells, responding to the chemokine MIP-3α. When culturing DCs from CD34+ cells, MIP-3α peaks at approximately days 7 to 10, decreasing considerably by day 13 with a concurrent increase in the expression of CCR7. Similarly, one can make this transition from CRC6 to CRC7 by culturing cells with CD40L stimulation.

T-Cell Priming

Activation of naïve T cells occurs only subsequent to priming by APCs containing high levels of antigen, costimulatory molecules, and proinflammatory cytokines. It requires 10 to 24 hours of engagement to become fully activated depending on the level of costimulatory molecules. Effector T cells, however, can become activated after triggering from fewer peptide-MHC complexes within 1 hour. In an allogeneic mixed lymphocyte reaction, only one DC is needed for every 3,000 T cells. T cells become activated after reaching a threshold of antigen-MHC cross-linking of the T-cell receptor (TCR). The presence of costimulatory molecules and especially the duration of the signal can modify the threshold for activation. DCs provide high levels of adhesion molecules that enable prolonged TCR stimulation. Furthermore, proliferation and cytokine production require higher levels of TCR occupancy than the induction of cytotoxicity.

Effector T cells undergo activation-induced cell death (AICD) after prolonged TCR signaling in the absence of costimulation. Thus, DCs also serve to protect T cells from AICD. In general, tumor cells do not express CD80 or CD86. Furthermore, after CD40 ligation, DCs produce IL-12 and IL-18, potent stimulators of IFN-γ and the Th1 response (93,94,95 and 96). In the absence of a professional APC, anergy or apoptosis is induced. DCs are also involved in regulating and priming the humoral immune response, as they regulate B-cell growth and differentiation (97,98). DCs orchestrate Ig class switching

of B cells, especially IgA2, thereby controlling mucosal immunity (99).

Dendritic Cells and the Tumor Microenvironment

Part of "18.7 - Dendritic Cell Vaccines "

It is well demonstrated that the immune system can recognize and destroy tumor cells in humans and in animal models. Tumors, however, evade immune recognition through numerous mechanisms, including:

1. Downregulation of MHC molecule expression
2. Secretion of inhibitory hormones, such as TGF-ß and IL-10
3. Upregulation of antiapoptotic proteins within the tumor, such as bcl-2
4. Diminished susceptibility to immune killing because of the inability to express or signal through Fas
5. Expression of apoptosis-inducing proteins, such as soluble and cellular FasL (100,101,102 and 103).

Tumors may also evade the immune system through tumor-induced DC apoptosis through regulation of bcl-2 and Bax expression (104).

Tumor-associated DCs undergo apoptotic death *in vivo*, and DCs isolated from tumor tissue showed significantly higher levels of apoptosis when compared with DCs isolated from spleen. CD40 ligation inhibits Fas-mediated apoptosis in human DCs (105). A variety of factors may negatively affect DC function in the tumor, including prostaglandins, nitric oxide, IL-10, TGF-ß, and various other poorly described tumor-suppressor products (106,107,108 and 109). Vascular endothelial growth factor alters the *in vitro* and *in vivo* development of DCs from bone marrow progenitors, in part by modifying NFκB production in bone marrow and mobilization into the nucleus (110,111). The initial notion that DCs are present within tumors to pick up tumor antigen and shuttle it to the lymph node to elicit the adaptive immune response may be a bit too simplistic. In fact, we and others have demonstrated the inability of tumor-derived DCs to express appropriate costimulatory molecules, class II MHC molecules, characteristic dendrites, and even mature dendrites from progenitors associated with their nominal "immunosuppressed state" (112,113 and 114).

Another means of DC-related tumor escape may reside with the macrophage. The tissue macrophage's major role is to eliminate apoptotic cells and debris. In the aberrant cytokine milieu of the tumor microenvironment, those macrophages that normally undergo a differentiation process to a DC may fail to become fully activated APCs. These cells may then become tolerogenic rather than immunogenic (115,116 and 117).

The failure of immunotherapy may be caused by this "counterattack" by the tumor against immune effector cells. We term apoptosis induced by the tumor on nonspecific T cells as *tumor-induced cell death* (118,119 and 120). To enhance the effectiveness of DC-based therapies, alternate approaches to delay AICD and TICD are being sought. An expected outcome of this approach is an enhanced quality and duration of an effective immune response. In addition, DCs that are not appropriately activated may induce a state of immune tolerance. Available literature suggests improved prognosis for cancer patients in relationship to tumor infiltration by DCs. This finding applies to a variety of tumor origins and suggests a positive therapeutic outcome if DCs are delivered to tumor sites. The dynamic relationship between tumor cells, DCs, and tumor-infiltrating lymphocytes within the tumor microenvironment are complex. Strategies that enhance DC number and prevent their premature apoptotic death at the tumor site could be therapeutic.

AICD, for example, is an apoptotic program that is induced after cognate antigen recognition in activated immune cells (121). This natural termination of an immune response is a powerful feedback mechanism that ensures removal of preactivated lymphocytes to avoid unwanted tissue injury and nominally returns the host to a state of homeostatic balance. Tumor cells, as well as normal cells, express molecules capable of modifying immunity. Unexpectedly, tumors cannot only induce AICD and eliminate presumably unnecessary specific effector lymphocytes but can also eliminate or induce anergy of other nonspecific T cells. TICD, which does not require cognate recognition, is a plausible means by which immune suppression is induced by tumor cells. The most frequently implicated mechanism mediating TICD is the Fas/FasL apoptotic pathway. Substantial criticism of the data associated with this premise has been presented given the difficulty in convincingly demonstrating this molecule on the cell surface.

Prevention of TICD may occur as a result of CD28 activation through the upregulation of bcl-xl, a member of the bcl-2 family of antiapoptotic proteins (122,123 and 124). IL-12 is protective of apoptotic death in activated T cells, making the presence of DCs, the

major source of IL-12 at the tumor site, potentially critical for expansion and protection of antitumor immunity (125). DCs also express significant amounts of CD80 and CD86, the ligands for CD28 (and cytotoxic T lymphocyte antigen-4) (126). The central role of DCs in antigen presentation and in T-cell priming and protection makes their use in cancer therapy enticing. The lack of adequate antigen presentation of tumor antigen by host DCs may be overcome by DC-based immunotherapy (127). Two fundamental approaches exist in the use of DCs for therapy: delivering tumor antigen into the DC or delivering DCs into the tumor (Table 18.7-3).

Dendritic Cell-Based Cancer Therapy

Part of "18.7 - Dendritic Cell Vaccines "

Delivering Tumor Antigens onto Dendritic Cells

Pulsing synthetic peptides derived from known tumor antigen precursors, such as MART-1 /Melan A, tyrosinase, carcinoembryonic antigen, HER2/NEU, or gp100, can load MHC complexes expressed on DCs (128,129,130,131,132,133,134,135,136 and 137). These peptides, however, only reside on the cell surface for a short period (hours) and are limited for use in patients who express an individual, specific MHC haplotype. Gene-based strategies do not require prior knowledge of the responder MHC haplotype or of the relevant MHC-restricted peptide epitope. Human DCs genetically engineered to express the melanoma antigens MART-1/Melan-A are able to generate MART-1 peptide-specific, class I-restricted CTLs in peripheral blood leukocyte cultures from normal donors (138).

Several disadvantages exist to the use of defined tumor antigen besides the overwhelming lack of known tumor rejection antigens for most human tumors. Where it has been tested most widely, the use of specific antigens benefit only a subpopulation of melanoma patients that express the relevant MHC allele, and even these patients may be prone to tumor resistance by mutations when a small repertoire of antigens are challenged. Furthermore, the ability to generate a CTL *in vitro* does not guarantee an effective immune response *in vivo*. DC-based strategies, which do not require prior knowledge of the responder MHC haplotype or of the relevant MHC-restricted peptide epitope, have also been developed using tumor itself as a source of antigen.

Multiple techniques have been described to load DCs with peptide when tumor rejection antigens are unknown. These range from "feeding" DCs tumor lysates (139,140), messenger RNA (141), acid-eluted peptides, apoptotic tumor, or creating tumor-DC fusion heteroconjugates (142,143). Coinsertion of known melanoma antigens with Th1 cytokines IL-12 or IFN-α enhances the magnitude of antigen-specific CTL reactivity in murine tumor models (144,145,146 and 147).

In 1998, tumor peptide-pulsed DC-derived exosomes (vesicles that contain high amounts of MHC, CD86, and peptide) were successfully used to prime specific CTLs *in vivo* and eradicate or suppress growth of established murine tumors (148). In a human chronic myeloid leukemia model, tumor cells incubated in GM-CSF, IL-4, and TNF-α differentiated into mature DCs capable of stimulating an autologous anti-chronic myelogenous leukemia CTL response.

Disadvantages of these techniques include the requirement for access to sufficient quantities of patient tumor and the possibility of autoimmune reactivity. We have observed vitiligo in many patients successfully treated for melanoma with various IL-2-based strategies; one of our patients developed rheumatoid arthritis after a complete response to DC-based immunotherapy (149). A major limitation to fusion heteroconjugates is the requirement for a pure and proliferating neoplastic cell line.

The use of RNA, DNA, and subtractive hybridization strategies could allow the enrichment and easy amplification of tumor-specific RNA (150,151,152 and 153). The ease in generating large quantities of nucleic acids gives RNA-based vaccines an advantage over tumor lysates, especially if multiple restimulations are needed using a small tumor sample. Some have suggested that microdissection might also allow capture of only tumor cell-derived messenger RNA from fresh tumors, as a major limitation of using protein-encoded antigens derived from tumor is the availability of tumor and the contamination by normal tissue.

Viral and nonviral vectors have been used to modify human DCs (154,155). The validity of genetic approaches was first confirmed with the use of the gene gun with low-transfer efficiencies (1%-5%) (156). The use of viral vector is the mainstay of gene delivery with the use of retroviral vectors (157,158 and 159), adenoviral vectors (160), and poxviral vectors (161,162). Considering the potency of DC to elicit an immune response, viral coat proteins likely stimulate DC activation and serve as a source of immunogenic peptide.

DCs pulsed with acid-eluted peptides elicit an effective antitumor response in M05 melanoma, C3 sarcoma, Meth A sarcoma, and 3LL lung carcinoma murine models (163,164). Eighty percent of mice receiving the peptide-pulsed DC vaccine exhibited tumor regression or were tumor free, or both. Furthermore, DCs pulsed with class I MHC-restricted peptide antigen induced protective immunity to lethal challenge with tumor cells bearing those same antigens. In these models, DCs grown in GM-CSF and IL-4 showed improved antitumor activity when compared with those grown in GM-CSF and TNF-α or GM-CSF alone. Furthermore, the route of vaccination (intravenous, intraperitoneal, or subcutaneous) had no apparent effect on tumor resistance. Some animals were able to reject a challenge

with an otherwise identical tumor that lacks the epitopes used in the original vaccination. This concept of epitope switching may play an important role in the induction of immunity in antigenically heterogeneous tumor populations.

The use of apoptotic bodies as a source of antigen has been proposed by Bender et al. (165,166 and 167). They demonstrated that DCs incubated with apoptotic macrophages infected with the influenza virus stimulated CTL activity significantly better than DCs incubated with influenza alone. We have used apoptotic bodies generated from ultraviolet radiation and NK-mediated death to generate potent antigen-bearing DCs to stimulate specific CTL activity (Fig. 18.7-7 and Fig. 18.7-8).
FIGURE 18.7-7. Dendritic cells engulfing apoptotic tumor. Scanning electron microscope image of normal adenocarcinoma cell *(top left)*. Apoptotic tumor after ultraviolet radiation *(top right)*. Normal immature dendritic cell *(bottom left)*. Dendritic cell after engulfing apoptotic tumor *(bottom right)*. (From Mailliard RB, Watkins S, and Lotze MT.)
FIGURE 18.7-8. Fluorescent microscopy of dendritic cell engulfing apoptotic tumor. Immature dendritic cell stained with CD80 *(left)*. Tumor stained with membrane dye clearly visible within dendritic cell *(right)*. Note: The intensity of micrograph B was significantly decreased, as the CD 80 staining was overwhelmingly bright. This demonstrates dendritic cell maturation with antigen uptake.

Human Trials

At least 30 separate clinical trials have been conducted using DCs, but, so far, only five reports have been published using antigen-pulsed DCs in humans (Table 18.7-4). In 1995, Mukherji used adherent monocytes stimulated with GM-CSF only. These cells were pulsed with a nonapeptide epitope from MAGE-1 and injected intradermally and intravenously into melanoma patients with the appropriate MHC class I molecule (A1). Cytotoxic T cells were found at the site of immunization and at distant metastatic sites. No clinical response, however, was observed. Noting the limitations of single peptide vaccination, the same group, in 1998, reported 17 patients with melanoma treated again with monocytes stimulated with GM-CSF alone and tumor lysates. These patients were injected intradermally with as many as 107 cells. No patient developed substantial toxicity; only 13 patients completed the protocol. Three patients, however, had disease progression and one patient died of a myocardial infarction. Only one patient demonstrated disease regression, although varied biologic responses were noted. These studies were limited by the use of GM-CSF–stimulated macrophages as APCs instead of DCs (168).

Table 18.7-4 Clinical Trials Using Dendritic Cell-Based Therapy

Author (Year)	Tumor Type	Method	Response
Mukherji (1995)	Melanoma	Monocytes + GM-CSF pulsed with single melanoma peptide	No clinical responses
Chakraborty (1998)	Melanoma	Monocyte + GM-CSF pulsed with tumor lysate	1 out of 13 with partial response
Hsu (1996)	B-cell lymphoma	DCs pulsed with idiotype protein	3 out of 4 with response
Nestle (1998)	Melanoma	DCs pulsed with tumor lysates or	Two complete and three partial responses out of 16
Holtl (1998)	Renal cell	Case report; Mature DCs pulsed with tumor lysate	A patient treated who had a significant response
Hall (1997)	Melanoma	Immature DCs pulsed with tumor lysates	One complete response and two partial responses
Tjoa (1999)	Prostate	DCs pulsed with two prostate-specific peptides	30% response rate; 58% of these were durable

DC, dendritic cell; GM-CSF, granulocyte-macrophage colony-stimulating factor.

In a promising study in 1996 by Hsu et al., four patients were adoptively transferred DCs for the treatment of B-cell lymphoma. DCs were isolated by leukapheresis and coculture with idiotypic Ig from autologous lymphoma. Patients were vaccinated four times intravenously, as well as given subcutaneous administration of idiotype protein. All patients developed measurable antitumor cellular immune responses and none developed significant side effects. One patient developed a complete tumor response and another, while having an ambiguous computed tomography scan, had no tumor by polymerase chain reaction analysis. A third patient had a partial regression (169).

In 1998, Nestle et al. reported the treatment of 16 patients with advanced melanoma with GM-CSF and IL-4–derived DCs pulsed with tumor lysates or a cocktail of melanoma peptide antigens depending on their MHC type. Two complete responses and three partial responses were noted (140). Murphy et al. treated patients with prostate cancer with autologous DCs and two HLA-A2–restricted prostate-specific membrane antigen peptides. They found that 30% of the evaluable patients were identified as partial responders. In addition, a 50% decrease of serum prostate-specific antigen or resolution of previously measurable lesions on imaging was detected. No significant side effects were noted other than rare, transient hypotension. In 1999, Tjoa et al. reported their follow-up on these patients. The average duration of response was 149 days in the metastatic group and 187 days for the local recurrence group. A majority of patients (58%) were still responsive at the end of the follow-up period, suggesting the durability of DC-based treatment strategies (170,171).

Finally, a report exists of a patient with renal cell carcinoma treated with mature DCs (CD83⁺) pulsed with tumor lysates. This patient experienced a significant but incomplete reduction of his tumor burden (172).

These studies demonstrate the possibility of designing effective cancer therapy using DC strategies. More DC-based trials from our institute and others are planned. Understanding optimal routes of administration, optimal methods to load DCs, and the role of concurrent cytokine therapy may significantly improve early promising results.

Delivery of Dendritic Cells into Tumor

The delivery of DCs into tumor is an alternative approach in generating an antitumor response. This can be done most generally by applying DC-mobilizing cytokines, such as FL, or by direct injection of DCs after activation or transfection by relevant cytokine genes.

FL is a member of a small family of "fms-like tyrosine kinase signaling" growth factors, including macrophage colony-stimulating factor and the c-kit ligand that stimulate the proliferation of hematopoietic cells by binding to and activating distinct tyrosine kinase receptors (173,174,175 and 176). Expression of the FL receptor is restricted to the most primitive hematopoietic progenitor cells, and FL stimulates the proliferation *in vitro* and the expansion and mobilization *in vivo* of progenitor cells (177). FL as a single factor has little proliferative activity on these cells, but it synergizes with a wide range of other cytokines to stimulate proliferation of these cells (178). FL also mobilizes stem and progenitor cells to peripheral blood and stimulates the production of DCs from early progenitor cells (179,180,181 and 182). FL has been used in the generation of DCs *in vitro.* In murine systems, FL induces complete tumor regression in a substantial proportion of MCA-sarcoma in mice. In the remaining mice, decreased tumor growth was noted. Transferring CD8⁺ cells from FL-treated mice into naïve irradiated mice conferred resistance to tumor challenge in these naïve mice (183). Antitumor activity in murine breast adenocarcinoma has also been reported (184).

FL is produced in Chinese hamster ovary cells with its transmembrane portion deleted. Normal individuals tolerate doses up to 100 µg per kg without difficulty with the exception of mild injection site discomfort and enlarged lymph nodes. Peripheral blood mononuclear cells (PBMCs) increased threefold, CD34⁺ cell by 20-fold, colony-forming unit granulocyte macrophage by 80-fold, and monocytes tenfold, which, like DCs, developed a multilobulated appearance (185,186). After 14 days of treatment, approximately 14% of the PBMCs were DCs (approximately 1 million DCs per mL of blood). In the mouse, lymphoid DCs have an enhanced capacity to make IL-12 (compared with myeloid DCs), and were identified as DR⁺, CD11c⁻, IL-3 receptor⁺, CD4⁺, CD45RA⁺. These lymphoid DCs constituted approximately 4% of the PBMCs, which is approximately a fourfold increase.

An alternative mobilization strategy involves the administration of IL-4 and GM-CSF systemically to mature macrophage progenitors into DCs. Animal models using the highly immunologic human papillomavirus–16-induced C3 sarcoma have demonstrated antitumor effects using this approach. Direct injection of DCs into tumor has achieved only modest success. In three different tumor models, this antitumor effect becomes substantial after transfection of these DCs with the gene encoding

IL-12 (187). Also under investigation is the use of inducible promoters driving expression of cytokine genes only when DCs encounter antigen-specific T cells in nodal sites.

Other Cancer-Related Uses for Dendritic Cells

Tumor antigens capable of yielding target epitopes for T-cell reactivity have been identified in the setting of various human malignancies. A number of groups, including our own, are using DCs to generate T cells recognizing occult tumor antigens *ex vivo* or to expand T cells for therapy without direct identification of antigens.

Dendritic Cell Generation

Part of "18.7 - Dendritic Cell Vaccines "

Some data suggest that CD34-derived DCs are more potent at T-cell stimulation (188). We are conducting a trial, planned to conclude in 12 months, designed to assess these two types of DCs. As well, much debate as to the use of mature or immature DC immunotherapy exists. Although mature DCs would logically be more stimulatory than immature DCs in stimulating a specific CTL response, these cells appear to be incapable of eliciting antitumor responses in murine tumor models, whereas GM-CSF/IL-4 cultured cells elicit therapeutic effects. These differences may be owing to the loss of phagocytic capability or because of problems related to trafficking to appropriate lymphoid sites. Phenotypic or allostimulatory capacity cannot distinguish effective versus ineffective cells for use in clinical trials.

CD34$^+$-derived DCs are generated in our institute from patients through a standard technique. Recombinant human G-CSF is given twice daily for 4 consecutive days at a dose of 8 µg per kg before collecting the mobilized PBMCs by leukapheresis. CD34$^+$ cells are then isolated using the Isolex-50 or Isolex-300 magnetic cell separation system on whole, unmanipulated collections. These selected cells are washed, suspended at a concentration of 1×10^6 cells per mL, and AIM-V media plated in 10% human AB (or autologous) serum with SCF (10 ng per mL), GM-CSF (1,000 U per mL), IL-4 (1,000 U per mL), and TNF-α (10 ng per mL) is added. At day 7, only fresh IL-4 and GM-CSF are added, allowing the cells to differentiate into immature DCs by days 14 to 17 (189,190,191,192,193 and 194).

CD14$^+$-derived DCs are generated by Ficoll separation of a patient leukapheresis collection. The mononuclear cell layer is then plated at a concentration of 1×10^7 cells per mL. After a 2-hour incubation, the nonadherent cells are removed and the remaining monocytes remain incubated for 1 week in serum-free AIM-V media with GM-CSF (1,000 U per mL) and IL-4 (1,000 U per mL) (195).

Dendritic Cell Delivery

Part of "18.7 - Dendritic Cell Vaccines "

One parameter that needs to be considered in adoptive approaches is the method of DC delivery. Many argue that subcutaneous injections are more efficacious than intravenous injections. Most of these studies have had nontherapeutic end points (196). We have noted comparable, and, perhaps, superior effects with intravenous administration of DCs. Anecdotal information from Gerold Schuler (*personal communication*, 1997) suggest that patients on HLA-A2 peptide-pulsed DC protocols using mature DCs only responded clinically with tumor regression when their DCs were administered intravenously and not subcutaneously. DCs have also been given under ultrasound guidance directly into lymph nodes (140).

Future Studies

Part of "18.7 - Dendritic Cell Vaccines "

Combinations of cytokines, such as FL, IL-2, IFN-α, or IL-12, seem likely to optimize DC-based clinical application via potent effects on DCs. Furthermore, these combined therapies would enhance T-cell survival given the high rate of spontaneous apoptotic death observed in T cells in the periphery of patients with a variety of neoplasms. It has taken more than 20 years to refine our approaches using T cells in the therapy of cancer. Although trials have not been able to predictably impact disease in patients with most tumor types, it is clear that clinical responsiveness is linked to enhanced T-cell immunity in many patients. Clearly, DCs play an important supportive role in promoting and maintaining antigen-specific T cells *in vivo.* In the future, DC-based strategies will likely become important components of biologic therapies for patients with cancer, and we are just beginning to determine the best means to use such cells.

Introduction

Part of "18.8 - Vaccines Against Carbohydrate Antigens on Glycolipids and Glycoproteins "

The most abundantly expressed antigens at the cell surface of cancer cells are carbohydrates. Although carbohydrate tumor antigens are not known to be recognized by T cells, they have been proven to be uniquely effective targets for antibody-mediated active and passive cancer immunotherapy in the adjuvant setting (see Chapter 16.5). If antibodies of sufficient titer can be induced against cell surface carbohydrate antigens to eliminate tumor cells from the blood and lymphatic system and to eradicate micrometastasis, as demonstrated in mice with antibodies against GD2 (1), this would dramatically alter our approach to treating the cancer patient. With continuing showers of metastasis no longer possible as a consequence of high levels of circulating antibodies, aggressive local therapies of already established metastasis might result in long-term control of even metastatic cancer. It is also possible that recognition of cell surface carbohydrate epitopes of glycolipids and glycoproteins could lead to:

1. Complement or other Fc-mediated inflammation
2. Decreased circulating tumor antigen as a consequence of high levels of antibodies

3.   Improved antigen presentation by specifically immune B lymphocytes, facilitating T-lymphocyte immunity, as demonstrated in other systems (2,3 and 4)

This is the rationale for vaccines against carbohydrate antigens, but implementation has proven more difficult than initially contemplated.

Lessons from Infectious Disease Vaccines and Experimental Autoimmunity for Overcoming Obstacles to the Development of Cancer Vaccines

Part of "18.8 - Vaccines Against Carbohydrate Antigens on Glycolipids and Glycoproteins "

A variety of obstacles to the development of effective cancer vaccines exist, but the single greatest obstacle is the poor immunogenicity of tumor-associated antigens, including tumor carbohydrate antigens. They are poor immunogens because they are expressed on many or some normal tissues, and, consequently, are tolerated immunologically to a greater or lesser degree. With regard to induction of experimental autoimmunity, injection of free antigen before normally pathogenic immunization (5) results in protection from autoimmunity (strengthening of tolerance). Similarly, it is expected that the poor immunogenicity of tumor antigens is reinforced by the presence of growing tumor and increasing quantities of shed antigen. Tumor antigens are poor immunogens not just because they are tolerated immunologically, but also because they are surrounded by autoantigens. Even as potent viral or bacterial antigens have been progressively purified or synthesized as single antigenic epitopes, they have become progressively less immunogenic. This is caused by the loss of the highly immunogenic surrounding antigens that augment the immune response by serving as immunologic carrier and adjuvant and the source of activated helper T cells. In the absence of strong bystander immunogens, the conditions necessary for optimal B- and T-lymphocyte responses to tumor antigens, including cytokine production by helper t lymphocytes and recruitment and activation of professional antigen-presenting cells, does not occur. The immune system uses the foreign milieu of viral or bacterial antigens to provide help for the immune response against the individual antigens, and it takes advantage of the normal self milieu of autoantigens to make immunization against autoantigens more difficult.

To further complicate the selection of tumor antigens for preparation of cancer vaccines, not all viral or bacterial antigens are useful targets for vaccination (6,7), and some are counterproductive. The selection of viral or bacterial antigens for construction of vaccines against infectious diseases is assisted by identification of postinfection immune responses, which are associated with protection from subsequent exposures. This was one of the criteria for the selection of GM2 ganglioside as a target for immunotherapy of melanoma (8,9), but most tumor antigens are not sufficiently immunogenic to induce an immune response naturally. Consequently, selection of new cancer antigens for vaccine construction has been based on a more empiric approach.

The final obstacles to the development of clinically effective cancer vaccines are the functional and antigenic heterogeneity, which are inherent features of malignancies, and the genetically based heterogeneity of responsiveness in the human immune response. Consequently, significant variability exists in the immune response to vaccination with even the same antigen in the same vaccine in different patients.

Based on these considerations, the design of tumor vaccines aimed at inducing an antibody response must include:

1.   Covalently conjugating tumor antigens to immunogenic foreign proteins for enhanced presentation to the immune system
2.   The use of a potent immunologic adjuvant to further augment immunogenicity
3.   Limiting reinforcement of tolerance by vaccinating early in the disease, preferably in the adjuvant setting
4.   The use of polyvalent vaccines to overcome the issue of tumor and host heterogeneity

Approaches for Augmenting the Immunogenicity of Carbohydrate Antigens: Results of Preclinical Studies

Part of "18.8 - Vaccines Against Carbohydrate Antigens on Glycolipids and Glycoproteins "

Antibody Induction

Of the various carbohydrate antigens, vaccines against gangliosides have been studied most intensively. Vaccination of mice with irradiated melanoma cells selected for GD3 expression plus adjuvants was able to induce low levels of immunoglobulin M (IgM) antibodies against GD3, but this could be accomplished more effectively and simply by immunizing with purified GD3 plus immunologic adjuvants. Although GD3 alone induced no response at all, GD3 adherent to *Salmonella* minnesota mutant R595 or liposomes containing monophosphoryl lipid A (MPL) induced moderate titers of IgM antibodies in most mice, higher titers than vaccines containing bacille Calmette-Guérin (BCG), alum, Freund's adjuvant, or a variety of other adjuvants (10). Attempts at augmenting the immunogenicity of GD3 by making minor structural modifications to the GD3 so it would be foreign and not recognized as self were unsuccessful (10,11). Although GD3 amide, GD3 lactone, GD3 gangliosidol, and GD3 acetylated at various sites induced higher titers of antibodies against themselves than GD3 did, these antibodies reacted with GD3 only weakly, no more strongly than antibodies induced by unmodified GD3. These findings supported tolerance to autoantigens, such as GD3, as the major obstacle to overcome in cancer vaccines against carbohydrate antigens and underscored the remarkable specificity of the antibody response.

Based on progress with conjugate vaccines against bacterial polysaccharide antigens, helling systematically compared the immunogenicity of conjugate vaccines constructed with different carriers and adjuvants using GD3 as antigen (12). Keyhole limpet hemocyanin (KLH) was the best of the six immunogenic carrier molecules tested; the conjugation method was important, and a potent immunologic adjuvant was required. GD3 conjugated to KLH at the ceramide double bond and mixed with immunologic adjuvant QS-21 (which is a purified saponin fraction obtained from the bark of the *Quillaja saponaria* Molina tree) (13) was optimal, inducing higher titers of antibody, and, for the first time, consistent IgG antibodies. Simple

mixture of GD3 and QS-21 or GD3, KLH, and QS-21 induced no antibodies. More recently, we have conducted similar experiments with or without conjugation using different carrier proteins and different adjuvants with two other ganglioside antigens, GD3 lactone (14) and fucosyl GM1 (15). In each case, antibodies against GD3 and fucosyl GM1 and against tumor cells expressing these antigens were highest when these gangliosides were conjugated to KLH and mixed with QS-21. The neutral glycolipids Globo H and Lewis^y (Le^y) have also been synthesized, conjugated to bovine serum albumen or KLH, and mixed with QS-21 or no adjuvant. Conjugation to KLH and mixture with QS-21 was optimal in each case, inducing antibodies in the mouse that reacted with, and mediated complement lysis of, tumor cells expressing these antigens (16,17).

This same vaccination approach against carbohydrate antigens Thomsen-Friedenreich antigen (TF), Tn, and sialyl Tn (sTn) expressed on mucins has proved optimal for antibody induction. TF antigen (Galß1-3galNAc-O-serine/threonine), as it is naturally expressed in desialylated porcine submaxillary mucin, and synthetic TF-ceramide with or without various adjuvants were not immunogenic. TF-KLH with or without complete Freund's adjuvant or dETOX [containing monophosphoryl lipid A (MPL) and BCG cell wall skeletons] was moderately immunogenic (median IgM and IgG titers, 1/40), whereas TF-KLH plus QS-21 or SAF-m (a lipid base adjuvant containing pleuronic block copolymer L121) was highly immunogenic with a median IgM titer of 1/160 and a median IgG titer of 1/10,000 (18). Tn (GalNAcα-O-serine/threonine) conjugated to ovine serum albumin or to a short synthetic lipopeptide and sTn-KLH have been used successfully for antibody induction in mice (19,20 and 21). Tn dimers and trimers (clusters) and sTn (N-acetyl neuraminic acidα2-3GalNAcα-O-serine/threonine) trimers on a serine backbone [sTn(c)] have also been used in conjugate vaccines (20,21 and 22). Although sTn and sTn(c) vaccines induce high-titer antibodies against the immunizing sTn epitopes, ovine submaxillary mucin, and tumor cells, their specificities were distinct. Antibodies induced by sTn(c) react with sTn(c) but not with sTn monomers, and sTn monomer–induced antibodies do not react with sTn(c) (21). Because Tn(c) and sTn(c) may be preferentially expressed on tumors as opposed to normal tissues, these clustered vaccines have generated considerable interest.

Protection against Tumor Challenge

Preclinical studies involving tumor challenge experiments with vaccines against carbohydrate antigens should more directly address the clinical relevance of vaccine-induced antibodies and be applicable to clinical trials in humans than vaccines against protein antigens. This is because carbohydrate antigens predominantly mediate antibody responses in the mouse and humans; assays for measuring these responses are available and have been shown to correlate to clinical outcome. Presentation by HLA or H2 antigens is not required. Three of the carbohydrate antigens that are of interest as human tumor antigens have been identified on murine cancers (Tn, TF, and GD2), and, in each case, immunization with synthetic conjugate (or glycoprotein) plus adjuvant has resulted in protection from tumor challenge (1,23,24).

Immunization with desialylated bovine or ovine submaxillary mucins (which contain large concentrations of Tn antigen) plus immunologic adjuvant DETOX resulted in protection from tumor recurrence in more than 50% of mice subsequently challenged with the syngenic mouse mammary tumor TA3-Ha (23). Protection from tumor challenge with TA3-Ha, which expresses large amounts of Tn and TF antigens, also resulted from immunization with a glycoconjugate vaccine containing synthetic TF antigen covalently attached to KLH and mixed with immunologic adjuvant DETOX (24). Protection from tumor growth was seen even if the intraperitoneal challenge was given first, followed by a low dose of cyclophosphamide (which had no detectable antitumor effect directly) plus immunization beginning 2 days after the tumor challenge. Comparable protection from intravenous tumor challenge with EL4 lymphoma cells (which express GD2) was induced by subcutaneous immunization with GD2-KLH glycoconjugate mixed with QS-21 administered before intravenous tumor challenge or beginning 1 day after tumor challenge (1). Complete protection from tumor outgrowth was also seen when vaccination was initiated on day 17, 1 day after foot amputation of a 16-day palpable EL4 footpad tumor. All untreated mice died of systemic metastasis within 30 days of foot amputation. The previously demonstrated consistent antibody induction in preclinical studies with a variety of carbohydrate conjugate vaccines and the demonstrated ability of tn-KLH, TF-KLH, and GD2-KLH vaccines to prevent tumor recurrence in tumor models simulating the adjuvant setting provided significant motivation for testing these conjugate vaccines in the clinic.

Clinical Trials with Carbohydrate Antigen Vaccines

Part of "18.8 - Vaccines Against Carbohydrate Antigens on Glycolipids and Glycoproteins "

The availability of reliable serologic assays to serve as surrogate markers in clinical trials has greatly accelerated progress in developing consistently immunogenic vaccines against carbohydrate epitopes on gangliosides, neutral glycolipids, and mucins.

Gangliosides

Gangliosides are acidic glycosphingolipids that express sialic acid at one end and ceramide at the other. They have been long known as prominent components of the melanoma cell surface. Tai et al. immunized 26 patients with a mixture of three allogenic cell lines and demonstrated antibodies against GM2 in ten patients and antibody against GD2 in two patients (25). We induced antibody against GM2 in 0% to 80% of patients depending on the cell lines chosen for vaccine production (26). Using irradiated melanoma cells, these vaccines induced only moderate titers of IgM antibodies (median titer ~1/160) and no IgG antibodies. These vaccines were difficult to prepare consistently and to administer. We were able to induce antibodies against GD2 in only occasional patients, and no antibodies against GD3.

We have conducted a series of small clinical trials using purified GM2 for vaccine production (26) based on studies with GD3 in the mouse. The serologic results are summarized in

Table 18.8-1 . The results were similar to those obtained previously in the mouse with one exception. Lipid A (or MPL) containing adjuvants (including R595 and liposomes) but not BCG were highly effective in the mouse, whereas the reverse was true in humans. Although lipid A and MPL activate macrophages in mice and humans, they are B-cell mitogens only in the mouse. When it comes to weak immunogens, such as these autoantigens, is appears that more is required of an adjuvant than antigen-depot effect and macrophage activation, the two traditional roles of adjuvants. Lipid A performs this in the mouse because of its mitogenic activity, and BCG is able to fill this role in humans because of the exquisite sensitivity of the human immune system to *Mycobacterium tuberculosis* and related mycobacteria.

Table 18.8-1 Peak GM2 Antibody Titer after Adjuvant Immunization of Stage III-IV Melanoma Patients

Vaccine	Total Patients Treated	IgM Antibodies		IgG Antibodies	
		Patients Responding	Median ELISA Titer	Patients Responding	Median ELISA Titer
GM2	5	0	0	0	0
GM2/R595	5	0	0	0	0
CY + GM2/R595	6	5	1/40	0	0
GM2/MPL Liposomes	6	1	0	0	0
GM2/Proteosomes	33	22	1/80	4	0
GM2/BCG	5	4	1/80	0	0
CY + GM2/BCG	58	50	1/160	6	0
CY + GM2-KLH	6	5	1/80	0	0
CY + GM2-KLH/BCG	6	4	1/160	1	0
CY + GM2-KLH/DETOX	6	5	1/160	0	0
CY + GM2-KLH/QS-21	9	9	1/640	8	1/160
GM2-KLH/QS-21	40	39	1/640	35	1/160

BCG, bacille Calmette-Guérin; CY, cyclophosphamide; ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin; KLH, keyhole limpet hemocyanin; MPL, monophosphoryl lipid A.

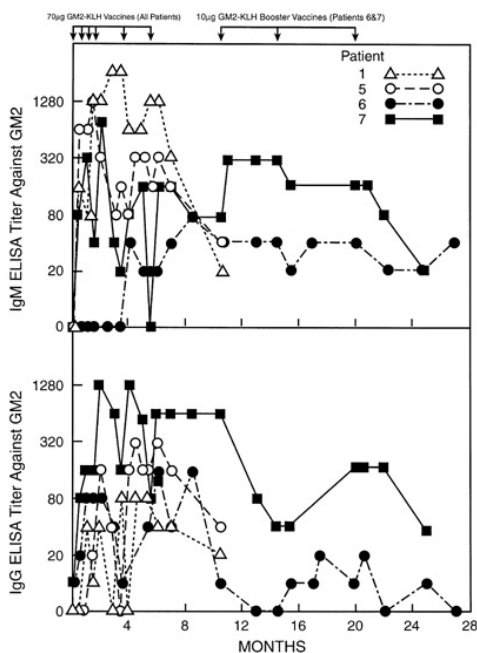
Ganglioside alone was not immunogenic, and GM2 conjugated to KLH without adjuvant or with BCG or DETOX was moderately immunogenic, similar to GM2 plus BCG (26). GM2 covalently conjugated to KLH and mixed with immunologic adjuvant QS-21 was consistently immunogenic. GM2-KLH plus QS-21 induced the highest and longest-lasting IgM titers against GM2 in patients, and, for the first time, consistent IgG antibodies as well. The IgG antibodies induced were of the IgG1 and IgG3 subclasses, and, like the IgM antibodies, were able to induce complement-mediated lysis of GM2-positive tumor cells (27,28). Although decreasing suppressor cell activity with low-dose cyclophosphamide was found to augment the antibody response to GM2/BCG (29), it did not further augment the response to GM2-KLH plus QS-21 (26). Two phase 1 trials identified 100 µg of QS-21 as the optimal dose of adjuvant (29) and doses of GM2 between 10 and 70 mg as comparable (30). The GM2 dose of 30 µg was selected for future trials. Coadministration of high-dose interferon-α with GM2-KLH plus QS-21 was shown to be safe and to have no impact on anti-GM2 titers (31). Recently, patients treated with repeated GM2-KLH/QS-21 booster vaccinations at 3- to 4-month intervals have been shown to maintain anti-GM2 IgM and IgG antibody titers for at least 2 years, as shown in Figure 18.8-1 .


FIGURE 18.8-1. Immunoglobulin M (IgM) and IgG antibody titers in four representative melanoma patients after immunization with 6 or 9 GM2-keyhole limpet hemocyanin (KLH) plus QS-21 vaccinations. Arrows indicate dates of vaccinations. (ELISA, enzyme-linked immunosorbent assay.)

Mixture with BCG and conjugation to KLH plus QS-21 have been used with other gangliosides. GD2/BCG and GD3/BCG were each used to immunize 12 patients. Antibodies against GD3 were not detected, and low-titer antibodies against GD2 were detected in only three patients (median titer, 1/40). GD3 congener/BCG vaccines were also tested and were not more effective in melanoma patients than they had been in the mouse (Table 18.8-2). GD3 lactones, GD3 amide, and GD3 acetylated in various locations plus BCG again induced antibodies against the synthetic immunizing gangliosides, which did not cross-react with natural GD3 or melanoma cells expressing GD3 (32,33). GD2 covalently conjugated to KLH plus QS-21 induced IgM antibodies in six of six patients (median titer, 1/160), but a GD3-KLH plus QS-21 vaccine was once again unable to induce antibodies against GD3 in 12 consecutive patients (26). The relative immunogenicity of these gangliosides in humans (GM2>GD2>GD3) is different than in the mouse (GD3>GD2>GM2), as a consequence of differential levels of tolerance resulting from the more extensive expression of GM2 in the liver and other normal tissues in the mouse, and the greater expression of GD3 on T lymphocytes (34) and normal stroma in humans.

Table 18.8-2 Comparison of Serologic Responses after Immunization with Optimal (Keyhole Limpet Hemocyanin plus QS-21) Conjugate Vaccines against Glycolipid Antigens

| | | Median ELISA Titer | | | | FACS | | | | | |

CDC, complement-dependent cytotoxicity; ELISA, enzyme-linked immunosorbent assay; FACS, fluorescence-activated cell sorter; Ig, immunoglobulin; Le^y, Lewis^y; pos, positive.

Three additional trials with ganglioside-KLH plus QS-21 vaccines have been conducted. In the first trial, bivalent vaccines containing 30 µg of GM2 and increasing doses of GD2 (35) confirmed the immunogenicity of GD2 in this conjugate vaccine and identified 60 µg of GD2 as the optimal dose per vaccine. In the second trial, GD3 lactone-KLH was used in place of GD3-KLH, and, for the first time, antibodies against GD3 by enzyme-linked immunosorbent and immune stain assays and against GD3-expressing tumor cells by fluorescence-activated cell sorter and complement lysis assays were detected in 8 of 12 patients (14). In the third trial, ten patients with small-cell lung cancer in complete or partial remission after chemotherapy were immunized with fucosyl GM1-KLH plus QS-21 vaccines after completion of chemotherapy (36). Expression of fucosyl GM1 is restricted to small-cell lung cancer and occasional normal cells in the pancreas and spinal cord. High-titer antibodies against fucosyl GM1 were induced in all patients, demonstrating that fucosyl GM1 is as immunogenic as GM2 and significantly more immunogenic than GD2 or GD3 (see Table 18.8-2). As with the GM2, GD2, and GD3 vaccines, antibody induction against fucosyl GM1 resulted in no demonstrable autoimmunity or other toxicity aside from that associated with QS-21, local erythema, and induration at vaccination sites lasting several days, and, in occasional patients, low-grade fever and malaise lasting as long as 36 hours (36).

Neutral Glycolipids
Globo H

Twenty patients with prostate cancer have been immunized with Globo H-KLH plus QS-21 vaccines containing 3, 10, 30, or 100 µg of Globo H (37,38). The 30-µg dose was selected as optimal for further trials. At this dose, all patients made IgM antibodies against Globo H (median peak titer, 1/1,280) and two patients made IgG antibodies with titers of 1/160 and 1/2,560. Inhibition studies with smaller carbohydrate molecules demonstrated that the antibody response was polyclonal with different antibodies in each serum recognizing at least several different epitopes on the globo H molecule. Sera reacted with Globo H extracted from biopsy specimens of prostate cancer and breast cancer but not extracts of melanoma, which does not express globo H. Reactivity with the cell surface of Globo H–positive cancer cells was demonstrated by strong flow cytometry reactions in four of five patients and strong complement-mediated cytotoxicity (more than 50% lysis) demonstrated in three of five patients as well. During 1999, nine breast cancer patients have been immunized with Globo H-KLH plus QS-21, and the results have been similar (see Table 18.8-2). All patients made IgM antibodies against globo H (median titer, 1/320); these antibodies reacted against globo H naturally expressed at the cell surface of breast cancer cells in six of nine patients, and strong complement lysis was seen with sera from five of nine patients.

Lewisy
Twenty-four ovarian cancer patients who were free of grossly detectable disease after systemic and intraperitoneal chemotherapy

were vaccinated with Le^y-KLH plus QS-21 vaccines containing 3, 10, 30, or 60 µg of Le^y (39). IgG antibody responses against Le^y were restricted to one or two patients at each of the dose levels, but IgM responses were more common. The 10-µg and 30-µg doses resulted in more frequent and higher titer IgM antibody responses against Le^y. No patients had IgM antibodies by enzyme-linked immunosorbent assay or fluorescence-activated cell sorter before vaccination. Four of six patients at the 30-µg dose level developed enzyme-linked immunosorbent assay titers of at least 1/320 after immunization. Similarly, four of six patients developed strong IgM reactivity by fluorescence-activated cell sorter against the Le^y-positive ovarian cancer cell line OVCAR3. The percentage of positive cells for these four patients by flow cytometry was 40%, 45%, 84%, and 97%. No IgG reactivity was detected (see Table 18.8-2). Complement-dependent cytotoxicity (CDC) ranged between 21% and 62% for these six patients with four patients showing at least a tripling of the percentage of CDC from a median of 6% prevaccination to 39% after vaccination.

Carbohydrate Antigens on Mucins

Part of "18.8 - Vaccines Against Carbohydrate Antigens on Glycolipids and Glycoproteins "

The immunogenicity of TF, Tn, and sTn antigens has been studied in a series of small clinical trials. The chemical structures of these antigens and their expression on various cancers and normal tissues are described in Chapter 16.5 .

TF and Tn

Pioneering trials by Springer were initiated in the mid-1970s with vaccines containing TF and Tn purified from natural sources and mixed with Typhoid vaccine as adjuvant (40). Springer described augmentation of natural levels of delayed-type hypersensitivity skin-test reactivity, induction of IgM antibodies, and a more favorable clinical outcome in vaccinated patients with breast cancer. O'Boyle used partially desialylated ovine submaxillary mucin (dOSM) containing Tn and sTn alone or mixed with BCG or DETOX to immunize 20 colorectal cancer patients (41). dOSM alone was not immunogenic, but with BCG was slightly more immunogenic than with DETOX, inducing a median IgM antibody titer against Tn of 1/40 and against sTn and OSM of 1/160. OSM, dOSM, and porcine submaxillary mucin (expressing Tn and TF) have been widely used as *in vitro* targets mirroring clinical relevancy because TF, Tn, and sTn, although expressed significantly by cell lines growing *in vivo* and in tumor biopsy specimens, are not well expressed by cell lines growing *in vitro.* Ten ovarian cancer patients were immunized with two different doses of synthetic TF-KLH (100 or 500 µg) plus DETOX (42). Natural pretreatment IgM and IgG antibody titers against synthetic TF were increased by vaccination in nine of ten patients. The 100-µg dose of TF appeared more immunogenic than the 500-µg dose. Reactivity of these IgM and IgG antibodies against natural sources of TF antigen was also seen, although at lower titers than against the synthetic TF. In a separate trial, groups of colorectal carcinoma patients were immunized with TF-KLH alone or TF-KLH plus DETOX (43). Once again, the TF-KLH plus DETOX vaccine was more immunogenic than TF-KLH alone, and the increase in antibody titers against natural sources of TF was lower than against synthetic TF.

Studies in the mouse have demonstrated that Tn-serine trimers or clusters (c) but not single Tn epitopes were recognized by monoclonal antibodies that react with Tn on tumor cells (20). Consequently, prostate cancer patients have recently been immunized with Tn(c)-KLH plus QS-21 and TF(c)-KLH plus QS-21 vaccines. IgM and IgG antibody titers against OSM and dOSM were 10- to 100-fold higher than seen with the previous vaccines. Antibody reactivity demonstrated by flow cytometry against tumor cells expressing TF and Tn was seen for the first time (44). These results are summarized in Table 18.8-3 .

Table 18.8-3 Comparison of the Serologic Responses to Immunization with TF, Tn, and sTn-KLH Conjugate Vaccines in Clinical Trials

Vaccine Antigen (Dose µg)	Adjuvant	No. Patients Treated	ELISA				References
			IgM		IgG		
			No. Pos	Median Titer	No. Pos	Median Titer	
TF (100)	DETOX	10	9	640	9	640	41
TF (100)	NONE	6	1	40	0	0	42
TF (100)	DETOX	6	4	320	0	0	42
TF(c) (10,30)	QS-21	Pending					
STn	DETOX	85	83	256		64	43

STn (100)	QS-21	5	4	80	3	40	40
STn(c) (30)	QS-21	9	9	1,280	8	1,280	46
Tn(c) (3,7,15)	QS-21	15	12	640	14	1,280	45

ELISA, enzyme-linked immunosorbent assay; FACS, fluorescence-activated cell sorter; Ig, immunoglobulin; pos, positive.

sTn

A variety of sTn-KLH conjugate vaccines mixed with various immunologic adjuvants have been tested in clinical trials. Breast cancer patients have been immunized with sTn-KLH plus

DETOX in combination with low-dose cyclophosphamide (300 mg per meter^2 intravenously 3 days before immunization), and high-titer IgM and IgG antibodies (median titer, 1/1,024) against synthetic sTn were induced in most patients (45). IgM and IgG reactivity against ovine submaxillary mucin (OSM) was lower (1/64) but clearly present, and titers were twofold to fourfold lower in patients not pretreated with low-dose cyclophosphamide. In a separate trial, patients with colon cancer were immunized with sTn-KLH plus DETOX or QS-21 (without cyclophosphamide) in the adjuvant setting (43). Median IgM and IgG antibody titers against synthetic sTn were two- and eightfold higher (1/5,120, and 1/2,560), respectively, with QS-21 than with DETOX, but IgM and IgG titers against OSM were only 1/80 and 1/40. Although sTn-KLH plus QS-21 vaccines clearly augment natural IgM antibodies and induce IgG antibodies against mucins, they induce far higher titers of antibodies against synthetic sTn.

In 1997, breast cancer patients were immunized with sTn(c)-KLH plus QS-21 (46). For the first time, median IgM titers against synthetic sTn and OSM were the same (1/2,560–1/1,520) and IgG titers were 1/1,280 and 1/640. Consistent reactivity with sTn expressed at the cell surface of cancer cells was demonstrated for the first time by flow cytometry with these sera. These results are summarized in Table 18.8-3 . They demonstrate that sTn(c) more closely resembles sTn, as it is expressed at the tumor cell surface, than individual sTn epitopes, and is therefore a better immunogen. A similar increase in relevant immunogenicity has been described using single sTn epitopes when they were packed more tightly onto the KLH surface (i.e., when sTn/KLH ratios were 2,000:1 or more) (43).

Clinical Impact of Immunization with Carbohydrate Antigen Vaccines

Part of "18.8 - Vaccines Against Carbohydrate Antigens on Glycolipids and Glycoproteins "

Vaccine-induced antibody responses against GM2 and sTn have been associated with a more favorable clinical course. A randomized trial with GM2/BCG was conducted in 122 stage III melanoma patients who were free of disease after resection of metastatic disease in regional lymph nodes (47). This trial was based on the previous demonstration that immunization with GM2/BCG induced IgM antibodies in 85% of patients and that the production of these antibodies correlated with a more favorable prognosis. Patients were randomized to receive five immunizations over a 6-month period with BCG alone (64 patients) or BCG with GM2 adherent to the BCG surface (58 patients). Fifty-seven patients had GM2 antibody, which was present naturally or vaccine induced, and these patients had a significantly increased disease-free (p = .004) and overall (p = .02) survival. Comparing the GM2/BCG and BCG groups, exclusion of all patients with preexisting GM2 antibodies (one patient in the GM2/BCG group and five patients in the BCG group) resulted in differences of 23% (from 27% of patients remaining disease free to 50%) in disease-free survival, and 14% in overall survival with a minimum follow-up of 50 months. When all patients in the two treatment groups were compared as randomized, these increases were 18% and 11% for disease-free and overall survival in favor of vaccination with GM2/BCG, with neither difference achieving statistical significance. Antibody responses were predominantly IgM of moderate titer and short lived (returning to baseline within 2 months of the final immunization).

Correlation between vaccine-induced antibody responses and clinical course has also been seen after immunization with sTn-KLH plus DETOX (48). In a series of 113 patients with various types of epithelial cancers, the 51 patients with high antibody responses to OSM after vaccination survived significantly longer than the 62 patients with lower antibody responses. Antibody responses against KLH showed no such correlation. In a separate study, improved survival was also seen in 25 patients with advanced breast cancer who had a high antibody response to the sTn vaccine in combination with intravenous cyclophosphamide compared with 25 patients with a low antibody response who did not receive the intravenous cyclophosphamide (45). The median survival increased from 13.3 months in patients with low anti-sTn antibody titers compared with 26.5 months in those with high responses.

Ongoing Trials and Future Directions

Part of "18.8 - Vaccines Against Carbohydrate Antigens on Glycolipids and Glycoproteins "

Randomized phase 3 clinical trials with GM2 and sTn conjugate vaccines are in progress. The trials with GM2-KLH plus QS-21 vaccines prepared by Progenics Pharmaceuticals, Inc. (Tarrytown, NY) are based on the higher-titer, longer-lasting antibodies against GM2 induced by the GM2-KLH vaccine compared with the previous GM2/BCG vaccine. Two randomized trials have been initiated. A trial comparing standard treatment (high-dose interferon) to GM2-KLH plus QS-21 vaccine is being conducted in patients with deep stage II primary melanomas (more than 4-mm depth) or stage III disease (lymph node metastasis) by the eastern cooperative oncology group, the southwest oncology group, the north central treatment group, Memorial Sloan-Kettering Cancer Center, and the Cancer and Leukemia Group B. Patient accrual was completed in September 1999. A second phase 3 trial was initiated in the latter half of 1998 in New Zealand, Australia, and subsequently in Europe and South America, comparing the same GM2 vaccine to placebo. A large, multicenter, randomized phase 3 trial with sTn-KLH plus DETOX prepared by Biomira Inc. (Edmonton, Alberta, Canada) was initiated late in 1998 in North America and Europe. The sTn-KLH plus DETOX vaccine (Theratope) is being compared with no treatment in patients with metastatic breast cancer who have had a complete or partial response to combination chemotherapy. This trial is based on the consistent immunogenicity, correlation of vaccine-induced antibody response to more favorable clinical outcome, and preclinical models for this vaccine (described above).

Although every indication exists that immunization with these single antigen vaccines may prove beneficial when administered in the adjuvant setting, in the long run polyvalent vaccines offer greater promise. As described above, we have induced consistent antibodies against GM2, fucosyl GM1, and sTn. Conjugate vaccines against GD3, GD2, Tn, TF, Globo H, and Le^y have induced antibody responses in 60% or more of patients. In most

cases, these antibodies have been demonstrated to react strongly with the cell surface of antigen-positive cancer cells, and this reactivity has induced strong complement-mediated cytotoxicity of antigen-positive tumor cells in the case of the glycolipid antigens. The known distribution of carbohydrate antigens on cancers and normal tissues was described in Chapter 16.5 . Based on this distribution and the results of vaccination trials demonstrating consistent immunogenicity of each of these antigens conjugated to KLH plus QS-21 vaccines, polyvalent vaccines against the cell surface carbohydrate antigens of a variety of malignancies are planned. These malignancies and the antigens considered for inclusion in the polyvalent vaccines are listed in Table 18.8-4 . Several antigens are conspicuously absent from this list because of a high risk of autoimmunity, including GM3, which is a melanoma ganglioside also extensively expressed in the liver, and Lewis^x and sialylated Lewis^x, which are epithelial cancer antigens that are also expressed on polymorphonucleocytes. Also Lewis^a, sialyl Lewis^a, and polysialic acid are omitted because they have not been tested. phase 2 polyvalent vaccine trials against melanoma, sarcoma, prostate cancer, and ovarian cancer are planned to begin before the end of 2000, and a phase 3 trial is to be initiated in patients with breast cancer in the year 2001.

Table 18.8-4 Carbohydrate Antigens for Polyvalent Vaccine Construction of Proven Immunogenicity in More than 60% of Patients

Tumor	Antigens
Melanoma	GM2, GD2, GD3L
Neuroblastoma	GM2, GD2, GD3L
Sarcoma	GM2, GD2, GD3L
B-cell lymphoma	GM2, GD2
Small-cell lung cancer	GM2, Fucosyl GM1, Globo H
Breast	GM2, Globo H, TF(c)
Prostate	GM2, Tn(c), sTn(c), TF(c)
Lung	GM2, Globo H, Le^y
Colon	GM2, sTn(c), TF(c), Le^y
Ovary	GM2, Globo H, sTn(c), TF(c), Le^y
Stomach	GM2, Le^y

Le^y, Lewis^y.

Conclusions

Part of "18.8 - Vaccines Against Carbohydrate Antigens on Glycolipids and Glycoproteins "

It is possible that improvements in our understanding of the requirements for optimal dendritic cell (and other professional antigen-presenting cell) activation and of the cascade of cytokines required for B-lymphocyte activation may result in more specific and powerful immunization approaches. The sequence of cytokines and other activities induced by potent adjuvants, such as QS-21, and carriers, such as KLH, however, may be impractical to imitate by administration of cytokines or genes coding these cytokines. In any case, the optimal approach for augmenting the antibody response against carbohydrate and peptide antigens at this time is conjugation to KLH and mixture with a potent adjuvant, such as QS-21.

The primary function of antibodies is the elimination of circulating viral or bacterial pathogens or toxins from the blood-stream, lymphatics, and interstitial spaces. Once induced, antibodies are ideally suited for eliminating circulating tumor cells and micrometastases from these spaces as well. Natural, tumor-induced and vaccine-induced antibodies against antigens expressed at the cancer cell surface have been correlated with an improved clinical outcome. In the mouse, passive administration of monoclonal antibodies and active induction of antibodies with cancer vaccines against cell surface carbohydrate antigens have resulted in prolonged survival and complete protection from tumor challenges administered before treatment, a setting similar to the adjuvant setting in humans. Carbohydrate antigens are the most abundant antigens at the cell surface of cancer cells, where they play important roles in cell-cell interactions, proliferation, and the metastatic process. They have been shown to be excellent targets for immune attack by antibodies against human cancers, especially in the adjuvant setting. Vaccines containing a variety of carbohydrate tumor antigens covalently attached to the immunogenic carrier protein KLH plus a potent immunologic adjuvant, such as QS-21, have been shown to induce antibodies against these antigens in cancer patients. These antibodies generally induce complement-mediated lysis and antibody-dependent cell-medicated cytotoxicity of antigen-positive tumor cells. Phase 3 clinical trials with GM2-KLH and sTn-KLH conjugate vaccines have already been initiated in the adjuvant or minimal disease setting in patients with melanoma and breast cancer. Phase 3 trials with polyvalent vaccines against several different antigens tailored for particular cancer types are planned for 2000 and 2001.

Basic Principles of Gene Therapy

19.1

Basic Principles and Safety Considerations

Kenneth G. Cornetta

Michael J. Robertson

Introduction

Part of "19.1 - Basic Principles and Safety Considerations "

Gene therapy can be defined as the transfer of genetic material with therapeutic intent. Gene transfer has become clinically feasible due to elucidation of the molecular basis for many diseases and improvement in techniques for manipulating genetic material in the laboratory. Gene therapy approaches would superficially appear to be best suited for the correction of inherited genetic diseases, such as hemoglobinopathies, immunodeficiency syndromes, and metabolic disorders. Indeed, clinical trials of gene therapy have been undertaken for adenosine deaminase (ADA) deficiency, cystic fibrosis, chronic granulomatous disease, and other genetic disorders. ADA deficiency, the first disease to be treated by gene transfer (1), illustrates characteristics considered to be ideal for successful gene therapy. ADA is a life-threatening disorder caused by mutations in a single human gene that has been cloned. The cells affected by the disease are readily obtainable for *ex vivo* manipulation and expression of the exogenous genetic material confers a selective advantage on the transduced cells. Moreover, precise regulation of transgene expression is not required, because elevated ADA levels do not appear to be harmful and levels as low as 5% of normal can correct the disease phenotype.

Although the inherited genetic diseases are an obvious target for gene therapy approaches, most gene-transfer clinical protocols submitted for regulatory review to date have involved patients with cancer. This reflects in part the inadequacy of conventional treatments for most advanced solid tumors; novel and potentially toxic treatments are considered justifiable in this situation. Moreover, malignant cells harbor genetic mutations that are believed to be responsible for the neoplastic phenotype and that may be amenable to correction through gene transfer approaches. Gene transfer techniques have facilitated the development of novel strategies for cancer therapy (Table 19.1-1). This chapter provides a brief summary of the gene transfer systems that are being used currently and then summarizes the safety and regulatory issues involved in producing clinical grade material for human gene therapy studies. It concludes with a discussion of several of these strategies.

Table 19.1-1 Selected Gene Transfer Approaches for Treatment of Cancer

Approach	Transgene	Target Cell	Goal
Cancer vaccine	Immunostimulatory molecules or defined tumor antigens[a]	Melanoma, renal cell cancer, other tumors	Stimulate antitumor immune response
Designer T cells	Chimeric T-cell receptor/anti-CEA antibody	Adenocarcinomas	Target effector-T cells to CEA-expressing tumors
Suicide gene	HSV-TK or cytosine deaminase	Mesothelioma, glioma, ovarian, colon, prostate cancer	Render tumor cells sensitive to ganciclovir or 5-fluorocytosine
Tumor-suppressor gene	Wild-type p53	Head and neck, lung, breast cancer	Inhibit proliferation, trigger apoptosis
Antisense	Antisense K-ras	Lung cancer	Inhibit oncogene expression
Myeloprotection	MDR-1, MGMT, DHFR	Hematopoietic stem and progenitor cells	Protect cells from cytotoxic therapy

CEA, carcinoembryonic antigen; DHFR, dihydrofolate reductase; HSV-TK, herpes simplex virus thymidine kinase; MDR-1, multidrug resistance gene 1; MGMT, methylguanine methyltransferase.

[a]Various immunostimulatory molecules (e.g., GM-CSF, IL-2, IL-4, IL-12, B7) and tumor antigens (e.g., MART-1, gp100, CEA, PSA) are under investigation.

Gene Transfer Techniques

Part of "19.1 - Basic Principles and Safety Considerations "

The term gene therapy *vector* refers to a system designed to transfer exogenous genetic material (the *transgene*) into a target cell. The simplest systems are vectors composed of naked DNA, usually in the form of plasmid DNA. Plasmids are designed to contain the gene of interest and regulatory elements that enhance gene expression. Plasmid vectors are limited by low gene-transfer efficiency and are not well suited to systemic administration, as the DNA may be degraded before sufficient material is exposed to the target tissue. To address these limitations several viruses have been engineered to transport genetic material (Table 19.1-2). Each of these vectors has its advantages and disadvantages. The critical determinants for choosing a particular vector system for a specific application include: (a) host range and tissue specificity; (b) ability to transfer genes to dividing versus nondividing cells; (c) capacity to integrate in the host genome versus episomal maintanance; (d) effects on target-cell viability and potential *in vivo* toxicity; (e) potential to generate replication-competent virus; (f) immunogenicity; (g) ease of manipulation; and (h) the amount of exogenous DNA that can be accommodated.

Table 19.1-2 Characteristics of Viral Vectors

	Murine Retrovirus	Adenovirus	AAV	Herpes Virus	Human Lentivirus
Genome	RNA	ds DNA	ss DNA	ds DNA	RNA
Transgene size[a]	3-7	7-36	2.0-4.5	10-100	8-9
Titer[b]	10^6-10^7	10^{11}-10^{12}	10^6-10^9	10^4-10^{10}	10^6-10^9
Host cell proliferation[c]	Required	Not required	Improves efficiency	Not required	Improves efficiency
Stable integration	Yes	No	Occasional	No	Yes
Immunogenicity	Low	High	Low	Variable	Not well studied

ds, double-stranded; ss, single-stranded.

[a]Approximate size (in kilobases) of transgene that can be accommodated.

[b]Infectious units per mL.

[c]Relationship between host cell proliferation and transduction efficiency.

Safety Considerations

Part of "19.1 - Basic Principles and Safety Considerations "

General Principles and Regulatory Issues

To justify initiating a particular gene therapy clinical trial, investigators must present evidence that the proposed treatment is reasonably safe for patients. Safety must be evaluated on a number of levels. The possible side effects of transgene expression must be considered. For example, excessive production of factor VIII could cause abnormal clotting after successful factor-VIII gene transfer to patients with hemophilia. Furthermore, the manufacturing process itself must be scrutinized to insure pathogens or toxic materials have not been introduced during vector production and that the generated material has sufficient activity to confer the intended therapeutic benefit (2). Finally,

the potential risks of the proposed vector system must be addressed; these are discussed more fully here.

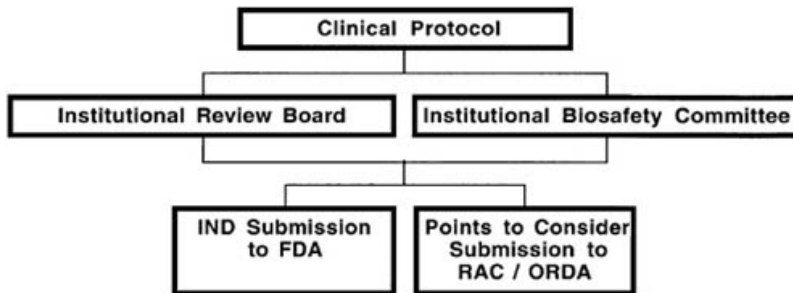
In the United States, a variety of regulatory and advisory bodies function to evaluate the safety profile of materials used in clinical gene therapy studies (Fig. 19.1-1). An Institutional Review Board must approve and monitor any research study involving human subjects. The Institutional Review Board must assure that clinical trials are based on a reasonable hypothesis and pose no undue risk to subjects participating in the trial. Informed consent must be obtained from patients receiving investigational therapy. Guidelines for conducting Institutional Review Board activity and oversight are provided by the National Institutes of Health (NIH) Office for Protection from Research Risks.


FIGURE 19.1-1. Review process for gene therapy protocols. Initial review of gene therapy protocols is performed at the local institutional committees that deal with human subjects and recombinant DNA work. After local approval, protocols are submitted, usually simultaneously, to the Recombinant DNA Advisory Committee (RAC) in the Office of Recombinant DNA Activities (ORDA), and to the U.S. Food and Drug Administration (FDA) in the context of an Investigational New Drug (IND) application.

The application of molecular biology techniques in laboratory and clinical settings has raised concern about potential misuse of recombinant genetic material. The Office of Recombinant DNA Activities (ORDA) was formed to oversee recombinant DNA research in the United States. ORDA has established guidelines dictating the containment measures that must be taken by investigators working with recombinant DNA. These are published in the Federal Register as the *NIH Guidelines for Research Involving Recombinant DNA Molecules* (July 5, 1994, 59 FR 34496; and an amendment effective April 29, 1999, published May 11, 1999, 64 FR 25361). The level of containment is determined by the organism from which the DNA is derived, the transgene that is to be expressed, the amount of viral sequences retained in the vector, and the presence of replication-competent virus. Local Institutional Biosafety Committees (IBC) are charged with insuring that recombinant DNA work is performed in compliance with ORDA regulations. Clinical trials involving use of recombinant DNA must be approved by the local IBC and subsequently submitted to ORDA for consideration by the Recombinant DNA Advisory Committee (RAC) (see Fig. 19.1-1). Investigators are required to address the "Points to Consider in the Design and Submission of Protocols for the Transfer of Recombinant DNA Molecules into One or More Human Subjects" listed in Appendix M of the *NIH Guidelines for Research Involving Recombinant DNA Molecules* and to respond to a series of questions regarding vector design, proposed use, and safety risks. An expedited review may be given to those protocols that use previously approved vectors and targets. Novel applications are reviewed before the entire RAC. The charge of the RAC is to insure the clinical trial is scientifically based, considers the ethical implications of the proposed work, and poses no unacceptable health risks to study participants or the population at large.

Vectors to be used for clinical studies in the United States generally require approval by the U.S. Food and Drug Administration (FDA) (3 ,4). Because gene therapy applications have not yet been approved for general clinical use, investigators are required to submit an Investigational New Drug application

(IND) that must be reviewed by the FDA before clinical trials are initiated. The FDA has thirty days to respond to an investigator after an IND submission. A hold can be placed on the trial if serious safety concerns are noted. If no concerns are raised, the investigator may begin the trial after the 30-day waiting period. The FDA does not approve vectors for routine clinical purposes but allows them to be used in clinical trials that are based on adequate data (5).

When evaluating an IND, the FDA addresses fundamental issues outlined in the *Code of Federal Regulations* (21 CFR 610, General Biological Products Standards). These include safety, identity, purity, potency, and efficacy. Review of gene therapy proposals is usually performed by the Center for Biologics Evaluation and Research (CBER) within the FDA (4). CBER reviews an IND for its preclinical safety data (toxicology) and manufacturing issues (identity, purity, and potency). Special emphasis is currently placed on safety because of the paucity of clinical efficacy data for gene therapy vectors. In an attempt to insure that the appropriate toxicology studies and an acceptable manufacturing process are identified before IND submission, the FDA encourages telephone conversation and offers the opportunity for a confidential pre-IND meeting early in the process of developing gene therapy clinical trials.

Toxicology studies attempt to determine the risks of vector administration. Safety issues to be addressed include: (a) toxicity of the vector alone (irrespective of the transgene), including its potential tumorigenicity; (b) toxicity of transgene expression *in vivo* that may not be apparent from *in vitro* studies; (c) occurrence and consequences of ectopic transgene expression in non-targeted tissues; (d) occurrence and consequences of immune responses to transgene or vector proteins; and (e) possibility of germ-line transduction. Preclinical toxicology studies should include doses equivalent to and higher than the intended human dose and, when appropriate, the toxic dose should be determined in animals (5). In general, some studies should be performed using the material intended for clinical use to detect contaminants introduced during the manufacturing process. The route of administration is generally the same as that intended for clinical use but studies evaluating other routes may be requested, in particular intravenous routes. Evaluations of animals used for toxicological studies may include blood chemistry evaluations and pathologic examination of organs. The species required for proper toxicological evaluation may vary with the vector, transgene, route of administration, patient population, and the disease being treated. The cost of these studies can be quite substantial, especially when nonhuman primate studies are required. Early discussion with the FDA during development of a toxicology plan may prevent delays and added expenses due to inadequate data. Recognizing that the costs of toxicological studies are often prohibitive to most gene therapy investigators, the NIH National Centers for Research Resources (NCRR) has provided funds for toxicology studies through the National Gene Vector Laboratories (6). Funds are also available for support of toxicological studies through the National Cancer Institute Rapid Access to Intervention Development (RAID) program for cancer gene therapy protocols.

Proper manufacturing practices must be used for clinical grade vector production (Fig. 19.1-2). Production of many vectors, in particular viral vectors, requires unique methods for which specialized testing is needed to ensure adequate purity, potency and identity. Several publications by the FDA and NIH can assist investigators in the design of their production and certification processes (Table 19.1-3). For example, production of retroviral vectors requires generation of a vector producer cell line by stable integration of one or more copies of the vector genome into the chromosomes of specially designed packaging cells. In most cases, a clone is selected for its ability to produce vector particles

at high titer. For most phase 1 clinical trials, such a clone is expanded to generate 100 to 200 vials of cells, which are cryopreserved and stored as the Master Cell Bank. Approximately 20 vials are used for certification assays (Table 19.1-4) and 10 archived per the *Code of Federal Regulations*. Extensive screening for replication-competent retrovirus is performed to detect recombination between vector and viral sequences within the cell line (1% of cells and 5% of the media must be screened). The use of fetal calf serum and porcine trypsin in the culture of these cells may require screening for bovine and porcine viruses. Because the packaging cell lines are of mouse origin various assays are used to detect contaminating murine pathogens. Sterility and *Mycoplasma* testing are similar to that performed on any product intended for human use and are described in the *Code of Federal Regulations* (21 CFR 610.12 and 610.30, respectively). Production and testing must also follow specific procedures for "Good Laboratory Practice" and "Good Manufacturing Practice" (21 CFR 58 and 21 CFR 210-211, respectively), including documentation and auditing procedures. The testing required for a particular vector varies significantly. For adenoviral vectors produced in human cell lines extensive screening of clinical material for human viruses is required during certification. Gene therapy is a rapidly changing technology. The requirements for toxicologic evaluation and certification continue to evolve as more sophisticated testing methods become available and further data regarding the performance of current producer cell lines and clinical toxicities are generated.

Table 19.1-4 Tests Used in Certification of Murine Retroviral Producer Cell Lines and Supernatant for Clinical Use

Master Cell Bank	Supernatant
Sterility	Sterility
Mycoplasma	Mycoplasma
RCR (eco, xeno, ampho, or GALV)	RCR (ampho)
Porcine virus	Porcine virus
Bovine virus	Bovine virus
Cell identity	Cell identity
Titer	Titer
In vivo virus assay	Endotoxin
MAP/LCM assay	General safety
In vitro virus assay	—
Vector sequence	—

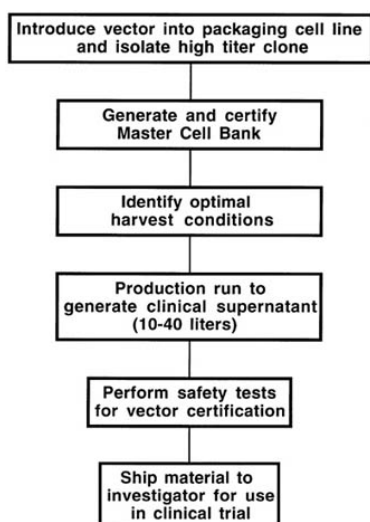
ampho, amphotropic; eco, ecotropic; GALV, gibbon ape leukemia virus; LCM, lymphochoriomeningitis virus; MAP, murine antibody production; RCR, replication competent retrovirus; xeno, xenotropic.


FIGURE 19.1-2. Clinical vector production. A schema for retroviral vector production used by the National Gene Vector Laboratory, illustrates the multistep process involved with generation and certification of clinical-grade material.

Once a Master Cell Bank is certified a vial of cells is thawed and expanded to generate the clinical grade supernatant. In the National Gene Vector Laboratory at Indiana University, the cells are propagated in roller bottles and approximately 10 to 20 L of material is harvested per run. Aliquots of cell-free supernatant are frozen and stored. Additional safety testing is performed on the supernatant (see Table 19.1-4), and once complete, the material is shipped to the investigator.

The costs associated with generation of a high-titer clone and Master Cell Bank and production of an adequate volume (˜20 to 40 L) of supernatant for a typical phase 1 study are in excess of $100,000 per retroviral vector. In general, production of supernatant is the least complicated and costly step in generating vector for clinical use. Certification testing in compliance with Good Manufacturing Practice and Good Laboratory Practice is the major cost of producing clinical material and is beyond the capability of most gene therapy investigators. To bridge the gap caused by the expense and effort required to produce this material, the NCRR has created the National Gene Vector Laboratories. This cooperative group of university-based production facilities generates clinical grade plasmid, retroviral, adenoviral, and adeno-associated virus (AAV)-based vectors. After successful review of a submitted application by an oversight committee, the clinical grade material for phase 1 and 2 trials are supplied to the investigator free of charge. To date, 63 clinical trials have been supported by the National Gene Vector Laboratories in fields ranging from cancer, human immunodeficiency virus infection, genetic disease, cardiology, and rheumatology.

Safety Issues with Specific Vector Systems

Part of "19.1 - Basic Principles and Safety Considerations "

Retroviral Vectors

Retroviral vectors are similar to their parent murine leukemia viruses in causing little direct toxicity to the infected cell. It is therefore not anticipated that administration of retroviral vectors to patients results in immediate serious adverse events. The major safety concerns with the clinical use of retroviral vectors relate to two potential delayed toxicities: (a) development of secondary malignancy due to insertional mutagenesis caused by integration of viral sequences into the host cell genome; (b) infection by replication-competent retrovirus. The latter could be generated by homologous recombination *in vitro* during vector preparation in packaging cells or *in vivo* after infection of patient cells by replication-defective vector.

It is not known whether murine retroviruses are pathogenic for humans. Amphotropic murine retrovirus administered intravenously to immunocompetent or moderately immunosuppressed rhesus monkeys is cleared from the serum within 15 minutes. Primate serum is known to inactivate murine retroviruses, which probably explains this rapid viral clearance (7 ,8).

Despite rapid disappearance of retrovirus from the serum, peripheral blood mononuclear cells of these animals were infected at very low frequencies. However, such infection was not associated with viremia or clinical illness (8). Two studies have evaluated monkeys exposed to replication-competent retrovirus during periods of severe immunosuppression after autologous bone marrow transplantation. Donahue et al. (9) attempted gene transfer into rhesus monkeys by coculturing bone marrow with packaging cells producing vector and replication-competent retrovirus. Three of ten animals developed lethal lymphomas of T-cell origin, which resembled the disease produced in mice by infection with Moloney murine leukemia virus. Two viruses were detected within lymphoma cells of the monkeys. These retroviruses arose by recombination between vector sequences, packaging sequences, and endogenous murine retroviral genome sequences (10 ,11). In a retrospective study of four monkeys exposed to replication-competent retrovirus in a similar transplant model, animals were clinically well more than 6 years after retrovirus exposure (12). In both studies, monkeys with detectable antiviral antibodies did not develop lymphoma, whereas animals with disease failed to mount antibody responses and had persistent viremia. These findings indicate that murine retroviruses can be pathogenic in severely immunocompromised primates. Great care must be taken, therefore, to ensure that replication-competent retroviruses are not inadvertently administered to patients during gene therapy using retroviral vectors.

Two steps have been taken to decrease the chance of accidental exposure to replication-competent retrovirus. First, packaging cell lines and retroviral vectors have been specifically designed to decrease the likelihood that recombination generates replication-competent virus [(13 ,14); for a detailed review, 15]. Second, careful screening methods have been developed to test vector preparations for contamination by replication-competent retrovirus (16 ,17). Guidelines for testing vector preparations before clinical use have been published (18), and the related methodology continues to be refined (19).

The potential for *in vivo* recombination of vectors with human endogenous retroviral sequences (HERV) is also a concern with retroviral gene transfer. The human genome contains many HERV; however, known HERV have mutations that render them replication-defective (20 ,21 and 22). The risk of recombination between HERV and retroviral vectors appears low because murine-based vectors and HERV share little sequence homology and differ in enhancer, promoter, and transfer ribonucleic acid binding sites. Furthermore, the same regions of the viral genome that have been deleted in the construction of retroviral vectors are frequently deleted in HERV sequence. Thus, HERV would be unlikely to complement retroviral vectors even if homologous recombination between them occurs. The factors that limit complementation of retroviral vectors by HERV should also apply to human retroviruses such as HIV and the human T-cell leukemia viruses. This hypothesis is supported by the data of Martineau and colleagues (19), who studied samples obtained from 81 human immunodeficiency virus–infected patients participating in a retroviral gene therapy protocol. No evidence of replication-competent murine retrovirus could be detected by sensitive polymerase chain reaction (PCR) and enzyme-linked immunosorbent assays in more than 500 samples that were tested. It is also reassuring to note that none of the clinical gene therapy trials performed so far have detected patient exposure to replication-competent retrovirus or any malignancies arising as a consequence of insertional mutagenesis.

Other risks, largely of a theoretical kind, could be associated with the use of retroviral vectors for gene therapy. On rare occasions virions can inadvertently package helper-cell messenger RNA (mRNA). A more common event is the transfer of virus-like 30 elements (VL30) (23 ,24) or intracisternal A-type particles (IAP) (25 ,26) contained within retroviral packaging cell lines. There are approximately 200 copies of VL30 and 1,000 copies of IAP sequences per haploid genome. Nevertheless, packaging of retroviral vector sequences is at least 10,000 times more likely than packaging of VL30 or IAP sequences. VL30 sequences have been transmitted to monkeys developing lymphoma after exposure to replication-competent retrovirus, but VL30 RNA was not transcribed (11). Transfer of these sequences during retrovirus-mediated gene therapy is not likely to be of clinical significance because both VL30 and IAP genomes are defective and noninfectious (27 ,28 and 29).

Adenoviral Vectors

The safety of adenoviral vectors for human gene therapy has been less well characterized than that of retroviral vectors. Because adenoviral DNA is maintained episomally and rarely integrates into the host genome, the risk of insertional mutagenesis should be minimal (30 ,31). Indeed, adenoviruses have not been convincingly associated with any human malignancy. However, the risk of generating replication-competent adenovirus is not negligible for first-generation adenoviral vectors. Wild-type, replication-competent adenoviruses generally cause only mild upper respiratory infections in immunocompetent humans (30 ,31). Nevertheless, fatal systemic adenovirus infections can occur in immunocompromised patients (32 ,33). Moreover, replication-competent adenovirus could act as a helper to complement the replication of the recombinant virus. This could potentially allow the transgene-containing vector to be disseminated to the tissues of a treated patient and even to be transmitted to other persons. Thus, prudence dictates that recombinant vector material that is to be used in clinical trials must be suitably tested for the presence of replication-competent adenovirus. Several detection methods have been developed, including lysis of noncomplementing cell lines, Southern blot analysis, and PCR techniques (34).

Other Vectors

AAV typically is not pathogenic, and AAV vectors are generally believed to have a favorable safety profile. As is the case with retroviral vectors, however, integration of AAV sequences into the host genome carries a risk of insertional mutagenesis. Furthermore, production of AAV vectors has generally required the use of adenovirus, so the contamination of AAV vector stocks with replication-competent adenovirus is a potential safety concern. At the time of this writing, the FDA is organizing a symposium

to discuss safety issues related to AAV vectors with the intention of developing a Master Drug File of preclinical and clinical data related to AAV vector administration. This file serves as a resource and reference for contributing investigators throughout the United States. It also supports IND applications involving AAV vector-based gene transfer that are submitted to the FDA. It has been proposed that the National Gene Vector Laboratory hold and administer this Master Drug File.

Because human lentiviruses can cause serious diseases, including the acquired immunodeficiency syndrome, substantial safety issues must be addressed with respect to the clinical use of lentivirus vectors. Several strategies are being pursued in attempts to improve the safety profile of these vectors. Production of vector by transient transfection using three-plasmid expression systems should greatly decrease the chance of recombination events that could result in generation of replication-competent virus. Deletion of accessory genes from lentivirus vectors does not prevent the transduction of nondividing cells (35 ,36) and should decrease the risk of toxicity. Development of self-inactivating lentivirus vectors may also enhance their safety (37 ,38), although similar murine retroviral vectors have not proven clinically useful (39). Most of the published studies regarding lentivirus vectors are concerned with vector design. Animal studies that examine the safety of administering various modified lentivirus vectors are generally lacking. Careful toxicology studies, particularly in nonhuman primates, are required before lentivirus vectors can be used in clinical trials.

Ethical Issues

Part of "19.1 - Basic Principles and Safety Considerations "

The ethical issues surrounding genetic engineering were debated long before gene transfer became technically feasible. The major ethical issues involve three key areas: (a) the goal of gene transfers; (b) the patient population targeted for gene therapy; and (c) the effects of gene transfer on the human germ line.

Goal of Gene Transfer

At least three goals of clinical gene transfer can be envisioned: (a) disease treatment, for which the transferred genetic material is intended to correct a specific genetic defect or modify a disease state; (b) enhancement engineering, whereby a specific phenotype (such as short stature) in a healthy person is altered by single gene insertion; and (c) eugenics, whereby complex human traits (such as personality, intelligence, etc.) are manipulated through alterations in many genes.

Transfer of genetic material for the sole purpose of treating serious disease has not generally provoked major ethical objections from the religious, political, or scientific communities. Current gene therapy protocols have followed the guidelines proposed by Anderson and Fletcher in 1980 (40), which indicate that the ethical application of gene-transfer technology requires demonstration of satisfactory gene transfer and expression as well as acceptable safety in preclinical studies. Specifically, the transgene of interest should be transferred to a sufficient number of target cells and be expressed at high enough levels for an adequate period of time to be of clinical benefit; transgene expression should not exceed levels that could be detrimental. Preclinical data should be available to predict the toxicity associated with vector administration and transgene expression, so that the risk-to-benefit ratio can be estimated.

Enhancement engineering has not been undertaken so far and remains an area of considerable ethical debate. The advantages and disadvantages of enhancement engineering are similar to those of enhancement procedures that do not involve gene transfer. It has been difficult to achieve consensus regarding a suitable distinction between enhancement procedures versus disease therapy. For example, what height should be used to distinguish short stature that is a normal variant from that which is a medical condition worthy of treatment? Should enhancement be distinguished from treatment using objective criteria (biochemical tests, nomograms, etc.) or social definitions of disability or disadvantage? Anderson has suggested that enhancement gene therapy may have a role in preventive medicine (41). For example, use of gene therapy to increase low-density lipoprotein (LDL) receptor levels and delay the onset of atherosclerosis in asymptomatic persons with familial hypercholesterolemia might be considered an acceptable form of enhancement engineering. Others would argue that this is not enhancement but treatment of a preclinical disease state. Precedent exists for gene therapy before the onset of symptomatic disease. Asymptomatic newborns with ADA deficiency have been treated with autologous cord blood cells transduced with retroviral vector expressing an intact ADA gene (42). Nevertheless, enhancement engineering has raised significant concerns about potential inappropriate use of gene transfer technology. Given known abuses with anabolic steroids, growth hormone, and other performance-enhancing medications, it is not unlikely that unapproved uses of gene therapy for enhancement purposes could be sought by patients or parents. These concerns are aggravated by the virtual absence of data on the long-term effects of gene therapy. If one accepts the premise that ethical gene therapy requires an appropriate risk-to-benefit ratio, better understanding of the long-term consequences of gene therapy is needed before it can be used as a means of enhancing physical or mental abilities.

Eugenics is essentially a subject for philosophic debate, due to the current paucity of data on the genetics of complex human traits. Some of the genetic factors that affect personality, intelligence, growth, and development have been identified, but the sophisticated understanding needed to meaningfully manipulate these traits is lacking. Nevertheless, the possibility of eugenics in the future provokes consideration of how the potential ability to alter complex human traits by genetic manipulation affects our notion of what it is to be human.

Patient Populations Chosen for Gene Therapy

Gene therapy is currently considered an investigational treatment. As is true of any clinical research, ethical conduct of gene therapy studies requires adequate protection of research subjects, including an obligation to obtain informed consent. It has been suggested that, in the early gene therapy clinical trials, the investigational nature of the treatment was not made sufficiently clear to patients (43). However, patients with cystic fibrosis who participated in a phase 1 study of gene therapy appear to have

had a realistic understanding of their low probability of clinical benefit (44). There are insufficient data to address this issue rigorously at the present time, and further study is needed.

One of the most active areas of ethical debate in gene therapy is the use of gene transfer in fetuses. Heretofore, diagnosis of some genetic diseases *in utero* has been possible, but corrective treatment for affected fetuses has not been available; the only therapeutic intervention that could be undertaken was elective abortion. Gene therapy offers the possibility of *in utero* treatment and has raised complex ethical issues reviewed by Fletcher and Richter (45). Participation in a fetal gene therapy trial may be morally preferable to abortion because of its potential therapeutic benefit for the fetus and because it is a means of decreasing psychological trauma for the parents. Nevertheless, fetal therapy raises several difficult issues. What is the moral and legal status of the fetus, and does it have rights similar to a child or patient? If so, how are these rights balanced against the rights of the mother? A child may receive medical treatment against his or her parents' wishes when the state determines this to be in the best interest of the child. If effective *in utero* gene therapy becomes available, should the state intervene when a mother refuses treatment for the fetus? Anderson and Zanjani have recently submitted proposals for the treatment of alpha thalassemia and ADA deficiency to the RAC. Their intention is to define and address the ethical issues before submission of an actual clinical research protocol. It has been debated whether current technical limitations in gene transfer are such that any risk to the fetus and mother is unacceptable (46 ,47). The possibility of germ-line gene transfer, although believed to be remote with current technology, has been a major concern for critics of fetal gene therapy (47). Moreover, a wide range of religious and political opinions persists regarding the acceptability of manipulating fetal tissues. Vigorous debate on this issue continues.

Effects of Gene Transfer on the Human Germ Line

Gene therapy can be divided into somatic cell versus germ-line therapy. In somatic cell gene therapy, a transgene is targeted to somatic cells of an individual with the intention of correcting a disease state. The transgene is not transferred to reproductive tissues and, hence, cannot be passed on to subsequent progeny (i.e., the gene pool is unaffected). In germ-line gene therapy, the vector is capable of insertion into the reproductive tissues, thereby altering the gene pool and having consequences for subsequent generations.

All current applications of gene therapy are directed at somatic cells. Most political and religious groups have not objected to gene therapy that does not affect future progeny. In contrast, germ-line gene therapy has raised major medical and ethical concerns, and very few people have argued in its favor. From a medical perspective, we do not know how a transgene inserted into the human germ line could affect the growth and development of future offspring. Unregulated expression of a transgene could be beneficial in certain adult tissues but could have disastrous consequences for a developing fetus. Resulting abnormalities could cause significant morbidity and mortality in first-generation offspring. More subtle abnormalities could elude detection for several generations, allowing dissemination of the deleterious genetic change in the general population. Furthermore, the vector backbone itself could have undesirable consequences and could not be eliminated from the germ line by currently available technology.

Unlike somatic-cell gene therapy, therefore, germ-line therapy requires a broader discussion of whether the risks (both foreseen and unexpected) are outweighed by potential benefit to society. Anderson has argued that germ-line gene therapy could be appropriate if three criteria are met (41). He suggests that sufficient experience with somatic gene therapy be available to gauge safety risks, that adequate animal studies be performed to ensure reproducibility and safety of the germ-line transfer procedure, and that there be public awareness and approval of the procedure. This view is not shared by many, for whom alteration of the gene pool is objectionable for scientific, ethical, or religious reasons. The RAC has stated that it "will not at present entertain proposals for germ-line alterations but will consider proposals involving somatic-cell gene transfer." Currently, most organizations that have considered this issue have recommended a moratorium on germ-line therapy, with continued discussion as the scientific and medical aspects of this approach mature.

In addition to the ethical issues discussed earlier, the development of gene therapy requires consideration of the socioeconomic implications of this new technology. If efficacy is established, gene therapy may prove to be one of the true revolutions in medicine. Nevertheless, the early development relies on free access to reagents (vectors) and support by government funding agencies for investigators in the academic community. Some of the most attractive applications for gene therapy are in genetic diseases that are rare but possess properties that make them ideal candidates for this approach. The rarity of such so-called orphan diseases makes them unattractive targets for investment of research resources by the pharmaceutical industry. Nevertheless, these orphan diseases offer an opportunity to improve gene transfer technology. Many believe that academic institutions are best suited for this initial research (48). How gene therapy approaches are developed by the pharmaceutical industry and how the new technology can be made available to patients in need, especially those in developing countries (49), are challenges as significant as the technical aspects of gene transfer.

Gene Transfer Applications for Cancer Therapy

Part of "19.1 - Basic Principles and Safety Considerations "

Since the first human gene-transfer experiment in 1989 (50), several hundred clinical trials involving gene transfer have been initiated. These clinical trials can be classified into two major categories: (a) gene-marking studies, in which gene transfer is used to determine the fate of cells infused into patients; and (b) gene therapy studies, in which an exogenous gene is expressed in a targeted cell to alter its phenotype in a clinically beneficial way.

Gene Marking Studies

Part of "19.1 - Basic Principles and Safety Considerations "

The first human gene transfer clinical trial was a marking study performed by Rosenberg and colleagues to determine the fate of

autologous tumor-infiltrating lymphocytes (TILs) after intravenous infusion (50). TILs are lymphocytes isolated from tumor-biopsy specimens and expanded for 4 to 8 weeks *in vitro* using recombinant human interleukin-2 (IL-2) (51 ,52). Intravenous infusion of expanded TILs together with high-dose bolus injections of IL-2 can induce objective tumor responses in patients with metastatic melanoma (52). The TIL gene-marking study demonstrated the safety of administering retrovirus vector-transduced cells to humans (50). No exposure of patients to replication-competent retrovirus was detected. This study also showed that adoptively transferred TILs can persist *in vivo* for several months and can home to sites of autologous tumor.

Gene-marking studies have also been used to investigate the biology of autologous hematopoietic stem-cell transplantation. Brenner and colleagues have unequivocally shown that neoplastic cells infused in autologous stem-cell products can contribute to relapse after high-dose therapy for acute leukemia and neuroblastoma (53 ,54). Similar studies have shown that leukemic cells in autografts contribute to relapse of chronic myelogenous leukemia after autologous transplantation (55). These gene-marking studies have also demonstrated that normal progenitor cells in the autografts contribute to long-term hematopoiesis after engraftment (55 ,56).

Gene Therapy Studies

Part of "19.1 - Basic Principles and Safety Considerations "

Gene-marking techniques represent a powerful new tool for addressing clinically relevant issues in cancer therapy. However, the remainder of this chapter focuses on the use of gene transfer with therapeutic intent. Some ongoing approaches to cancer therapy using gene-transfer technology are summarized in Table 19.1-1 and discussed here.

Stimulation or Enhancement of Antitumor Immunity

A major strategy for exploiting gene transfer techniques in cancer therapy involves attempts to promote antitumor immune responses. Preclinical studies have conclusively shown that the mammalian immune system can recognize and eliminate malignant tumor cells *in vivo* (57 ,58). Depending on the particular experimental system used, participation of helper effector T cells, cytotoxic T-lymphocytes (CTLs), natural killer (NK) cells, and other cell types has been implicated in the eradication of tumor cells in preclinical animal models. Clear understanding of the gene-transfer approaches for promoting antitumor immunity requires some knowledge of fundamental immunology.

Optimal activation of naïve CD4+ T cells requires at least two major signals (59 ,60). Signal 1 is provided by ligation of the T-cell receptor (TCR) complex by specific antigenic peptide bound in the cleft of major histocompatibility complex-class II molecules. Signal 2, also known as *costimulation*, is provided by engagement of CD28 on the T-cell surface by members of the B7 family of costimulatory molecules on the surface of professional antigen-presenting cells (APCs). Although activated B cells and monocytes can function as APCs, the most potent known APCs for T-cell activation are dendritic cells (61). Following activation and clonal expansion, activated CD4+ T cells differentiate into helper effector cells of either the Th1 or Th2 phenotype (62 ,63). Th1 cells produce cytokines, such as IL-2, IFN-γ, and tumor necrosis factor (TNF), that stimulate monocytes and NK cells and promote the differentiation of activated CD8+-T cells into CTLs. Thus, Th1 cells are crucial for the development of cell-mediated immune responses to intracellular pathogens and some neoplastic cells. In contrast, Th2 cells produce cytokines, such as IL-4, IL-5, IL-10, and IL-13, that promote humoral immunity and the recruitment and activation of eosinophils. Th2 cells are characteristically recruited during immune responses to helminths and other extracellular pathogens. Whether a CD4+ T cell develops into a Th1 or Th2 effector cell appears to depend predominantly on the cytokine milieu present when the cell is activated and undergoing differentiation (62 ,63).

Activation of naïve CD8+ T cells also requires two signals. Ligation of the T-cell receptor by peptide antigen/major histocompatibility complex-class-I complexes provides signal 1; the nature of signal 2 for CD8+ T cells has not been fully elucidated but requires the presence of helper CD4+ T cells. It appears that an important costimulatory ligand for CD8+ T cells is transiently expressed on APCs after the latter interact with activated CD4+ T cells (64 ,65 and 66). Induction of the costimulatory ligand requires interactions between CD40 on the APC and CD40 ligand transiently expressed on activated CD4+ T cells. Differentiation of activated CD8+ T cells into functional CTLs is promoted by cytokines produced by Th1-helper-effector cells (62 ,63).

Despite extensive preclinical data demonstrating the existence of antitumor immune responses *in vivo*, it is obvious that most patients with cancer have not mounted an effective immune response to their tumor. This could be due to defects in antigen presentation, costimulation, or differentiation of activated T cells into functional effector cells. Gene therapy strategies have been developed to address each of these possibilities.

Gene Transfer into Tumor Cells: Cancer Vaccines

A major gene transfer approach for cancer therapy is the introduction of genes into tumor cells to promote their immunogenicity. Extensive preclinical studies have shown that introduction of genes encoding immunostimulatory molecules can induce the rejection of malignant tumor cells (Table 19.1-5). For example, transduction of the B7-1 or B7-2 genes into murine tumor-cell lines does not affect their growth *in vitro* or in immunodeficient mice but markedly reduces their tumorigenicity in immunocompetent syngeneic mice (67 ,68 and 69). In contrast, syngeneic mice depleted of CD8+ T cells fail to reject B7-transduced tumor cells, confirming the participation of CD8 T cells in tumor rejection. Immunocompetent mice that have rejected B7-transduced tumor cells can subsequently reject an implant of nontransduced tumor cells. This suggests that vaccination with B7-transduced tumor cells can elicit durable antitumor immunity. However, transduction of B7-1 or B7-2 into poorly immunogenic tumors does not stimulate effective immune responses (67 ,69). Thus, B7 gene transfer may not be optimal

for cancer vaccine strategies involving poorly immunogenic human tumors.

Table 19.1-5 Selected Preclinical Studies of Gene-Transduced Tumor Cells

Author (Reference)	Cytokine Gene Transduced into Tumor Cells	Tumor Model	Reduction of Tumorigenicity[a]	Response in Established Tumors[b]	Induction of Durable Tumor Immunity[c]
Vieweg (73)	IL-2	MatLyLu prostate cancer	Yes	Yes	Yes
Golumbek (127)	IL-4	Renca renal cell cancer	Yes	Yes	Yes
Porgador (128)	IL-6	D122 lung cancer	Yes	Yes	Yes
Aoki (129)	IL-7	203 glioma	Yes	Not reported	Yes
Tahara (72)	IL-12	MCA207, 102 sarcoma	Yes	Yes	Yes
Gansbacher (130)	IFN-γ	CMS-5 sarcoma	Yes	No	Yes
Asher (131)	TNF-α	MCA205 sarcoma	Yes	No	Yes
Dranoff (71)	GM-CSF	B16 melanoma	Not evaluable	Yes	Yes
Chen (78)	Flt3 ligand	C3L5 breast cancer	Yes	Not reported	Yes
Townsend (68)	B7-1	K1735 melanoma	Yes	Not reported	Yes
Yang (69)	B7-2	P815 mastocytoma	Yes	Not reported	Yes

[a]Effects of transducing gene on the ability of tumor cells to grow in syngeneic animals.

[b]Effects of vaccination with cytokine-transduced tumor cells on established nontransduced tumors.

[c]Ability to reject subsequent challenge with nontransduced tumors.

An alternative approach is transduction of tumor cells with genes encoding cytokines (70). This approach allows high levels of cytokines to be produced in the vicinity of the transduced tumor cells, thus potentially avoiding the toxicities associated with systemic administration of pharmacologic doses of cytokines. Paracrine production of cytokines might also mimic more closely the situation that occurs during physiologic immune responses. Paracrine production of several cytokines using this approach has been shown to inhibit tumorigenicity and promote durable, specific antitumor immunity in preclinical models (see Table 19.1-5). Unlike B7 gene transfer, cytokine gene transfer has proved efficacious even in models using poorly immunogenic tumors (71 ,72). Furthermore, vaccination with tumor cells transduced with several cytokines can provoke the rejection of established, nontransduced tumors (72 ,73 and 74). These results raise the hope that cancer vaccine therapy could be used to treat patients with cancer.

The mechanisms by which vaccination with cytokine gene-transduced tumor cells stimulate tumor rejection and durable antitumor immunity have not been completely defined and are probably variable. IL-2 and IL-12 secreted by transduced tumor cells presumably directly stimulate immunologic effector cells, such as CD4[+]-T cells, CD8[+]-T cells, or NK cells (72 ,73). In some animal models, granulocyte-macrophage colony-stimulating factor (GM-CSF)-transduced tumor cells stimulate antitumor immunity more potently than tumor cells expressing several known immunostimulatory molecules (71 ,75). It is believed that paracrine production of GM-CSF leads to the recruitment and activation of professional APCs, and that presentation of tumor antigens by these activated APCs potently induces specific T-cell immune responses (71). Flt3 ligand strongly induces differentiation and expansion of dendritic cells *in vitro* and *in vivo* (76 ,77). Stimulation of dendritic cells may thus account in part for the efficacy of vaccination with Flt3 ligand-transduced tumor cells in a breast cancer model (78). Nevertheless, NK cells may also contribute to the elimination of malignant tumors after vaccination with GM-CSF or Flt3 ligand gene-transduced cancer vaccines (74 ,79).

Many clinical trials of cancer vaccination using gene-transduced tumor cells have been initiated (Table 19.1-6). These clinical trials involve autologous or allogeneic tumor cells that have been transduced *in vitro* with genes encoding immunostimulatory cytokines or costimulatory molecules. Results of a phase 1 clinical trial of vaccination with irradiated, GM-CSF gene-transduced autologous melanoma cells have been published (80). Autologous tumor cells were successfully harvested and transduced with the GM-CSF gene using replication-incompetent retroviral vector for 29 of 33 patients. Delayed-type hypersensitivity reactions in response to intradermal injection of irradiated, nontransduced autologous melanoma cells occurred after vaccination in all 21 evaluable patients. These reactions were characterized by dense infiltration by T lymphocytes and eosinophils. Immune responses to metastatic lesions could be detected in 11 of 16 patients from whom metastases were resected after vaccination. These were characterized by diffuse infiltration of metastatic lesions by T cells and plasma cells, extensive necrosis of melanoma cells, and fibrosis. Antimelanoma IgG antibodies were detected after vaccination in the serum of seven patients who were tested. Minor objective tumor responses were observed in five patients. This study confirmed the feasibility and safety of administering irradiated, GM-CSF gene-transduced autologous tumor cells to patients with metastatic melanoma. Demonstration of antimelanoma immune

responses in treated patients supports further clinical evaluation of this vaccine strategy.

Table 19.1-6 Clinical Trials of Gene-Transduced Tumor Cells

Tumor Cells	Transgene	Tumor Types
Autologous	IL-2, IL-4, IFN-γ, GM-CSF, B7-1	Melanoma, renal cell cancer, breast cancer, ovarian cancer, prostate cancer, lung cancer, neuroblastoma
Allogeneic	IL-2, B7-1	Melanoma, renal cell cancer, breast cancer

Although successful *in vitro* gene transfer into autologous tumor cells has been shown in several cancer vaccine studies, several limitations to this approach exist. Patients without readily accessible superficial metastases must undergo invasive surgical procedures to obtain autologous tumor. Furthermore, routine growth of autologous tumor cells *in vitro* has proved difficult for many common cancers. Several approaches have been taken to circumvent these problems. Use of allogeneic tumor-cell lines obviates the need to obtain autologous tumor samples for vaccine production. Moreover, these cell lines can be readily grown *in vitro.* Clinical trials of cancer vaccines based on allogeneic cell lines are in progress for melanoma, renal cell cancer, and breast cancer. Disadvantages of this approach include the potential hazards of exposing patients to allogeneic tumor-cell lines and possible lack of shared antigens between the cell lines and patients' autologous tumor cells. A different strategy for producing autologous tumor vaccines is *in vivo* injection of tumor masses with transgene-containing vectors. Clinical research protocols have been developed in which vectors encoding IL-2, IL-12, GM-CSF, IFN-γ, or B7-1 are injected into tumor masses *in situ.* Preliminary results of some of these trials have been reported (81 ,82 and 83). Although retrovirus vectors have been used in many of these clinical trials, adenoviral vectors may be better suited for this approach. Because prolonged expression of the transgene is not required, the failure of adenoviral vectors to stably integrate is not a problem. Unlike retroviral vectors, adenoviral vectors can efficiently transduce nondividing cells. Because the malignant cells in most macroscopic tumors are not actively dividing at any given time, it is expected that transgene expression in most primary tumors is higher after transduction using adenoviral as opposed to retroviral vectors. Furthermore, the intrinsic immunogenicity of adenoviral vectors may be advantageous in this setting (84). Adenoviral sequences could act as an adjuvant in stimulating specific antitumor immune responses. Moreover, adenoviral peptides could promote nonspecific destruction of the transduced tumor cells, leading to uptake of tumor-specific antigens by professional APCs. Several clinical studies of cancer vaccines produced by transduction of tumor cells with adenoviral vectors are being conducted (85 ,86 and 87).

Gene Transfer into Normal Cells: Cancer Vaccines

An alternative gene therapy strategy for generating cancer vaccines is transfer of vectors encoding tumor antigens. Although true "tumor-specific" antigens have not been clearly defined in humans, several tumor-associated antigens have been shown to be suitable targets for cancer vaccine approaches in preclinical models. Clinical studies of local or systemic injection of vectors encoding carcinoembryonic antigen, prostate specific antigen, and the melanoma-associated antigens MART-1 and gp100 are in progress (83 ,88). An advantage of this approach is its relative simplicity compared with generation of autologous tumor-cell vaccines. Furthermore, the antigenic stimulus is known, allowing monitoring of specific immune responses as a surrogate end point. A theoretical disadvantage is that the antitumor immune response stimulated by this approach would be focused on a single antigen. Selection *in vivo* for antigen-loss variants could thus limit the efficacy of this approach. In contrast, autologous tumor-cell vaccines could potentially induce immune responses to multiple tumor antigens, some of which might be required for maintenance of the neoplastic phenotype.

Gene Transfer into Normal Cells: Adoptive Immunotherapy

Gene transfer can also be used to modify immune effector cells in attempts to promote antitumor immune responses. The Rosenberg group has introduced the TNF gene into TILs used for adoptive immunotherapy of cancer (89). High concentrations of TNF produced by transduced TIL that accumulates at tumor sites after intravenous injection could enhance the efficacy of TIL therapy. A different strategy for adoptive immunotherapy involves the transfer of chimeric TCR/antibody genes (90). Investigators have engineered chimeric genes that encode the variable regions of the immunoglobulin gene linked to the ζ chain of the TCR. Transduction of this gene into polyclonal T cells allows the latter to be triggered by cells that express the antigen recognized by the antibody encoded by the native immunoglobulin gene. Infusion of chimeric TCR/antibody gene-transduced T cells can successfully treat antigen-bearing tumor cells in preclinical models (91 ,92). Clinical trials of adoptive immunotherapy using chimeric TCR/antibody-transduced autologous T cells have been developed for patients with ovarian and colorectal cancer.

Introduction of Suicide Genes

Part of "19.1 - Basic Principles and Safety Considerations "

Suicide genes encode proteins that convert relatively nontoxic molecules into toxic species. For example, the herpes simplex virus thymidine kinase (HSV-TK) is about 1,000-fold more efficient than mammalian thymidine kinases at phosphorylating ganciclovir. Ganciclovir monophosphate can then be sequentially converted by mammalian thymidine kinases to ganciclovir triphosphate, which inhibits DNA polymerase and is thus toxic to cells. Systemic administration of ganciclovir after intratumoral injection of fibroblasts transduced with an HSV-TK retroviral vector can induce regression of gliomas in rats (93). Adjacent normal brain tissue exhibited no toxicity; this was expected, because normal brain tissue does not proliferate and therefore should not be susceptible to transduction by retroviral vectors. The efficacy of HSV-TK transduction of tumors followed by ganciclovir therapy has been confirmed in several preclinical models (94). Major tumor regression has been observed despite the observation that only a small fraction of tumor cells generally has been transduced with the HSV-TK gene. The nature of the "bystander effect" of transduced on nontransduced tumor cells appears to be complex and remains to be fully elucidated. Diffusion of phosphorylated ganciclovir species from transduced to nontransduced cells via gap junctions occurs *in vitro* (95) and may contribute to the bystander effect *in vivo.* However, some investigators have found that immune effector

cells participate in the bystander effect *in vivo* (96 ,97). Indeed, preclinical studies have shown that HSV-TK gene therapy and immunostimulatory therapy can exert synergistic antitumor effects in murine models (97).

Clinical trials of HSV-TK suicide gene therapy have been initiated. Several investigators are conducting studies in which ganciclovir is given after the HSV-TK gene has been introduced into tumor cells *in vivo* using retroviral or adenoviral vectors. This approach is being tested in patients with brain tumors, mesothelioma, or ovarian cancer. The generally higher transduction efficiency of adenoviral vectors is a potential advantage for this approach (98). Moreover, the strong immunogenicity of adenoviral vectors might provoke immune destruction of transduced tumor cells and enhance the immunologic component of the bystander effect (84). However, increased toxicity could also occur due to destruction of normal tissues that have been transduced by the adenoviral vector. Retroviral vectors, which transduce only dividing cells, might thus be preferred for situations in which avoidance of adjacent normal tissue damage is particularly important (e.g., treatment of brain tumors).

An alternative strategy for suicide gene therapy involves transducing allogeneic immunocompetent cells with the HSV-TK gene before adoptive transfer. A majority of patients with chronic myelogenous leukemia in hematologic or cytogenetic relapse after allogeneic BMT who are given donor leukocyte infusions (DLI) achieves durable molecular remissions (99 ,100). DLI has also been successfully used to treat posttransplant Epstein-Barr virus (EBV)-related lymphoproliferative disorders (101). However, DLI is associated with a substantial risk of graft-versus-host disease (GVHD). Bonini has reported a study in which HSV-TK-transduced donor leukocytes were given to eight patients with relapsed leukemia or EBV-associated lymphoproliferative disease after BMT (102). Transduced cells could be detected in the bone marrow and peripheral blood of all but one patient for up to 12 months postinfusion and antitumor responses were observed in five patients. Two patients developed acute GVHD after DLI. PCR-detectable transgene-expressing cells and clinical signs of GVHD disappeared in both patients after administration of intravenous ganciclovir. A third patient developed chronic GVHD after DLI, which improved after ganciclovir therapy; transgene-expression cells were decreased but not eliminated by ganciclovir in this patient. Clinical trials are being conducted at several centers using HSV-TK-transduced donor leukocytes to treat malignancy relapse and certain infectious complications after bone marrow transplantation.

Another suicide gene under active investigation for cancer therapy is the cytosine deaminase gene (103 ,104). Cytosine deaminase converts the nontoxic fluoropyrimidine 5-fluorocytosine to 5-fluorouracil. 5-Fluorouracil is converted by endogenous cellular enzymes into fluorodeoxyuridine monophosphate, which inhibits thymidylate synthase activity, and fluorouridine triphosphate, which can be incorporated into RNA and interfere with RNA processing and transcription (105). Transduction of the cytosine deaminase gene renders tumor cells exquisitely sensitive to 5-fluorocytosine *in vitro* and *in vivo.* As with HSV-TK gene transfer, evidence exists that cytosine-deaminase gene transfer into tumor cells promotes antitumor immune responses (103).

Replacement of Defective Tumor-Suppressor Genes

Several tumor-suppressor genes, including p53, RB, APC, and WT1, were identified by their association with rare kindreds afflicted by hereditary cancers (106 ,107). However, it is now known that many common sporadic tumors harbor inactivating or recessive mutations in one or more tumor-suppressor genes. Gene transfer techniques can be applied to introduce wild-type copies of tumor-suppressor genes into malignant cells, thus potentially reversing the neoplastic phenotype. There has been considerable interest in targeting the p53-tumor suppressor gene for this approach. p53 mutations occur commonly in a variety of human cancers, including those of breast, lung, colon, prostate, bladder, and cervix (108). Transduction of a p53 transgene has been shown to inhibit tumor growth both *in vitro* and *in vivo* (109 ,110 ,111 ,112 and 113). Use of adenoviral vectors to deliver the p53 transgene to human tumors is being evaluated in phase 1 clinical trials (114). Objective responses of some tumors injected with the viral vector have been described. Preclinical studies also support gene replacement therapy using vectors encoding p21, p16, and RB (115 ,116). Given the relatively low gene transfer efficiencies achieved with currently available vectors, however, it is difficult to believe that tumor-suppressor gene therapy can be efficacious for bulky or disseminated cancers. Despite a possible bystander effect of gene therapy on nontransduced tumor cells, effective replacement of tumor-suppressor genes most likely requires technical advances in gene transfer efficiency.

Inhibition of Transforming Oncogenes

In contrast to tumor-suppressor genes, oncogenes promote neoplastic transformation by acquiring dominant or gain-of-function mutations. Excessive expression or dysregulated activity of the protein products of oncogenes is believed to contribute to the malignant phenotype (107 ,117). Thus, disruption of oncogene expression could be therapeutically beneficial. The antisense strategy includes several related approaches for achieving this goal. Antisense oligodeoxynucleotides are synthetic nucleotides that are complementary to short sequences of specific mRNAs (116 ,118). When successfully introduced into a cell, the antisense oligonucleotide can bind to the mRNA, preventing its translation and/or accelerating its degradation. Antisense oligonucleotides have been shown to efficiently inhibit *in vitro* the activity of several oncogenes. Moreover, antisense oligonucleotides specific for bcl/abl, c-myc, c-myb, and c-raf-1 have been shown to inhibit *in vivo* tumorigenesis in murine models (119 ,120 and 121). A major limitation of systemic antisense therapy is the rapid degradation of oligonucleotides *in vivo* and their inefficient uptake into potential target cells. Modifications of their phosphate backbone have rendered antisense oligonucleotides more resistant to digestion by nucleases. Antisense oligonucleotides have been conjugated to lipophils and incorporated into liposomes in attempts to enhance their delivery to target cells (118).

An alternative approach is to transduce cells with vectors encoding antisense RNA. Complementary DNA encoding antisense RNA can be delivered using any of the viral vectors systems described above. This approach has been used to successfully inhibit the expression of c-myc and K-ras *in vitro* and to reverse the transformed phenotype of cell lines *in vitro* and their tumorigenicity *in vivo* (122 ,123 ,124 and 125). Phase 1 clinical trials of retroviral vectors encoding antisense mRNA specific for K-ras are in progress (126).

Conclusion

Part of "19.1 - Basic Principles and Safety Considerations "

The number of gene therapy clinical trials has increased exponentially since the results of the first gene-marking study were published in 1990 (50). Most of these clinical trials have involved patients with cancer. A variety of strategies are being developed that use gene-transfer technique for cancer therapy; however, unequivocal clinical benefit has yet to be shown in any gene therapy trial. Assessment of the therapeutic efficacy of gene transfer approaches requires longer follow-up and additional studies. Almost all gene therapy trials performed to date have been phase 1 studies that sought to evaluate safety and address issues regarding dose and schedule. Several gene therapy applications are poised to enter phase 2 studies that can begin to evaluate efficacy. Nevertheless, many of the phase 1 trials have demonstrated low gene transfer efficiencies. Thus, the value of extensive phase 2 testing is doubtful unless gene transfer efficiency can be substantially improved. Indeed, technical limitations currently represent the major obstacle to progress in gene therapy. These limitations are being addressed by ongoing basic research efforts, including the development of improved vector systems. As gene-transfer technology becomes more powerful and sophisticated, anticipated outcomes and ethical issues also need to be continually addressed (43).

Animal models of genetic diseases indicate that gene therapy has considerable potential. Preclinical tumor models have also been encouraging. However, translating successful approaches developed in animal models to human cancer therapy has proved notoriously difficult. Therefore, data from preclinical gene therapy studies must be viewed with caution. Nevertheless, gene-transfer techniques have made possible a variety of novel approaches for cancer treatment. Solutions to the technical challenges of gene delivery and expression should allow exploration of new therapeutic options for patients with cancer.

Introduction

Part of "19.2 - Gene Transfer into Mammalian Cells "

The methods used to transfer nucleic acid (oligonucleotides, RNA, or DNA) into mammalian cells, either *ex vivo* or *in vivo*, form the bases of all approaches to gene therapy, as this determines the efficiency and duration of the effect induced. The current methods used for gene transfer into mammalian cells can be described in two broad categories, physical-chemical or viral. Examples of the physical-chemical approach include direct introduction of the DNA using injection, particle bombardment, or electroporation, calcium phosphate transfection, complexation with cationic lipids or polymer, or linkage to a specific ligand, and the use of the corresponding receptor. Virus-based gene delivery systems attempt to exploit aspects of the natural viral life cycle to elicit high-efficiency gene transfer. Viral vectors have been developed from many different viruses, from small RNA-based viruses to complex DNA viruses. Viral vectors are the most efficient vehicles for gene delivery because these make use of receptors or other interactions with the cell that have evolved over time. Current gene-delivery systems all have advantages and limitations for the treatment of various genetic and acquired diseases (Table 19.2-1). However, a method that would allow highly efficient and stable gene transfer to a wide range of cancer cells regardless of their state of proliferation in a safe and controllable, tissue-specific or inducible manner would be superior. This review gives an introduction to the different gene transfer systems currently being developed for gene transfer into mammalian cells.

Table 19.2-1 Summary of Commonly Used Vectors

Gene Transfer System	Description	Advantages	Disadvantages	Vector and Insert Sizes
Retrovirus	Replicative defective vectors based on MoMLV	Extensively studied	Low titer	8-10 kb
	Most gene transfer conducted *ex vivo*	Stable integration into host-cell genome	Infection limited to dividing cells	8-10 kb
		Efficient gene transfer	Limited *in vivo*	
Adenoassociated virus	Naturally replication- defective	Long-term expression	Requires helper virus (adeno- or herpes simplex virus) for production	5 kb
	Can integrate into host cell genome	Potential for stable integration into host-cell genome	Limited insert size (<5 kb)	4.0-4.5 kb
	Site-specific integration (Chr19)	Infection of nondividing cells	Low titer	
Adenovirus	Replication-defective vectors based on adenovirus 2 or 5 (serotype C)	High titer	Immunogenic	36 kb
	Efficient entry into most cell types	Stimulation of T- and B-cell responses	7.5 kb except when utilizing "gutless" vectors	
		High level of expression	Transient expression	
		Infection of nondividing cells		
Vaccinia virus	Naturally replication-competent	Efficient entry into most cell types	ImmunogenicSafety concerns in immunosuppressed patients	187 kb
	Transient gene expression	High level of expressionInfection of nondividing cells	25 kb	
DNA/Protein liposome complexes	Complex of plasmid DNA and cationic lipid	No size constraints	Limited persistence	No limit
		No viral genes	Low efficiency of transfer	No limit
		No risk associated with random integration	Complexes highly heterogeneous and formulation dependent	
Naked DNA	Engineered bacterial plasmid	Easy to prepare	Inefficient entry and uptake in most cell types	No limit
		No size constraint	Limited persistence	No limit

MoMLV, Moloney murine leukemia virus.

Note: The most commonly used gene transfer systems are briefly described including their advantages and disadvantages. In every system, the gene of interest is cloned into either the viral-vector genome or a modified bacterial plasmid.

Physical-Chemical Gene Transfer Approaches

Part of "19.2 - Gene Transfer into Mammalian Cells "

Naked DNA

Naked DNA in the form of an oligonucleotide or as a plasmid can be used to modulate endogenous gene expression or to express a new gene respectively. Oligonucleotides are short nucleic acid molecules (15 to 20 nucleotides) that can be based on DNA, RNA, or both. The direct intravenous administration of oligonucleotides has been exploited in a number of cancer clinical trials with the aim of transfecting cancer cells with an oligonucleotide that targets a specific cancer-related gene. The principal interaction exploited to produce a therapeutic effect is the alteration of gene expression by the hybridization of an oligonucleotide [with a sequence complementary to a messenger RNA (mRNA) transcript] to this mRNA target (1 ,2). The binding of the antisense oligonucleotide to the mRNA arrests translation and can induce the destruction of the specific mRNA. Targets of antisense oligonucleotides relevant to gene therapy for cancer include various growth factors associated with tumorigenesis; adhesion molecules; cytokines; and transcription factors and oncogenes, for example, *c-myb* and *bcr-abl*, respectively (3). Early *in vitro* studies used unmodified phosphodiester oligonucleotides; however, these molecules are highly susceptible to exonuclease degradation, and, thus, for *in vivo* application, a more stable molecule is required. Of the analogues produced, phosphorothioates-based oligonucleotides have been the most extensively studied and are currently in use in clinical trials in patients with acute myelogenous leukemia and myelodysplastic syndrome (4). However, further studies are necessary to evaluate the potential of these antisense oligonucleotides, as problems with *in vivo* delivery, production, and toxicity remain.

Another common application of the direct administration of naked DNA has been as part of a variety of vaccination strategies or other immunologically based cancer treatments. The DNA, encoding the gene or genes of interest, is usually incorporated into a plasmid. Plasmids are circular, double-stranded DNA (dsDNA) molecules found naturally in a wide variety of bacteria. Recombinant plasmids are modified natural plasmids from which unwanted or unnecessary DNA sequences have been removed; plasmid vectors are well characterized and can be relatively easily manipulated and purified using standard molecular biology techniques (5). The gene of interest is usually in the form of a complementary DNA that has been generated from the corresponding mRNA and thus contains only the appropriate coding information for that gene. Intramuscular

injection of naked DNA expressing a given protein has been shown to elicit a protective immune response (both cellular and humoral) against the expressed protein in several animal models (6). It appears that the DNA is taken up by myocytes, which express the protein; the protein is then processed into peptides, which are taken up as antigens by antigen-presenting cells, leading to an immune response (7). An important component in the induction of this immune response appears to be the immunogenicity of the plasmid DNA itself. Plasmid DNA is produced in bacteria and thus carries a bacterial DNA methylation pattern, which differs from that seen in mammalian cells. This hypomethylated state of CpG motifs can yield a nonspecific immune response to the plasmid itself and is thus recognized as a foreign molecule by mammalian cells (8). Antitumor responses can be elicited by vaccination in several ways. One strategy is to coexpress tumor-associated molecules such as the carcinoembryonic antigen, which is expressed in a number of cancers including gastric, pancreatic, and colorectal, with genes encoding immunomodulating proteins such as the B7-1 costimulatory molecule (to increase antigen presentation) or granulocyte-macrophage colony-stimulating factor (9). Direct injection, and/or particle bombardment of plasmids expressing these molecules can induce a specific anticarcinoembryonic antigen and thus potentially an antitumor response. Another approach has been to generate DNA vaccines consisting of antiidiotypic single-chain antibody fragments that correspond to the immunoglobulin molecules expressed by malignant B-cell clones. This type of strategy has been used to protect against B-lymphoma (10) and more recently has been adapted to induce responses against both lymphoma and myeloma (11).

Cationic Lipids

Cationic liposomes are membranous lipid vesicles that enclose an aqueous volume and carry a net positive charge. The combination of plasmid DNA, which has a net negative charge, with the positively charged cationic lipids causes the formation of liposome complexes, or lipoplexes (12 ,13). Mammalian cells take up these lipoplexes by mechanisms that are still unknown. The initial interaction between the cell and the lipoplex is electrostatic; endocytosis, phagocytosis, pinocytosis, and direct fusion with the cell membrane may all play a role in lipoplex cell entry depending on the cell type. The DNA and the lipid appear to be closely associated, protecting at least a proportion of the DNA from enzyme digestion, allowing sufficient molecules to reach the nucleus. DNA likely needs to be released from lipoplexes before entry into the nucleus (14). Plasmid DNA is the most commonly transferred genetic material; however, RNA, antisense oligonucleotides, and DNA up to 150 kilobase (kb) in length have also been transferred using this technique (15 ,16).

Several different cell types have been transfected using a variety of different cationic lipid preparations including mixtures of dioleoyl phosphatidylethanolamine (DOPE) with DOTMA (lipofectin), DOTAP (Boehringer Mannheim, Indianapolis, IN), DMRIE (Vical, Inc., San Diego, CA), DC-Chol: DOPE (17), and GL67 (18). The determination of the optimal formulation of any given lipoplex is critical, as this can influence the level of gene transfer and expression obtained by several orders of magnitude. The most important variables to be considered are the ratio of the nucleic acid and the cationic lipid, the concentration of these components, and the total amount of DNA and lipid (19). Several cationic polymers have also been synthesized that have similar properties to cationic lipids when used as gene transfer agents. Examples of these include polyethylenimine and polyamido-amine polymers (20 ,21).

The first clinical attempt to genetically modify tumors *in situ* using lipoplexes involved the direct injection of an allogene coding the histocompatibility antigen HLA-B7 complexed with the cationic liposome DMRIE:DOPE. The aim was that the transient expression of the foreign antigen HLA-B7 on the cell surface of the tumor, in this case melanoma lesions, should induce a systemic antitumor immune reaction in the host (22). A few examples of other antitumor genes that have been transferred by lipid-mediated gene transfer include p53, tumor necrosis factor-α, and interferon-β. Although this strategy can yield very high transfer efficiencies *in vitro*, the *in vivo* levels are far less encouraging. Further applications of liposomes in cancer gene therapy require further improvements in gene transfer efficiency, gene expression, and specific targeting of the vectors by conjugating ligands specific for tumor surface antigens to lipid moieties.

Receptor-Mediated Gene Transfer

By linking various receptor-specific ligands to polycations such as protamine or polylysine that bind nucleic acids, DNA can be delivered to different cell types via a specific receptor. Receptor targets that have been used include the transferrin receptor and the asialoglycoprotein receptor, which is specific for liver cells (23 ,24 ,25 and 26). This strategy has an advantage compared with other methods in its potential for specific targeting to different cell types depending on the receptor-ligand combination used. However, the efficiency of transfer and the level of expression achieved using receptor-mediated transfer is relatively low because of lysosomal degradation of the introduced DNA; coinfection with inactivated adenovirus or addition of the drug chloroquine has been used to overcome this problem by enhancing lysosomal release (27). Mohr and colleagues have recently developed a system to target gene transfer to hepatocellular carcinoma cells *in vitro* using a novel monoclonal antibody, AF-20, conjugated to the gene delivery system (28).

Virus-Mediated Gene Transfer

Part of "19.2 - Gene Transfer into Mammalian Cells "

Viral gene transfer vectors can be categorized on the basis of the fate of the introduced genetic material (Fig. 19.2-1). Retroviral- and lentiviral-mediated gene transfer results in the integration of the vector into the host genome (see Fig. 19.2-1A), whereas adenoviral-mediated gene transfer results in episomal maintenance of the vector (see Fig. 19.2-1B).
FIGURE 19.2-1. A: Integrating vectors. Virus particles bind to specific receptors on the surface of target cells. These vectors are internalized and their genome enters the cell. In the case of retroviruses, the single-stranded RNA genome is converted into double-stranded DNA by the reverse transcriptase enzyme encoded by the virus. The double-stranded DNA is taken up by the nucleus and integrates within the host genome as a provirus. The integration is random for retroviruses. Lentiviruses have a similar life cycle, whereas adenoassociated virus vectors do not replicate through an RNA intermediate. B: Nonintegrating vectors. Adenovirus bind to specific receptors on the surface of susceptible cells. These viruses are then adsorbed and internalized by receptor-mediated endocytosis. The viral genome enters the cytoplasm of the cell. The double-stranded DNA genome is taken up by the nucleus. In contrast to adenoviral vectors, vaccinia-based particles are found in the cytoplasm of cells. Nonviral based gene transfer of DNA results in episomal maintenance of plasmid DNA in the nucleus.

Retroviral Vectors

Retroviruses have an RNA genome that replicates by forming a DNA intermediate—a provirus—that integrates randomly into

the host genome (29). Retroviruses have been shown to infect fibroblasts, epithelial cells, and hepatocytes, but have been used most extensively in the transduction of hematopoietic cells. Several vectors have been developed, but the most widely used are based on the Moloney murine leukemia virus (MoMLV) with the therapeutic gene of interest replacing the viral gene sequences, *gag, pol*, and *env.* Retroviral-mediated gene transfer is dependent on a two-component system, the packaging cell and viral vector. A packaging cell is a cell that contains a retroviral genome from which the signals for encapsidation of the viral genome into virus particles have been removed. The viral genome in the packaging cell line produces all of the proteins necessary for virus replication and assembly (*gag, pol*, and a variable *env*), but cannot create an infectious particle due to the lack of a transferable viral genome. A retroviral vector that contains a gene or genes of interest and a promoter complement the packaging cell genome in that it lacks all of the normal viral protein coding sequences but retains the encapsidation signals (30 ,31 ,32 ,33 ,34 ,35 ,36 and 37). The introduction of a gene expression cassette [the gene(s) of interest plus the necessary regulatory sequences] into the vector is usually performed with the retroviral vector in the form of a plasmid. Standard molecular biology techniques can be used to clone the gene expression cassette between the two flanking long-terminal repeat sequences of the retroviral genome. Gene expression can be driven by the retroviral long-terminal repeat sequence or by the introduction of an exogenous promoter.

The first step in retrovirus production is the transfection of the retroviral vector-plasmid DNA into a packaging cell line. The vector DNA is transcribed into an RNA that can be packaged into retroviral particles that bud from the cell membrane. The medium into which the retrovirus is secreted is called the *retroviral vector supernatant.* When this infectious retroviral vector supernatant is added to cells, the viral particles bind to the cell and the retroviral vector RNA genome enters the cell. The retroviral genome is subjected to RNA-dependent reverse transcription that results in the production of a double-stranded DNA copy of the input viral RNA. Within the nucleus, the DNA copy is inserted into the host cell genome. It should be noted that reverse transcription and integration require cell division, and, although retroviral-mediated gene transfer is highly efficient, it is not effective for nondividing cells. Because the retroviral vector is replication-defective, this process is referred to as *transduction* rather than *infection,* as with a replication-competent virus (31).

The viral tropism of retroviruses is determined by the envelope glycoprotein. Modifications of the sequences encoding the envelope protein can be made within the packaging cell lines. Retroviruses can be classified by this tropism. Ecotropic viruses target murine and other rodent cells, whereas xenotropic viruses target nonrodent mammalian cells. Amphotropic viruses target mammalian cells including rodent cells. Other envelope sequences derived from the Gibbon ape leukemia virus and vesicular stomatitis virus G glycoprotein (VSV-G) have been used in virus production. Gibbon ape leukemia virus-based retroviruses predominantly infect primate cells, while VSV-G-derived viruses infect a wide range of vertebrate cells (38). Additionally, sequences such as those encoding epidermal growth factor or insulinlike growth factor have been fused to *env* in an attempt to produce viral particles that target specific cell types (39 ,40 and 41).

Theoretically, integration of the retroviral vector as a provirus should lead to maintenance of the transgene in the infected cells and transfer to any progeny; however, expression of the transgene can be transient, probably as a result of downregulation of transcription rather than gene loss (42). Other problems currently limiting their broader application include the potential that the random integration events may lead to transformation (insertional mutagenesis) or the possibility that replication-competent viruses may be formed through recombination or complementation by proteins expressed by other viruses and the inability of retroviruses to infect nondividing cells (43 ,44 and 45).

Because high levels of transduction can be achieved with retroviral vectors *ex vivo*, they have been used in cancer gene therapy for applications that can exploit this property. Gene transfer of an immunostimulatory molecule such as GM-CSF into tumor cells before infusion into patients either as a tumor cell vaccine or as tumor infiltrating lymphocytes have been efficacious (46 ,47). Vector producer cells have also been injected into patients with recurring gliomas for delivery of "suicide" genes (48).

Lentivirus Vectors

Lentivirus vectors based on the human immunodeficiency virus (HIV-1), equine infectious anemia virus, and feline immunodeficiency virus are the most recent additions to a growing list of gene transfer vectors (49). As with MoMLV-based vectors, these retroviruses are also comprised of an RNA genome. However, the major advantage to the use of these viruses is their ability to infect and stably integrate into nondividing cells. Most of the lentivirus vectors in use are based on the HIV-1 genome. To create a safe gene transfer vector based on this human pathogen, its genome was separated onto three different plasmids and mutated to produce replication-defective particles much less likely to recombine to form wild-type HIV-1. The first plasmid is the vector that contains an internally promoted transgene, the HIV-1 packaging signal, the *cis*-acting reverse transcriptase, and integration signals. The second plasmid expresses all of the HIV-1 proteins except for the envelope *(env).* The final plasmid encodes an envelope capable of pseudotyping the virus particles, most commonly VSV-G (50). Several studies both *in vitro* and *in vivo* have demonstrated successful gene transfer including transduction of nondividing hemopoietic cells at high efficiencies (up to 90%) and sustained gene expression in several target tissues of interest: liver (8 weeks), and muscle and brain (6 months) with no obvious immune response (51 ,52 ,53 and 54). The major drawback to the use of this vector is the safety concern that wild-type HIV-1 could be generated after administration of the vector system *in vivo.* This issue may be addressed by further deleting the HIV-1 genes and production of a packaging cell line (55).

Adenoassociated Viral Vectors

Adenoassociated virus (AAV) is a small, single-stranded DNA virus that may serve as a viable alternative to retrovirus in some instances. AAV is a defective human parvovirus in that it requires a helper virus for infection, usually an adenovirus or herpesvirus. In the absence of helper virus, the AAV genome (provirus) integrates into the host chromosomal DNA in a relatively site-specific manner and establishes latency, which has been maintained in cultured cells for more than 100 serial passages (56). As would be expected given its need for coinfection with adenovirus, AAV exhibits tropism for the airway (57 ,58). AAV vectors have also been successfully used to transfer genes into muscle and liver (59 ,60 and 61). AAV vectors containing a variety of different genes have been constructed and successfully shown to transfer and express genes both *in vitro* and *in vivo* regardless of the mitotic state of the target cell. A significant limitation exists, however, to the size of the insert that these vectors can accommodate [4.0 to 4.5 kilobase (kb)] and manipulation of the genome appears to disrupt the site-specific nature of the integration process (62). Also, the lack of packaging cell lines limits the production of relatively high-titer AAV vectors. AAV vectors can be used for a variety of cancer treatment approaches, delivery of antisense genes, "suicide" gene therapy by transfer of the herpes simplex virus thymidine kinase (HSV-*tk*) gene, and, recently, for the delivery of antiangiogenesis factors including angiostatin and endostatin (63 ,64).

Adenoviral Vectors

Adenoviruses are small, nonenveloped viruses. Their genome consists of a linear, dsDNA of approximately 36 kb in length, which codes for at least 30 different mRNA transcripts. The adenovirus (Ad) genome is organized into two groups of genes (early and late), depending on the role the protein products play in the life cycle of the virus (65). One of these genes, *E1a,* is of particular interest with respect to the development of adenoviral vectors. The deletion of this gene renders the adenovirus replication-deficient in many cell types. Other vectors have also been deleted in the *E3* gene (that encodes a polypeptide that influences immune recognition of the infected cell) (66). More recently, second-generation viruses have been developed that contain alterations in the *E2* gene, which further block expression of the Ad late genes, which encode the viral structural proteins (67). The deletion of these endogenous sequences allows for insertion of the DNA that is to be transfected, without affecting the ability of the virus to package the DNA into the viral capsid. The most

commonly used recombinant adenoviruses are based on serotypes 2 (Ad2) and 5 (Ad5). The wild-type virus (Ad2/Ad5) is most commonly associated with respiratory illnesses in humans and believed to be nononcogenic. Adenoviruses infect nondividing cells, but expression is transient because the DNA does not integrate into the host genome but is maintained episomally. Replication-deficient viruses must be propagated in 293 cells, human embryonic kidney cells, which have an integrated fragment of adenovirus (left arm of Ad5) that expresses the *E1* functions *in trans* (68).

Adenoviral vectors have numerous advantages for use in gene therapy. Titers of the recombinant viruses can be as high as 10^{12} plaque-forming units per mL, depending on the transgene inserted within the deleted region. The therapeutic gene expression cassette may be as large as 8 kb of DNA (69) with recent studies describing vectors with capacities of up to nearly 34 kb following deletion of most of the Ad genome (70). These viral vectors are capable of efficiently transducing a broad range of target cells, both *in vitro* and *in vivo,* including endothelial cells, neurons and muscle, and, in particular, because of their natural tropism, several different cell types associated with the respiratory tract (71 ,72 ,73 and 74). Adenoviral vectors are strongly immunogenic, however, which may preclude repeat administration without immune modulation or utilization of alternate serotypes (75 ,76 and 77). Because of their ability to efficiently transduce a wide range of cells with a high level of transient transgene expression, adenoviral vectors have been used primarily for delivery of cytokines, costimulatory molecules, tumor-suppressor genes, and "suicide" genes, including HSV-*tk* and cytosine deaminase (CD) (78 ,79). Although treatment of an entire tumor mass is not likely, the two "suicide" gene therapy strategies make use of a phenomenon referred to as the *bystander effect*, in which genetically modified cells are toxic to surrounding unmodified cells, which become susceptible to the prodrug. Recently, combinations of these approaches have been used in an attempt to fully eradicate the tumor mass (80 ,81). Modifications to the adenoviral fiber protein, including inclusion of an RGD peptide, have also been applied to direct these vectors specifically to tumor cells (82 ,83).

Herpes Simplex Virus Vectors

Herpesviruses are a diverse family of large DNA viruses all capable of establishing lifelong latency (84). Gene delivery vectors based on HSV have two major advantages over other viral vectors. First, very large inserts can be accommodated and packaged within the HSV particle. For example, the full-length complementary DNA for huntingtin (approximately 10 kb) can be packaged in these virions (85). Second, HSV vectors have a natural tropism for cells in the central nervous system. This may allow for the tropism to be exploited for the delivery of HSV-*tk* gene to brain tumors (86 ,87). Several clinical trials are currently in discussion that would use this system. HSV vectors can be produced by use of a helper virus system or an amplicon system. The first approach is based on construction of viruses lacking either single or combinations of essential genes that can accommodate the insertion of at least 40-kb DNA. By necessity, the debilitated recombinant viruses must be grown in cell lines expressing the deleted viral genes (88 ,89). The amplicon approach is based on defective HSV genomes, which arise spontaneously, by recombination. These are amplified during serial passages at high multiplicities of infection. The defective genomic subunit referred to as an *amplicon* consists of the terminal *a* sequence containing the packaging signal and an origin of viral replication but lacks both viral structural-protein sequences and sequences encoding proteins for viral-DNA synthesis and exocytosis. These proteins must be supplied for the amplicons to be made. Theoretically, amplicons could accommodate inserts as large as 150 kb. Amplicons are arranged from head-to-tail in virions and have been shown to efficiently express cellular genes incorporated into them (90 ,91). Tumor cells infected with HSV alone are destroyed during viral replication even without a transgene. HSV-*tk* is transferred to the cancer cells allowing for sensitivity to the prodrug ganciclovir. HSV vectors have also been used for the transfer of interleukins to glioma in mice and enhancement of *tk* delivery by addition of tumor necrosis factor-α both *in vitro* and *in vivo* (92 ,93). Although toxicity is not critical when treating cancer cells because the focus is usually on cell death, viral toxicity and transient expression limit gene-transfer strategies for HSV especially when used for central nervous system treatment. Deletion of a combination of the immediate-early genes including a transcriptional transactivation showed decreased cytotoxicity allowing for more efficient gene transfer and extended gene expression from HSV vectors and may be important for broader usage of HSV for gene transfer (94).

Epstein-Barr Virus Vectors

Epstein-Barr virus (EBV) is another member of the herpesvirus family that causes mononucleosis in its acute viral-replication state and polyclonal B-lymphoproliferative diseases in its latent infectious state. The latent replication origin, ORI-P, allows for viral replication in human cells without cell lysis. Episomal replication is only maintained in cells expressing EBV nuclear antigen (EBNA1) gene (95 ,96). This type of replication is the basis for EBV vectors for gene transfer. EBV-episomal vectors have been used recently to transfer the adenosine deaminase gene to CD34+ cells *in vitro* although the safety of using this system *in vivo* remains uncertain. An HSV/EBV hybrid has also been constructed that makes use of the EBV ORI-P element and EBNA1 that allows for replication and maintenance of the EBV genome as an extrachromosomal entity in dividing cells (97). This hybrid strategy, which can be efficiently packaged using an HSV-1–helper virus, may be useful in the treatment of dividing cells such as *in vivo* prodrug delivery to tumor cells.

Vaccinia Virus Vectors

Vaccinia virus is a member of the *Poxviridae* family and, like HSV, possesses a complex dsDNA genome, which contains 186 kb encoding more than 200 proteins. Most of the viral genes can be deleted and replaced by marker or therapeutic

gene(s) except for the ITR sequences within the genome that are responsible for viral replication. Recombinant vectors are achieved by homologous recombination after transfection of vaccinia virus-infected cells with plasmid DNA constructs (98). This virus is replication-competent and cytopathic with a broad host range and the capability to infect both vertebrate and invertebrate hosts (99). The advantages of using vaccinia viruses for gene transfer include their ability to accommodate inserts of at least 25 kb allowing for large or multiple gene inserts; their ability to infect cells regardless of their mitotic state; and their cytoplasmic replication, which avoids any potential for chromosomal mutation on insertion (100). However, vaccinia has been widely used as a vaccine for smallpox, therefore, administration of vaccinia virus for gene transfer could be impaired by a robust host immune response. In contrast, this potential disadvantage (intrinsic antigenicity) can be exploited to elicit an immune response against tumor-associated antigens to activate an antitumor immunotherapeutic response *in vivo* (101). Vaccination of tumors with cytokines including IL-12 have also resulted in a high level of expression as well as inhibition of tumor growth as a result of the cytopathic nature of the vaccinia virus (102).

Hybrid Virus Vector Systems

Several groups have described hybrid viral strategies that attempt to use the advantages of the two parental vectors while limiting, or compensating for, the effect of their respective disadvantages. For example, adenoviral vectors have the ability to transduce a broad range of cell types including nondividing cells, but transgene expression is short lived (usually 21 to 28 days). In contrast, retroviral vectors based on MoMLV have the advantage of generating stable, long-term expression as a result of proviral integration, but they only transduce dividing cells. One system developed by Feng and coworkers consisted of two adenoviruses: one carrying a retroviral transcription unit encoding green fluorescent protein (GFP) and a second expressing retroviral *gag, pol*, and *env* functions was used to transduce ovarian tumor cells (SKOV3.pi) *in vivo*. Coinjection of both adenoviruses resulted in more efficient transduction of the tumor compared with administration of the adenovirus carrying the GFP vector alone (103). A second group used an adenovirus carrying a retroviral vector to generate high-titer retrovirus from retroviral packaging cells (104) and a series of transcomplementing adenoviruses expressing (a) a retroviral vector, (b) retroviral *gag* and *pol*, and (c) the VSV-G envelope. Administration of the transcomplementing adenoviruses to tumor cells *in vivo* lead to the generation of a retroviral vector, which could subsequently infect adjacent cells (105).

Other hybrids under development include retroviruses and Alphaviruses, which have the potential to include complex mammalian regulatory sequences, including intron and untranslated regions, because their replication bypasses the nucleus and takes place solely in the cytoplasm within an autocatalytic loop that has the potential to generate large amounts of transferred gene product such as a tumor-suppressor gene, "suicide" gene, or cytokine (106 ,107). Other Alphavirus vectors expressing either HSV-*tk* and targeted using an antibody, or expressing IL-12, have recently been reported and may prove to be useful for cancer gene therapy applications (108 ,109).

Summary

Part of "19.2 - Gene Transfer into Mammalian Cells "

The utilization of gene therapy in the arsenal of treatment strategies for cancer is still in the preliminary stages with optimal vector delivery systems and therapeutic genes for any given tumor still only an educated guess based on our understanding of carcinogenesis and gene transfer studies to date (Table 19.2-2). Current approaches to gene therapy for cancer are focused on introduction of genetic material for systemic antitumor immunity by expression of cytokines, costimulatory molecules, foreign histocompatibility genes, vaccine strategies, induction of susceptibility to a prodrug, expression of tumor-suppressor gene products, and downregulation of oncogenes often using antisense oligonucleotides (Table 19.2-3). For gene therapy to be a feasible alternative or addition to traditional clinical intervention, the therapeutic gene needs to be expressed at high levels and targeted specifically to tumor cells to minimize toxicity to normal cells. Targeting may be achieved by including inducible or tumor-specific promoters or by conjugating tumor-specific antigens to the vector. Clinical trials incorporating the individual patients' genetic mutations and antigenic determinants into the treatment protocol may allow for the efficient and specific gene transfer of therapeutic DNA, RNA, or oligonucleotides by a variety of vectors that, more likely than not, differ from cancer to cancer and possibly even patient to patient. Unfortunately, no gene transfer system exists that allows for specific targeting for metastatic cancer, or that can guarantee gene transfer to all cells for a localized tumor. A primary experimental difficulty impeding the success of gene transfer is the lack of an effective *in situ* gene delivery method that would allow for effective delivery to solid organs and tissues, accessibility to target cells, and potential treatment for dominant negative or pathologic gene products and storage diseases. Although a universal delivery system for all maladies seems unlikely, development of effective schemes for one or more specific diseases is an attainable clinical goal.

Table 19.2-2 Summary of Gene Transfer Vectors Utilized in Both Open and Closed Cancer-Related Clinical Protocols[a]

Gene Transfer Vector	Utilized in Number of Protocols
Viral vectors:	
Retrovirus	89
Adenovirus	46
Poxvirus (vaccinia, canarypox, fowlpox)	17
Herpes simplex virus	1
Nonviral vectors:	
Naked DNA	7
Cationic lipid	35
Other: RNA	1
Total	196

[a]Numbers reflect completed protocols at various review levels. Information provided by the National Institutes of Health, Office of Recombinant DNA Activities, Bethesda, MD. (As of February 10, 1999.)

Gene Therapy: Clinical Applications

20.1

Gene Therapy Using Lymphocyte Modification

Patrick Hwu

Introduction

Part of "20.1 - Gene Therapy Using Lymphocyte Modification "

Adoptive immunotherapy, the transfer of T cells to patients, has produced relevant clinical results in several settings, including the use of tumor-infiltrating lymphocytes (TILs) in melanoma patients (1); donor lymphocytes (2) and cytomegalovirus-reactive T-cell clones (3) in allogeneic transplant patients with lymphoid malignancies; and Epstein-Barr virus (EBV)-reactive T cells in patients with transplant-related EBV lymphomas (4). The ability to efficiently gene-modify primary lymphocytes has created opportunities to confer new properties to adoptively transferred cells in an attempt to increase their efficacy or safety profile and to understand their biology *in vivo* (Table 20.1-1).

Table 20.1-1 Potential Gene Therapy Approaches to Improve Lymphocytes Used in Adoptive Immunotherapy

Gene	Rationale
TNF	Interfere with tumor blood supply
Chimeric antibody/T-cell receptor (variable region of monoclonal antibody plus T-cell signaling chain)	Alter recognition of T cell (non-MHC-restricted)
Alpha and beta chain of TCR that specifically recognizes tumor antigen	Alter recognition of T cell (MHC restricted)
Suicide genes	Enhance safety profile of donor lymphocytes
IL-2 receptor	Increase sensitivity to administered IL-2
Erythropoietin, IL-3, or GM-CSF receptors (or chimeras using IL-2 receptor cytoplasmic domains)	Substitute IL-2 dependence for a less toxic molecule
Adhesion and costimulatory molecules	Enhance lymphocyte ability to traffic to tumor sites or to become activated on contact with tumor
IL-2	Increase lymphocyte survival *in vivo*
MDR	Select antitumor lymphocytes *in vivo* with chemotherapy (e.g., Taxol)

GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-2, interleukin-2; MDR, multi-drug resistance gene; MHC, major histocompatibility complex; TNF, tumor necrosis factor.

Initial studies used marker genes to follow transferred cells and their progeny *in vivo* to investigate the survival and trafficking of these cells after infusion. Following this, cytokine genes were introduced into lymphocytes in an attempt to improve their efficacy against tumor. More recently, receptor genes, using native T-cell receptor (TCR) alpha- and beta-chains or fusion proteins with antibody variable regions, have been used to alter T-cell specificity to allow the recognition of tumor targets. Finally, in the setting of allogeneic bone marrow transplantation (BMT) for lymphomas, donor T-cell infusions can be effective against the tumor but can induce life-threatening graft-versus-host disease (GVHD). Therefore, suicide genes have been used in donor lymphocytes in an attempt to increase their safety profile in this setting.

However, the use of gene-modified lymphocytes first requires a safe, efficient, and reliable method of stable gene transfer into primary T cells.

Methods of Gene Transfer into Lymphocytes

Part of "20.1 - Gene Therapy Using Lymphocyte Modification "

Although many methods of gene transfer into mammalian cells exist, such as electroporation and calcium phosphate transfection, most do not allow efficient DNA transfer in primary lymphocytes. In contrast to gene transfer into tumor cells and many other cell types, which can be successfully performed using a variety of methods, the efficient expression of foreign DNA in lymphocytes presents unique problems and challenges, requiring a careful selection of the mode of gene transfer. Large numbers of T cells are required for adoptive therapy, and, consequently, a relatively efficient method of gene transfer is needed to allow the growth of an adequate number of transduced cells. These therapies are often used in patients with advanced malignancies; thus, the generation of cells must be performed in a timely fashion, underscoring the need for an efficient method of gene insertion. Finally, although several methods exist to genetically modify T-cell tumor lines or established, long-term T-cell clones, adoptive immunotherapy often requires the use of bulk populations of nontransformed, primary T-cell lines.

With these stringent requirements, traditional nonviral methods of gene transfer, such as electroporation, calcium phosphate transfection, and lipofection, are not adequate for the genetic modification of lymphocytes for use in adoptive therapy.

In the 1970s, however, the finding that tumor viruses transferred genetic material to transformed cells led to the idea of using these viruses as vectors for gene transfer. Since the mid-1980s, these viral vectors have been refined for use in high-efficiency gene transfer into many cell types in the absence of replication-competent virus. Although improvements in gene transfer and expression techniques are needed for optimal use in lymphocytes, viral vectors have enabled the study of genetic modification as a means to improve effector cells for adoptive therapy. The most important of these vectors have been derived from murine retroviruses.

Retroviral Vectors and the Use of Alternative Envelope Genes

Part of "20.1 - Gene Therapy Using Lymphocyte Modification "

Retroviral virions each consist of two single strands of RNA (ssRNA) within a protein core, or capsid, surrounded by a lipid

envelope. On binding of a protein on the retroviral envelope to a cell-surface receptor, the retrovirus enters the cell. During migration to the nucleus, the RNA is reverse-transcribed to DNA, which, on entering the nucleus, is integrated into the host genome. This integrated retroviral genome, termed the *provirus*, then uses host cell transcriptional machinery to express the proviral genes. This leads to the manufacture of structural viral proteins and enzymes necessary for production of further retroviral particles. Packaging of proviral-RNA transcript into newly forming virions (encapsidation) is dependent on a specific sequence termed Ψ+ (5).

To modify the retroviral genome to safely introduce genes into mammalian cells, all structural genes are removed from the retrovirus and are replaced with the gene of interest. The encapsidation and replication signals, however, are retained. This replication-incompetent retroviral vector is then packaged into retroviral virions using cell lines (packaging cells) that contain helper-plasmid sequences encoding all of the viral proteins (Fig. 20.1-1). The helper sequences, consisting of the retroviral *gag/pol* and *env* genes, do not themselves contain the Ψ+ sequence, and thus are not packaged into newly forming virions to produce replication-competent virus. However, retroviral vectors, which contain the Ψ+ sequence followed by the gene of interest, are packaged into the retroviral virions on transfection into packaging cells. Because retroviral vectors do not contain any retroviral structural genes themselves, they can be used to safely transfer the gene of interest into target cells in the absence of wild-type, replication-competent retrovirus (5,6).
FIGURE 20.1-1. Production of retroviral vectors with packaging cells. The gene of interest is cloned into a retroviral vector and then transfected into a helper cell line, which provides the retroviral structural genes in *trans.* The retroviral structural genes cannot be packaged due to the absence of a packaging sequence (Ψ), whereas the retroviral vector can be packaged, thereby producing a replication incompetent retrovirus. (LTR, long terminal repeat.) (From Eglitis MA, Anderson WF. Retroviral vectors for introduction of genes into mammalian cells. *Biotechniques* 1988:6;608-614, with permission.)

Retroviral packaging cells can use a variety of envelope genes from other viruses. Because the envelope protein is the primary determinant of the host range of the retrovirus, the particular envelope or pseudotype used can have a profound impact on transduction efficiencies (7). Table 20.1-2 lists a number of envelope genes along with their relative host ranges. The development of packaging cell lines using alternative envelope genes has resulted in significant advances in the ability to transduce primary

lymphocytes. Retroviral vectors produced from the PG13 packaging cell line (8), which uses the gibbon ape leukemia virus envelope, are capable of transducing B cells (9) and T cells (10) with significantly higher efficiencies compared to those derived from amphotropic packaging cell lines. In one study, transduction of primary T cells was fourfold to 18-fold higher with PG13-packaged vectors compared to amphotropic PA317-packaged vectors (Table 20.1-3) (10). This was found to correlate with an eightfold to 19-fold higher expression of the gibbon ape leukemia virus envelope receptor (Pit-1) compared to the amphotropic receptor (Pit-2) in primary T cells (Table 20.1-4), although other factors besides receptor expression have been found to play a role in transduction efficiency (11). By combining the use of PG13-packaged vectors with a 1-hour centrifugation at 1,000 g, Bunnell et al. were able to obtain transduction efficiencies of primary T cells in the 40% range (12).

Table 20.1-2 Envelopes Used for Retroviral Vectors

Envelope Source	Host Range Includes
Ecotropic	Mouse, rat
Amphotropic	Human, mouse, rat, rabbit, cat, dog, monkey
GALV	Human, rat, rabbit, cat, dog, monkey (not mouse)
VSV-G	All

GALV, gibbon ape leukemia virus; VSV-G, vesicular stomatitis virus G glycoprotein.

Pit, gibbon ape leukemia virus envelope receptor.

[a]Per 20 μg of total RNA.

[b]Ratios were corrected for loading by multiplying by (ß-actin$_{Pit-2}$ ÷ ß-actin$_{Pit-1}$). The ß-actin values were obtained by measuring radioactive counts per minute (ß-emissions) of ß-actin probe hybridized to Pit-2 and Pit-1 blots.

From Lam JS, Cowherd R, Rosenberg SA, Hwu P. Improved gene transfer into lymphocytes using retroviruses that express the gibbon ape leukemia virus envelope. *Hum Gene Ther* 1996:7;1415-1422, with permission.

The vesicular stomatitis virus-G glycoprotein (VSV-G) can also be used to pseudotype retroviral vectors (13). Unlike other envelope proteins, the VSV-G protein confers enhanced physical stability to retroviral particles, allowing concentration with ultracentrifugation to titers of 10^9 or higher. VSV-G pseudotyped retroviral vectors have a wide host range and have been used successfully to transduce primary T cells (14,15).

Other Viral Vectors

Part of "20.1 - Gene Therapy Using Lymphocyte Modification "

Retroviral vectors offer the advantage of permanent integration within the host genome and the transfer of only the gene of interest without transferring other viral genes. Because of these properties, retroviral vectors have been the most widely used vectors for gene-therapy clinical protocols. However, in comparison to many other cell types, such as tumor cells and fibroblasts, retroviral transduction into lymphocytes results in lower transduction efficiencies and levels of gene expression. For these reasons, current efforts are focused on developing alternative vectors for use in lymphocytes.

These alternatives include vectors based on recombinant adenovirus (16), adenoassociated virus (AAV) (17), and poxviruses (18,19,20 and 21). All have advantages and disadvantages compared to retroviruses for gene transfer into lymphocytes, and their ultimate utility for this purpose is based on further study, as well as the particular goals and requirements of lymphocyte transduction with the specific gene of interest for a particular application.

Of these potential viral vectors for lymphocyte transduction, only AAV, like retroviruses, can permanently integrate the introduced gene into the target-cell genome. In contrast, gene transfer via adenoviral vectors or pox vectors is transient, and expression thus decreases as the cell divides. Pox vectors, however, have the capability of transducing cells with high efficiency, including lymphocytes *(unpublished studies in our laboratory)*, compared to retroviral vectors. Adenoviral vectors appear to be capable of transducing lymphocytes with relatively high efficiency, compared to retroviruses, but gene expression has been low *(preliminary studies from our laboratory)*. AAV vectors have not yet been

fully tested in lymphocytes, partially due to the difficulty in producing high-titer, purified AAV vector stocks.

Because adenoviral, AAV, and retroviral vectors rely on eukaryotic or viral promoters, which require host transcriptional machinery, gene expression can be regulated by normal host mechanisms. Studies thus far of retroviral gene transfer into lymphocytes have revealed that levels of vector-derived transcript in transduced lymphocytes were significantly lower compared to that in transduced tumor cells (22). With the current cellular and viral promoters available, gene expression in primary lymphocytes is relatively low, compared to the abundant levels of expression observed in most other cell types. Therefore, the use of adenoviral, AAV, and retroviral vectors in lymphocytes is currently limited by the levels of gene expression obtainable from currently used promoters. Although this level of expression may be adequate for some applications, full utility of these vectors is realized only after new promoter or enhancer regions are identified, which allow improved expression in primary lymphocytes.

In contrast, poxviruses, such as vaccinia and fowlpox, contain genes that encode their own RNA polymerases, allowing transcription to occur in the target-cell cytoplasm independent of host cell transcriptional machinery. Consequently, foreign gene expression is significantly higher with poxviruses compared to other methods. However, vaccinia vectors are eventually toxic to host cells, and, in our experience, result in lymphocyte cell death within 72 hours. In contrast, fowlpox vectors have not been toxic to lymphocytes, while allowing high levels of gene expression in some cultures in preliminary experiments. As previously discussed, though, gene transfer is transient, and gene expression decreases as the cells divide *(unpublished studies in our laboratory)*.

Thus, alternative viral vectors for gene transfer into lymphocytes are currently under study, and each have their own advantages and disadvantages. It is likely that some vectors are most amenable to a particular application while others are more useful for another application, depending, for example, on the levels and duration of gene expression required.

Marking Studies

Part of "20.1 - Gene Therapy Using Lymphocyte Modification "

The introduction of foreign DNA into humans raised many safety issues concerning patients and the general public. The first gene-transfer study in humans, performed in the Surgery Branch of the National Cancer Institute, used a marker gene conferring neomycin resistance (Neo^R) to assess the safety and feasibility of transferring foreign genes into humans. The trial was performed using TILs retrovirally transduced with the replication-defective N2 vector containing the gene encoding the bacterial enzyme neomycin phosphotransferase (Fig. 20.1-2) (23,24). Sensitive S+/L- studies were performed to rule out the presence of replication-competent retrovirus. Ten patients were treated, and no safety or toxicity problems were detected from the gene transfer. Because a novel gene was introduced into TILs that could be distinguished from endogenous DNA, the survival and distribution of the TILs could be followed *in vivo.* Furthermore, as TILs proliferated *in vivo*, daughter cells would all be marked with the Neo^R gene as well. Using polymerase chain reaction analysis, which was capable of detecting 1:10,000 to 1:100,000 cells, peripheral blood and tumor cells were analyzed for presence of the Neo^R gene. Neo^R TILs were found in tumor biopsies up to 64 days and in peripheral blood up to 189 days after injection (Fig. 20.1-3) (24,25).
FIGURE 20.1-2. Schematic diagram of the LNL6 retroviral vector, which contains the gene for neomycin resistance. The vector is a derivative of the Moloney murine leukemia virus. (LTR, long terminal repeat; Neo^R, neomycin resistance.) (From Miller AD, Buttimore C. Redesign of retrovirus packaging-cell lines to avoid recombination leading to helper-virus production. *Mol Cell Biol* 1986:6;2895-2902, with permission.)
FIGURE 20.1-3. Results of polymerase chain reaction assays of peripheral blood mononuclear cells *(circles)* and tumor biopsy specimens *(squares)* obtained from patients at various intervals after the infusion of gene-transduced tumor-infiltrating lymphocytes. Open symbols denote negative results, and solid symbols positive results. All results were corroborated in at least two separate Southern blot assays. The assays were performed and assessed in a blinded fashion. (PBL, peripheral blood lymphocyte.) (From Rosenberg SA, Aebersold P, Cornetta K, et al. Gene transfer into humans—immunotherapy of patients with advanced melanoma, using tumor-infiltrating lymphocytes modified by retroviral gene transduction. *N Engl J Med* 1990:323;570-578, with permission.)

Since this initial study using Neo[R]-marked TILs, other groups have also begun gene-marking studies using melanoma TILs (26,27), renal TILs (28), bone marrow stem cells (29,30), and anti-human immunodeficiency virus (HIV) cytotoxic T cells (31). Using gene-marked, EBV-specific cytotoxic T lymphocytes (CTLs) in immunocompromised patients, Heslop et al. found that EBV precursors could proliferate in response to *in vivo* or *ex vivo* viral challenge for as long as 18 months (Fig. 20.1-4) (32).
FIGURE 20.1-4. Recruitment of gene-marked, Epstein-Barr virus (EBV)-specific cytotoxic T lymphocytes (CTLs) by antigenic stimulation *in vivo.* DNA was obtained from peripheral blood mononuclear cells of a patient between 0 and 108 weeks after bone marrow transplantation (BMT) and divided into two portions. One was analyzed by polymerase chain reaction amplification using EBV-specific primers, whereas the second was amplified using neomycin-specific primers. The figure shows the relationship between levels of EBV-DNA and the presence of neomycin resistance (Neo[R])-marked, EBV-specific, gene-positive T cells. (MNC, mononuclear cells.) (From Heslop HE, Ng CY, Li C, et al. Long-term restoration of immunity against Epstein-Barr virus infection by adoptive transfer of gene-modified virus-specific T lymphocytes. *Nat Med* 1996:2;551–555, with permission.)

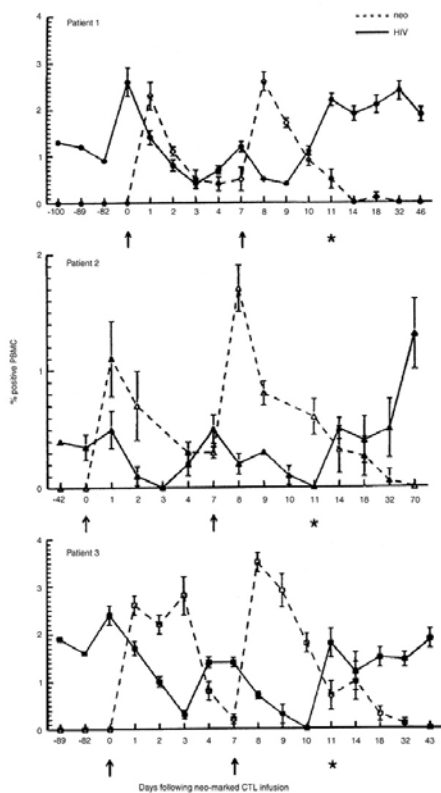
Researchers at the University of Washington in Seattle have used Neo[R]-marked HIV type 1 (HIV-1), *gag*-specific CD8[+] CTL clones to treat HIV-infected individuals (33). Using polymerase chain reaction amplification for the Neo[R] gene followed by *in situ* hybridization with fluorescein-labeled Neo[R]-specific oligonucleotides, the percentage of circulating transduced cells could be quantitated by flow cytometry. One day after cell infusion, 2.0% to 3.5% of CD8[+] cells circulating in the periphery were Neo[R] positive. The frequency of Neo[R]-modified CTLs was found to correlate inversely with the percentage of HIV-infected cells in the peripheral blood after cell infusion (Fig. 20.1-5). Additionally, Neo[R]+ CTLs were found to accumulate in lymph node biopsies obtained 4 days after cell infusion (2.2% to 7.9%) compared to the concurrent percentages of Neo[R]+ CTLs circulating in the periphery (0.5% to 0.7%). Neo[R]+ CTL aggregates were found in the parafollicular regions of the lymph node near cells that were productively infected with HIV. This illustrates the utility of cell marking to determine not only the overall traffic and survival of infused cells, but also their microanatomic localization.


FIGURE 20.1-5. Temporal relationship between the percentage of human immunodeficiency virus (HIV)-specific CD8[+] T cells marked with neomycin (Neo[R]) resistance and the percentage of CD4[+] T cells expressing HIV-gag messenger RNA in peripheral blood mononuclear cells (PBMCs) of three patients collected before, during, and after adoptive transfer of Neo[R]-modified, HIV-specific cytotoxic T lymphocyte (CTL) clones. Up arrows *(horizontal axis)* indicate the days CTLs were infused. (From Brodie SJ, Lewinsohn DA, Patterson BK, et al. *In vivo* migration and function of transferred HIV-1-specific cytotoxic T cells [see comments]. *Nat Med* 1999:5;34–41, with permission.)

Cytokine Genes

Part of "20.1 - Gene Therapy Using Lymphocyte Modification "

Having demonstrated the safety and feasibility of using gene-modified cells in humans with marking protocols, the next step was to use this novel approach to increase the antitumor potency of TILs. In a gene therapy trial for cancer at the Surgery Branch of the National Cancer Institute, TILs were retrovirally transduced with the gene for tumor necrosis factor alpha (TNF-α). In a number of murine tumor models, systemic TNF-α has resulted in the dramatic regression of advanced disease (34,35 and 36). Humans, however, can tolerate only 2% of the systemic TNF dose (per weight) required in mice, due to dose-limiting hypotension (37,38,39,40 and 41). Impressive tumor regressions have been seen in patients treated locally with high concentrations of TNF given either as an intralesional injection (42,43) or as an isolated limb perfusion (44). Regressions of liver metastases have been seen in patients treated with TNF administered as an isolated hepatic perfusion (45). Therefore, tumor regressions are possible when adequate local concentrations of TNF can be achieved. Because TILs have been demonstrated to accumulate at sites of tumor (46,47 and 48), the transduction of TILs with the TNF gene may allow high concentrations of TNF to be delivered locally in the absence of systemic toxicity (22).

TILs retrovirally transduced with the TNF-α complementary DNA (cDNA), using a bicistronic vector that also contained the neomycin resistance gene, was found to contain a high percentage of transduced cells within the population after selection in the neomycin analog G418 (22). Although Southern blot analyses of DNA from G418-selected TILs demonstrated that the foreign TNF gene was inserted in the genome with adequate efficiency, TNF gene expression was suboptimal. However, other cell types, such as fibroblasts and tumor cells, transduced with the identical retroviral vector produced high levels of TNF. Northern blot analyses demonstrated that transduced TILs had significantly lower levels of vector-derived transcript compared to transduced tumor (Table 20.1-5). Therefore, promoter or enhancer regions that direct higher levels of gene expression in primary lymphocytes should be identified to optimize this treatment strategy.

Table 20.1-5 Transcription of the LTSN Tumor Necrosis Factor (TNF) Vector: A Quantitative Comparison between Transduced Tumor-Infiltrating Lymphocytes (TILs) and Transduced Tumor Cells

Patient No.	% Full Length, 5"LTR-Generated, 4.0-kb TNF Transcript in TILs Compared to MEL-TNF tumor[a],[b]
1102	0.8
1104	1.6
1118	6.4
1122	36.0
1126	3.9
1143.A	13.8
1144	10.8
1155	9.3
1160	3.9
1166	8.4
Mean (SEM)	9.5 (3.2)

LTR, long terminal repeat; LTSN, TNF-containing retroviral vector; MEL-TNF, TNF-transduced melanoma cell line; TNF, tumor necrosis factor.

[a]Transduced and selected TIL cultures were compared with a transduced, fully selected MEL-TNF.

[b]RNA probed with ^{32}P-labeled TNF complementary DNA (cDNA). All comparisons of RNA between TILs and tumor were corrected for loading differences via use of actin controls, background differences, and differences in percent of cells transduced. All values were quantitated directly via beta scope, and the correction factors were incorporated into the following formula: corrected percentage of long terminal repeat-derived transcript (LTRDT) from tumor $= \frac{(LTRDT_{TIL} - Background_{TILNV})/(Actin_{TIL} - Background)}{(LTRDT_{tumor} - Background_{tumorNV})/(Actin_{tumor} - Background)} \times \frac{1}{T_{TIL}} \times 100\%$ where T_{TIL} = calculated fraction of TIL transduced (compared to the 100% transduced MEL-TNF tumor line).

From Hwu P, Yannell, J, Kriegler M, et al. Functional and molecular characterization of TIL transduced with the TNF-alpha cDNA for the gene therapy of cancer in man. *J Immunol* 1993:150;4104-4115, with permission.

Besides TNF, other growth factors and their receptors may have utility when overexpressed in adoptively transferred lymphocytes. Interleukin-2 (IL-2) is a cytokine that signals T-cell growth. On T-cell stimulation, production of IL-2 and IL-2 receptor is upregulated, resulting in T-cell proliferation (49). Studies in murine tumor models have demonstrated that systemic IL-2 administration enhances the antitumor response from TILs (50) and have suggested that this is due to the ability of systemic IL-2 to maintain *in vivo* viability and to stimulate proliferation of the administered TILs. Marking studies using Neo[R]-transduced TILs in cancer patients suggested that TILs were not detectable long after the discontinuation of systemic IL-2 treatment (24). The duration of IL-2 administration is limited in humans due to adverse reactions, such as hypotension. Thus, one possible approach to improve adoptive immunotherapy is to modify lymphocytes so that they can either sustain themselves through autocrine pathways or respond to alternative cytokines administered exogenously that have milder adverse reactions.

Potentially, insertion of the IL-2 gene into effector T cells could support continued growth *in vivo* without the need for exogenous IL-2. Yamada and colleagues (51) inserted the human IL-2 gene into the IL-2-dependent CTL line (CTLL) and found that the cells could grow *in vitro* in the absence of IL-2. Additionally, IL-2-transduced CTLL formed subcutaneous tumors in nude mice. Karasuyama et al. (52) introduced murine IL-2 cDNA into the IL-2-dependent murine T-cell line HT-2. The transfectants proliferated autonomously *in vitro*, and high IL-2-expressing clones developed tumors *in vivo.* Treisman et al. (53) introduced the IL-2 cDNA into the murine T helper cell line 14.1 (54), which is specific against sperm-whale myoglobin. The IL-2-transduced 14.1 cells proliferated autonomously in the absence of exogenous IL-2 and maintained specificity against sperm-whale myoglobin, as measured by specific release of murine interferon-γ.

One potential limitation in attempting to generalize this approach to primary, tumor-reactive T cells is that it might require the constitutive expression of the high-affinity IL-2 receptor. Normally, high-affinity IL-2 receptor expression is upregulated after T-cell stimulation with specific antigen (49). *In vivo*, tumor-reactive T cells could potentially interact with antigen, resulting in upregulation of IL-2 receptor. Alternatively, the concomitant introduction of the IL-2 receptor chain genes into T cells might be necessary.

Another approach toward maintaining T-cell viability *in vivo* is to introduce receptor genes responsive to alternative growth factors less toxic to patients than IL-2 (55). The IL-2 receptor is a member of the cytokine receptor superfamily, which includes the receptors for IL-3, IL-4, granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-6, IL-7, erythropoietin (Epo), and granulocyte colony-stimulating factor (55). These receptors

share consensus sequences in their extracellular domains. Several are heteromultimeric, and some have been shown to share a common chain (56,57,58 and 59).

Kitamura et al. (60) expressed the human IL-3 receptor in murine IL-2-dependent CTLL-2 cells and found that the modified cells could proliferate in response to physiologic concentrations of human IL-3, in the absence of IL-2. Similarly, CTLL-2 cells transfected with the α and β subunits of the human GM-CSF receptor could proliferate in response to low concentrations of human GM-CSF. These results suggest that signal transduction from the IL-2, GM-CSF, and IL-3 receptors may share common components. However, conflicting reports exist on the ability of the erythropoietin receptor to induce proliferation in IL-2–dependent cells. Showers et al. (61) reported that Epo-R–transfected CTLL-2 cells could proliferate in response to Epo in the absence of IL-2, but a similar study by Yamamura et al. (62) failed to confirm this. Both studies, however, reported that an Epo-R–transfected IL-3–dependent cell line, Ba/F3, could proliferate in response to Epo alone. Thus, while similarities seem to exist in signal transduction between the IL-3 and Epo receptors, it is not clear whether the Epo and IL-2 receptors share such similarities.

Another strategy toward substituting IL-2 dependency for other ligands is the construction of chimeric receptors using the cytoplasmic domains of the IL-2 chains joined to the extracellular regions from another cytokine receptor. This would more likely ensure that signal transduction occurred along physiologic pathways consistent with normal IL-2 stimulation. One approach uses the extracellular domains from the GM-CSF receptor joined to the transmembrane and intracellular domains of the IL-2 receptor. Because CTLs produce GM-CSF but not IL-2 on activation, it is hoped that transfected cells proliferate on contact with antigen via an autocrine loop (63).

Applying these strategies to primary effector T cells has been difficult due to the limited expression of transgenes in these cells. Additionally, many cytokine receptors consist of two to three different chains, requiring the introduction of multiple genes, which has been difficult to accomplish with adequate efficiency in primary T cells.

Because of the possibility of tumor development with these approaches, the concomitant introduction of a suicide gene might be required. This would be especially important in those situations resulting in autocrine loops consisting of high constitutive production of both ligand and receptor. For example, the introduction of the IL-2 gene into T cells that constitutively express large amounts of high-affinity IL-2 receptor would more likely result in tumorigenic T cells than with T cells that only express high-affinity IL-2 receptors after T-cell stimulation.

Receptor Genes that Alter T-Cell Specificity

Part of "20.1 - Gene Therapy Using Lymphocyte Modification "

Chimeric Antibody and T-Cell Receptor Genes

Use of adoptive immunotherapy against many histologic types of cancer is limited by the difficulty in isolating and expanding specific antitumor T cells from these tumor types. However, monoclonal antibodies exist that bind to specific tumor types. By joining the antigen-binding variable regions of antibody genes with T-cell signaling chains, chimeric TCRs can be constructed to direct T-cell specificity (Fig. 20.1-6). T cells of undefined specificities could then be genetically modified with the appropriate chimeric receptor gene to confer antitumor activity. This approach has the potential to generalize the applicability of adoptive immunotherapy.
FIGURE 20.1-6. The chimeric immunoglobulin T-cell receptor (TCR) combines antibody-variable regions with T-cell signaling chains. In this diagram, a single-chain antibody (scFv) fragment derived from the variable regions of a monoclonal antibody is joined to the crystallizable fragment (Fc) receptor chain, although other signaling chains, such as the TCR-ζ chain, can be used for T-cell signal transduction.

The first demonstration of an immunoglobulin (Ig)/TCR chimera was reported in 1987 by Kuwana et al. (64). Using a monoclonal antibody (MAb) against phosphorylcholine (PC), they joined the light chain variable (V_L) and heavy chain variable (V_H) region genes to the Cα- and Cβ-chain genes of the

TCR. Murine thymoma EL4 cells cotransfected with $V_LC\alpha/V_HC\beta$ or $V_LC\beta/V_HC\alpha$ gene combinations exhibited increased cytoplasmic calcium concentrations when stimulated with PC-positive bacteria. Similarly, Gross et al. (65) constructed Ig/TCR chimeric receptors using an MAb against trinitrophenyl (TNP). Jurkat (a human T-cell line) or MD.45 (a hybridoma cell line) cells transfected with $V_LC\alpha/V_HC\beta$ or $V_LC\beta/V_HC\alpha$ gene combinations exhibited specific IL-2 secretion or nonmajor histocompatibility complex-restricted cytolysis when cocultured with TNP-labeled cells. Similar studies were also performed by other groups (66,67) using antidigoxin or anti-PC MAb systems in EL-4 cells, Jurkat cells, and transgenic mice.

Although these initial approaches confirmed that chimeric Ig/TCR genes could be functional in select transformed T-cell lines, this strategy required the insertion of two genes. Because primary T cells used for adoptive immunotherapy are relatively difficult to genetically modify, the insertion of two separate genes is not ideal for a clinical approach. Therefore, Eshhar et al. (68) used a single-chain antibody (scFv) approach whereby the V_L and V_H domains are joined by a flexible linker (69,70 and 71). ScFv regions have been shown to exhibit similar specificities and affinities compared to normal antibody variable regions. The scFv gene was then joined to the TCR ζ chain or Fc receptor γ chain, both of which are closely related and capable of activating T cells when cross-linked (72,73,74,75 and 76). Thus, on a single gene, the scFv-γ/ζ design (see Fig. 20.1-6) provides both antigen recognition and T-cell signal transduction. ScFv-γ/ζ constructs derived from anti-TNP MAb were capable of redirecting MD.45-hybridoma cells against TNP-labeled targets (68).

Hwu et al. (77) demonstrated the feasibility of using this approach against human tumor, using gene-modified primary T cells. Melanoma-specific human TIL was gene-modified with scFv-γ receptor genes derived from MAb against TNP (Sp6) or ovarian cancer (MOv18). TIL retrovirally transduced with the ovarian cancer receptor gene (MOv-γ TIL) specifically lysed a human ovarian cancer line (IGROV-1) (Fig. 20.1-7). Similarly, Sp-γ and MOv-γ TIL specifically released GM-CSF when cocultured with the appropriate antigen. To assess the *in vivo* efficacy of such an approach, murine TILs derived from methylcholanthrene-induced colon carcinoma were retrovirally transduced with the MOv-γ receptor gene. Intraperitoneal MOv-TIL significantly increased survival in nude mice that had received IP human ovarian cancer cells 3 days before the TIL. Additionally, intravenous MOv-TIL significantly decreased the number of lung metastases in mice that 3 days before were given an irrelevant, syngeneic tumor transfected with the appropriate ovarian antigen gene (78).
FIGURE 20.1-7. Transduction of tumor-infiltrating lymphocytes (TILs) with an antiovarian chimeric-receptor gene (MOv-γ) results in specific lysis against ovarian cancer cells. Nontransduced (NV), Sp-γ (anti-trinitrophenyl)-transduced, and MOv-γ-transduced TILs were studied for their ability to lyse the ovarian cancer cell line IGROV-1. All TILs, which were derived from melanoma, could lyse the autologous melanoma cell line (not shown), but the IGROV-1 ovarian cancer cell line was only lysed by MOv-γ-transduced TILs. (From Hwu P, Shafer GE, Treisman J, et al. Lysis of ovarian cancer cells by human lymphocytes redirected with a chimeric gene composed of an antibody variable region and the Fc-receptor gamma-chain. *J Exp Med* 1993:178;361–366, with permission.)

Besides triggering direct T-cell activation with γ and ζ chains, antibody variable regions can be coupled to other signaling chains such as the intracellular portion of CD28, an important T-cell costimulatory receptor. This approach has been found to enhance T-cell survival and proliferation *in vitro* (79).

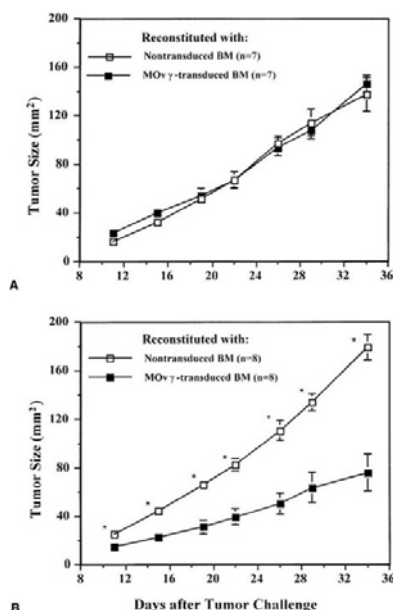
Most recently, the transduction of hematopoietic stem cells with chimeric receptor genes has been under investigation, as this may not only provide a stable supply of redirected T cells, but also granulocytes, macrophages, and natural killer cells, all of which may have significant antitumor activity on expression of chimeric receptor genes. Mice that received MOv-γ-transduced bone marrow cells exhibited significant antigen-specific antitumor activity *in vivo* (Fig. 20.1-8) (80).


FIGURE 20.1-8. Tumor growth in MOv-γ-reconstituted mice. Ten months after bone marrow (BM) transplantation, MOv-γ- and control-reconstituted mice were subcutaneously inoculated with 1×10^5 24JK or 24JK-FBP tumor cells, the latter expressing the FBP tumor antigen recognized by MOv-γ. Tumor size was measured from day 11 to 34 after initial tumor inoculation twice a week in a blinded fashion, and expressed as square millimeter (mm²) by multiplying 2 perpendicular diameters. A: Mice inoculated with 24JK tumor cells. B: Mice inoculated with 24JK-FBP tumor cells. The result represents one of two identical but independently executed experiments. Error bars are standard error of mean. Asterisks indicate differences are statistically significant (p_2 <0.005). (From Wang G. A T cell-independent antitumor response in mice with bone marrow cells retrovirally transduced with an antibody/Fc-gamma chain chimeric receptor gene recognizing a human ovarian cancer antigen. *Nat Med* 1998:4;168–172, with permission.)

These strategies have the potential of widely generalizing the use of adoptive immunotherapy. ScFv-γ/ζ receptors have been constructed against breast cancer using an anti-HER-2 MAb (81), colon cancer using an anti-GA733 MAb (82), and HIV using an anti-gp41 MAb (83). This strategy could be applied to a wide range of cancer histologies or infectious diseases for which appropriate MAb exist.

Native T-Cell Receptor Genes

T-cell specificity can also be altered by the introduction of genes encoding native TCR. The TCR consists of an α- and β-chain heterodimer that confers the ability to specifically recognize peptide and major histocompatibility complexes on antigen-presenting cells and target cells. TCRs derived from melanoma-specific CTLs have been identified, cloned, and characterized (84). Clay et al. (85) transduced primary lymphocytes with a TCR gene specific for the MART-1 melanoma tumor-rejection antigen. Because the TCR consists of two individual chains, a retroviral vector was constructed that used internal ribosomal entry sites (IRES sequences), which allow the translation of multiple genes from a single transcript (Fig. 20.1-9). Primary T cells transduced with this construct were capable of specifically recognizing tumor cells expressing the MART-1 melanoma tumor antigen in the context

of HLA-A2 (Table 20.1-6). As more TCRs recognizing specific tumor antigens are characterized and cloned, this strategy may generalize the use of adoptive immunotherapy, circumventing the need to isolate T cells with specific reactivities from individual patients.

Table 20.1-6 Lysis of MART-1–Positive Cells by T Cells Transduced with a MART-1–Specific T-Cell Receptor Gene

Clone	E:T Ratio	% Specific Lysis T2+ Irrelevant	T2+ MART-1	888 MEL	888 A2 MEL

MEL, melanoma cell line.

Note: Peripheral blood mononuclear cells (PBMCs) from three normal donors (65,66,67) were transduced with a T-cell receptor (TCR) gene recognizing the MART-1 melanoma tumor antigen; 24 of 29 clones were specifically lytic against HLA-A2+ target cells pulsed with the MART-1 immunodominant peptide (range of lysis, 18% to 100%; mean, 64.5%), and 15 of 29 clones specifically lysed an A2+ melanoma cell line (range of lysis, 15% to 85%; mean, 42.1%).

From Clay TM, Custer M, Sachs J, et al. Efficient transfer of a tumor antigen-reactive TCR to human peripheral blood lymphocytes confers antitumor reactivity. *J Immunol* 1999:163;507–513, with permission.

FIGURE 20.1-9. Retroviral construct encoding the α and β chains from a T-cell receptor recognizing the MART-1 melanoma antigen. The α chain is driven by the long terminal repeat (LTR) from the Moloney murine leukemia virus, whereas the β chain is driven from the SRα promoter. (IRES, internal ribosomal entry site; Neo[R], neomycin phosphotransferase gene; pA, polyadenylation signal; Ψ+, packaging signal; SA, splice acceptor; SD, splice donor.) (From Clay TM, Custer M, Sachs J, et al. Efficient transfer of a tumor antigen-reactive TCR to human peripheral blood lymphocytes confers antitumor reactivity. *J Immunol* 1999:163:507–513, with permission.)

Suicide Genes

Part of "20.1 - Gene Therapy Using Lymphocyte Modification "

Adoptively transferred T cells have been safely administered to many patients since 1988. However, in specific situations, the adoptively transferred cells may be toxic to the host, such as in the treatment of immunocompromised HIV patients. In the setting of allogeneic BMT for hematologic malignancies, donor lymphocyte infusions can be highly effective against tumor and EBV-induced lymphoma, but may also incite GVHD. In an attempt to increase the therapeutic index of adoptively transferred

cells in these situations, suicide genes can be introduced into lymphocytes to specifically delete the transduced cells should they become toxic to patients *in vivo.* The gene for herpes thymidine kinase (hTK) has been used for this purpose, as it specifically sensitizes cells to the antiviral agent ganciclovir.

In one study using hTK-transduced donor lymphocytes, three of eight patients receiving donor lymphocytes after allogeneic BMT for hematologic malignancies developed acute or chronic GVHD. In these patients, ganciclovir administration significantly diminished the number of circulating hTK-transduced cells within 24 hours, resulting in complete or partial remissions of the GVHD (86) (Table 20.1-7).

Table 20.1-7 Effect of Ganciclovir Treatment on Elimination of Herpes Thymidine Kinase-Modified Donor Lymphocytes and on Graft-versus-Host Disease (GVHD)

Patient	GVHD (grade)	Proportion of Transduced Peripheral Blood Lymphocytes (%)		Clinical Outcome of GVHD
		Preganciclovir	24 h after ganciclovir	
1	Acute skin (II/III)	13.4	$<10^{-4}$	CR
2	Acute liver (III)	2.0	$<10^{-4}$	CR
8	Chronic lung, skin, gastrointestinal	11.9	2.8	PR

CR, complete remission of GVHD; PR, partial remission of GVHD.

In another study, anti-HIV CTLs were transduced with a fusion gene encoding hTK and the selectable marker hygromycin before administration in HIV-infected patients (87). Because HIV patients are immunocompromised, the CTLs could be eradicated with ganciclovir should the transduced cells become toxic. However, initial results of the trial revealed that the patients were developing cellular immune responses against the hTK-hygromycin fusion protein (Table 20.1-8), thus demonstrating that foreign genes, including selectable markers, can themselves become targets of the host immune response.

Table 20.1-8 HyTK-Specific Cytotoxic T Lymphocyte (CTL) Responses before Initiating and 1 Week after Completing Four Courses of Adoptive Immunotherapy with HyTK-Transduced CD8⁺ Human Immunodeficiency Virus-Specific CTL Clones

Patient	E/T	Preinfusion CTL response to HyTK Target cell (% lysis)		Postinfusion CTL response to HyTK Target cell (% lysis)	
		Mock	HyTK	Mock	HyTK

Overview and Summary

Part of "20.1 - Gene Therapy Using Lymphocyte Modification "

The ability to introduce foreign genes into T cells has opened exciting opportunities for enhancing the adoptive immunotherapy of cancer. For adoptively transferred lymphocytes to be most effective, they must survive and proliferate *in vivo*, recognize tumor cells, and respond with an adequate effector mechanism. Attempts are under way to improve on each of these steps through gene modification. The introduction into lymphocytes of the genes encoding IL-2, IL-2 receptor, or other growth-factor receptors or chimeras may lead to increased survival of lymphocytes *in vivo.* The use of chimeric-antibody/TCR genes or native α/β TCR genes may allow enhanced recognition of tumor *in vivo.* Additionally, this approach may enable the generation of tumor-specific lymphocytes against histologies from which specific antitumor lymphocytes are difficult to grow. Finally, the introduction of the gene for TNF may enhance T-cell effector function by enabling lymphocytes to deliver high concentrations of TNF to tumor sites, without causing systemic TNF toxicity.

For these approaches to succeed, progress is required in the development of vectors, resulting in enhanced transduction efficiencies and gene expression in primary T lymphocytes. Ultimately, vectors whose expression can be regulated *in vivo* may be of great clinical utility. In addition, further progress is needed toward the understanding and resolution of other primary challenges in improving the clinical outcome in patients receiving adoptively transferred T cells. For example, although it is known that adoptively transferred T cells can cause the regression of large tumor burdens in some patients, the percentage that traffic to and penetrate into the tumor is often small. A greater understanding of the adhesion molecules and intracellular signals that

are necessary for T cells to mobilize into solid tumors may lead to improved abilities to genetically manipulate T cells to allow them to more effectively traffic to these sites.

Introduction

Part of "20.2 - Gene Therapy Using Stem Cell Modification "

If a genetic modification technique is to have a long-lasting effect on the disease process of a cancer-causing disorder during the lifetime of the affected individual, the genetic element must be introduced into a stem cell of the target tissue such that continued expression of the gene is ensured. The delivery of the gene to the target tissue must not diminish the self-renewal potential of the target cell. The properties of stem cells from all tissues studied thus far have provided obstacles to the implementation of genetic modification strategies. These obstacles include the low frequency of stem cells in any tissue, the quiescent or nondividing nature of most of these cells, the absence of methods with which to isolate and purify these cells before or after modification, and the lack of detailed knowledge about the types of receptors on the surface of these cells.

In the beginning, gene therapy studies were designed to use retroviral vectors to introduce the therapeutic transgenes into the DNA of the target stem cells to produce a durable modification of the phenotype of the cell (1). Genetic therapy strategies have since been expanded to include the use of adenoviral and adeno-associated viral vectors for the modification of the phenotype of a target cell and the introduction into tissues of vectors carrying therapeutic transcription units (2). In the case of the adeno-associated viral vector, the nucleic acid of the vector is stable in a nonintegrated form in the nondividing differentiated cells of a tissue (e.g., myotubes) for up to a year (2). The transcription unit is engineered so that the protein produced will be secreted into the systemic circulation for diseases arising from a protein that is missing from the bloodstream (2).

Initially, the studies of the use of genetic elements to correct constitutional or acquired disorders leading to unregulated growth focused on stem cells derived from primarily hematopoietic tissue. The target tissues have been expanded into stem cells from the central nervous system, connective tissue, bone, muscle cells, and liver cells. These efforts, which have had very limited success in delivering therapeutic genes to cells that exhibit indefinite self-renewal, have taught us indirectly about the biologic properties of stem cells in these tissues.

In this chapter, we discuss the development of genetic modification techniques for hematopoietic stem cells. This discussion includes a description of the vectors available, the systems used for delivering such vectors, the cell and animal models in which the success or failure of such gene delivery techniques are studied,

and the clinical trials that have taught us much about the challenges to be overcome in this field.

Properties of Stem Cells

Part of "20.2 - Gene Therapy Using Stem Cell Modification "

The frequency representation of stem cells in tissues is usually very low, approximately 1 per 10,000. This low level and the fact that the majority of the stem cells in any tissue have been found to be quiescent have frustrated attempts to isolate these cells and to characterize their immunophenotype and biologic properties. Indeed, controversy exists as to whether these cells can be brought into cycle without committing them to a program of differentiation that limits their self-renewal (3,4 and 5). Existing experimental evidence suggests that it is difficult to modify human hematopoietic stem cells with retroviral vectors without reducing their self-renewal capacity, but it may be possible with hematopoietic stem cells from the mouse (6,7,8 and 9).

It is not yet clear whether the stem cell compartment present at birth can be expanded during postnatal life. In the succession model of hematopoiesis—based on experimental evidence involving retroviral modification of mouse stem cells (6)—the number of stem cells present at birth is fixed and can never be expanded. During life, these stem cells are activated one by one, and the replication events that involve each, as they become active in cellular division, result in symmetric cellular divisions (both daughter cells are similar). These divisions are polarized in terms of increasing levels of maturation and decreasing capacity for self-renewal with succeeding replication events. In addition, the subsets of genes, which define the functional state of the differentiated tissue arising from the stem cell, or the lineages of cells that exist within the tissue, become activated during this process of sequential maturation.

In this model, the stem cell compartment resembles the ovary, which contains the lifetime allotment of eggs at birth. During life, these are used sequentially. If the same is true of hematopoietic tissue, then the bone marrow's staggering cell production (250 billion cells per day) arises from a hierarchical array of cells emanating from a small subset of stem cells available at birth. In addition, the progeny of these stem cells are actively replicating for only a finite period (several months).

An alternate hypothetical model of hematopoiesis from stem cells that accounts for the evolution of a hierarchical array of ever-expanding numbers of hematopoietic cells at increasing levels of maturation and differentiated phenotype and decreasing levels of self-renewal stipulates that both symmetric and asymmetric cellular divisions occur at all levels of maturation. The occurrence of the asymmetric cellular division produces one daughter cell that retains the undifferentiated phenotype of the mother cell and one daughter cell that acquires a new more mature or differentiated phenotype. This acquisition results in a change in maturation and gene expression as well as diminished capacity for self-renewal. In symmetric cellular division, in this model, both daughter cells retain the phenotype of the mother cell.

The mechanism that controls whether a symmetric or asymmetric division occurs in this latter model has been hypothesized to be either instructional (i.e., an extracellular signal, such as a growth factor that triggers the asymmetric division) or noninstructional (i.e., an intrinsic property of the genetic program). The intrinsic programming of an asymmetric cellular division could hypothetically be dependent on the number of replication events allowable at each stage of maturation, or a stochastic model, in which the majority of replication events are symmetric, and the infrequent asymmetric division occurs randomly. Another property of this model is that the number of symmetric replication events is in the majority at each stage, but the frequency of the asymmetric replication events increases as maturation proceeds.

The number of replication events a stem cell would undergo is far lower in the succession of hematopoiesis model. From a theoretical point of view, the probability of acquisition of somatic mutations from errors in DNA replication or exposure to mutagens increases dramatically when the number of replication events exceeds 1 billion.

The succession of hematopoiesis model, if true, would protect the organism from acquisition of mutations that lead to hematopoietic diseases such as myelodysplastic syndrome or leukemia but would also limit the potential for developing genetic therapy for cancer with a lifelong impact, through the use of stem cell modification.

The resolution of this question about this very basic property of stem cells might largely determine the potential for developing genetic therapy that involves insertion of vector DNA into the target cell DNA and thereby has a lifelong effect. In the dividing tissues, the genetic modification procedure must successfully modify a very early cell to have a lifelong impact. For the modification of tissues with no cellular division, or only scheduled intermittent cellular division, it is not necessary to modify a stem cell to ensure a change of the tissue cell phenotype with respect to the reversal of a disease process through genetic therapy. An example of this is provided by the work of Herzog and colleagues (2).

The proliferating tissues of the body (which would require genetic modification of stem cells) include the hematopoietic system, the endothelial vascular system, bone, all epithelial tissues (e.g., lung, breast, prostate, ovary, bladder, cervix, skin, gastrointestinal tissues), and those components of nondividing tissues that are turning over [i.e., the glial cells of the central nervous system, the fibrous or stromal cells of all epithelial and hematopoietic tissues, and the mesenchyme-derived cells that line all of the body cavities (the cerebrospinal fluid system, pleural space, peritoneal space, pericardial sac, and serosal surfaces of joint spaces)]. Tissues that are not replicating, and therefore could be used as small units from which a gene product could be released into the systemic circulation, include the liver, muscle, and neurons of the central nervous system. The muscle cells (nondividing myotubes) have been used to express therapeutic proteins in replacement strategies for constitutional disorders involving coagulation factors (2).

Indirect Stem Cell Findings

Part of "20.2 - Gene Therapy Using Stem Cell Modification "

Much more has been learned indirectly about stem cell properties, through the study of settings in which repopulation of tissue is undertaken. Repopulation involves the transfer of stem

cells from one individual to another, and the study in this setting of chimeras and mosaicism in tissues (with respect to genetic or immunohistochemical markers), either in the steady state, or in transplantation experiments with or without genetic modification.

Unless a subset of stem cells has a selective competitive advantage, mixtures of stem cells with polymorphic markers (made so that the ratio of two variants is different in each of a series of sequential independent transplant experiments) retain the frequency that exists at the time of transplant throughout the lifetime of the animal. This principle results in mosaicism in tissues with respect to properties such as X-chromosome condensation and produces mixtures of hematopoietic cells, which may differ with respect to the ratio of different surface immunophenotypic markers, for which no selective pressure exists. This principle also leads to mixtures of hematopoietic cells that are genetically modified or not modified (marked) after a gene marking experiment (see Retroviral Vectors).

The number of receptors on stem cells that can be used for engaging viruses is very low in the early stages of cell maturation (10). As discussed later, this presents a significant obstacle in delivery of the gene therapy vectors to stem cells, because the number of surface molecules involved in viral binding or uptake into cells is very low or nonexistent on the stem cells. The current approach to this problem is to pseudo-type the retroviral vectors (11); to create targeting bifunctional antibody molecules for targeting the vectors to the stem cells (12); to engineer the surface-binding virus-binding coat proteins, so that they will selectively bind to the plasma membrane receptors unique to cells at the earliest stages of maturation (13); or to construct chimeric vectors that use the adeno-associated vector infection to deliver to the target cell a receptor transcription unit that enables the retroviral vector to infect the target cell (14). These steps accomplish two things:

1. The vector becomes competent to bind and to be taken up into the target stem cell.
2. The vectors are not sequestered from the stem cells by binding to the vast excess of more differentiated cells that are irrelevant for self-renewal in a specific tissue.

Chimeras of adenoviral and retroviral vectors have also been constructed to combine the best of both vectors and to circumvent the restriction that the distribution of the amphotropic receptor imposes on retroviral vectors (15).

For long-term modification of early hematopoietic cells—the viral vectors derived from the retrovirus and adeno-associated virus (vectors capable of generating integrant vector transgenes)—the vector must be able to traffic the viral complementary DNA (cDNA; in the case of retroviral vectors) or DNA (in the case of adeno-associated vectors) into the nucleus, where it can be integrated in the nondividing cell. This has been a problem, because unlike DNA viruses, which can traffic DNA into the nucleus of the nondividing cell, the retroviral vector is incapable of trafficking its cDNA through the nuclear membrane into the nucleus. Thus, to integrate the cDNA of a retroviral vector into host cell chromosomal DNA, the cell must pass through S phase and mitosis, in which the nuclear membrane disappears, thereby allowing the retroviral cDNA access to the host chromosomal DNA. There, the retroviral LTRs can mediate the integration of the vector cDNA. Thus, the frequency of integrants of vector cDNA in stem cells is very low, due to (a) lack of binding of the vector to the target stem cell and (b) inability of the vector cDNA to pass through the nuclear membrane of the nondividing stem cell (the majority of stem cells). The recent strategy to avoid this obstacle has been to use the human immunodeficiency virus-associated vectors in which the long terminal repeats (LTRs) and viral proteins can traffic the cDNA of the vector through the intact nuclear membrane of the nondividing cell to generate integrants (16).

Once integrated into the chromosomal DNA of the host cell, the retroviral genome encounters another problem: extinction of expression of the vector transgenes. This problem reflects the fact that a mechanism to limit the expression of vector transgenes is in place in embryonic and early undifferentiated stem cells. One strategy to overcome this obstacle was to change the transcriptional regulatory elements of the retroviral vectors to those of the mouse embryonic stem cell retroviruses (17). These elements are not subject to the extinction mechanism to the degree observed in the Maloney retroviral vectors.

Thus, as the biology of the stem cell has become more fully understood, strategies have been developed to attempt circumvention of these intrinsic limitations of the stem cell.

Vector Delivery Systems

Part of "20.2 - Gene Therapy Using Stem Cell Modification "

Several different viruses have been used to engineer safety-modified delivery vehicles. Each of these has advantages and disadvantages for the specific properties of the stem cell, some of which were discussed in the previous sections. In this section, the complementary discussion is undertaken: how the properties of the various viruses produce advantages or disadvantages for genetic modification of the stem cell.

Retroviral Vectors

The retroviral vector, which is used for gene therapy, is usually derived from murine RNA tumor or leukemia viruses and consists of two identical sequences called long terminal repeats (LTRs) at the 3" and 5" boundary of the vector, which contain transcriptional regulatory elements, elements for replication, and elements for integration of the vector cDNA into the host chromosomal genome. The *gag, pol*, and *env* genes, normally found between the LTRs, have been removed from the retroviral vector, but the packaging sequences necessary for assembly of the retroviral vector in a packaging cell line that carries the *gag, pol*, and *env* genes as integrants remains near the 5" LTR. The recombinant vector carries the therapeutic transcription unit under the control of the retroviral LTR, or an independent promoter. The capacity of this vector is 7 kilobase (kb).

The ligands on the envelope proteins of the retroviral vectors exhibit species-specific tropisms that depend on the distribution of the receptors that bind to them on mammalian cells (Table 20.2-1).

Table 20.2-1 Retroviral Vector Ligands for Mammalian Cell Receptors

Receptor	Functions	Species
Ecotrophic	Amino acid transporter	Mouse
Amphotropic	Phosphate channel	Mouse, dog, human
Gibbon ape leukemia virus	Phosphate channel	Dog, nonhuman primate, and human

Orlic and colleagues (10) showed that expression of the amphotropic receptor on stem cells was prohibitively low, which

has led to attempts to make the retroviral vector more sensitive to retroviral gene therapy vectors by pseudo-typing the vectors with the Gibbon ape leukemia virus envelope ligand or with the vesicular stomatitis virus G protein (11). The receptors for both of these ligands are highly represented on the surface of the stem cell.

Other workers have attempted to target the vector to the stem cell by using bispecific antibodies (12), re-engineering the ligands available on the envelope protein of the retroviral vector, or by replacing the amino-terminal end of the amphotropic receptor ligand by ligands present on the surface of the producer cell (13). These vectors are chimeric for the wild-type amphotropic ligand and the recombinant ligand. Kasabara et al. (13) have succeeded in placing the c-kit receptor ligand and the ligand for the erythropoietin receptor on the end of the amphotropic ligand on the retroviral vector.

As outlined above, the retroviral vector is incapable of delivering its cDNA into the nucleus of the nondividing stem cell, because this virus does not produce any protein that can traffic the cDNA of the retroviral vector into the nucleus. Two approaches have been taken to circumvent this problem:

1. Many workers have attempted to promote the integration of retroviral transgenes into the chromosomal DNA of the stem cells by exposing the stem cells to late-acting growth factors, such as granulocyte-macrophage colony-stimulating factor and interleukin-3 (IL-3) and IL-6, in the presence of serum and stem cell factor (18,19). Although this has increased the transduction frequency of the stem cells with retroviral transgenes, exposure to late-acting growth factors in the presence of serum and supercritical fluid has reduced the reconstitution and self-renewal capacity of the stem cell in the transplantation setting (20). This reduction has resulted in only transient engraftment with vector-modified cells in the post-transplant animal and in clinical marking trials (21,22,23 and 24). To circumvent this serum-induced decrement in engraftment, workers have shifted to serum-free conditions for the stem cell modification setting; conditions in which the replication of the stem cell can occur in the absence of conditions that limit the self-renewal properties of these vectors (25,26).

2. Some researchers have switched to the lentiviral vector, the cDNA of which can penetrate the intact mammalian nuclear membrane (16). This method has led to the successful modification of hematopoietic stem cells as well as nondividing muscle cells and central nervous system neurons, which are also nondividing. This technique is discussed in greater detail later, under Lentiviral Vectors .

The low titer sometimes found with retroviral vectors has been addressed by a vertical flow transduction device developed by Palsson et al. (27). The passage of an entire volume of suspended vector particles increases the number of particles to which the target cell is exposed and results in an increase in the transduction frequency.

Another problem is that the amphotropic and other ligands involved in the engagement of the retroviral vector with the target cell membrane are unstable in the serum-containing medium at 37°C. These vector ligands are stable for only 2 hours in the presence of complement-containing serum. This issue is sidestepped by using antibodies to protect this ligand or by carrying out the transduction in serum-free medium or in the presence of complement inactivators.

Adeno-Associated Viral Vectors

The adeno-associated virus is a defective DNA virus that requires helper functions to be provided by the adenovirus. It is a small vector (7 kb) that has identical sequences called *inverted terminal repeats* (ITRs), which are located at the 5" and 3" ends of the vector. The *rep* and *cap* genes, which are normally located between the ITRs, are no longer present in the recombinant adeno-associated vector, and in their place is the therapeutic transcription unit under the control of its own transcriptional promoter. Until recently, the *cap* and *rep* genes were placed on a separate plasmid and cotransfected into the producer cell line along with the plasmid carrying the recombinant adeno-associated vector bearing the therapeutic transcription unit. In addition, infection of the producer cell line with wild-type adenovirus would be required to provide the helper functions required for replication. The expression of the *rep* and *cap* genes and the adenoviral infection were both toxic to the producer cell, thus requiring multiple sequential rounds of production. This problem has been solved with the cloning of the adenoviral vector helper functions.

Despite the limitations of small capacity (5 kb of DNA) and the requirement for target stem cell replication for integration of the transcription unit carried by the vector, the adeno-associated viral vector has been useful because its nucleic acid is retained for long periods in the cytoplasm of cells, where the transcription unit can be expressed without integration of the adeno-associated viral vector DNA for long periods. Early on, the adeno-associated vector was used to transfer replacement transcription units for single-gene defects of hematopoietic cells (28,29). If the target cell is nondividing, a stable pattern of transgene expression from the episome without integration is observed. One example was the use of the adeno-associated vector to deliver the gene for hemophilia B to myotubes, from which the transgene can be expressed and the protein product released into the bloodstream for up to 1 year at levels that prevent spontaneous bleeding (2). The adeno-associated vector is of potential value, but its use in hematopoietic stem cells has not yet resulted in stable expression in early hematopoietic cells.

Adenoviral Vectors

The adenoviral vector is a 38-kb DNA virus that is nonpathogenic for normal immunocompetent individuals due to the very

robust immune (both cellular and humoral) response it generates. Among immunoincompetent individuals, however, this virus is very dangerous, and infection can result in loss of life. The vector has a wide host range, which depends on the binding of the fibrillar protein to the Coxsackie virus-associated receptor, which is widely distributed on the surface of most mammalian cells. After binding, viral uptake depends on the presence of certain integrin receptors (alpha-V, beta-3, or beta-5) on the surface of the target cell, which interact with the penton proteins of the virus (located at the base of the fibrillar protein) (30). Once taken up and released from the endosome, the adenoviral DNA is transported through the intact nuclear membrane into the nucleus, where the DNA is transcribed into RNA and ultimately translated into protein in the cytoplasm.

The adenoviral vector used for genetic therapy has been rendered nonreplicative by removal of the *E1A* and *E1B* genes (and in some instances the *E3* gene) of the virus. The transgene expression lasts 14 days. The vector evokes an immune response that destroys the cells in which the virus transgene is being expressed and this limits to 2 weeks the period during which the transgene is expressed. This vector is not integrated into host chromosomal DNA. On the basis of work in several laboratories (31,32), it appears that the integrin receptors required for viral uptake are not represented on the earliest of the hematopoietic stem cells, which are therefore resistant to infection by this virus. During the induction of maturation of the earliest hematopoietic stem cells, when it is exposed in the presence of serum to the hematopoietic growth factors stem cell factor, IL-3, and IL-6, the integrin receptors necessary for viral infection appear on the cell surface as the stem cell matures and the vector transgenes are expressed within the cell (32). This maturation, which is necessary for the expression of the integrin receptors required for viral entry into the stem cell, reduces the self-renewal potential of the genetically modified stem cell, thus leading only to short-term effects. Thus, the adenoviral vector is not now a candidate for the delivery of transgenes to hematopoietic stem cells because of the absence of the receptors necessary for its uptake.

Several investigators have made use of bifunctional antibodies or re-engineering of the fibrillar protein of the vector that mediates initial binding to target cells to deliver the vector to specific types of cells (33,34). It has not yet been possible to modify the penton protein so that its specificity for the alpha-V, beta-3, and beta-5 integrins can be changed. Other investigators are studying ways of using cationic lipids to promote the uptake of viral genomes (both adenoviral and adeno-associated vectors) in order to broaden the host range of vectors for hematopoietic stem cells (35).

Lentiviral Vectors

One of the most exciting breakthroughs in the attempt to develop methods to deliver genetic elements to the hematopoietic stem cell has been the engineering of lentiviral vectors, which have the capacity to deliver their cDNA, once generated in the cytoplasm of nondividing cells, through the intact nuclear membrane of the nondividing cell, to the nucleus, where the vector cDNA is integrated into the target cell. This vector has been stripped of its replicative machinery and envelope protein. To produce the vector, a three-way transfection of the recombinant vector carrying the therapeutic gene with its own promoter, another plasmid with the replication cassette for the virus, and a third plasmid carrying the envelope pseudo-type envelope protein system is carried out. Miyoshi et al. (16) have shown that this vector is competent to modify nondividing myotubes, neurons, and hematopoietic cells. A performance analysis of this vector system, using animal models in which the repopulating capability of cells modified by this vector can be tested, is under way in many laboratories.

The potential clinical utility of this vector will depend on the results of ongoing experiments to determine its safety in humans.

Gutless Adenoviral Vectors

In an attempt to decrease the cellular immune response (which limits the adenoviral vector transgenes' duration of expression) and to increase the capacity of the adenoviral vectors for domains of the mammalian chromosome (which are extensive), Schneider and coworkers (36) have reported the construction of the so-called gutless adenoviral vectors. These vectors are useful only for nondividing cells, because they are replication incompetent.

Episomal Nonviral Vectors

Proteins produced by certain DNA viruses, such as the E2 protein (37) of the human papillomavirus (HPV) or the EBNAI protein (38) of the Epstein-Barr virus (EBV), that tether the episomal DNA to the mammalian chromosomal proteins have been identified. This tethering protects viral DNA from nuclease destruction and preserves equal partitioning of the DNA between daughter cells in dividing cells. The E2 protein plays this role in the latent HPV infection of germinal epithelial cells (37). The E2 protein connects the long control region of the episomal DNA origin of replication of HPV with chromosomal proteins. The EBNAI protein connects the chromosomal proteins and the ORI-P promoter of the EBV episome (38), which contains the origin of replication of the EBV episomal DNA.

Banerjee et al. (38) have explored the use of vectors carrying the ORI-P of EBV and EBNAI to tether therapeutic expression vectors to the mammalian chromosome. This technique results in retention of therapeutic expression plasmids carrying the origin of replication of EBV in cells expressing the EBNAI EBV protein for months. An advantage of this type of vector is the almost unlimited capacity (150 kb), which allows the introduction of entire regions into the vector in a way that ensures correct and natural expression driven by elements such as the long control region. Because the expression vectors express their transgenes without being integrated into the chromosomal DNA, the transgenes are not subject to the usual variation in the levels of expressions of integrated transcription units that arise from the presence of negative regulatory transcriptional elements in the vicinity of an integration site. Banerjee et al. (38) succeeded in using such vectors to reverse the phenotype of cells from Fanconi's anemia patients. Others have used such elements to maintain the entire beta-globin developmental gene cassette.

Adjuncts to Vector and Nonvector Gene Delivery Systems

Part of "20.2 - Gene Therapy Using Stem Cell Modification "

Vertical Flow Transduction Systems

Bernhard Palsson and his co-workers (27) have reported the development of a filtration transduction system in which suspensions of retroviral vector particles produced at low concentrations can be pulled through a membrane on which the target cells can be distributed, bringing the entire population of vector particles into contact with the target cells. Otherwise, the 0.3-mm thick diffusion path limits the number of particles that can reach the target cells. The more dilute the vector preparation, the more unlikely it is that any vector particle will connect with a target cell because of the very short diffusion path of a very large particle such as a vector. Thus, in a static transduction system, most of the viral particles produced go to waste. The vertical flow transduction system is of tremendous advantage for increasing the probability that a viral particle will encounter a rare target such as the stem cell.

Concentration Systems

Because of the instability of the retroviral envelope, it is very difficult to concentrate the retroviral vector without decreasing the number of functional infectious particles. In contrast, the adenoviral vector can be concentrated by physical means (i.e., cesium gradient centrifugation) without loss of activity.

Centrifugation Transduction

Increases in the transduction frequency have been observed when mixtures of target cells and supernatants of retroviral vectors are subjected to centrifugation. The mechanism through which this adjunct works is unknown.

Engineering of the Binding Proteins

To reduce the loss of the delivery vector to cells that are irrelevant to the goal of engraftment or repopulation, the binding proteins have been engineered so that the vector will bind only to the target cell (13). Doing so increases the effective ratio of infectious particles to target cells.

Conditional Replication Competency

Another potential solution to the huge number of target cells—conditional replication competency within the target cell population—has been accomplished by Heise et al. (39). Two of the problems in gene therapy vector design include reaching the very-low-frequency cells and the loss of the vectors due to binding to irrelevant cells. The solution to both of these problems is to confer replication competency on the vector. Thus, even if the frequency of collision and infection of a vector particle with the target cell is one in a million, as long as one collision occurs, the infected cell could release more particles for infection of other cells. Unfortunately, with a particle that has the capability of integrating into the chromosomal DNA of the target cell, the probability of an adverse event due to integration mutagenesis becomes an issue. Thus, all of the work on conditionally replication-competent vectors is targeted to adenoviral vectors rather than retroviral vectors.

Cationic Lipid Complexes

The coating of nucleic acid, which is a highly charged molecule, with molecules that are not repelled by the plasma membrane, such as cationic lipids, may promote the entry of nucleic acid carrying a gene or transcription unit (35). The lipid delivery systems are intrinsically less directed than a vector. To compensate for this, liposomal delivery vehicles have been coated with polyethylene glycol to reduce the rate of nonspecific binding to any plasma membrane.

Gene Gun

Another physical means of delivering genetic material is to accelerate small particles that carry nucleic acid so that these particles penetrate the skin surface and are deposited in cells. This delivery method, although unaccompanied by the risks of a viral vector, is less efficient than lipid complexes or vectors.

Serum-Free Transduction Systems

The recent development of culture systems that preserve the self-renewal capacity of the stem cell is a breakthrough. Several laboratories have demonstrated that serum-free, chemically defined culture media can support stem cell replication without reducing their self-renewal capacity (25,26). Thus, the *in vitro* triggering of a replication event need not necessarily result in the commitment of the cell to maturation and a reduction of the stem cells' self-renewal capacity. These media will be used in future attempts to create conditions that lead to the modification of stem cells by retroviral vectors and other vectors that require integration of the vector nucleic acid for expression of the transgene.

Microinjection

DNA can be injected intranuclearly into the target cell, but the number of such injection events falls far below the number of cells needed to produce a biologically significant event in tissue unless the transgene confers a selective advantage for the modified cell. An example is the adenosine deaminase transgene that produces a protein of relevance for the correction of a disease state and confers a selective advantage on the target cell.

Recombinant Fibronectin Systems

One of the most important developments in the field of retroviral vector–mediated modification of suspension cells is the use of a recombinant fragment of fibronectin that binds both the hematopoietic stem cells (via the alpha-1, beta-5 integrin receptor) and the vectors used for genetic modification. Hanenberg et al. (40) have succeeded in using plates coated with a recombinant fragment of the fibronectin molecule. These plates have been used in a clinical trial of the multidrug resistance gene-1 (MDR-1) retroviral vectors and have shown transduction of the hematopoietic cells at levels ranging from 20% to 50% (41). These fragments are of use in that they bring the vector and target cells together. The

use of the fibronectin fragment increases the frequency of the transduction of the suspension cells in that they become monolayer cells. In addition, the effective titer of the vector is increased, because the vectors become concentrated on the bottom surface of the plate, thereby increasing the effective concentration of the viral particles in the target cells' vicinity. These monolayer systems are in wide use, and the aggregate impact of these studies will soon be recognized.

Model Systems for Evaluation of Stem Cell Modification

Part of "20.2 - Gene Therapy Using Stem Cell Modification "

Because the stem cell cannot be isolated, the success of a genetic stem cell modification transduction experiment can only be measured indirectly, usually by the progeny of the stem cell. Often the duration of the genetic modification in a proliferating population is the criterion used to determine whether a stem cell has been modified. If a stem cell population is known to evolve into separate lineages, then the representation of the genetic element in all of the progeny, which develop into the independent lineages, is a measure of the stem cell modification. Both cell culture systems and animal models are used in the measurement of the success of a genetic modification experiment.

Usually, the duration of the cells that contain the genetic modification is a criterion of the immaturity of the cell that has been modified. The distribution of the transgenes into all of the lineages that arise from the differentiation of the stem cell is also a criterion of success. The systems used to measure such success are described below. All of these systems are designed to determine the number of replication events modified cells can carry out after modification.

Long-Term Marrow Culture Systems

In long-term marrow culture systems, genetic modification is carried out on a population of enriched cells in the most immature cells of that tissue (42). The cells are placed into culture in a system that supports the continued proliferation of the cells. Aliquots are taken from the cultures weekly, and the number of differentiated clonogenic progenitors growing in suspension are determined. The longer the genetically modified clonogenic progenitors persist in the culture, the earlier the cell was modified. These cultures are usually carried out for 5 to 6 weeks. The use of the long-term bone marrow culture (43) or simply stromal monolayers (44) has produced increments in transduction frequency. The use of genetically modified stromal layers has also increased the transduction frequency into clonogenic progenitor cells (45,46), but the effect on the persistence of genetically marked progeny of long-term repopulating cells in animal transplantation systems has not been definitively shown.

Transplantation Systems in Small and Large Immunocompetent Animals

The ultimate measure of the stem cell is its ability to reconstitute an entire organism. Thus, in stem cell modification experiments, the ability to modify a population of cells enriched in the immature cells without reducing the stem cells' ability to reconstitute an organism into which they have been transplanted is the ultimate measure of the quality of the stem cell modification conditions. In a mouse transplantation experiment, the mouse cells are exposed to conditions designed to promote the introduction of the genetic element into the target stem cell population. Then these cells are infused into a lethally irradiated recipient that is isogenic with the donor of the stem cells. The length of time the genetically modified cells persist in the infused animal is a measure of success of the genetic modification (8,47,48,49 and 50). To truly test the self-renewal capability of the modified cells, the marrow or hematopoietic cells of an animal that has been lethally irradiated and transplanted with a modified population are collected and infused into a second lethally irradiated recipient. This is called the *serial transplant.* Because one-tenth of the total number of stem cells from the original donor are taken for the initial transplant, exhaustion of the stem cell pool can occur within a small number of serial transplants. This is known as *stressing the self-renewal capability* of the modified cells. Similar models have been developed for dogs (8) and primates.

Xenotransplantation Systems

Nonobese Diabetic Mouse X-Linked Severe Combined Immunodeficiency Disease Mice

The measurement of the replicative potential of a population of mouse hematopoietic cells after a genetic modification procedure is directly informative about the properties of the mouse hematopoietic stem cell, but the results of these experiments do not necessarily apply to human hematopoietic stem cells. Thus, it is necessary to test the proliferative potential of human hematopoietic stem cell in animal models. The laboratory of John Dick (51) was the first to establish that human hematopoietic cells could be maintained in the immunodeficient recipient animals.

Fetal Sheep Model

Porada and colleagues (52) have shown that the injection of human hematopoietic cells into fetal sheep *in utero* results in the engraftment of human hematopoietic cells for the lifetime of the sheep. That species barriers can be transcended has provided a powerful model of the assessment of the replication potential of human stem cells. Porada et al. (52) have shown that the incubation of stem cells *in vitro* in serum-free medium can be carried out without reducing the engraftment potential of human hematopoietic cells beyond 2 years. In comparison, incubation of human hematopoietic cells in serum-containing medium results in exhaustion of human hematopoiesis in 1 to 2 years. Genetic modification has been carried out in this model (51).

Marking Studies of Marrow and Peripheral Blood Cells

Part of "20.2 - Gene Therapy Using Stem Cell Modification "

When genetic therapy studies began, the first question posed was whether vectors could be used to deliver transgenes into somatic cells such that transgenes would be integrated into the chromosomal DNA of the target cell.

The answer from several years of very systematic studies is unequivocally yes; it is possible to deliver transgenes to target cells (7,8 and 9). But the full answer is that it depends on the type of cell, the conditions used for the transduction, the vector backbone used, and the transcriptional regulatory elements in the vector.

In the beginning, murine leukemia and sarcoma viruses were used as the basis on which the vectors (Maloney murine sarcoma virus and Harvey sarcoma virus) were built. Because the RNA of the vector, which is converted into cDNA in the cytoplasm, cannot pass through the intact nuclear membrane, these cells are capable of integrating their transgenes into chromosomal DNA of dividing cells only. Thus, for the vector's cDNA to integrate, the cell must divide. In contrast, the cDNA of lentiviral vectors can pass through the intact nuclear membrane into the nondividing cell and be integrated (16).

Another factor limited the utility of retroviral vectors as they were originally built: The receptors on the surface membrane of the target cells for the ligand on the envelope of the retrovirus are not found on the surface of immature cells. Thus, although the virus can infect mature cells, the percentage of early or immature cells that can be infected by the retroviral vector is very low—if not nonexistent (10).

Finally, the duration of expression of the retroviral transgenes, once integrated into the target cell DNA, is sometimes short-lived owing to the tendency of stem cells to methylate the transcriptional regulatory elements of the vector, whereas this is less likely to happen in more mature cells.

Thus, when the first studies of *ex vivo* marking of hematopoietic cells collected from donors were carried out, the transduction conditions used were designed to stimulate a replication event in the target cells by adding exogenous hematopoietic growth factors and fetal bovine serum to the culture medium. This type of transduction design often used a preincubation of the cells in serum-containing medium and then exposure of the cell to recombinant growth factors followed by 2 days of incubation in the presence of growth factors, serum, and the vector supernatant. Finally, the cells were incubated in the absence of the vector for an additional day to promote integration.

In general, the incidence of the marking was 10% to 20% in the clonogenic progenitors before transplantation of the vector-exposed cells into the recipient animals or patients, but the percentage of cells that were vector-positive after transplantation was low in all of these experiments (7,9,53,54). Some investigators tried to increase the level of the integration in the transduced population by sorting out the transduced cells physically or by marker resistance selection.

The first two marking trials to be published were carried out with leukemia cells (7,8 and 9), using a short incubation that would merely deliver the vector inside the hematopoietic cells, without eliciting a replication event *ex vivo*. In both cases—one in childhood acute myelogenous leukemia (7) and the other in adult chronic myelogenous leukemia (9)—the transgenes were detectable in the leukemia cells as well as in normal cells at a rate of 1% to 5% after transplantation of the cells into the intensively treated recipients. When long-term follow-up was available, the transgenes were detectable in all lineages (7). The transgenes continued to be detectable for up to 5 years but at low frequency (7). These studies indicated that retroviral vectors could transduce stem cells but at low frequency. Later trials using serum-containing medium and more prolonged incubation in breast cancer patients or acute myelogenous leukemia patients undergoing autografts showed even lower posttransplant frequency of marked cells (53,54). A comparison was made of short-term exposure of hematopoietic cells to vector supernatants (4 to 6 hours) with longer exposure (2 to 4 days), but no difference between these two methods was identified (55). Unfortunately, the vast majority of the cells transduced were not the immature stem cells but the more mature cells with limited self-renewal capacity. The level of genetic modification and the duration of this marking was higher in clinical conditions in which the progeny of the modified stem cells has a selective advantage, as in the adenosine deaminase gene replacement studies (56); whether this was due to the *in vivo* selection, the use of cord blood, or the optimization of *in vitro* modification (57) is not known. Much higher levels of genetic marking were achieved with lymphocytes in the adenosine deaminase replacement studies (58).

Chemotherapy Protection

On the basis of the results of the gene marking trials, which showed that a low level of modification could be achieved, three groups [National Institutes of Health, Columbia University, and the University of Texas M. D. Anderson Cancer Center (47,48,49 and 50)] tested the hypothesis that the presence of the MDR-1 chemotherapy resistance gene in the vector could be used to select cells that were positive for the vector MDR-1 transcription unit. MDR-1 codes for an adenosine triphosphate–dependent membrane pump protein (*p*-glycoprotein) that transports alkaloids out of the modified cells, thus protecting them from chemotherapy. Normally, *p*-glycoprotein is expressed at high levels in early hematopoietic precursors, but the expression levels fall as hematopoietic cells mature, resulting in levels that are insufficient to protect more mature cells. All three of these trials were based on animal model data in the mouse that showed evidence for success in the transduction of the hematopoietic target cell and presence of ample levels of the vector-positive cells posttransplant (47,48,49 and 50). In addition, one of the trials showed that the delivery of chemotherapy posttransplant resulted in an increase in the level of the transduced cells, which carried a gene the product of which could confer resistance to the conditions of selection (47).

When these strategies were applied to clinical trials in human patients (21,22,23 and 24), the results fell far short of the high expectations that were held for the therapy on the basis of early experience in mouse models (47,48,49 and 50). In contrast to that experience (47,48,49 and 50), in the clinical trials, only very short-term engraftment could be measured posttransplant and the level of vector-positive cells was very low in patients after transplant (21,22,23 and 24).

A recent discussion of the reasons for these results has been published (59). All of the trials used transduction conditions that involved at least 4 days of incubation in medium supplemented with serum, late-acting hematopoietic growth factors (e.g., IL-3), and stem cell factor. These conditions were used to trigger a replication event in the cells infected with the retroviral vectors that carried the chemoprotection gene (i.e., the MDR-1 gene), which coded for the ATP dependent membrane *p*-glycoprotein.

The presence of stem cell factor and IL-3 in serum has been reported after the initiation of human MDR-1 trials to induce

maturation of the early hematopoietic cells (20). The level of posttransplantation chemotherapy delivered to patients was very low, thus failing to provide a selective advantage for the modified cells. The titers of the retroviral vectors were low. Finally, the transcriptional regulatory elements of the vectors were subject to silencing in the stem cells. Thus, these early trials were subject to several problems:

1. The transduction conditions were such that the early stem cells would lose their reconstitution capability.
2. The vectors used could not infect the stem cell.
3. The vectors used carried transgenes that could be extinguished in the stem cells.
4. Only dividing cells (which excludes most of early stem cells) would take up the vector and integrate it into the chromosomal DNA.

In the present era, the feasibility of transducing hematopoietic cells with vectors carrying chemotherapy resistance genes is being addressed once again. These studies use vectors exhibiting higher titers and higher doses of posttransplantation chemotherapy (24). Improved conditions for the *in vitro* transduction, using the fibronectin recombinant fragment, which brings the stem cells and the vector physically together are being used (41). In the future, other modifications in the vectors, such as the lentiviral vectors, or retroviral vectors of the Maloney or Harvey types that can be pseudo-typed so that the infectivity of the stem cells can be increased, and with transcriptional regulatory elements that are not extinguished in stem cells, will be studied as well. This direction of research with MDR-1 may be complicated by the report in a mouse model of myelodysplastic syndrome after MDR-1 modification (60). However, many other chemotherapy protection transgenes are currently being investigated.

Chemotherapy Sensitization

In addition to being used for chemotherapy protection, vectors have been used to selectively sensitize tumor cells that contaminate collections of autografts to the effects of chemotherapy (62,63 and 64). Because adenoviral vectors are so efficient in infecting epithelial cells, they have been used to carry chemotherapy sensitization genes into the neoplastic cells that contaminate autografts. A wide selection of chemotherapy sensitization genes is available for modification of the target epithelial cells. Herpesvirus thymidine kinase was used first to selectively sensitize breast cancer cells to the effects of chemotherapy (61). Herpesvirus thymidine kinase can catalyze the phosphorylation of antiviral agents, such as ganciclovir, that are not phosphorylated mammalian cell thymidine kinase. These vectors have proved very efficient in producing the death of cells infected with the adenoviral vector. A limitation of the herpesvirus thymidine kinase/ganciclovir system is that the incorporation of the ganciclovir, once phosphorylated by the viral thymidine kinase, depends on cellular division. So once again, the vector effect depends on the target cell dividing. This restriction is significant, because the majority of epithelial neoplastic cells are nondividing. Investigators have attempted to circumvent this limitation by exploiting what is called the *bystander effect*, which is based on the transfer of the vector transgene product from infected to uninfected cells. The herpesvirus thymidine kinase system has been much more useful in vectors used to modify lymphocytes to prevent graft-versus-host disease because the lymphocytes can be stimulated to divide and incorporate the retroviral vectors efficiently without diminishing the proliferative potential of these cells. Moreover, the modified cells can be selected, either physically with a surface tag or by growth selection under antibiotic negative selection. Other investigators have attempted to use adenoviral vectors carrying the *p53* or *Bcl-X* short transcription units for selective reduction of the neoplastic cells that contaminate hematopoietic cells in autografts (62,63).

A second transgene, cytosine deaminase, is being used to sensitize neoplastic cells, which contaminate hematopoietic autografts to the effects of chemotherapy (31). Cytosine deaminase is a bacterial gene (64) that catalyzes the conversion of a nontoxic precursor, 5-fluorocytosine, into a chemotherapy agent, 5-fluorouracil. The levels of phosphorylated 5-fluorouracil inside epithelial cells are so high that sufficient incorporation into RNA occurs such that the processing of messenger RNA is disrupted and eventually even the nondividing cells die of protein starvation (65). Hirschowitz et al. (66) have used such vectors in normal volunteers as well as in patients with colon cancer that had metastasized to the liver. Early hematopoietic stem cells cannot be infected by adenoviral vectors because the vector requires the presence of the αvß3 integrin receptor, which is not present on early hematopoietic stem cells. Thus, selectivity of action can be engineered into therapeutic approaches based on these vectors.

Current efforts involve engineering of the fibrillar protein of the adenoviral vector so that it will bind to hematopoietic cells. Bispecific antibodies are also being used to deliver adenoviral vectors to hematopoietic stem cells (12). Finally, adenoviral vectors, which are conditionally replication-competent in cells of different epigenotypes (39), are being developed so that these vectors can be used to modify the hematopoietic stem cell. This strategy is sometimes based on the introduction of transcriptional promoters that are specific for the regulatory environments of different tissues (67).

Vector Targeting

Phage display screening has been used to collect all of the immunoglobulin genes circulating in cancer patients and to use panning or sequential negative selection of these populations of phage to produce phage clones that bear immunoglobulin genes specific for particular types of tumor cells (68). In fact, it is possible to derive human single-chain immunoglobulin antibody molecules that are specific for tumor cells and not reactive for normal cells (68). The specificities to which these antibody molecules are reactive are often glycoprotein modifications of commonly expressed tumor cells that are specific for the tumor cell on the basis of glycosylation. The utility of such single-chain antibody molecules for targeting vectors to the target cell is only now being evaluated.

One of the most troublesome problems with vector-mediated gene delivery of all kinds is that vectors bind to normal cells, and the number of normal nontarget cells often vastly exceeds the

number of target cells, whether they be normal or abnormal. To render genetic therapy more specific and to increase the frequency of vector-modified cells, attempts to genetically engineer the vector envelope proteins in the case of retroviral vectors or to engineer the fibrillar proteins of adenoviral vectors have been carried out with significant success. In the case of retroviral vectors, the ligand on the retroviral vector surface that engages the amphotropic receptor of the mammalian cell has been engineered so that it presents ligands for lineage and stage-specific hematopoietic receptors for growth factors. Kasabara et al. (13) have introduced the amino-terminal end of erythropoietin at this position. His vectors have been shown to transduce specifically erythroid precursors. In addition, this same group has placed the ligand that engages the stem cell factor receptor, c-kit, and this vector transduces early but not late hematopoietic cells (13). Although this work has been successful as a feat of genetic engineering, the utility of these vectors has been limited by other weaknesses of the retroviral vector: primarily the restriction of transduction to dividing cells and the loss of expression in stem cells owing to methylation inhibition of the vector transcriptional regulatory units, and the continued expression of the wild-type receptor ligand.

Attempts to target adenoviral vectors are more complex than for retroviral vectors because the fibrillar protein—the first point of contact between the adenoviral vector and its receptor on the surface of the mammalian cell—is a trimer of fibrillar proteins and even small changes in the backbone structure of this protein can destabilize its trimeric nature. However, many of the experimental approaches for this re-engineering have been very successful. Such engineering efforts that involve the adenoviral vector are more useful than the retroviral vector because the adenoviral vector can express its transgene in nondividing cells as an episome and because the virus has a wide host range in terms of infection. The targeting of the adenoviral vector to the stem cell thus becomes a priority to avoid its being consumed by binding to irrelevant cells and thereby unavailable to target cells.

The most successful and active group in this regard is led by David Curiel (12,33,34). This group has used bispecific antibody molecules to deliver the vector to specific target cells. One end of the molecule engages the end of the fibrillar protein, called the knob protein, and the other end of the bispecific antibody engages an antigen or receptor on the surface of the target cell.

This effort is still evolving, and some groups are using functional screening with adenoviral vectors that have reporter genes (e.g., the green fluorescent protein) and libraries of random amino acid peptides that are inserted into the knob of the fibrillar protein to select adenoviral vectors that will bind selectively to any cell, even when the cell-specific antigen is not known. Another challenge is to make the adenoviral vector conditionally replication-competent within the target cell so that all of the members of a population of cell in a tissue or in a tumor nodule will be infected by the vector.

Gene Replacement Studies for Hematopoietic Disorders

One dream of genetic therapy is to develop strategies that will replace missing genes, in single-gene constitutional disorders, resulting in reversal of the abnormal phenotype of a disease process. This goal has been elusive because the insertion of transcription units into the chromosomal DNA was originally thought to be a requisite step in this process. This focus on integration of transcription units has limited the success of replacement strategies because the stem cells in a tissue, which must be modified to produce a correction of the abnormal phenotype that has a lifelong impact, are nondividing. Thus, the retroviral vector is unable to affect these cells, and the change of phenotype has often been only short term.

The adeno-associated adenoviral vector has also been studied as a means for the introduction of transcription units into chromosomal DNA. Unfortunately, the same restriction that has limited the utility of the retroviral vectors—the inability to modify a nondividing cell—also applies to the adeno-associated vector. The adenoviral vector DNA can maintain itself in the cytoplasm and nucleus of a nondividing cell for months, if not years (2). This discovery has led to preclinical animal model data showing that the gene for hemophilia B can persist in the cytoplasm of cells infected with the adeno-associated vector transcription units for more than a year. This persistence results in the release of factor IX into the systemic circulation in quantities sufficient to reverse the abnormal phenotype of this disorder (spontaneous bleeding into the joint spaces) in a strain of hemophilia dogs. This finding, reported by Herzog et al. (2), has led to the initiation of clinical trials of this strategy in human patients. The strategy involved the injection of the infectious but replication-incompetent vector into the nondividing myotubes of dogs. The transcription unit was engineered with signal sequences that result in the secretion of the protein produced from the transcription unit into the systemic circulation. This breakthrough is a validation of the paradigm of genetic therapy via vector-mediated delivery. Achievement of this success followed years of unsuccessful trials with both retroviral and adeno-associated vectors, which have clarified the limitations of each and the needs of transcription units within modified cells.

Publication of the successful reduction to practice of a lentiviral vector that carries a reporter gene has signaled a new direction in strategies for the modification of hematopoietic stem cells (16). In theory, this modification will lead to the reversal of the abnormal phenotype members of specific lineages of hematopoietic cells or to the use of hematopoietic cells as vehicles with which to correct abnormalities in any tissue that involve a protein product released into the systemic circulation. The issue to be addressed experimentally is the safety of these vectors. The envelope proteins necessary to the vectors' infection and destruction of the cellular immune response that leads to acquired immunodeficiency syndrome have been removed from the vectors in order to safely modify these vectors. The genes that code for viral products essential to completion of the viral life cycle have also been removed. This removal has not necessarily solved all of the safety concerns that arise from the fear that recombinant vectors may recombine with wild-type vectors in individuals whose infection with wild-type acquired immunodeficiency syndrome viruses may be undetectable at the time of vector introduction. In an attempt to further reduce the probability that these vectors could recombine and produce a replication-competent recombinant, most of the sequences in the recombinant safety modified vector, which are homologous to the wild-type vector, have been removed. These are called third-generation lentiviral safety modified vectors.

Very early in the field of genetic therapy, experiments showed that the clones of retroviral integrants that dominate the marrow hematopoietic cells would change with time. This finding suggested that a succession of stem cells that are active at any given time persist in terms of proliferation and generation of progeny in the lineages of the bone marrow. This sequential model predicts that the genetic modification of a stem cell at a given time, with a given pattern of expression, may not persist for more than 6 months—only to be replaced by another cohort of stem cells that could display another pattern of expression because the integration sites are random within the genome and the level of transcriptional activity in each of these regions is different. This issue of sequential stem cell activation (sequential versus continuous) has not been resolved, and the outcome of current experiments designed to resolve this question will determine the strategies necessary to ensure that expression of a transcription unit is reliable and unchanging over a period of months to years. Alternatively, if it turns out that the progeny to cells that are modified persist only for a short time and the majority of the stem cells are inaccessible to gene therapists, the gene modification may have to be repeated every 6 months. The level of success at each of the six monthly intervals may determine the feasibility of using multiple sequential modifications for the maintenance of a corrected phenotype of a single-gene defect.

Because endothelial cells line the vessels of the body and because they have been shown to arise from a stem cell precursor that shares the stromal cell as a common precursor, the use of the endothelial cell or the common precursor cell has emerged as a major goal of gene therapy. The vector systems that have been used include retroviral and adenoviral vectors. The endothelial cells have been used as targets for cancer vaccine therapy because they are the first to come into contact with injected vectors. Phage display libraries have been used with intravenous injection in mouse models to show that the molecules presented in the endothelial surface of different tissues are specific for each of these tissues. The identities of the molecules in each of these different tissues are just now being elucidated. When these molecules are identified, the feasibility of targeting therapy to specific tissues will increase. Even before the identification of these specificities, strategies are being pursued that involve insertion into the hinge region of the fibrillar protein of a library of random amino acid dodecapeptides, which can target the vectors to any cell.

General Issues to Be Resolved

Part of "20.2 - Gene Therapy Using Stem Cell Modification "

Many issues must be resolved before genetic therapy is successful for hematopoietic stem cells. As outlined, one issue is the pattern of activation of stem cells in the bone marrow. If it is found that the majority of stem cells are inaccessible to the modification of genes at any given time or that a succession of active stem cells exist in hematopoietic tissue, then the genetic modification will have to be administered repeatedly to cells with short-term self-renewal capacity.

If the use of lentiviral vectors that integrate into the chromosomal DNA of nondividing cells is successful, a single genetic modification may have a lifelong impact, provided transgene expression can be maintained. To achieve lifelong expression, the transcriptional regulatory elements of viruses, such as the mouse embryonic stem cell virus, that continue to be expressed in transduced stem cells and embryonic cells for prolonged periods will be used.

If the adenoviral vectors can be engineered to be conditionally replication-competent, with a very low background in nontarget cells, these vectors can be used to treat single-gene defects affecting hematopoietic cells, provided the immune response to the adenoviral proteins can be prevented.

Finally, many genes need to be expressed only for a short time. The expression of a therapeutic gene must be regulated developmentally. The gene may be required to be expressed intermittently so that it can respond to changes in the systemic circulation in a way that is integrated into the systemic response to external stimuli. The level of the gene expression may also be important. Nowhere has this proved to be more of a problem than in the case of the globin genes. To avoid the ineffective erythropoiesis seen in thalassemia, the balance between alpha- and the nonalpha-globin genes must be absolute. Because the tissue-specific regulators of these genes are located both near and far from the genes that are regulated, it has been difficult to engineer vectors that are suitable for the correction of globin gene defects. The ability to engineer complex regulatory elements that are tissue-specific and that respond to factors in trans in a physiologic way is a major priority for the future.

Suicide Gene Therapy

David L. Bartlett

J. Andrea McCart

Introduction

Part of "20.3 - Suicide Gene Therapy "

Gene therapy for cancer can be divided into indirect (e.g., vaccines) and tumor-directed approaches. The tumor-directed approach requires vectors that specifically express genes in tumor cells in order to mediate their own death. Cell death can be immunologically mediated, as in the case of cytokine gene expression, or secondary to apoptosis, as in the case of tumor suppressor gene replacement. Another tumor-directed method is the expression of an enzyme that converts a systemically delivered,

nontoxic prodrug into a toxic agent within the cell. *Suicide gene therapy* has become synonymous with this enzyme/prodrug approach, which is also known as *gene-directed enzyme/prodrug therapy.* This technique requires that a gene encoding an enzyme normally not present in human cells be targeted to cancer cells and allow high expression of the enzyme within the cancer cells. The prodrug must be nontoxic and taken up into the cancer cell after systemic delivery, where it is converted into a toxin. The toxin should kill the cancer cell expressing the gene as well as surrounding cells not expressing the gene (bystander effect).

The herpes simplex virus thymidine kinase type 1 *(HSV-tk)* gene was initially called a *suicide gene* by Plautz et al. (1) when it was included in a retrovirus intended for long-term replacement gene therapy. If the retrovirus was inserted into the genome such that malignant transformation occurred, the transformed cells and resultant tumor could be eliminated with the nontoxic prodrug ganciclovir (GCV), which in the presence of *HSV-tk* is converted into the toxic metabolite ganciclovir triphosphate. This "suicide" system was designed to enhance the safety of clinically utilized retroviruses. Previously, Moolten (2) demonstrated that the *HSV-tk* system could eliminate tumors that were stably transfected with the *HSV-tk* gene. His intention was to create tissue mosaicism for drug sensitivity, ensuring that any tumor arising clonally could be eliminated without affecting a large percentage of normal cells in the organ. This concept was then expanded into an active cancer therapy by Huber et al. (3). They achieved hepatoma-specific cytotoxicity using a retrovirus containing the α-fetoprotein promoter controlling expression of the varicella zoster virus thymidine kinase *(VZV-TK)* gene, followed by exposure to the nontoxic prodrug 6-methoxypurine arabinonucleoside (ara-M). *VZV-TK* converted ara-M to ara-M monophosphate in hepatoma cells, resulting in cytotoxicity.

The enzyme/prodrug strategy has many theoretical advantages over other forms of cancer gene therapy. As opposed to vaccine approaches, suicide gene therapy does not depend on the host's immune system and tumor immunogenicity, which to date have not been reliably understood, controlled, or manipulated. Suicide gene therapy should be applicable to all histologies, and the bystander effect allows surrounding cells not expressing the gene to be killed, unlike suppressor gene replacement strategies or antisense oncogene strategies, which would not be expected to have a bystander effect. Another advantage of the enzyme/prodrug approach is that the toxic effect is not seen until the prodrug is delivered. Therefore, prodrug delivery acts as a controllable switch for activation of the system. This allows *in vitro* expansion of viruses expressing these genes without concern for host cell toxicity. It also allows a buildup of enzyme within the tumor *in vivo* before prodrug delivery, which should improve potency and lead to an enhanced bystander effect.

Limitations to this form of therapy include (a) the potential toxicity to surrounding normal cells, as the converted toxin is generally not specific for tumor cells, and (b) a significant percentage of cells within a tumor must express the gene of interest, requiring a highly efficient vector. A number of enzyme/prodrug systems have been described and are summarized in this chapter. In addition, a review of published clinical trials using suicide genes is included.

Suicide Gene Vectors

Part of "20.3 - Suicide Gene Therapy "

The ideal suicide gene vector provides highly efficient, tumor-specific gene delivery and expression. The advantage of suicide gene therapy over other forms of gene therapy (correcting inborn errors of metabolism) is that gene expression can be transient. Gene expression must only last long enough to mediate the death of the cell. The disadvantage is the need for a highly efficient and specific vector, such that the majority of cells within a tumor express the gene of interest. Whereas many suicide gene systems function efficiently *in vitro*, the main limitation to clinical application is the poor efficiency of current vectors *in vivo.* Achieving even 1% to 2% transduction efficiency *in vivo* with a systemically delivered vector is beyond the capability of most current vectors. Nevertheless, vector development is progressing at a rapid pace, and the technological feasibility of an efficient, tumor-specific vector exists.

The most commonly studied vectors for tumor-directed gene therapy include viruses, plasmid DNA delivered via liposomes, and protein/DNA complexes. Characteristics of these vectors are summarized in Table 20.3-1 . Originally, Huber et al. (3) described the use of retroviruses expressing a suicide gene under the control of a tissue-specific promoter as described above. A nonreplicating retrovirus can safely provide long-term gene expression via integration into the host genome and theoretically provides some tumor specificity because it can only transduce dividing cells. Retroviral integration into the genome could be oncogenic, but this is of minimal concern in the setting of transient gene expression for cancer therapy. Unfortunately, retroviruses are relatively inefficient and difficult to produce in high titers for clinical studies. In addition, only a small percentage of cells within a tumor are dividing at any one time, greatly limiting the *in vivo* transduction efficiency. These limitations led to the injection of retroviral producer cells into tumors, which release retroviruses over a long period, and should improve the chance of stable integration of the gene of interest into tumor cells. Culver et al. (4) demonstrated dramatic growth inhibition of gliomas in rats after injection of 3×10^6 murine fibroblasts producing a retrovirus expressing *HSV-tk* followed by systemic GCV. Although conceptually appealing, this method requires that producer cells be evenly distributed throughout the tumor and survive immunologic clearance in order for prolonged release of retroviruses.

Table 20.3-1 General Characteristics of Commonly Studied Vectors for Suicide Gene Therapy

Vector	Efficiency of Gene Transfer	Potential Tumor Targeting	Potential Tumor-Specific Gene Expression	Potential Tumor-Specific Amplification	Lack of Preformed Immunity	Nonimmunogenic (Multiple Dosing)	Production Efficiency/Quantity
Viral							
Retrovirus	-	+	+	-	+	-	-
Adenovirus	±	+	+	+	±	-	+
Herpes	+	-	+	+	±	-	+
Vaccinia	+	±	-	+	-	-	+
Nonviral							
Naked DNA	-	-	+	-	+	+	+
Liposomes	-	+	+	-	+	+	+
Protein-DNA complex	-	+	+	-	+	+	+
Other							
Endothelial cells	-	+	-	+	+	±	±
Bacteria	-	+	-	+	±	-	+

+, favorable; -, unfavorable; ±, neither favorable nor unfavorable.

Note: Vectors are rated as favorable or unfavorable relative to the other vectors.

Attention was then turned toward more efficient vectors, which do not require dividing cells for successful gene delivery. The most studied vector in this regard has been the adenovirus. Adenovirus has many advantages over other vectors, including its abilities to grow in high titers [10^{12} plaque-forming units (PFUs) per mL], to infect and express genes in nondividing cells of multiple histologies, and to create a safe nonreplicating virus by deletion of early genes. Smythe et al. (5) demonstrated *in vitro* efficacy of an adenovirus expressing *HSV-tk* in pleural mesothelioma. Chen et al. (6) initially reported the use of adenovirus to express the *HSV-tk* gene as an intratumoral treatment for experimental gliomas in nude mice, demonstrating dramatic inhibition of tumor growth. Since then, many articles have described successes with intratumoral injections of adenoviruses expressing suicide genes in animal models, and numerous clinical trials have been instituted.

Although it demonstrates improved *in vivo* transduction efficiencies compared to retroviruses, the adenovirus has many limitations. Cell infection occurs via the coxsackievirus and adenovirus receptor (CAR) (7), which is variably present in different tumor and host tissues (8). Cell lines with low levels of CAR may not achieve more than 10% transduction efficiency under ideal conditions *in vitro* and worse *in vivo.* Chen et al. (6) showed that a stereotactic injection of 10^8 PFU of adenovirus into 0.4-mm^2 intracerebral tumors resulted in an antitumor response. Larger tumors, such as those encountered in patients, would require multiple injections of much larger quantities of virus, and this may not be feasible. Intravenous injection of adenovirus is not a reasonable option because it leads to infection of normal tissues that have the CAR receptor (e.g., normal mouse hepatocytes), leading to unacceptable toxicity. A strong immune response to the viral proteins and preformed circulating antibodies in 98% of adults further limits the expected magnitude and duration of gene expression (9). Adenoviral efficiency can be improved through CAR-independent infection and tumor-specific replication as discussed under Tumor-Specific Targeting .

Other viruses that have been studied as suicide gene vectors include the replication-competent herpesvirus and vaccinia virus. A replicating virus should allow enhancement of gene expression throughout a tumor. The infection of a cell with a single virus particle can lead to the release of thousands of progeny viruses, which will infect surrounding cells and slowly spread throughout the tumor (until eliminated by the host's immune system). Although a replicating virus leads to the death of infected cells, concomitant expression of a suicide gene could lead to bystander killing of noninfected cells, thus increasing the chance of a significant tumor response before immunologic clearance of the vector (Fig. 20.3-1). The safety of a replicating vector is a major concern, but genetically altering the virus to allow tumor-specific replication should prevent systemic host infection. The addition of a suicide gene may also improve the safety of a replicating vector either by causing cell death before the virus has a chance to replicate or by directly inhibiting viral DNA replication. Herpes simplex virus is a large DNA virus with efficient uptake resulting in high levels of gene expression. Although the wild-type vector is able to cause latent infections of nerve cells, specific mutations in the genome can prevent this (ICP34.5 mutation). This vector appears to be more efficient for *in vivo* gene transfer than a nonreplicating adenovirus. Vaccinia is a large DNA virus that infects multiple cell types and undergoes cytoplasmic replication using proteins synthesized

and packaged by the virus itself, resulting in very high *in vitro* and *in vivo* efficiency. The cytosine deaminase (CD) suicide gene system can inhibit viral replication *in vitro* and prolong survival *in vivo* after a lethal injection of replicating vaccinia virus (Fig. 20.3-2).
FIGURE 20.3-1. Schematic representation of the *in vivo* bystander zone with a nonreplicating (A) and replicating (B) vector. A replicating vector leads to a higher number of cells expressing the gene and, therefore, an improved bystander zone. Note that *in vivo*, the diffusible toxin may readily enter the bloodstream and diffuse away from the tumor microenvironment. Thick-walled circles indicate blood vessels; shaded cells indicate infected cells; dense particles represent toxins.
FIGURE 20.3-2. Survival of athymic (C57BL6) mice injected intratumorally (subcutaneous MC38 tumor) with a lethal dose of replicating vaccinia virus (VVLUC, control expressing luciferase; VVCD, expressing cytosine deaminase) followed by treatment with intraperitoneal (i.p.) 5-fluorocytosine (5-FC) for 14 days. All animals died from viral toxicity (not tumor). The VVCD-treated animals show prolonged survival, demonstrating protection from virus toxicity by prodrug conversion and presumed inhibition of viral DNA synthesis and replication by 5-fluorouracil.

The immune response to viral vectors remains a significant obstacle to successful gene therapy. Although the development of viruses that evade the immune system has been proposed, these vectors would theoretically be unsafe in the general population. *In vivo* recombination events could lead to an ubiquitously infectious virus that cannot be eliminated by the host. Reversible immunosuppression—as a means of allowing gene expression long enough to provide an antitumor response, followed by immune recovery to eliminate the vector and ensure the safety of the host—may be an alternative.

Plasmid DNA delivered by liposomes and protein/DNA complexes have undergone significant improvements to enhance transfection efficiency (10). These approaches have the benefit of an almost unlimited delivery capability, including repeated dosing without immunologic clearance. Nevertheless, the *in vivo* efficiency remains unsatisfactory and may never surpass that of a virus that has evolved solely for the purpose of expressing genes within host cells. The main limitation appears to be inefficient mechanisms of uptake and escape of the DNA from the cellular endosomal shunt (11). As liposomes become more complex, incorporating proteins that bind to cell surface receptors and enhance efficiency, the disadvantages associated with viral therapy become more pronounced (12 ,13). With continued technological modifications, an artificial system may have many potential advantages over viral vectors.

Other vectors for suicide gene therapy have been proposed, such as the delivery of cells carrying suicide genes to tumors, without the tumors themselves expressing the genes. By delivering a prodrug that is converted within the transduced cells, surrounding tumor cells may also be killed owing to the bystander effect. This system would require a diffusible toxin. One example is endothelial cells, which seem to track to tumors when injected systemically (14). Bacteria such as salmonella and clostridium may also be an option (15). Although these vectors are mostly of theoretical interest at this time, they highlight the versatility and utility of an effective enzyme/prodrug system.

Tumor-Specific Targeting

Part of "20.3 - Suicide Gene Therapy "

Vector targeting has been achieved by controlling gene transcription, viral infectivity, or viral replication. Many tissue- and tumor-specific transcriptional regulatory sequences have been described (Table 20.3-2). Using genetic sequences that control the expression of therapeutic genes in cancer cells is an ideal way to take advantage of the genetic differences between tumor and normal cells. These transcriptional regulatory sequences consist of classical promoter regions (where initiation of transcription occurs) and enhancer elements that recruit polymerases to the promoter in a cell-specific manner. Many tissue-specific promoters sacrifice promoter strength for specificity and are unable to express therapeutic genes at a clinically useful level. Enhancer elements, often included as multiple repeats, can markedly upregulate gene expression while maintaining specificity (16). Siders et al. (17) demonstrated high levels of gene expression specifically in melanoma cells using the tyrosinase promoter coupled to a dimer of the tyrosinase-enhancer element. This technique allowed efficient transcriptional targeting of melanoma

cells. Many transcriptional regulatory signals are active at low levels in normal cells or are specific for a tissue or cell type. For example, the tyrosinase promoter is specific for all melanin-producing cells in the body. This may lead to unacceptable toxicity if melanin-producing retinal cells are destroyed. The most appealing promoters are those that are specific for tumor cells, such as oncofetal antigen promoters (α-fetoprotein, carcinoembryonic antigen) or specific for genes upregulated in transformed cells such as the E2F-1 transcription factor. Parr et al. (18) demonstrated that the E2F-1 promoter mediated high levels of marker gene expression specifically in cancer cells *in vivo* and could eradicate established gliomas when used to express a toxic gene. Promoters active in nonessential tissues (e.g., prostate-specific promoters) are also useful, where ablation of the normal tissue will have minimal side effects.

Table 20.3-2 Specific Promoters for Suicide Gene Therapy

Promoter	Specificity
Tissue-specific	
Prostate-specific antigen, kallikrein 2	Prostate/prostate cancer
Tyrosinase	Melanocytes/melanoma
Albumin, hepatitis B virus core promoter	Liver/hepatoma
Growth hormone	Pituitary/pituitary cancer
Osteocalcin	Bone/osteosarcoma
Myelin basic protein, glial fibrillary acidic protein	Glial cells/glioblastoma multiforme
Thyroglobulin	Thyroid/thyroid cancer
CD11	Leukocytes/lymphoma
B-casein	Mammary/breast cancer
Surfactant	Bronchoalveolar/lung cancer
mck	Myogenic cells/rhabdomyosarcoma
kdr, tir, e-selectin	Endothelial cells/tumor vasculature
Tumor-specific	
α-Fetoprotein	Oncofetal/hepatoma
Carcinoembryonic antigen	Oncofetal/colon cancer
MUC-1	MUC-1 producing tumors
erbB-2	ErbB-2 expressing tumors
grp 78/BiP	Stress inducible glucose regulated/ tumor-specific
pax3 DNA binding, site prs-9	Alveolar rhabdomyosarcoma
Secretory leukoprotease inhibitor	Carcinomas
Hexokinase type II	Glycolysis regulator/tumor-specific

Altering viral coat proteins to allow specific binding to tumor cell surface antigens or receptors is another means of targeting that is actively being investigated. This includes the expression of antitumor single-chain antibody fragments on the viral coat that will target tumor antigens, as well as the expression of peptides that act as ligands for tumor-specific receptors. Altering the viral coat can enhance viral uptake into otherwise resistant tumor cells, as well as potentially inhibit infection of normal cells. Martin et al. (19) incorporated a single-chain antibody (ScFv), directed against high-molecular-weight melanoma-associated antigen (HMWMAA), into the retroviral envelope and demonstrated preferential infection of melanoma cells. Dmitriev et al. (20) showed that incorporation of an Arg-Gly-Asp-containing peptide, specific for the αvβ3-integrin, into the HI loop of the fiber knob coat protein of adenovirus resulted in CAR-independent infection and increased infectivity by two to three orders of magnitude in otherwise resistant cells.

Perhaps the most important step towards a clinically relevant vector for suicide gene therapy has been the development of viruses that specifically replicate in tumor cells. Adenovirus has been engineered for this purpose. The adenovirus E1B 55-kd gene product is considered essential for viral replication and acts by binding *p53* and preventing cellular apoptosis, a natural antiviral response. It was believed that deleting the *E1B* gene in adenovirus would limit replication to *p53*-mutant cancer cells (or cells with other downstream mutations in the apoptotic pathway), in which apoptosis was already blocked. Bischoff et al. (21) demonstrated *in vitro* specificity for *p53*-mutant tumor cell lines with this vector and significant tumor regression *in vivo.* Other investigators have subsequently questioned the mechanism for this specificity (22 ,23 and 24). Nevertheless, this replication-selective virus was shown to have an antitumor effect and is currently being investigated as an oncolytic virus in clinical trials. Wildner et al. (25) demonstrated that the inclusion of the *HSV-tk* gene in this replication-specific virus led to an improved antitumor response with GCV treatment compared to a control replicating virus.

Another means of engineering a tumor-specific replication competent adenovirus is by using tissue-selective promoters to express essential viral genes. Rodriguez et al. (26) created an adenovirus expressing the essential *E1A* gene under the control of the prostate-specific antigen enhancer and promoter. They achieved prostate-specific viral replication, which resulted in tumor regression when injected intratumorally.

The herpes simplex virus has also been genetically altered to achieve tumor-specific replication. Deletion of genes, such as thymidine kinase, ribonucleotide reductase, and neurovirulence factor (ICP 34.5 gene), which are essential for nucleotide synthesis and viral replication in nondividing cells, allows tumor-specific replication with decreased toxicity (27). The addition of a suicide gene should further enhance the antitumor response over that of a replicating virus. We have been interested in exploring the vaccinia virus as a suicide gene vector because of its remarkable efficiency as a cytoplasmic virus. We have found that a TK-deleted vaccinia virus selectively replicates in tumor tissue *in vivo* when injected systemically and can lead to a survival advantage and some cures when combined with the *CD*/5-fluorocytosine (5-FC) or purine nucleoside phosphorylase *(PNP)*/6-methylpurine deoxyriboside (6-MPDR) systems in a murine model of hepatic metastases (28 ,29) (Fig. 20.3-3).
FIGURE 20.3-3. Survival in athymic (C57BL6) mice with hepatic metastases (intrasplenic MC38 injection) after intraperitoneal (IP) delivery of a thymidine kinase-deleted vaccinia virus expressing purine nucleoside phosphorylase (PNP), followed by systemic therapy with 6-methylpurine deoxyriboside (6-MPDR). Treatment animals survived significantly longer than controls, with 50% long-term cures. All deaths were due to hepatic replacement with tumor. No viral deaths were noted at this dose. PBS, phosphate buffered saline. (Adapted from Puhlmann M, Gnant M, Brown CK, et al. Thymidine kinase deleted vaccinia virus expressing purine nucleoside phosphorylase as a vector for tumor directed gene therapy. *Hum Gene Ther* 1999;10:649-657.)

Bystander Effect

Part of "20.3 - Suicide Gene Therapy "

The bystander effect of an enzyme/prodrug gene therapy system is essential for the killing of surrounding tumor cells that do not express the gene of interest. This is the most significant advantage of suicide gene therapy over other forms of tumor-directed gene therapy (e.g., tumor suppressor gene replacement). Once a prodrug is converted to a toxin within a tumor cell, that toxin can affect surrounding cells through one of three mechanisms: (a) free diffusion through the cell membrane, (b) intercellular transport via gap junctions (13), or (c) delivery in apoptotic vesicles for phagocytosis.

The advantage of freely diffusible toxins is that cell-to-cell contact is not required, and cells at a distance may be exposed to the toxin. The disadvantage is the higher potential for toxicity to normal cells. For example, PNP converts 6-MPDR into the highly potent and diffusible toxin 6-methylpurine (6-MP). The *in vivo* efficacy of the *PNP*/6-MPDR system is limited by systemic toxicity of the converted prodrug, and the therapeutic window seems narrow. The bystander effect of toxins requiring intercellular communications (e.g., the *HSV-tk*/GCV system) has the advantage of being safe for surrounding normal cells, but the antitumor effect can be quite variable depending on the concentration of gap junctions. Tumor cells may lose these communications as they become less differentiated. Mesnil et al. (30) demonstrated that HeLa cells lacked both gap junctions and a bystander effect using the *HSV-tk*/GCV system. By transfecting with a gene-encoding connexin 43 (a gap junction protein), a bystander effect could be elucidated (30). Both the connexin 43 gene and a suicide gene could be transferred in a single vector to optimize the bystander effect, but the complexity of this system may decrease efficiency.

Cells undergoing toxin-mediated apoptosis may theoretically have a bystander effect by transferring toxins via apoptotic vesicles, which are phagocytosed by surrounding cells. This has been visualized *in vitro* by cell-to-cell transfer of fluorescent-labeled compounds (31). The *in vivo* significance of this phenomenon is unknown.

In vitro studies are ideal for demonstrating a bystander effect, where the mixing of different ratios of transduced cells expressing the gene of interest with untransduced cells allows determination of the percentage of transduced cells required to kill the entire cell population. The zone of cells affected by the converted toxin *in vitro* (bystander zone) may have no correlation to the zone of cells that will be exposed *in vivo*. *In vitro* studies allow an even distribution of the gene throughout the cells, and the converted toxin is released into the supernatant that continually bathes surrounding cells. This will not be the case for most *in vivo* gene transfer, in which toxins will preferentially diffuse into the bloodstream and be taken away from the tumor microenvironment, increasing systemic toxicity while limiting the *in vivo* bystander zone.

Other factors that may be responsible for a bystander effect *in vivo* that are not seen *in vitro* include (a) immunologic/cytokine-mediated effect and (b) toxicity to vascular endothelial cells resulting in an ischemic effect. *In vivo* therapy with the *HSV-tk*/GCV system has resulted in hemorrhagic necrosis of the tumor within 24 hours of prodrug administration. This dramatic effect is not consistent with cytotoxicity from converted prodrug, suggesting a cytokine-mediated hemorrhagic necrosis such as that seen with tumor necrosis factor. This inconsistency suggests that the inflammatory response to toxin-mediated cell death may result in a cytokine cascade that causes coagulative necrosis of the tumor (32). Melcher et al. (33) demonstrated that a toxin-mediated necrotic cell death uniquely results in heat shock protein release and an inflammatory response.

An *in vivo* virus-mediated oncolysate may also act as a potent vaccine. The *in vivo* destruction of cells leads to efficient uptake and presentation of tumor antigens by immune effector cells. Evidence supports an improved antitumor effect in an immune-competent mouse compared to a T cell-deficient mouse, using the *HSV-tk*/GCV system, even though gene expression should be higher and more prolonged in the immune-deficient mouse (34). Cytotoxic T cells appear to be responsible for bystander killing and immune memory (35). It is possible that distant uninfected tumor may be responsive to immune destruction if tumor-specific cytotoxic T cells are generated. These cytotoxic T cells may also protect against the growth and development of metastatic disease. The application of this observation to humans is not clear. In an attempt to enhance the *in vivo* bystander effect, investigators have combined suicide gene systems with cytokine genes to enhance the immune response (36 ,37).

It is theoretically possible that damage to vascular endothelium from diffusion of a converted prodrug or from direct gene transfer to endothelial cells may lead to vascular thrombosis and ischemic necrosis. This would lead to a higher percentage of tumor cell death than could be explained by the *in vitro* bystander effect. Diffusible toxins may have some advantage because gap junctions between tumor cells and endothelial cells are unlikely.

Many techniques to improve the bystander effect have been tested. For some systems, expression of the enzyme on the cell surface by the addition of a secretory leader sequence and transmembrane domain may enhance the bystander effect. This method ensures improved access of the enzyme to the prodrug, allows extracellular conversion of the prodrug, and facilitates diffusion of the converted toxin. Marais et al. (38) demonstrated that the carboxypeptidase G2 (CPG2) enzyme could function as a cell surface protein.

Suicide Gene Systems

Part of "20.3 - Suicide Gene Therapy "

The various suicide gene systems are summarized in Table 20.3-3 .

Table 20.3-3 Enzyme/Prodrug Systems

Enzyme	Prodrug	Active Drug
Herpes simplex virus thymidine kinase	Ganciclovir	Ganciclovir triphosphate
Varicella-zoster virus thymidine kinase	(E)-5-(2-bromovinyl)-2"-deoxyuridine (BVDU)	BVDU triphosphate
Cytosine deaminase	5-Fluorocytosine	5-Fluorouracil
Purine nucleoside phosphorylase	6-Methylpurine deoxyriboside	6-Methylpurine
β-lactamase	7-(4-Carboxybutanamido)-cephalosporin mustard	Phenylenediamine mustard
Carboxypeptidase G2	4-[(2-Chloroethyl)(2-mesyloxyethyl)amino] benzoyl-L-glutamic acid (CMDA)	4-[(2-Chloroethyl)(2-mesyloxyethyl)amino] benzoic acid (CJS11)
Cytochrome P450-2B1	Cyclophosphamide /ifosfamide	Acrolein + phosphoramide mustard
Escherichia coli nitroreductase	CB1954 (5-aziridin-1-yl-2-4-dinitrobenzamide)	5-Aziridin-1-yl-4-hydroxylamino-2-nitrobenzamide
Xanthine-guanine phosphoribosyl transferase	6-Thioxanthine	6-Thioxanthine monophosphate
β-Glucuronidase	Epirubicin -glucuronide	Epirubicin
Thymidine phosphorylase	5"-Deoxy-5-fluorouridine	5-Fluorouracil
Deoxycytidine kinase	Cytosine arabinoside	Cytosine arabinoside monophosphate
Carboxylesterase	7-Ethyl-10-[4-(1-piperidino)-1-piperidino] carbonyloxycamptothecin (CPT-11)	7-Ethyl-10-hydroxycamptothecin (SN-38)
Linamarase/β-glucosidase	Linamarin/amygdalin	Cyanide
Carboxypeptidase A	Methotrexate -phenylalanine	Methotrexate
Cytochrome P450-4B1	2-Aminoanthracene, 4-ipomeanol	Unknown alkylating agents

Herpes Simplex Virus Thymidine Kinase

The prototypical suicide gene system is the *HSV-tk*/GCV system. *HSV-tk* phosphorylates nucleoside analogs (GCV/acyclovir) into their monophosphate and triphosphate forms, which are incorporated into DNA during cell division, leading to cell death. Moolten (2) first demonstrated in 1986 that transfection of the *HSV-tk* gene into sarcoma cells rendered them sensitive to the cytotoxic effects of GCV. Since then, numerous studies have demonstrated the efficacy of the system. Many strategies for delivering the *HSV-tk* gene have been used, including liposomal

transfections (39), retroviral transductions (40 ,41), and adenoviral infections (5 ,42 ,43 ,44 ,45 and 46). One advantage of this system is that only dividing cells are affected, so systemic toxicity is minimal. Another advantage is that GCV has been shown to be safe in humans and is readily available.

In vitro treatment of glioma cells with a nonreplicating adenovirus carrying *HSV-tk* was cytotoxic to cells in the presence of GCV at multiplicities of infection above 150 (42). Smythe et al. (6) demonstrated that 10% to 20% of mesothelioma cells expressing the *HSV-tk* gene were able to sensitize 70% to 80% of cells to GCV, indicating a fairly significant bystander effect in these cells. Although GCV triphosphate is unable to freely diffuse across the cell membrane, a variable bystander effect is seen. Several investigators have studied this phenomenon because a strong bystander effect is thought to be essential *in vivo* when tumor cell transduction is inefficient. The *in vitro* bystander effect for the *HSV-tk* system is thought to be mediated by gap junctions that allow transport of GCV triphosphate between cells (47). The observation that cell lines with relatively few gap junctions had minimal bystander effects (47 ,48 and 49) led to the upregulation of a gap junction protein (connexin 43) in a glioma cell line that increased the bystander effect *in vitro* and *in vivo* as discussed above, under Bystander Effect .

Several *in vivo* studies have demonstrated the potential therapeutic utility of this system. Subcutaneous sarcomas in Balb/C mice, retrovirally transduced with the *HSV-tk* gene, demonstrated a complete response after treatment with intraperitoneal (i.p.) GCV (40). Hepatic metastases transduced *in vivo* with a retrovirus expressing *HSV-tk* were treated with twice-daily injection of GCV for 5 days. This led to a significant inhibition of tumor growth compared to that seen in control subjects (41), with some complete regressions. Nonreplicating recombinant adenovirus carrying the *HSV-tk* gene has been used in many tumor models. Mice with intracerebral gliomas were injected intratumorally with adenovirus carrying *HSV-tk* and then received i.p. GCV twice daily for 6 days. This resulted in a 23-fold decrease in tumor size compared to that seen in control subjects and two complete regressions. No toxicity to the surrounding normal brain was found (42). Similar adenoviral/*HSV-tk*/GCV systems have effectively treated experimental ovarian cancer (44), head and neck cancer (43), breast cancer (45), and melanoma (46). No systemic toxicity from the converted prodrug has been demonstrated.

Varicella Thymidine Kinase

Varicella zoster virus is a virus in the Herpesviridae family whose TK gene shares 28% homology with the *HSV-tk* gene and has a different substrate specificity (50). Several prodrugs have been tested for activity in a suicide gene system using *VZV-TK*, including GCV, acyclovir, (E)-5-(2-bromovinyl)-2"-deoxyuridine (BVDU) (50), and others (51).

Breast cancer cells retrovirally transfected with *VZV-TK*, or controls, were treated with GCV, acyclovir, or BVDU. In nontransduced controls, toxicity was minimal owing to the prodrugs. In transduced cell lines sensitivity to GCV or acyclovir was minimally increased but sensitivity to BVDU was extreme (400- to 2,000-fold over that of parental cells) (50). Fifty percent of glial cells were needed to express the *VZV-TK* in order to see a global cytotoxic effect. The bystander effect was dependent on the cell line tested rather than the *VZV-TK*/BVDU system itself (50) and may be a reflection of the number of intercellular gap junctions, similar to the *HSV-tk* system.

Subcutaneously injected cells expressing the *VZV-TK* gene were similarly sensitive to BVDU. Significant dose-dependent growth inhibition was seen after eight daily i.p. injections of BVDU, although no complete regressions were seen (50). No systemic toxicity from the converted prodrug was found.

Cytosine Deaminase

CD is a bacterial enzyme that deaminates cytosine to uracil and 5-FC to 5-fluorouracil (5-FU) (52 ,53). Because it is not normally present in mammalian cells, the CD gene is useful in suicide gene systems. Transfer of the CD gene to mammalian tumor cells allows local conversion of 5-FC to 5-FU, which

inhibits both RNA and DNA synthesis and leads to cell death (52 ,53). 5-FU is an effective chemotherapy agent and has selectivity for dividing cells. It is standard therapy for various gastrointestinal and breast cancers. The prodrug 5-FC is well tolerated by humans and has been used in antifungal therapy.

Several methods to selectively transfer the CD gene to tumor cells have been used, including plasmid transfections (52 ,54 ,55), retroviral transduction (35 ,52 ,56 ,57), adenoviral infection (58 ,59 ,60 ,61 and 62), vaccinia infection (29 ,62), and antibody conjugates (63).

In vitro studies have demonstrated the ability to sensitize tumor cells to 5-FC by expression of the CD gene (52 ,54 ,50 ,51). The ability of 5-FU to diffuse through the cell membrane makes this an attractive system because of the bystander effect. When 20% of the cells expressed the CD gene, 60% to 80% cytotoxicity was seen after 4 days (54 ,57). The detection of 5-FU in the supernatants of CD-transduced cells suggests that direct cell-to-cell contact (as in the TK systems) is not needed for a bystander effect (54 ,57).

Subcutaneous tumors retrovirally transduced with the CD gene showed significant growth inhibition, which was further improved with earlier treatment and higher doses of 5-FC (36 ,56). The use of viruses to deliver the CD gene to subcutaneous xenografts has also been successful with significant growth inhibition (58) or tumor regression (60 ,62) when injected intratumorally. Intrahepatic (59) or intravenous (61) delivery of an adenovirus carrying the CD gene inhibited tumor growth after 5-FC administration with no systemic toxicity from the prodrug or its metabolites. Intravenous delivery of an antibody-CD conjugate followed by i.p. 5-FC led to high tumor levels of 5-FU compared to that in other organs. This may be an additional method for achieving high tumor levels of 5-FU without systemic toxicity (63).

Purine Nucleoside Phosphorylase

PNP is an enzyme involved in the purine salvage pathway. Both prokaryotic and eukaryotic enzymes exist, but they use unique substrates (64). Only Escherichia coli PNP can convert adenosine and adenosine analogs and has a tenfold higher activity against purine arabinosides (64), allowing the system to be used in enzyme-prodrug therapy. E. coli PNP converts the prodrug 6-MPDR to the toxic metabolite 6-MP, which is highly toxic to tumor cells via inhibition of both RNA and protein synthesis. Although this prodrug is well tolerated in animals, it has not been used in humans. Fludarabine is another substrate for this enzyme that has been used in humans for the treatment of hematologic malignancies and is associated with systemic toxicity at high doses.

In vitro studies have shown greater than 90% cytotoxicity in multiple cell types by day 5 after PNP gene transfer (16 ,65 ,66). These studies highlight several advantages of the PNP system:

1. The conversion from 6-MPDR to 6-MP is very efficient with minimal measurable prodrug in cell supernatants by day 3 (16).
2. Because 6-MP inhibits both RNA and protein synthesis, it does not require cell proliferation to have an effect.
3. 6-MP is freely diffusible across cell membranes, leading to a strong bystander effect. Complete cytotoxicity was seen in vitro when as little as 2% of cells expressed the PNP gene (66), illustrating the potency of the system.

In vivo studies have shown efficacy of this system in nude mice. Parker et al. (67) showed significant regression of subcutaneous tumors, retrovirally transduced to express the PNP gene, when treated with 6-MPDR for 3 days. In addition, no toxicity due to systemic 6-MP was seen for this dosing regimen. Puhlmann et al. (28) showed efficacy in a hepatic metastases model using a replicating vaccinia virus to deliver the PNP gene. Nude mice with hepatic metastases were treated with i.p. vaccinia virus carrying the PNP gene, followed by either weekly or every other daily injections of 6-MPDR. Both groups had a significant prolongation of survival with a 30% and 50% cure rate, respectively. No evidence of toxicity from the converted prodrug was seen with this dosing regimen, but significant hepatic toxicity was seen at higher doses, presumably owing to the potency and diffusibility of 6-MP (28). This system is ultimately limited by systemic toxicity of the converted prodrug, requiring careful prodrug dosing.

β-Lactamase

β-Lactamase is a bacterial enzyme that confers resistance to β-lactam antibiotics by cleavage of the amide bond in the β-lactam ring (68). The synthesis of nontoxic prodrugs, consisting of cephalosporins conjugated to chemotherapy agents, has allowed the system to be used for suicide gene therapy because the conjugated prodrug is similarly cleaved, releasing active drug. Several prodrugs have been synthesized for this system including cephalosporin-doxorubicin (C-Dox), 7-(4-carboxybutanamido)-cephalosporin mustard (CCM), cephalosporin-mitomycin C, cephalosporin-paclitaxel, and cephalosporin-carboplatinum (68 ,69 and 70). Tumor-specific antibodies conjugated to the β-lactamase enzyme have allowed tumor-targeted activation of the various prodrugs (69 ,70 ,73 ,74 ,75 and 76).

In vitro studies showed that treatment of melanoma cells with an antibody/β-lactamase conjugate, followed by the prodrugs C-Dox and CCM, led to a four- and 30-fold increase, respectively, in the sensitivity of cells to the prodrugs, although some nonspecific prodrug toxicity was seen (69). Subcutaneous melanoma xenografts in nude mice treated weekly with antibody/β-lactamase and C-Dox showed tumor regression that eventually progressed (69). In contrast, similar treatments using CCM led to complete long-term regression in 80% of the mice. Although some neurologic toxicity was seen with C-Dox, no systemic toxicity from the CCM was seen (69). Similar studies using antibody/β-lactamase/C-Dox to treat xenografts of breast and colon carcinoma cells showed tumor growth inhibition in both histologies with minimal toxicity (73), although no complete regressions were seen. Finally, nude mice with subcutaneous melanoma xenografts were treated using a single-chain antibody/β-lactamase fusion protein in combination with CCM. Complete tumor regressions, in the majority of animals treated with CCM 12 hours after delivery of the fusion protein, were seen with no evidence of systemic toxicity (75). Although this system has not been studied in a gene

delivery approach, the ß-lactamase protein is extremely versatile and should be functional in this context.

Carboxypeptidase G2

CPG2 is a bacterial enzyme that catalyzes the hydrolytic cleavage of folates and methotrexate to pteroates and L-glutamic acid (77 ,78). Similar cleavage releases active alkylating agents from prodrugs synthesized with a glutamic acid group blocking the enzyme's function (77 ,78). Various methods of tumor-specific expression of CPG2 have been studied, including antibody targeting (78 ,79 and 80) and stable transfection (38), suggesting it would be a good enzyme for use in a suicide gene system.

Stable transfection of colon and ovarian carcinoma cell lines with CPG2 resulted in a 16- to 95-fold increase in sensitivity to the prodrug 4-[(2-chloroethyl)(2-mesyloxyethyl) amino] benzoyl-L-glutamic acid (38). One hundred percent cytotoxicity was seen when 3.7% to 12.0% of the cells expressed CPG2 (38). In vivo studies have used tumor-specific monoclonal antibodies conjugated to CPG2 as a means of enzyme delivery (78 ,79 and 80). A nude mouse model of human choriocarcinoma showed significantly increased survival when treated with anti-human chorionic gonadotropin antibody/CPG2 conjugates, followed by only three doses of prodrug 72 hours later (78). Subcutaneous colon carcinoma xenografts had significant growth delay when treated with antibody/CPG2 conjugate followed by prodrug, although the tumors subsequently regrew (80). Minimal toxicity to the prodrug and its metabolites was seen.

Cytochrome P450-2B1

Cytochrome P450-2B1 (CYP2B1) is a naturally occurring liver enzyme necessary in the conversion of cyclophosphamide and ifosfamide to their 4-hydroxy derivatives (81 ,82). These metabolites are unstable and further degrade to become the toxic metabolites acrolein and phosphoramide mustard, which cause protein and DNA alkylation, respectively (82). Because tumor levels of the enzyme are low (82), these chemotherapeutic agents are normally metabolized in the liver, leading to systemic toxicity before a maximal tumor response. Use in a suicide gene system allows upregulation of CYP2B1 expression in tumor cells, leading to local conversion of cyclophosphamide and ifosfamide and potentially less systemic toxicity. This system is appealing because it may enhance the effect of agents that have already shown to be effective in cancer therapy and for which a safety profile has already been defined.

In vitro studies demonstrated that glioma cells (81 ,82) and breast cancer cells (83), stably transfected with the CYP2B1 gene, acquired sensitivity to cyclophosphamide and ifosfamide (81 ,82 and 83). This sensitivity was blocked by the CYP2B1 inhibitor metyrapone (82 ,83). A significant bystander effect was seen when 20% to 50% of the cells expressed the CYP2B1 gene (82 ,83), and this persisted in co-culture experiments, suggesting that direct cell contact is not needed for this effect.

Several studies (81 ,82 and 83) have shown enhanced sensitivity of subcutaneous tumors (glioma, breast cancer) retrovirally transduced with CYP2B1 (ex vivo) to cyclophosphamide. In one study, this led to complete inhibition of tumors in 95% of animals after a single i.p. injection of cyclophosphamide (82). Inoculation of retroviral producer cells or replication-deficient adenovirus expressing the CYP2B1 gene into intracerebral gliomas led to prolonged survival after one dose of i.p. cyclophosphamide (84). No notable toxicity from the cyclophosphamide conversion was found at the doses studied.

Finally, Chase et al. (85) were able to show that intratumoral injection of a CYP2B1-expressing herpes simplex virus and cyclophosphamide had an enhanced oncolytic effect compared to the virus alone.

Nitroreductase

Initial studies of the alkylating agent CB1954 showed promise in a rat Walker tumor model; however, human trials were disappointing (86). Subsequently it was shown that the human equivalent of rat DT diaphorase was inefficient at converting CB1954 to its active metabolite, the 4-hydroxylamino derivative that causes DNA cross-linking and cell death (86). The identification of a bacterial enzyme with similar activity (87)—E. coli nitroreductase (NTR)—led to its use in suicide gene systems (88 ,89 and 90), in which tumor-specific expression of the bacterial enzyme would render tumor cells uniquely sensitive to CB1954.

In vitro studies have shown a ten- to 100-fold increase in sensitivity of pancreatic, colonic (88), and mammary (90) cell tumor lines to CB1954 when transfected with plasmids expressing the NTR gene. Retroviral transduction led to a 17- to 500-fold increase insensitivity to CB1594, which correlated with the amount of NTR produced by the cells (88). Cell mixing experiments demonstrated a significant in vitro bystander effect if 30% of the cells express the gene. Transgenic mice engineered to express a CD2/NTR transgene in T cells and thymocytes had much smaller spleens and thymuses and a significantly increased level of apoptosis in these organs 5 days after treatment with CB1954 (89). Clark et al. (90) showed that transgenic mice expressing NTR under the control of the ß-lactoglobulin promoter, had increased levels of ntr mRNA and protein in mammary glands compared to other tissues, and treatment with CB1954 resulted in disrupted mammary glands with increased apoptosis. Nonspecific toxicity from the prodrug or converted active drug was not seen.

Xanthine-Guanine Phosphoribosyl Transferase

Traditionally, the E. coli xanthine-guanine phosphoribosyl transferase (GPT) gene has been used for positive selection in a purine salvage pathway (91) as it catalyzes the conversion of xanthine, hypoxanthine, and guanine to their respective monophosphates. Cells that express the GPT gene can use xanthine as a purine analog in the presence of mycophenolic acid and hypoxanthine, which inhibit the mammalian pathway. Conversely, GPT has been used to selectively sensitize tumor cells to 6-thioxanthine (6-TX) (92 ,93) as it is incorporated into this purine synthesis pathway. Mroz and Moolten (93) showed that retrovirally transducing the GPT gene into sarcoma cells conferred an 86-fold increased sensitivity to 6-TX. Tamiya et al. (92) showed that glioma cells were sensitive to 6-TX at an

LD50 of 2.5 µM when transduced with *GPT*. Untransfected cells were minimally sensitive at 50 µM. As well, a significant bystander effect (75% cytotoxicity) was seen when 10% of the cells expressed *GPT*. This effect was abrogated when the cells were separated, suggesting that cell-to-cell contact was required (92). Syngeneic Balb/C mice injected subcutaneously with a transduced sarcoma cell line showed complete regression in 95% of the animals after 5 days of treatment with 6-TX. A 10% treatment mortality due to toxicity of the converted prodrug was seen and was eradicated with an alternate-day dosing schedule (93). Nude mice subcutaneously injected with transduced glioma cells showed a significant inhibition of tumor growth when treated with i.p. 6-TX for 10 days at a reduced dose, with no treatment toxicity (92). In the same study, nude mice with transduced intracerebral gliomas showed prolonged survival after 6-TX treatment. In another study (94), similar subcutaneous tumor inhibition was seen, and regrowth was correlated with loss of the retrovirally expressed *GPT* gene after 3 weeks. In this study, survival after intracerebral tumor injection was prolonged by 6-TX, in the presence of the *GPT* gene. Pathologic evaluation of these brains did not show any neurotoxicity from the 6-TX treatment (94).

β-Glucuronidase

β-Glucuronidase (GUS) is a glycosidase normally present in low amounts in normal human tissues (95) and slightly higher levels in tumor tissues (96 ,97). GUS hydrolyses inactive glucuronide conjugates into active drugs (98). Several glucuronide prodrugs have been described for use in a GUS suicide gene system, including conjugates of epirubicin (95), daunorubicin (90), *p*-hydroxyaniline mustard (99), and doxorubicin (100). Although these prodrugs are nontoxic in animals, they have not been used in humans.

GUS has been conjugated to monoclonal antibodies (95 ,98 ,99 and 100) to increase tumor-specific expression. Haisma et al. (95) used the anti-pan carcinoma antibody (323/A3) conjugated to GUS and demonstrated equivalent activity of the antibody-GUS/epirubicin-glucuronide to epirubicin alone *in vitro*, demonstrating activation of the prodrug. Similar effects were seen for the daunorubicin prodrug (98). A single-chain antibody against the pan carcinoma antigen conjugated to GUS was also effective against an ovarian cell line treated with a doxorubicin-glucuronide prodrug (100). *In vivo* treatment of a rat hepatoma model of ascites, with a hepatoma cell-specific antibody conjugated to GUS, resulted in long-term cure of rats when treated with three i.p. injections of the *p*-hydroxyaniline glucuronide prodrug (99). Minimal toxicity of prodrug conversion was noted despite the presence of native GUS in some tissues (99).

Other Suicide Gene Systems

Several other suicide gene systems have been described. Thymidine phosphorylase, which catalyzes the reversible phosphorolytic cleavage of thymidine, deoxyuridine, and their analogs, has been used to convert the prodrug 5"-deoxy-5-fluorouridine to 5-FU (101). Cytosine arabinoside (ara-C) requires phosphorylation by deoxycytidine kinase (dCK) to form its active metabolite. Delivery of dCK to glioma cells sensitized them to treatment by ara-C (102). Overexpression of a rabbit carboxylesterase was shown to sensitize human cells to 7-ethyl-10-[4-(1-piperidino)-1-piperidino]-carbonyloxycamptothecin (CPT-11) by its conversion to an active metabolite (SN38) (103). Both β-glucosidase (104) and the plant equivalent linamarase (105) have been shown to hydrolyse amygdalin and linamarase, respectively, to cyanide. This hydrolysis leads to tumor-specific toxicity when delivered via antibody targeting (104) or retroviral transduction (105), with no noted systemic toxicity (105).

Bovine carboxypeptidase A has been shown to cleave the amide bond of a methotrexate-phenylalanine prodrug, yielding free methotrexate (106). This enzyme was conjugated to a monoclonal antibody for tumor-specific delivery, and *in vitro* studies showed that ovarian carcinoma cells became sensitive to the methotrexate-phenylalanine prodrug in the presence of carboxypeptidase A (106). Finally, a novel rabbit cytochrome P450 isoenzyme (CYP4B1) has been shown to convert the prodrugs 2-aminoanthracene and 4-ipomeanol into toxic alkylating agents (107). Glioma cells stably transfected with *CYP4B1* showed increased sensitivity to 2-aminoanthracene and 4-ipomeanol *in vitro* and *in vivo* compared to controls. A strong bystander effect was seen, with 70% to 80% cytotoxicity when 1% of the cells expressed the *CYP4B1* gene (107).

Comparison of Suicide Gene Systems

Part of "20.3 - Suicide Gene Therapy "

Few studies have compared the efficacy and bystander effects of the different suicide gene systems. The use of different promoters and different delivery systems (plasmid, retroviral, adenoviral) makes head-to-head comparisons necessary. Trinh et al. (108) compared the *HSV-tk*/GCV and *CD*/5-FC systems. Plasmids containing each gene under the control of the cytomegalovirus promoter were stably transfected into cells and rendered the cells sensitive to their respective prodrugs. Prodrug treatment resulted in complete regression of all subcutaneous xenografts when 100% of the cells expressed either *HSV-tk* or *CD*. However, when only 10% of cells in the tumors expressed *HSV-tk*, only a slight inhibition of growth was seen after treatment with GCV. In contrast, when only 4% of cells expressed the *CD* gene, 60% of tumors had a complete response to 5-FC. The inability of GCV to diffuse readily from cell to cell is one likely explanation for this difference; different cell lines may show different results (108).

Hoganson et al. (109) compared the efficacy of *HSV-tk*/GCV, *CD*/5-FC, and *DCK*/ara-C against lung adenocarcinoma cell lines. Stable transduction of cell lines with retroviruses expressing the suicide genes under the control of the CMV promoter showed that both *HSV-tk* and *CD* could confer sensitivity to GCV and 5-FC, respectively. However, only the *CD* system demonstrated a bystander effect with 60% growth inhibition by day 7 when only 10% of the cells expressed the gene. Transduction with *DCK* did not improve sensitivity of the cell lines to ara-C (109).

Nishihara et al. (110) retrovirally transduced thyroid carcinoma cell lines with the *HSV-tk, CD, NTR*, or *DCK* genes

under the control of a long-terminal-repeat promoter. *HSV-tk*/GCV demonstrated the best therapeutic index (IC50 parental cells/IC50 transduced), ranging from 31 to 120 depending on the cell line, whereas *DCK*/ara-C had minimal effect compared to control (therapeutic index: 1.2 to 1.5). Comparison of *in vitro* bystander effects indicated that the *CD*/5-FC system (90% growth inhibition when 20% of cells expressed *CD*) was superior to both *NTR*/CB1954 (90% inhibition when 50% of cells expressed *NTR*) and *HSV-tk*/GCV (90% inhibition when 80% of cells expressed *HSV-tk*). This effect was not assessed *in vivo* (110).

In summary, although the cytotoxicity of the *HSV-tk*/GCV system was equal or better than other systems studied, the *in vitro* bystander effect was minimal. Although this may not predict *in vivo* results, a suicide gene system with a strong bystander effect is needed for cancer treatment *in vivo*, given the poor transduction efficiencies of current vectors.

Combined Modalities

Part of "20.3 - Suicide Gene Therapy "

Because of the limitations inherent in vector systems and limited therapeutic results from suicide gene systems *in vivo*, modifications have been tested that combine different modalities for an enhanced tumor response. These modifications include combining suicide gene therapy with conventional chemotherapy and radiotherapy, combining multiple suicide genes, and combining oncolytic viruses with suicide genes. As the systems become more complicated, it will be increasingly difficult to assess whether the advantages of the gene therapy approach are real compared to systemically delivered agents.

Double suicide gene systems have been included in a single vector as a means of enhancing response, and these systems have the theoretical advantage of more potent killing of infected cells and cells within the bystander zone. Aghi et al. (111) demonstrated synergistic *in vivo* activity of combined *HSV-tk*/GCV and *CD*/5-FC systems in stable transfectants. Graham and Prevec (112) created a *CD-TK* fusion gene that demonstrated enhanced cytotoxicity after delivery of both GCV and 5-FC. Both the *HSV-tk*/GCV and *CD*/5-FC systems have been shown to enhance radiation sensitivity of experimental tumors (113 ,114). Rogulski et al. (115) demonstrated marked improvement in cure rates *in vivo* when radiation was added to *CD-TK* fusion gene therapy.

The combination of a replicating oncolytic virus with a suicide gene system may have significant therapeutic potential. The suicide gene may extend the zone of necrosis beyond that the virus alone could accomplish. Wildner et al. (116) demonstrated that a tumor-specific replicating adenovirus (E1b M$_r$ 55,000 deleted) expressing *HSV-tk* achieved superior tumor response *in vivo* after addition of GCV, compared to the oncolytic effect of the virus alone. Freytag et al. (117) combined an oncolytic adenovirus (E1b M$_r$ 55,000 deleted) with the *CD-TK* fusion gene and radiotherapy to achieve marked *in vivo* efficacy. Puhlmann et al. (28) demonstrated a 50% cure rate using a systemically administered replication-competent vaccinia virus expressing PNP followed by 6-MPDR for disseminated hepatic metastases in a murine model (see Fig. 20.3-3).

Clinical Trials

Part of "20.3 - Suicide Gene Therapy "

Animal models are often insufficient and inappropriate for investigating gene therapy with viral vectors. Tissue selectivity of viruses may be completely different in humans compared to animal models. In addition, the immune response to the vector is different in humans, making it difficult to extrapolate gene expression data from animal experiments. The strong immune response in humans may change the toxicity profile predicted from animal experiments, because tissue inflammation from the immune response may mediate more toxicity than virus-mediated cell death. Preformed antibodies from prior exposure to viruses may greatly limit gene expression in patients and may also result in unexpected toxicities. Therefore, vectors and suicide genes need to be studied in humans. The clinical trials to date have been essential for initiating our understanding of these vectors, despite having demonstrated minimal therapeutic effect.

Knowing the limitations of current vectors, clinical trials have studied the intratumoral injection or regional administration of viruses into the peritoneal or pleural cavity. The true clinical applicability of these systems is limited, and local injection of a vector for gene delivery and conversion of a prodrug ultimately needs to be compared to local injection of the toxic agent. Some theoretical advantages to local gene therapy exist. Intracellular toxin formation may be more potent than extracellular delivery. Cells resistant to topical 5-FU may be sensitive to intracellular production of 5-FU via conversion of 5-FC. Tumor-specific viral replication and tissue-specific gene expression may help prevent toxicity in the normal cells surrounding the tumor, which may be affected by direct local injection of toxic agents. This is especially important for brain tumors, in which minimizing toxicity to normal cells is essential for acceptable morbidity. Appropriately, patients with brain tumors have been among the first investigated with this strategy.

Regardless of the ultimate clinical utility, local injection of vectors has been an important first step toward the clinical use of suicide genes for cancer therapy. Of 300 proposed gene therapy trials, approximately 10% involve the use of suicide genes, and the majority use the *HSV-tk*/GCV system (Table 20.3-4). The first clinical gene therapy trial using a suicide gene was proposed by Freeman (118) and approved in 1991. It consisted of infusing *HSV-tk*-transduced ovarian cancer cells into the peritoneal cavity for the bystander treatment of ovarian cancer. Because this was a tumor confined to the peritoneal cavity, it allowed a regional approach to vector delivery. This therapy relied on the transduced tumor cells intermixing with the tumor cells present in the peritoneal cavity and then killing them by virtue of the bystander effect after prodrug delivery. The first patient was treated in 1993. The results of this trial have not been published to date.

CD, cytosine deaminase; TK, thymidine kinase.

Data from Human gene marker/therapy clinical protocols. *Hum Gene Ther* 1999;10:1043-1092.

Ram et al. (119) investigated the *HSV-tk* system for malignant brain tumors. Murine retroviral producer cells, which generated retroviruses expressing *HSV-tk*, were injected into brain tumors. Fifteen patients were treated using computed tomography-guided stereotactic injections of varying doses of cells (2.5 × 10^8 to 1 × 10^9 cells) in linear tracts 3 to 6 mm apart within the tumor, followed in 7 days by intravenous GCV (5 mg per kg b.i.d.) for 14 days. Five lesions in four patients had at least a

partial response, including two complete responders. The responding lesions were all small (average volume, 1.4 mL). Two patients suffered neurologic deficits from intratumoral hemorrhage as a result of the injections, two had worsening seizures, and one had new seizures. Up to 14 injections per tumor were given. Retroviral producer cell antibodies were detected in 10 of 15 patients. Two tumors were resected before GCV treatment, revealing *HSV-tk* mRNA by *in situ* hybridization in cells immediately adjacent to the injection tracts, including some endothelial cell transduction. Overall, the percentage of cells expressing the gene was low and probably explains the minimal response. This trial was followed by four similar trials by different investigators.

Klatzmann et al. (120) reported results from murine retroviral producer cells (M11) injected into the surgical cavity margins after surgical debulking for recurrent glioblastomas in 12 patients. The cells were injected tangentially and orthogonally at 1-cm intervals along the tumor margin to a maximum depth of 1.5 cm. The number of injections ranged from 15 to 55, and the number of cells injected ranged from 7.1 to 9.8×10^6. Three patients had easily controlled hemorrhage at the time of injections. GCV (5 mg per kg) was given twice daily for 14 days, beginning 7 days after injection of the producer cells. It is difficult to assess safety and efficacy in an adjuvant trial, because complications are common after aggressive surgery alone, and it is difficult to predict the outcome from surgical resection alone. Nevertheless, they concluded the therapy was both safe and efficacious with a 25% 4-month disease-free survival rate.

Klatzmann et al. (121) also reported a similar trial of retroviral producer cells injected into cutaneous melanoma nodules. Toxicity was limited to inflammatory skin reactions at the injection site and fever after repeated injections. The gene could be demonstrated in tumor nodules by polymerase chain reaction in three of six patients, and none of the injected lesions had objective responses.

Investigators from the University of Pennsylvania first used intratumoral injection of adenovirus expressing the *HSV-tk* gene for the treatment of brain tumors, and intrapleural injection for the treatment of mesothelioma. Sterman et al. (122) reported the results of a phase 1 clinical trial in malignant mesothelioma. Twenty-one patients were treated with intrapleural administration of adenovirus expressing *HSV-tk* followed by 2 weeks of systemic therapy with GCV (5 mg per kg b.i.d.). The viral dose was escalated from 1×10^9 PFU to 1×10^{12} PFU without reaching dose-limiting toxicity. Side effects included fever (100° to 102°F 6 to 12 hours after viral injection), anemia, transient liver enzyme elevations, and bullous skin eruptions. A temporary systemic inflammatory response was noted at the highest dose, manifested by hypotension immediately after vector delivery. The toxicity seemed to be related to an inflammatory response to the adenovirus and not to prodrug conversion. Immune manipulation may improve this inflammatory reaction. Subsequently, they have pretreated

patients with high-dose steroids to improve viral tolerance. Although gene expression from the pleural tumor was detectable by polymerase chain reaction in 11 of 20 posttreatment biopsies, overall the percentage of transduced cells was low and limited to the tumor surface. The success of gene transfer did not correlate with the titer of pre-existing adenoviral antibodies, but it did correlate with the viral dose.

Other histologies that have been treated with intratumoral or regional administration of *HSV-tk*-expressing adenoviral vectors include head and neck cancers, hepatocellular cancers, hepatic metastases, lung cancer, ovarian cancer, and prostate cancer. Crystal et al. (123) were the first to use the *CD*/5-FC system in a clinical trial, giving intratumoral injections of adenoviruses expressing the *CD* gene into hepatic metastases from colorectal cancer. Other studies using *CD* for breast cancer are under way.

A practical use for suicide genes in cancer management is the stable transduction of donor lymphocytes with *HSV-tk* in patients undergoing allogeneic bone marrow transplantation. This technique allows treatment of graft-versus-host disease by killing the donor cells responsible for the problem with delivery of GCV. It has been tested in clinical trials (124). Theoretical limitations of this therapy include the possible increased immunogenicity of the transduced cells, which may have a negative impact on engraftment.

Conclusions

Part of "20.3 - Suicide Gene Therapy "

The concept of genetic manipulation of tumor cells to mediate their own death is exciting and can be envisioned as an effective cancer treatment. Although numerous methods are effective *in vitro*, the limitation *in vivo* is inefficient gene delivery to tumor cells. The almost unlimited ability to genetically engineer viruses should eventually allow the development of an efficient vector that is tumor-specific and safe for the patient and the environment. Although nonviral vectors ultimately may be more useful than viruses, they are currently less efficient. When the ideal vector is created, it will be important to perform *in vivo* comparisons of suicide gene systems to demonstrate which has the largest bystander zone with acceptable systemic toxicity. The combination of an efficient, specific vector and a potent suicide gene system should lead to a significant therapeutic response.

Perhaps the biggest obstacle to effective suicide gene therapy will be the immune system, which will either result in the inability to express genes in a large enough population of tumor cells or will mediate unacceptable toxicity due to the inflammatory response to the vector. Immunologic manipulation of the patient may be required to allow the level and duration of gene expression necessary to achieve a tumor response. All of these technological advances appear within reach, making the future of suicide gene therapy very promising.

20.4

Gene Therapy Using Direct *In Vivo* Gene Injection

Bingliang Fang

Jack A. Roth

- Introduction
- Gene Transfer Vectors
- Genes for Anticancer Therapy

Introduction

Part of "20.4 - Gene Therapy Using Direct Gene Injection "

Gene therapy was originally envisioned as a technique for restoring the expression of normal genes in inherited monogenic disorders, such as adenosine deaminase deficiency and cystic fibrosis. However, the clinical application of gene therapy has focused on cancer with the attempts to use genes as anticancer agents and immunostimulants. In this chapter, the applications of gene therapy using intratumoral injection for local-regional tumor control and induction of an antitumor immune response are reviewed.

Gene Transfer Vectors

Part of "20.4 - Gene Therapy Using Direct Gene Injection "

Gene transfer vectors are agents that constitute or contain therapeutic genes for delivery into target cells. A vector can be naked DNA or RNA, DNA or RNA attached to other agents (e.g., peptides or liposomes), or a virus particle containing a therapeutic gene. Several different delivery systems [reviewed elsewhere (1 ,2)] have been developed, but there are still no perfect universal vectors. Here, we briefly discuss the vectors used in direct *in vivo* injection. Readers who are interested in recent developments in vector and gene delivery technology are encouraged to consult other chapters on the basic aspects of gene therapy.

Viral Vectors

Adenovirus

Adenovirus is one of most popular vectors in the field of gene therapy because of its ease of production and high *in vivo* transduction efficiencies. It is also widely used for direct *in vivo* injection. Usually, adenoviral vectors are constructed by replacing the E1 region with an expression cassette of the desired transgene (3). The vectors are generated and propagated in packaging cells, such as 293, that provide E1 functions in trans (4). However, it is possible to generate adenoviral vectors containing only the replication origin and packaging signal. In this case, a helper virus is required for vector production (5). For efficient production of vectors, the vector genome should be between 27 and 37 kilobases long (75% to 104% of the wild-type viral genome) (6 ,7).

In vivo administration of adenoviral vector has been shown to result in the highly efficient delivery of genes to a variety of tissues (8 ,9 and 10) and to induce complete phenotypic corrections of genetic disorders in mice (11 ,12), rabbits (13 ,14), and dogs (15). This vector system has also been extensively used for *in vivo* cancer gene therapy both preclinically and clinically (16 ,17 and 18) [see Roth and Cristiano (19) for review]. In most cases, constructing adenoviral vectors is quite straightforward (3). However, constructing vectors that express highly proapoptotic or cytotoxic genes may become problematic. For example, constructing an adenoviral vector that would express high levels of Fas ligand, *BAX*, or *BAK* proved to be difficult because of the high apoptotic activities of the proteins (20). Yet, we have demonstrated that this obstacle can be overcome by using a *GAL4* gene regulatory system along with adenovirus-mediated gene codelivery (21). The synthetic *GAL4*-responsive promoter, which consists only of *GAL4*-binding sites and a TATA box, has extremely low basal transcriptional activities in the absence of its transactivator but 10^4- to 10^6-fold higher activity in its presence both *in vitro* and *in vivo* (22). Constructing adenoviral vectors that contain a *BAX* or *BAK* gene driven by this minimal promoter is straightforward, and the transgene expression can be efficiently induced by coinfecting cells with a vector expressing a transactivating protein, the GAL4/VP16 fusion protein (21).

Extensive efforts have been made to develop novel adenoviral vectors by (a) modifying the adenoviral genome to inactivate viral gene expression (23 ,24 ,25 ,26 ,27 and 28) or (b) modifying viral proteins to enhance transduction efficiency in refractory cells or enhance targeting (29 ,30 ,31 ,32 ,33 and 34). Other strategies for improving direct *in vivo* gene delivery with adenoviral vectors have also been tried. One involves modulating the host immune response to adenoviral vector to prolong transgene expression and offset the effect of humoral immune response. It has been demonstrated that transgene expression is prolonged in newborn or immunocompromised mice and in animals treated with immunosuppressive agents (12 ,35 ,36) or agents such as anti-CD4 antibody or CTLA4-Ig that block activation of the immune system around the time of vector administration (37). Improving efficiency in repeated administration of adenoviral vectors has also been attempted. For example, concurrent administration of interleukin-12 (IL-12) or high-dose cyclophosphamide can reportedly inhibit the development of neutralizing antibodies (38 ,39). Treating animals with low-dose etoposide can suppress the formation of neutralizing antibodies and enhance intratumoral transgene expression in immunized animals, suggesting that repeated adenovirus-mediated gene therapy may be achievable in cancer patients concomitantly receiving certain chemotherapeutic agents (40).

Adeno-Associated Virus

Use of adeno-associated virus (AAV) as a vector for gene transfer and gene therapy has been comprehensively reviewed (41 ,42 and 43). AAV vectors have been used to transduce a wide range of cell types *in vitro*, including respiratory epithelial cells, bone marrow, and lymphocyte-derived cells. *In vivo* transduction in lung and brain has been observed in rodents and nonhuman primates. A phase 1 human trial of gene therapy for cystic fibrosis using an AAV vector is currently underway.

The advantages of using AAV as a vector for gene therapy include (a) its ability to infect nonreplicating cells and to be integrated into the host genome so that the therapeutic gene will persist in transduced cells and (b) its lack of viral coding sequences, which therefore avoids the immune response elicited by expression of vector proteins in transduced cells. Disadvantages are (a) the labor intensiveness of vector production and (b) the low efficiency of transduction owing in part to the vector's single-stranded genome. Conversion of the single-stranded DNA into double-stranded DNA before expression of the transgene is a limiting step in AAV-mediated gene transfer (44). Nonetheless, AAV is exceptional at transducing muscle tissue, as shown by the high level of stable transgene expression achieved in mouse muscle after intramuscular injection of purified vector (45). More recently, it was shown that a relatively high level of transgene expression in liver could be achieved by portal vein injection of vectors (46 ,47). When transduced, AAV vector genomes either remain as a head-to-tail circularized episomal monomer and concatemer in transduced cells or are integrated randomly into the host genome as concatemers (48).

Retrovirus

Retroviral vectors have been extensively used for *ex vivo* gene delivery and are the most useful vector for stably integrating foreign DNA into target cells. They are not efficient for direct *in*

vivo injection because of inactivation by host complement (49). Efforts are under way to improve *in vivo* transduction efficiency of retroviral vectors. For example, vectors produced in packaging cells of human origin may escape complement inactivation (50). Modifying the viral envelope for targeted delivery [for review, see Schnierle and Groner (51)], producing higher titers of vector, and generating lentivirus-based vectors capable of transducing nondividing cells are also under intensive studies (52 ,53).

Other Viral Vectors

Vaccinia Virus

Vaccinia virus is a member of the poxvirus family, which is unique in that its viral DNA replication and RNA transcription occur exclusively in the cytoplasm. Several attributes of poxviruses have led to their extensive use as expression vectors, including their capacity for carrying large amounts of DNA and their wide range of hosts (54 ,55). Because the vector's RNA is transcribed in the cytoplasm, therapeutic gene expression requires either poxvirus promoters or bacteriophage RNA polymerases and cognate promoters. Thus far, this vector has been used in clinical trials to deliver genes encoding tumor antigens (e.g., melanoma antigen, carcinoembryonic antigen, prostate-specific antigen), interleukins (e.g., IL-1β, IL-12), and costimulatory molecule B7 (56 ,57 and 58).

Replication-Competent Viruses

Until recently, viral gene expression and viral replication were believed to pose safety concerns in gene therapy. Therefore, most efforts in developing viral vectors for gene therapy were directed at removing or inactivating viral genes and generating packaging cell lines that could produce high titers of vectors with minimal likelihood of generating replication-competent viruses. Nevertheless, the destructive effect of virus replication could also be beneficial as long as the replication was limited to tumor cells. On this basis, a replication-competent adenovirus, herpes simplex virus, and reovirus have been tested for use in treating cancers (59 ,60 ,61 and 62). Adenovirus with a mutation in E1B region has been reported to replicate specifically in *p53*-mutated tumors (59) and may be useful for cancer therapy because *p53* is the most frequently mutated gene identified in human cancers (63). However, studies indicate that lytic infection of cells with E1B-mutated adenovirus does not depend on *p53* status and that *p53* may play a necessary part in mediating cellular destruction via a productive adenovirus infection (64 ,65).

Nonviral Vectors

Naked DNA

Naked DNA (i.e., purified plasmids) can be introduced into cells in a variety of physical or chemical ways. The physical techniques for *in vivo* gene delivery include direct injection and injection by *gene gun* (high-velocity bombardment of tissues with DNA attached to gold particles). Direct injection of DNA vectors into muscles can result in sustained, albeit low, expression of introduced genes (66 ,67). In other tissues, however, DNA uptake after direct injection is minimal. Nevertheless, studies showed that high levels of transgene expression can be achieved in liver and lung if plasmid DNA can be retained in these organs for a prolonged time (68 ,69). Direct injection of plasmid DNA expressing a tumor antigen has also been used in clinical trials of cancer vaccination (58). Delivery by gene gun can induce gene expression in skin, liver, and tumor models (70).

DNA-Carrier Complexes

Liposomes are the most popular nonviral vectors for gene delivery [for review, see Gao and Huang (71); Lee and Huang (72)]. Liposomes, when combined with DNA of any size, form a lipid-DNA complex that can be delivered to many cell types. They are also actively used in clinical trials for *in vivo* and *ex vivo* delivery of genes encoding cytokines, immunostimulatory molecules, and adenoviral E1A genes. Successful intravenous gene delivery via liposomes has been reported in animals (73 ,74). At present, most liposomes are prepared from biodegradable cationic lipids, although preparing them from anionic or neutral lipids has been proposed (72). Incorporating neutral lipids into cationic liposomes has been shown to increase vector stability after systemic administration. Mechanical extrusion of liposomes has also been reported to increase transduction efficiency (75). In general, however, the expression of genes introduced via liposomes remains low and transient. Peptides have also been exploited for gene delivery. For efficient gene delivery, a peptide should be (a) capable of binding to DNA, (b) efficiently internalized by cells, (c) capable of disrupting the endosomal membrane, and (d) capable of carrying DNA to the nucleus. Peptides that bind specifically to certain cell-surface molecules may be useful for targeted gene delivery.

Genes for Anticancer Therapy

Part of "20.4 - Gene Therapy Using Direct Gene Injection "

With the progress in mapping, cloning, and functionally characterizing the human genome and genomes of other organisms, a growing number of established and potential anticancer genes are being identified and tested. In fact, it is virtually impossible to list here all the genes that might be used for cancer gene therapy. For this chapter, however, we have classified genes used in cancer gene therapy into four categories according to their targets: (a) genes targeted to tumor cells, (b) genes targeted to the immune system, (c) genes targeted to tumor microenvironments or tumor vasculature, and (d) genes targeted to normal, nonmalignant cells. Such classification is arbitrary because some genes may affect more than one class of target. For example, IL-12 is used to augment antitumor immunity, yet it has a strong effect on tumor angiogenesis. *p53* promotes apoptosis of tumor cells, suppresses angiogenesis by downregulating vascular endothelial growth factor (VEGF) expression, and has also been proposed as a target for a tumor vaccine. These genes are potential targets for gene therapy approaches. Clinical trials completed or in progress using these approaches are summarized in Table 20.4-1 .

Table 20.4-1 Worldwide Clinical Trials for Cancer Gene Therapy with Direct Intratumoral Injection

Principal Investigator	Protocol	Target Cell	Vector	Delivery Vehicle	No. of Patients Entered	Evidence of Gene Expression[a]	No. and Type of Response[b]	Adverse Reactions[c]
Immunotherapy/cytokine								
A. E. Chang (Univ. of Michigan Medical Center, Ann Arbor, MI)	Immunotherapy for cancer by direct gene transfer into tumors	Melanoma cells	HLA-B7, 2-microglobulin	Lipid	10	Y	NA	None
	Phase 2 study of immunotherapy of metastatic cancer by direct gene transfer	Cancer cells	HLA-B7, 2-microglobulin	Lipid	0	NA	NA	NA

CR, complete response; HNSCC, head and neck squamous cell carcinoma; *HSV-tk*, herpes simplex virus thymidine kinase; IL-2, interleukin 2; MR, minor response; N, no; NA, not available; NSCLC, non-small-cell lung cancer; PR, partial response; SD, stable disease; Y, yes.

[a] *In vivo* or in target cell.

[b] All principal investigators were asked to use the following response criteria: CR was defined as disappearance of all clinical evidence of tumor in the treated area for local treatment or for all lesions for systemic treatment without the appearance of new lesions for at least 4 weeks. Patients evaluable for a less-than-complete response were those having a bidimensionally measurable tumor. PR was defined as a ≥50% reduction in the sum of the products of the diameters of the measurable disease, including the treated lesion for local treatment or all lesions for systemic therapy. MR was defined as a 25% to <50% reduction in the sum of the products of the diameters of the measurable lesion. Patients were designated as having progressive disease if they showed a ≥25% increase in the size of their disease or if they developed unequivocal new lesions during treatment, and as having stabilization if they had any tumor change that did not meet the criteria described here.

[c] Related to gene transfer.

Survey forms were sent to all cancer gene-therapy protocol principal investigators with results tabulated and verified by each investigator as of June 19, 1996.

Genes Targeted to Tumor Cells

Genes targeted to tumor cells include those that kill tumor cells or change the biologic properties of malignant cells. Among these are genes that activate anticancer prodrugs, genes that interrupt tumorigenic processes, genes that are cytotoxic or proapoptotic and promote cell death directly, and genes that change biologic properties (e.g., invasiveness and metastasis) of malignant cells.

Prodrug Activation

Genes that encode enzymes capable of converting nontoxic prodrugs into highly toxic metabolites have been extensively tested in cancer gene therapy on the premise that their actions will limit the toxic metabolites locally to tumor sites, thereby remarkably reducing the systemic side effects of chemotherapy. Genes that might be used this way have been reviewed by Connors (76). The most commonly explored prodrug-activating gene is the thymidine kinase gene of the herpes simplex virus type 1 *(HSV-tk). HSV-tk* converts the nucleoside analog ganciclovir to its monophosphate form by phosphorylation. This monophosphate is subsequently modified into its toxic triphosphate form by endogenous cellular enzymes and then incorporated into nascent DNA, thus causing chain termination and cell death. The rate of monophosphorylation of ganciclovir by endogenous cellular thymidine kinase is, however, three orders of magnitude lower than that of *HSV-tk.* Because phosphorylated ganciclovir cannot pass through the plasma membrane, it accumulates within the cell, resulting in enhanced anticancer activity. The untransduced neighboring cells are also killed by the so-called bystander effect. The underlying mechanisms are not fully understood.

Another prodrug-activating system involves the use of the fungal or bacterial gene encoding the enzyme cytosine deaminase. Cytosine deaminase, which is not found in mammalian cells, converts the antifungal drug 5-fluorocytosine (5-FC) into the anticancer drug 5-fluorouracil (5-FU) through deamination. The transfer of the cytosine deaminase gene into mammalian cells renders them selectively sensitive to 5-FC. A bystander effect has also been observed in this system: Released 5-FU can diffuse to nearby tumor cells and pass through their cell membranes.

A third prodrug-activating system involves a bacterial nitroreductase that catalyzes CB1954 reduction, thus generating a 4-hydroxylamine metabolite. This molecule then reacts with thioesters, such as acetyl CoA, to produce a highly cytotoxic difunctional alkylating agent capable of cross-linking DNA and 10,000 times more cytotoxic than its parental prodrug (77). Again, a bystander effect for CB1954 when activated by nitroreductase has been reported. Unlike *HSV-tk*, however, the anticancer activity of the CB1954 nitroreductase system does not require cells to be in S phase, thus suggesting that this prodrug may be used to eliminate nondividing neoplastic cells.

Intratumoral implantation of murine fibroblasts that express the *HSV-tk* gene was done in 15 patients with progressive growth of recurrent malignant brain tumors (78). Gene transfer was limited but some antitumor activity was noted in five patients.

Tumor Suppressors and Antioncogenes

So far, *p53* is the most extensively tested tumor suppressor gene used for cancer gene therapy, both in research and clinic. The *p53* gene is the most frequently mutated gene in human cancers (63,79), and its absence or inactivation of wild-type *p53* may contribute

to malignant transformation. Theoretically, then, replacement of a functional copy of the tumor suppressor gene in cells with a homozygous loss of function could restore normal growth and proliferation pathways. The need to correct all genetic lesions in every malignant cell with a gene-based drug may seem daunting, especially given that no currently available technique can deliver a therapeutic gene or its product to all tumor cells; however, studies undertaken in our laboratory and subsequently by others have shown that it may not be necessary to reverse all the genetic changes in a cancer cell to have a therapeutic effect. Indeed, the restoration of wild-type *p53* expression in cells with mutant or deleted *p53* is sufficient to cause apoptosis or growth arrest despite the presence of multiple genetic abnormalities present in such cells (19). Moreover, other studies have shown that the presence of a wild-type *p53* gene may sensitize tumor cells to chemotherapy and radiation therapy (80). For instance, one study demonstrated that introducing the wild-type *p53* gene could enhance tumor cell sensitivity to cisplatin and other agents (18).

Besides *p53*, other tumor suppressor genes are being rapidly added to the list of candidate genes for cancer gene therapy. The genes most frequently abnormal in terms of mutations or absence of expression include genes regulating the cell cycle, tumor suppressor genes, and oncogenes (Fig. 20.4-1). Among them are the retinoblastoma *(RB)*, von Hippel-Lindau, breast cancer *(BRCA1)*, mutated in multiple advanced cancers 1/phosphatase and tensin homologue *(MMAC1/PTEN), p16, E2F,* and fragile histidine triad *(FHIT)* genes. Clinical trials with *BRCA1* and *RB* have already been initiated. Although the classification of *E2F* and *FHIT* as tumor suppressor genes remains controversial, *in vitro* and *in vivo* studies have demonstrated that they cause apoptosis of tumor cells and inhibit tumor growth after their adenovirus-mediated transfer into tumor cells (81,82 and 83). However, introducing *FHIT* gene to cultured normal human bronchial epithelial cells did not induce apoptosis (83).
FIGURE 20.4-1. Molecular pathways in oncogenesis. This figure shows the interrelationships between tumor suppressor genes, oncogenes, and other genes regulating cell-cycle progression and apoptosis. These genes and their pathways represent potentially important targets for gene replacement strategies.

While research into restoring the functions of tumor suppressor genes continues, so does fervent research into inactivating activated oncogenes. Three members of the ras family of oncogenes—H-*ras*, K-*ras*, and N-*ras*— are among the most commonly activated oncogenes in human cancers and thus excellent therapeutic targets. The *RAS* genes encode a protein with GTPase activity that localizes to the inner surface of the plasma membrane. A single mutation in the genes is sufficient to render the gene product transforming. Several strategies have been designed to combat these gain-of-function mutations, including ones using antisense nucleotides, ribozymes (84,85), and intracellular single-chain antibodies (86). *In vivo* gene therapy with K-*ras*, c-*fos*, and c-*myc* antisense nucleotides and a single-chain antibody to erbB-2 are currently under clinical trials (58).

Clinical Studies with Tumor Suppressor Gene p53

Local control of the primary tumor is an under appreciated problem in oncology. For example, up to one-third of patients with non-small cell lung cancer (NSCLC) die only from progression of the local tumor, and in patients undergoing radiation therapy, local control is achieved less than 20% of the time (87). Furthermore, improved local control has translated into improved survival (88).

Intratumoral injection has been most widely studied with viral vectors expressing the wild-type *p53* gene. In our initial human study, nine patients with NSCLC received a retroviral vector containing the wild-type *p53* gene under the control of a beta-actin promoter (15). All patients had failed other treatments and had tumors documented as having a *p53* mutation. Because transduction via retrovirus was known to yield low titers of the transduced gene, the vector was injected into the tumor on 5 consecutive days, using either a bronchoscope or, in the case of chest wall lesions, percutaneous needle.

Regression of the injected lesion was seen in three patients, whereas stabilization of disease was seen in three others (Fig. 20.4-2). In one patient who died of a progressive kidney metastasis, no evidence of viable tumor at the treated site was found on autopsy 4 months after injection. One patient had progressive primary disease, and two were inevaluable (one was intolerant of the general anesthetic and did not complete treatment, and one died within 3 weeks of treatment). Polymerase chain reaction (PCR), *in situ* hybridization studies, or both of posttreatment biopsies before evaluation of treatment effects from eight patients showed that tumor cells had indeed integrated vector DNA sequences, in up to 20% of cells in certain areas of tumor. An important finding was that terminal deoxynucleotidyltransferase-mediated dUTP-biotin nick end labeling (TUNEL) staining (which detects DNA nicking and therefore indicates apoptosis) of posttreatment biopsy samples increased after treatment, compared with the pretreatment baseline.
FIGURE 20.4-2. Pretreatment *(top, bottom left)* and 30-day posttreatment *(top, bottom right)* bronchoscopic images of patients 1 *(top left, right)* and 5 *(bottom left, right).* The lesion is situated in the left mainstem bronchus on the division of the upper and lower lobes; biopsies showed squamous cell carcinoma *(arrowheads; top left).* Left mainstem bronchus 30 days after ITRp53A injection; five independent biopsies showed absence of viable tumor cells *(top right).* Adenocarcinoma obstructing the right upper lobe orifice *(bottom left).* Right upper lobe orifice *(arrowheads; bottom right)* 30 days after treatment; biopsies in this region showed residual adenocarcinoma.

No side effects attributable to the *p53*-vector sequences occurred in any patient, although bronchoscopy-related complications occurred in three patients. We found no evidence of retroviral sequences in DNA extracted from lymphocytes, sputum samples, or various nontumor tissues obtained at autopsy on three patients. These results thus confirmed a high safety profile, successful delivery of normal *p53* sequences to tumor cells, and a biologic effect of the transduced gene.

These promising results have been supported by a two-arm study in which a wild-type *p53* gene was given to 52 patients with NSCLC, using an adenovirus vector. Patients received adenovirus *p53* (Ad-*p53*) either alone or preceded by cisplatin (CDDP) (80 mg per m^2 over 2 hours, 3 days before *p53* injection). (CDDP was chosen because of the preclinical studies that had shown a synergistic effect with *p53* gene replacement.) *p53* treatment was given as a single intratumoral injection, either bronchoscopically or under computed tomographic guidance, once per month for up to 6 months. Most patients had received previous chemotherapy, in some cases with cisplatin, and all had progressive tumor growth on conventional therapy before entry into the study.

As with the study using the retroviral vector, both clinical and laboratory evidence of *p53* expression was seen. Ad-*p53* alone (26 evaluable patients) mediated two partial responses and stabilization of disease in 16 patients (Fig. 20.4-3). Progression-free survival was increased with a higher dose of Ad-*p53*. Ad-*p53*/CDDP (23 evaluable patients) mediated a partial response in two patients previously treated with CDDP. One additional patient achieved a partial response but did not have the required follow-up documentation to confirm the response. Progression-free survival was prolonged with Ad-*p53*/CDDP as compared to Ad-*p53* alone. A majority of patients also had evidence of vector DNA by vector-specific PCR of posttreatment biopsies. DNA extracted from 18 of 21 evaluable tumors from patients receiving Ad-*p53* alone showed vector-specific adenoviral sequences. All tested tumors above 10^6 plaque-forming units (PFU) showed evidence of adenoviral sequences by DNA-PCR. Vector-specific mRNA *p53* sequences were detected by reverse transcriptase-PCR in 12 of 26 specimens with adequate RNA. *p53* transgene expression was noted in nine of 16 patients (56%) treated at doses above 10^9 PFU as opposed to only three of 10 patients (30%) treated with 10^9 PFU or less. Transgene expression of *p53* occurred after initial and subsequent treatments at all dose levels above 10^6 PFU. The mean pretreatment apoptotic index was 3.6 ± 1.0% (mean ± SEM) with 95% confidence intervals of 1.5% to 5.8% for patients receiving Ad-*p53* alone. Eleven of 24 evaluable patients fell outside the 95% confidence intervals with apoptotic indices of 7% to 87% in posttreatment tumor biopsies. No consistent change in inflammatory cell infiltration was seen after Ad-*p53* treatment in posttreatment tumor biopsies, suggesting that nonspecific inflammation or immune-mediated effects were not responsible for the antitumor effects noted.
FIGURE 20.4-3. Pretreatment (A), 1 month posttreatment (B), 8 months posttreatment (C), and 16 months posttreatment (D) computed tomographic scans of patient after six courses of 10^9 plaque-forming units of adenovirus *p53* (Ad-*p53*). A: Recurrent left upper lobe adenocarcinoma *(white arrow)*, which progressed after 66 Gy of external beam radiation therapy and six courses of Taxol/carboplatin. B: Tumor regression *(white arrow)* after one course of Ad-*p53* treatment. C: Tumor regression *(white arrow)* after six courses of Ad-*p53* gene therapy. D: Stable tumor *(white arrow)* 18 months after beginning treatment with Ad-*p53*. No viable tumor was demonstrated during the last 4 months of therapy (14 sequential percutaneous biopsies), and the patient was observed off all treatment for 12 months without evidence of tumor progression. (Reprinted with permission from Swisher SG, Roth JA, Nemunaitis J, et al. Adenoviral-mediated *p53* gene transfer in advanced non-small cell lung cancer. *J Natl Cancer Inst* 1999;91:763-771.)

Although antiadenovirus antibodies were detected in all patients after one treatment, subsequent treatments were not accompanied by anaphylaxis or other toxicities except transient fever. Perhaps surprising, despite high levels of serum antiadenovirus antibody, *p53* transgene expression occurred in the tumor cells and clinical responses were maintained. Of 12 patients receiving endobronchial injections with an obstructed airway, six showed opening of the airway. Vector-related adverse

events were minimal. No grade 4 toxicity was seen, and grade 3 vector-related toxicity was limited to one incident of nausea after Ad-*p53* injection. Toxicity related to CDDP was not increased when Ad-*p53* was added.

Even though these studies corrected only one of the many genetic abnormalities present in NSCLC, the evidence suggests an antitumor effect based directly on *p53*-mediated apoptosis, as shown in both the retroviral *p53* and Ad-*p53* trials. The two trials provided no evidence for the contrary view that tumor stabilization and regression resulted from a nonspecific immune reaction. In the adenovirus-*p53* study, vector DNA was detected by PCR in the majority of patients, but fewer patients showed evidence of gene expression. Detection of gene expression after transfer of wild-type *p53 in vivo* is difficult because successful transfer and expression of wild-type *p53* in a tumor may destroy evidence of gene expression if apoptosis is induced and the cells die. However, in those patients in whom serial gene expression could be quantitated by immunohistochemistry, it was clear that expression of the transgene occurred despite the presence of high titers of antiadenovirus antibody. It is possible that serum antibodies have little effect because of poor penetration into solid tumors, as a result of high interstitial fluid pressure. It is not known whether suppression of the antiadenovirus immune response would further enhance the levels of transgene expression in the tumor. In any case, repeated intratumoral injections of Ad-*p53* appear safe despite increases in antiadenovirus antibodies.

Similar results were observed in 33 patients with incurable recurrent local or regionally metastatic head and neck squamous cell carcinoma receiving intratumoral injections with or without tumor resection (75). In 17 patients evaluable for response, two showed tumor regression greater than 50%, six showed stable disease for up to 3.5 months, and one resectable patient had a complete response. There was no dose-limiting toxicity up to 10^{11} PFU, and no serious adverse events occurred.

Clinical trials reported in abstract form have confirmed the safety and efficacy of Ad-*p53* gene replacement for recurrent ovarian carcinoma (89). A total of 37 women who had received an average of 12 pretreatment chemotherapy cycles (range, 5 to 37) were treated with intraperitoneal doses of Ad-*p53* ranging from 7.5×10^{10} to 7.5×10^{13} particles as a single dose for 5 consecutive days. Reduction in CA125 levels were observed in over half of the patients.

Proapoptotic and Cytotoxic Genes

The importance of apoptosis in tumorigenesis and antitumor therapy has been recognized. Emerging evidence suggests that many antitumor therapies function by inducing apoptosis in tumor cells (90,91 and 92). Because they vary in their susceptibility to apoptosis induction, tumor cells may respond to chemotherapy or radiation therapy by undergoing apoptosis, whereas normal cells merely undergo cell-cycle arrest. This important difference provides a therapeutic window of opportunity. A major mode of cellular resistance to antitumor therapy may be insensitivity to apoptosis induction (90,93,94).

Genes involved in apoptotic pathways have been reviewed (91,92,95). In addition, strategies using tumor suppressor genes and antioncogenes have similarly been used to manipulate genes involved in the apoptotic pathway to elicit antitumor effects directly or to sensitize tumor cells to other therapeutics. For example, introducing the gene for Fas or Fas ligand or for a single-chain antibody to Bcl-2 resulted in tumor cell killing or tumor regression in animal models (96,97 and 98). Accumulating evidence also suggests that the status of *BAX* gene expression correlates with clinical outcomes of cancer patients (99,100,101,102,103,104,105 and 106). More recently, it has been shown that overexpression of *BAX* reduces efflux and therefore enhances the intracellular accumulation of the chemotherapeutic agent paclitaxel (104). Nevertheless, constructing viral vectors that express highly apoptosis-inducing genes may prove difficult because of the potential toxic effect on packaging cells. As mentioned above, this problem can be solved by using the *GAL4* gene regulatory system, and adenovirus-mediated gene codelivery.

Genes That Alter Malignant Behaviors

The penetration of basement membranes by malignant cells is the critical event in tumor invasion and metastasis. It is known that cellular protease (e.g., metalloproteinases and serine proteases) activities must be elevated for tumor cells to cross the basement membrane and subsequently metastasize. Therefore, proteins that inhibit these proteases' activities (e.g., the tissue inhibitor of metalloproteinase, plasminogen activator inhibitors, and serpins) may be used as therapeutic agents for cancer treatment (107,108). Proteins involved in cell-cell or cell-extracellular matrix adhesion [e.g., immunoglobulins, integrins, cadherins, selectins, and hyaluronic acid receptors and their ligands (e.g., CD44)] have been found to be involved in the metastatic process [extensively reviewed in Guenthert and Birchmeier (109)]. They can also be the targets of cancer gene therapy, as the metastatic process can be disrupted by manipulation of these molecules. For example, the urokinase-type plasminogen activator receptor (u-PAR) on the surface of tumor cells binds to u-PA released from surrounding cells. This u-PAR/u-PA complex focuses proteolytic activity onto the tumor cell surface by converting the plasma protein plasminogen into the serine protease plasmin. In addition, overexpression of u-PAR in breast cancer cells results in increased tumor invasion and metastasis (110). The use of an adenoviral vector expressing antisense u-PAR sequences for cancer gene therapy is currently under testing in experimental tumor models.

Genes Targeted to the Immune System

It has long been believed that tumor cells themselves contain specific antigens. Thus, the immune system should be able to detect and eliminate malignant cells in the body. However, in many cases, tumor-specific antigens are too weak to elicit a helper T-cell response or a cellular cytotoxic response, and immune anergy ensues. Moreover, in the majority of malignancies aroused in immunocompetent hosts, tumor cells have devised stratagems to escape immune surveillance. Transforming growth factor β1, for example, is secreted by several tumor types and has immunosuppressive properties (111). Low or absent expression of class I major histocompatibility complex (MHC) molecules may lead to inadequate presentation of antigens on tumor cells (112,113 and 114).

Consequently, for several decades, great effort has been directed toward developing a strategy of cancer immunotherapy and testing various immunomodulatory agents for their ability to increase immune responses against malignancies. It is now known that to elicit an anticancer immune response requires three synergistic components: (a) tumor antigens bound with HLA molecules for presentation to the immune system, (b) costimulatory signals for efficient antigen presentation, and (c) cytokines or growth factors for the recruitment and proliferation of tumor-reactive lymphocytes. Therefore, genes that encode various cytokines, costimulatory molecules, allogenic antigens, and tumor-associated antigens are currently being intensively tested for their ability to augment tumor-specific immune responses (115,116 and 117). It is foreseeable that the identification of tumor rejection antigens and the characterization of the critical components of the afferent and efferent limbs of the immune response that are defective in cancer patients will remain important topics of research (118,119,120 and 121).

At present, most protocols of cancer immune gene therapy involve the delivery of genes directly into tumor cells, although the introduction of genes into lymphocytes or antigen-presenting cells (APCs), mainly dendritic cells, is also being tested. The rationale for intratumoral delivery of cytokines, costimulatory molecules, and antigens is that local delivery of the cytokines will limit their systemic toxicity and that tumor cells may function as APCs if costimulatory molecules are present in them (122,123). New insights into the molecular biology of antigen processing and presentation have revealed that dendritic cells play a critical role in the induction of primary, cell-mediated immune responses (124,125 and 126). Moreover, T-cell priming can occur only in the context of MHC-peptide complexes expressed by host APCs but not by immunized tumor cells (127). However, antigen can be transferred from cells expressing the antigen to the APCs, a process triggered by inflammatory reactions that cause the degradation and release of antigen from the dying cells. This process is called *cross-priming* or *indirect presentation.* Cytokines or costimulatory molecules delivered to tumor cells are believed to enhance the transfer of tumor antigens to APCs. Thus, *ex vivo* gene delivery to cultured autologous APCs such as dendritic cells or direct *in vivo* gene delivery to APCs may be more efficient in stimulating cellular antitumor immunity (125,126). Despite these promising approaches, however, a variety of important issues remain to be addressed, including the

heterogeneity of tumor cells, the alteration of the biologic properties or gene expression in metastatic versus parental tumor cells, and the suppressed expression in tumor cells of MHC molecules essential for their recognition by the immune system.

Introduction of a gene encoding a foreign class I major histocompatibility protein can trigger an immune response to the foreign antigen. This in turn can generate a cytolytic T-cell response against nontransduced tumor cells by increasing the local immune response. In one clinical trial, the *HLA-B7* gene in DNA-liposome complexes was injected to the tumors of melanoma patients who were *HLA-B7* negative. Recombinant HLA-B7 protein was shown in tumor biopsies from all five patients. Immune responses to *HLA-B7* and autologous tumors were detected. An increase in the frequency of *HLA-B7*-reactive cytotoxic lymphocytes was detected after treatment. Tumor-specific cytotoxic lymphocytes were detected in posttreatment lymphocytes originating either from peripheral blood or the tumor. One of five patients showed regression of injected and uninjected nodules (128).

Genes Targeted to Tumor Vasculature

Depriving tumor cells of nutrients by blocking or reducing the blood flow to tumors has already been explored in experimental tumor models and achieved by direct occlusion of the tumor vasculature or by inhibition of angiogenesis in tumors (129,130). Therapeutic approaches that target the tumor vasculature rather than the tumor cells themselves hold great promise for a broad spectrum of and high capacity for antitumor activity. Such approaches, while damaging only a single vessel, might kill millions of tumor cells.

Angiogenesis, a complex process involving cell-cell and cell-matrix interactions, is essential for the growth and metastasis of solid tumors. This process is strictly controlled by a redundant system of pro- and antiangiogenic paracrine peptide molecules [reviewed by Fan et al. (131), Norrby (132), Augustin (130)]. The balance between these positive and negative regulators of angiogenesis in the local tumor environment is important for the homeostasis of microvessels. It is now known that tumor cells can secrete proangiogenic paracrine factors and thus stimulate endothelial cells to form new blood vessels.

Of the more than 20 proangiogenesis peptides identified so far, VEGF and placenta growth factor have been shown to directly influence the behavior of endothelial cells. VEGF is also abundantly secreted by tumor cells, and its expression is upregulated by hypoxia, a microenvironmental condition that exists preferentially in solid tumors. Cellular *p53* status and c-src activity also influence VEGF expression (133,134). Introducing the wild-type *p53* gene into tumor cells suppressed VEGF expression and inhibited angiogenesis in experimental tumors (135), whereas using antisense or soluble receptor molecules to block the functions of VEGF and other angiogenic factors reportedly suppressed tumor growth in animal models (136,137).

Genes encoding antiangiogenesis peptides have also been used to suppress angiogenesis in tumors. Of these, the IL-12 gene has already entered clinical trials. A potent immune system modulator, IL-12 also significantly inhibits angiogenesis and upregulates the expression of E-cadherin, a metastasis suppressor. Other angiogenic inhibitors that have shown therapeutic promise are angiostatin and endostatin (138,139 and 140). For instance, introducing angiostatin complementary DNA into tumors established in mice inhibits angiogenesis, tumor growth, and metastasis in certain animal tumor models.

Genes Targeted to Normal Cells

Systemic chemotherapy is currently one of the most effective and widely used forms of antitumor treatment. Its efficacy is limited, however, by the destructive effects that can be inflicted on normal tissues before doses sufficient to achieve efficient tumor killing are reached. Indeed, this acute toxicity most often manifests itself as myelosuppression. Autologous bone marrow replacement has been successfully used to combat this acute hemopoietic toxicity. However, as autologous bone marrow replacement is used more and more, the frequency of therapy-related malignancies will probably also rise because of the presence of malignant cells in the transplants.

Alternatively, hematopoietic stem cells and early progenitors can be protected by augmenting their resistance to the toxic and mutagenic effects of antitumor agents. This may be accomplished by transferring appropriate drug-resistance genes into hematopoietic cells *ex vivo* and then transplanting the cells back into the patient. Thus far, drug-resistance genes have been tested for their ability to protect normal cells from the toxic effects of conventional doses of chemotherapy. The first such study attempted to enhance marrow protection during chemotherapy by transferring the multiple-drug resistance gene *MDR1* into normal bone marrow and blood-derived stem cells (141,142). Other genes that have been tested for the same purpose include the DNA repair protein *O*-methylguanidine-DNA-methyltransferase, which protects hematopoietic cells from nitrosourea-induced toxicity (143), and methotrexate-resistant dihydrofolate reductase, which protects against methotrexate toxicity (144).

There are, however, at least two problems with this strategy of drug resistance. First, the current technology is limited to bone marrow only, so the toxic effects in unprotected nonhematologic cells may limit the dose of chemotherapy. Second, the cancer cells in bone marrow may be transduced with the drug-resistance gene, resulting in a drug-resistant relapsed tumor. Thus, to avoid the transduction of malignant cells, hemopoietic stem cells are isolated by CD34 column fractionation before they are treated with a drug-resistant vector.

Antisense Oligodeoxynucleotides

Irina Lebedeva

C. A. Stein

Introduction

Part of "20.5 - Antisense Oligodeoxynucleotides "

A major problem with the use of cytotoxic and biologic agents in the treatment of human cancer is the lack of specificity. Many systemic targets other than those critical to the growth and reproduction of the malignant cell may be attacked during the clinical course of treatment; this inevitably leads to systemic toxicity to the patient, and in turn leads to a diminution in drug dose, dose intensity, and therapeutic efficacy.

It is the idea of specificity of treatment that provides the impetus to use antisense oligonucleotides as therapeutic agents. In one of several possible antisense approaches, the idea of specificity is embodied in the ability of messenger RNA (mRNA) to bind to its complement via Watson-Crick base pair formation. In theory, if the protein that results from the translation of any mRNA is necessary for cellular growth and division and if the translation of that mRNA into protein can be blocked, then cellular reproduction can also be blocked (Fig. 20.5-1). (It should be noted that the selection of mRNA that is necessary changes over time. What was thought necessary in the early 1990s is now perhaps not entirely so because of a greater appreciation of the redundancy of intracellular pathways.) It had been long postulated that one way to inhibit translation of mRNA into protein would be to anneal to it a short, sequence-complementary oligodeoxynucleotide (oligo) (1). It was believed, and may well be true in some cases, that the resulting mRNA-DNA hybrid would then be impervious to ribosomal read-through; this oligo would thus cause cessation of protein synthesis. Because, by convention, the mRNA strand is the sense strand, the oligo is known as the *antisense strand.* Because an oligo of more than 15 to 17 nucleotides in length would have a unique sequence relative to the entire human genome, absolute specificity would, in theory, be assured. These were the assumptions that directed antisense research over the past 15 years. This research has, indeed, led to several human clinical therapeutic trials and the approval by the U.S. Food and Drug Administration of the antisense oligonucleotide fomivirsen, which is active in the treatment of cytomegalovirus retinitis (2). Many other trials have not been successful, which cannot be too surprising given the novelty of this technology.
FIGURE 20.5-1. A schematic representation of the basis of antisense oligodeoxynucleotide-mediated inhibition of gene expression. The flow of genetic information in untreated cells (A) is from DNA to RNA to protein. When the cells are treated with oligodeoxynucleotides complementary to a specific messenger RNA (B), the oligodeoxynucleotides hybridize to messenger RNA and cause inhibition of protein synthesis. In theory, the size and the sequence of the oligodeoxynucleotide exert specificity. [From Sharma HW, Narayanan R. The therapeutic potential of antisense oligonucleotides. *Bioessays* 1995;17(12):1055–1063, with permission.]

Some of the first antisense experiments were performed by Stevenson and Zamecnik (3,4) who manually synthesized a series of phosphodiester oligomers complementary to the terminal reiterated sequences of the Rous sarcoma virus mRNA. They found that reverse transcriptase activity was drastically decreased in the supernatants of infected chick embryo fibroblast cells, but lack of a convenient synthetic method made further work difficult. Soon thereafter, a major advance in oligo synthetic chemistry was made by Caruthers (5) and his coworkers, who developed the phosphoramidite method of oligonucleotide synthesis. The method made possible the synthesis of oligonucleotides of virtually any length with only ˜1% product loss during each coupling step of monomer to the growing chain. Automation quickly followed, leading to several generations of so-called gene machines. These machines have made oligo synthesis almost routine for many laboratories; their industrial counterparts are capable of synthesizing grams of material at a time.

Over the past 15 years, a large amount of effort has gone into solving problems resulting from certain structural features of DNA. The simplest class of oligonucleotide that can be synthesized contains a phosphodiester linkage at each phosphorus atom, and is called *normal* or *phosphodiester DNA.* A major problem with the use of this type of oligonucleotide is that ubiquitous intra- and extracellular nucleases rapidly and completely digest them. Digestion appears to occur predominantly from the 3" to 5" direction (6), although endonuclease digestion (at internal sites) probably occurs in at least some human tumor cell lines. Digestion may be vitiated by heat inactivation of the serum at 65°C but not eliminated. Also, it should be remembered that the concentration of an n-mer oligo on a per base basis is n times the molar concentration of the oligo. Complete digestion of a phosphodiester oligomer, therefore, yields large quantities of nucleotide monophosphates that may have significant biologic activity, as has been pointed out by Vaerman et al. (7). For example, deoxyadenosine monophosphate, a product of phosphodiester oligonucleotide digestion, can be transformed into dATP. This molecule can inhibit ribonucleotide reductase, which is necessary to synthesize deoxyribonucleotides from ribonucleotides. Additionally, deoxyadenosine triphosphate can form a complex with the proteins Apaf-1 and procaspase

9 (8), which appears to initiate the intracellular apoptotic process. Control oligonucleotides without the same proportions of bases may produce entirely different results. Therefore, molecules that contain only phosphodiester linkages cannot be used as antisense oligomers.

Since 1980, significant effort has been expended to develop nuclease-resistant oligonucleotides. Spearheading these efforts were P. Miller and P. Ts'o at Johns Hopkins, who synthesized methylphosphonate oligonucleotides (9,10), and W. Stec and G. Zon (11), who, based on earlier work of F. Eckstein and colleagues (12), synthesized phosphorothioate oligonucleotides. In the methylphosphonate oligonucleotide, a methyl group replaces one of the nonbridging oxygen atoms at phosphorus. If a methylphosphonate linkage is placed at each phosphorus, the result is nuclease indigestibility but also net loss of the negative charge. These uncharged methylphosphonate oligonucleotides are significantly less soluble than their charged congeners, which may result in formulation difficulties with some methylphosphonate oligonucleotides and the need for using high concentrations (>50 µM) to achieve biologic effects. Methylphosphonate oligonucleotides have been shown to block translation of a mutated Ha-ras allele in transformed NIH 3T3 fibroblasts without affecting the wild-type allele (13), but there have been relatively few other successful antisense experiments published using methylphosphonate oligonucleotides at the time of this writing. This may be due to one serious drawback to the tissue culture or *in vivo* applications of methylphosphonate oligonucleotides and to uncharged oligomers in general. Methylphosphonate oligonucleotides and other nonanionic antisense oligonucleotides, such as peptide nucleic acids, do not act as substrates for ribonuclease (RNase) H activity.

As of this writing, RNase H activity appears to be the major driving force behind what is experimentally observed as antisense inhibition of protein translation. The enzyme is ubiquitous; its function is to cleave the RNA strand of an mRNA-DNA duplex. The oligomer can then dissociate from the cleaved message and interact with another uncleaved target, in effect making antisense oligonucleotides catalytic. Although this hypothesis is attractive and probably true, it has never been rigorously proven to be so in mammalian cells. If true, though, it would seem to indicate that the antisense effect must take place in the nucleus, because that is where the majority of the RNase H activity is located. Evidence that tends to support this view is that in the absence of oligonucleotide carriers (e.g., cationic lipids, polyamines), nuclear localization of fluorescent oligomer does not occur, and neither does antisense activity (except perhaps under certain circumstances.

RNase H does not require 100% complementarity of oligo with mRNA to cleave the mRNA strand. In fact, it is generally believed that only a six-base region of complementarity may be necessary (14). This fact creates an unusual set of counterintuitive problems. It is accepted that the higher the melting temperature of the DNA-mRNA duplex, the more likely that translation will be inhibited. However, if increased Tm is obtained by lengthening the oligomer, the phenomenon of irrelevant cleavage appears. *Irrelevant cleavage* refers to the RNase H cleavage (14,15) of nontargeted duplexes and is due to the minimal cleavage requirements of RNase H. Thus, if a six-base region of complementarity is all that is required for cleavage, then the longer the antisense oligonucleotide, the more six-base motifs are contained within it, and thus the more cleavage of nontargeted mRNAs bearing that motif theoretically occur. However, if the oligomer is too short, the Tm may be too low for optimal hybridization. Each of these difficulties seems to be minimized at a length of approximately 18- to 20-mer, which appears to be the optimum length for an antisense oligonucleotide.

We have encountered irrelevant cleavage in some of our recent studies on the antisense oligonucleotide inhibition of protein kinase C-α (PKC-α) protein expression (16). The earliest work with these oligonucleotides was performed by Dean and colleagues (17), who evaluated two 20-mer phosphorothioate oligomers, Isis 3521 and Isis 3522. The former is targeted to the 3" UTR of the mRNA and the latter to the initiation codon region. In our work (16), PKC-α, but not PKC-α, -ß1, -δ, or -ε protein, and mRNA expression were more than 80% (n = 13) inhibited by both. However, Isis 3521 also inhibited (>90%) PKC-ζ protein and mRNA expression, which Isis 3522 did not. This may be accounted for by irrelevant cleavage, as there is an 11-base contiguous complementarity between Isis 3521 and the PKC-ζ mRNA, but only a four-base complementarity between it and Isis 3522 (Fig. 20.5-2). Similarly, we have identified several antisense oligonucleotides that target the bcl-xL mRNA in prostate cancer cells that also, presumably because of complementarity and irrelevant cleavage, eliminate bcl-2 protein expression as well. These oligonucleotides are modified at the C5 position of each pyrimidine in the molecule by a propyne residue, which dramatically increases the Tm of the DNA-mRNA (18,19) and hence irrelevant cleavage as well. Such molecules may find clinical application, because it is difficult to believe that downregulation of only a single intracellular target, given the redundancy in intracellular pathways, is sufficient to kill a single cell, much less a collection of the heterogeneous cancer cells typically found in patients. In fact, in the experiments described, synchronous downregulation of bcl-xL and bcl-2 does inhibit cellular proliferation

to some extent, but does not lead to extensive apoptosis. However, the prostate cancer cells do become sensitized to the proapoptotic effects of several chemotherapeutic agents, including paclitaxel (Taxol), mitoxantrone, and etoposide.
FIGURE 20.5-2. Regulation of protein kinase C (PKC) isoform expression by complexes of phosphorothioate oligonucleotides with tetra meso(4-methylpyridyl)porphine (TMP) in the T24 bladder-carcinoma cell line. The phosphorothioate oligonucleotide ISIS 3521 directed against the PKC-α messenger RNA (mRNA) causes irrelevant cleavage of the PKC-ζ mRNA. Western blots of total protein lysate stained with the corresponding monoclonal antibodies are shown. (MAb, monoclonal antibodies, mRNA, messenger RNA.) (From Benimetskaya L, Takle O, Vilenchik M, et al. Cellular delivery of antisense oligodeoxynucleotides by a novel cationic porphyrin vehicle. *Nucleic Acids Res* 1998;26:5310-5317, with permission.)

Perhaps the most important modification made to generate nuclease-resistant oligo substitutes a sulfur atom for a nonbridging oxygen atom at each phosphorus, producing a phosphorothioate oligo. The use of these molecules as antisense agents has been reviewed several times (20,21). The substitution retains the net charge and the property of aqueous solubility, but phosphorothioate oligonucleotides hybridize with their complementary mRNAs with lower Tm relative to phosphodiester oligonucleotides. Phosphorothioate oligonucleotides are nuclease resistant both *in vitro* (22) and *in vivo* (23), but in fact can be slowly digested. The rate of digestion seems to be dependent on sequence (phosphorothioate and phosphodiester linkages 5" to purines are stable), and on the stereochemistry at phosphorus. [The oligonucleotide phosphorothioate-linkage is chiral (i.e., has the property of handedness). The two enantiomers are named Rp and Sp. The Rp stereoisomer is digested as rapidly as a phosphodiester linkage, whereas the Sp linkage is digested more slowly.] Intracellular digestion can lead to the release of nucleotide monophosphorothioates, which may also be growth inhibitory in some cell lines. In other lines, these molecules may actually be growth stimulatory, with SdG monophosphorothioate being perhaps the most active (24). However, evidence demonstrating that this set of events actually occurs *in vivo* is currently lacking. Phosphorothioate oligonucleotides may act as substrates for RNase H activity when hybridized to their complement, but they can also bind to human RNase H in a nonsequence-specific manner and can competitively inhibit the binding of the enzyme to its DNA-mRNA substrate (25). This type of behavior implies that there may only be a narrow intracellular concentration range in which phosphorothioate oligonucleotides are active antisense agents in at least some human cells.

Several other types of oligonucleotides are nuclease resistant and may act as antisense agents (Fig. 20.5-3). Oligoribonucleotides, when modified at the 2"-O position on the ribose moiety with a methyl or other alkyl group, become nuclease resistant and may be useful as antisense agents. They also dramatically increase the Tm of the mRNA-DNA duplex although they are not substrates for RNase H activity (26). They are finding use now as a member of novel chimeric oligonucleotides (27,28), which contain a central core of phosphorothioate linkages to preserve RNase H activity flanked at the 3" and 5" termini by 2"-O-methylribonucleotides to block nuclease digestion and increase Tm. This strategy also probably increases irrelevant cleavage. The phosphate backbones may be removed entirely and replaced with polyamide structures to which the nitrogenous bases are linked (29). These so-called peptide nucleic acids (PNAs) hybridize extremely well to their targets, but are not highly soluble in physiologic saline, are not internalized well by cells, and are in general not useful as antisense oligonucleotides. Many efforts are underway to attempt to expand the range of utility of PNAs to take advantage of their duplex-stabilizing ability, mostly by incorporating them into chimeric oligomers.
FIGURE 20.5-3. Modifications of antisense oligonucleotides: (a) an unmodified 5"-TpC-3" dimer; (b) phosphorothioate linkage; (c) N3"-P5" phosphoroamidate linkage; (d) peptide nucleic acid linkage; (e) 2"-O-propyl ribose; (f) 2"-methylethoxy ribose; (g) C-5 propynyl U; (h) C-5 thiazole U; (i) C-5 propynyl C; (j) phenoxazine C. (From Wagner RW. The state of art in antisense research. *Nat Med* 1995;1:1116-1118, with permission.)

Oligonucleotides may also be useful in the targeting of individual cellular genes at the DNA level. This is because a polypyrimidine oligo can bind in the major groove of the DNA to form a triple helix. Binding of the oligo to the double helix is a consequence of so-called Hoogsteen base pairing and is stable in the presence of divalent cations for CG...C and TA...T triplets. *In vivo* transcription of the interleukin-2a receptor (30) and of c-myc (31) by targeting of the genomic promoter region has been thus accomplished by the use of triplex-forming phosphodiester oligonucleotides in what has been termed *antigene therapy.* Imaginative variants of the triple helix approach, using the formation of regions of contiguous triplex helix and duplex formation by a single mRNA-targeted phosphodiester oligo or hairpin oligonucleotides forming triple helices with single-strand regions of mRNA, have also been proposed, but at the present time little *in vivo* data is available for evaluation.

Interpretation of Data: The Problem of Nonsequence Specificity

Part of "20.5 - Antisense Oligodeoxynucleotides "

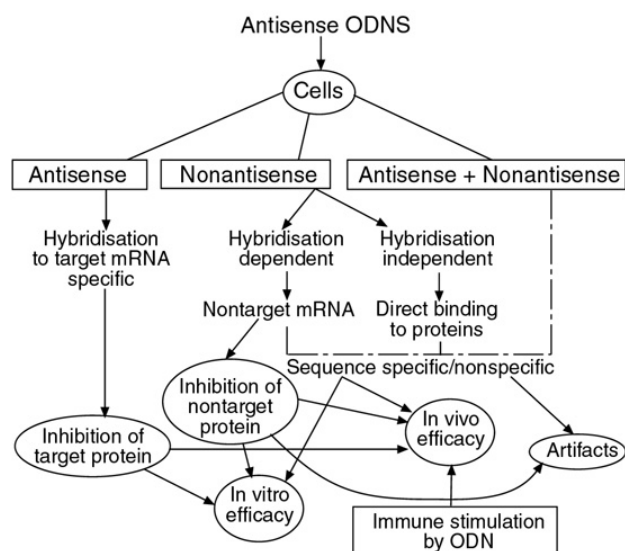
It is not possible to interpret literature data in which antisense effects are purportedly documented without an understanding of the effects of the oligo, which confound this antisense interpretation (Fig. 20.5-4). This is especially true of phosphorothioate oligonucleotides, for which nonsequence specificity is a major problem.


FIGURE 20.5-4. A current view of the mechanisms of action of antisense oligodeoxynucleotides (ODNs). Antisense ODN action is complex and involves multiple mechanisms. Multiple controls are needed to rule nonsequence specificity of an ODN. Nonspecific components can mimic specific effects in biologic assays, making interpretation difficult. It is highly likely that specific and nonspecific components coexist in any given antisense ODN experiment. (mRNA, messenger RNA.) (From Sharma HW, Narayanan R. The therapeutic potential of antisense oligonucleotides *Bioessays* 1995;17(12):1055–1063, with permission.)

This nonsequence specific inhibitory activity highlights one of the most significant problems with the use of chemically modified oligonucleotides. This activity, due to the polyanionic backbone of the oligo, is particularly pronounced for phosphorothioate oligonucleotides. This is reflected in the fact that the binding of a phosphorothioate oligo to a protein usually occurs with a dissociation constant (K_d) that is one to three orders of magnitude lower than that of the isosequential phosphodiester oligo. These values of K_d can lie in the low nanomolar range (32,33) and may approach the affinity of the oligo-bound protein for its natural ligand, whereupon a nonspecific biologic effect of the phosphorothioate oligo can be observed. Such nonsequence specificity of the phosphorothioates has resulted in dose-limiting clinical toxicity in several trials.

It appears that the high-affinity protein binding of phosphorothioate oligomers is specific for heparin-binding proteins (34,35), and in that sense, these antisense oligonucleotides are heparin-mimetics. Nanomolar affinity binding can be observed for basic fibroblast growth factor and other members of the fibroblast growth factor family. Binding can also easily be observed to the proangiogenic vascular endothelial growth factor (VEGF); to platelet-derived growth factor; and to a wide variety of other heparin-binding proteins, including CD4 (32), laminin, and fibronectin [thus dramatically affecting cellular adhesion (36)], Mac-1 (CD11b/CD18), both α and β subunits (37), and to heparin-binding proteins that are cell-surface receptors, including epidermal growth factor receptor (EGFR) (but not EGF, which is not heparin binding), and the VEGF receptor flk-1 (38). The interaction of phosphorothioates with heparin-binding proteins appears to be completely independent of stereochemistry at phosphorus (39). Binding to EGFR (38), however, has curious biologic consequences; the binding of the cognate ligand EGF is inhibited and receptor phosphorylation blocked by phosphorothioate oligonucleotides in a length- and concentration-dependent manner. On the other hand, in the absence of the cognate ligand, receptor autophosphorylation is stimulated. Observations of this kind point out the potential difficulties in data interpretation if cells are treated with naked oligonucleotide (i.e., without a carrier) at high concentration (>10-20 µm). Under these conditions, the biologic activity of phosphorothioate oligonucleotides exclusive of Watson-Crick hybridization is so extensive that the cellular context in which any event is observed cannot be the same as in the untreated cell.

Interpretation of Results: The G-Quartet Problem

Part of "20.5 - Antisense Oligodeoxynucleotides "

It has been shown that certain sequence motifs are overrepresented in reports of oligonucleotides that produce antisense effects (40). These include the GG, GGG, and GGC motifs, which are present at a frequency of 9.9%, 3.4%, and 3.1%, respectively, in a series of successful antisense oligonucleotides. Some sequence motifs occurring at a low frequency in mRNA are found more often in antisense oligonucleotides. For example, the sequence GACG, with an overall frequency of occurrence in mRNA of 0.41%, is present in 10% of 206 evaluated antisense oligonucleotides.

Another sequence motif that appears rather frequently is four contiguous guanosine residues. The trouble arises because this motif has a tendency to form higher order structures; in one

such structure, four individual strands interact to form a tetraplex (41,42). (Thus, DNA can exist in single-stranded, duplex, triplex, and tetraplex forms.) The tetraplex is held together by Hoogsteen base-pair formation between guanosine residues, and the cavity formed has a high affinity for and is stabilized by monovalent cations, although they are not absolutely required for tetraplex formation. Other higher order structures, such as duplexes, can also be formed by Hoogsteen base-pair formation between two identical strands or between nonidentical strands that contain the G-quartet motif. Furthermore, no rules at present define the orientation of the strands in either a duplex or tetraplex. In the latter, for example, all strands may be parallel, or three may be parallel and one antiparallel, or two may be parallel and two antiparallel, etc., leading to a bewildering variety of compounds that all may potentially be in equilibrium with each other in solution. Additionally, the ability of any G-tetrad containing oligo to form tetraplexes depends to some extent on the flanking sequences, but even more so on its position within the molecule. G-tetrads found at or near (probably within three to four bases of) either the 3" or 5" molecular termini can form extremely stable tetraplexes that occasionally can dissociate under strenuous conditions (43). Such species can easily be observed on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) slab gels because they migrate slowly in an electric current. When the four contiguous G are in the center of the molecule, however, tetraplexes may form that dissociate in slab gels but can still be observed by their characteristic migration via capillary gel electrophoresis (44). This is what is observed with the antisense c-myc codon 2–9 18-mer phosphorothioate oligo that has been used in several studies since 1988.

A problem with the use of this type of molecule is that a sense control would not contain four contiguous G, but a four contiguous C residue, which does not have the same ability to form higher order species as the four contiguous Gs. Furthermore, scrambled sequences are not controls if the integrity of the G-quartet is not maintained, or if the four contiguous Gs are not placed in the same position in the control as in the antisense molecule. To further complicate the picture, tetraplexes appear to have increased nonsequence specificity versus the single-stranded form, probably related, at least in part, to charge density (43).

The net effect of all of these caveats is to make the use of four contiguous Gs containing oligonucleotides for antisense purposes problematic and not recommended. In 1997, we performed a series of experiments to show that, depending on the target, such oligonucleotides may mimic antisense activity but are actually related solely to the presence of higher-order structures, such as duplexes and tetraplexes (43). The target was one of the proteins composing the nuclear transcriptional regulatory factor nuclear factor kappa B, p65, or RelA. A 20-mer phosphorothioate oligo at 20 μm had been shown to downregulate RelA protein expression in a variety of cell types both in tissue culture and in xenografted tumors (45). However, this oligo contained the sequence 5" GAGGGG...., which was shown to form stable tetraplexes and other less well-defined higher-order structures. The ability of the monomer to form tetraplexes was eliminated by the substitution of 7-deazaguanosine for guanosine at a single position in the G-tetrad. This blocks Hoogsteen base-pair formation while only minimally decreasing (0.5˚C) the Tm of Watson-Crick duplex. This substituted molecule does not produce antisense activity, suggesting that what was observed with the original molecule was not due to antisense at all but rather due to a nonspecific effect of the tetraplex. Because of problems of this type, and the fact that commonly used techniques such as SDS-PAGE may erroneously not identify tetraplexes or other higher-order structures, it is probably best not to use molecules containing this motif in any antisense experiments.

Interpretation of Results: The Numbers Paradox

Part of "20.5 - Antisense Oligodeoxynucleotides "

An additional seldom-spoken paradox further adds to the quandaries of interpretation of literature-derived data (46). As demonstrated in carefully constructed studies, it has been the almost universal observation that for every eight or so oligomers tested against any one particular target, only one is active. In fact, the ratio of one success in eight tested seems to be the best such attained; 1 success in 12 or, or even 1 in 15 seems to be more common. Tu et al. (47) culled 2,026 reports of successful antisense inhibition from the biomedical literature. Data include:

1. 1,655 (81.7%) citations tested one antisense oligonucleotide only
2. An additional 248 (12.2%) tested two or three
3. Another 81 (3.9%) evaluated from four to nine
4. Only 42 (2.1%) examined more than 10

Thus, 93.9% of the experiments were successful using less than three tested oligonucleotides (and the great majority used only one), when detailed studies by scientists experienced in the field have conclusively shown that at the best only one in eight antisense oligonucleotides (12.5%) is successful. (Success often meant cell death. Phosphorothioates can produce cell death by many mechanisms.) This could mean that the published literature represents a selection bias—that, in fact, perhaps eight times more than 1,655 (equaling 13,240) unique oligomers were evaluated, the literature reporting only the 12.5% positive results. This may in part account for the discrepancy, but it cannot be the only explanation, because certain sequence motifs are highly overrepresented in this group of successful experiments. The other possibility is that some, if not many, of the 1,655 citations do not represent an antisense observation, but combinations of antisense plus nonsequence specificity, or antisense plus cytotoxicity (which may promote antisense efficacy by promoting endosomal leakage of sequestered oligomer), coupled in some cases with G-quartet effects. But without in-depth evaluation, it may be difficult to sort all this out in any given paper after the passage of some years.

None of the preceding discussion should imply that obtaining antisense results is not possible. It assuredly is possible (at least within certain confidence intervals), but doing so requires that certain rules be followed, as in any other area of science. Given here are a series of such rules that we have derived empirically

from our own work and that of countless others over the past decade. We believe that if closely adhered to, they provide a good chance that almost any target can be downregulated by an antisense approach. This does not mean that the level of the target is the only level altered by treatment with antisense oligonucleotides, and in that sense we doubt very much that anything approaching absolute specificity exists. However, this point may or may not be of significance depending on the outcome desired by the experimentalist. Over the past several years, the antisense biotechnology field has significantly progressed in its understanding of how to conduct meaningful experiments that do not conflate an antisense effect and non-sequence-specific behavior g. An initial set of guidelines were published in 1994 (49) but have not been updated to reflect experience.

Antisense Rules: Guidelines To Experimental Design

1. At the present time, the best and most readily commercially available oligonucleotides have the phosphorothioate backbone (see 2). Do not use unprotected phosphodiesters, as the mononucleotide products of enzymatic digestion may cause problems (e.g., inhibition of cellular growth). dG-methylphosphonate may be the most toxic, at least in some cases. Obtain the oligomers from a reputable manufacturer. Never store oligonucleotides in water. The pH of such a solution falls in an acidic urban environment, leading to depurination and strand cleavage. Instead, they should be stored between pH 7.5 and 8.0 in buffer, such as tris-ethylenediaminetetraacetic acid, at -20°C (although they survive almost indefinitely at 4°C).

2. Nonsequence specificity must be minimized. The lower the concentration of oligonucleotide used in the experiment, the better. Phosphorothioate 3" and 5" endcapped oligomers (three phosphorothioates per terminus, the remainder of the linkages' phosphodiester) preserve RNase H activity and diminish sulfur content, and thus nonsequence specificity. C5-propyne substitution at one or more pyrimidine residues in the oligomer, or 2"-O-methyl-RNA substitution may increase Tm and potentiate the antisense effect. Use these judiciously, however, as irrelevant cleavage also probably increases, and the C5-propyne residues may be toxic, especially *in vivo.*

3. To find an active oligomer, randomly generate a panel of 30-40 oligomers by walking along mRNA. For every eight to ten oligonucleotides tested, probably just one is active. (This can be an expensive way of doing things, but at the moment, there is little other choice. However, it is possible that the TCCC motif may promote activity because RNase H prefers purine cleavage site mRNA.) mRNA-folding programs are not predictive of active molecules and have little or no value in selecting target sites because they cannot account for local, critical microenvironments at the mRNA level. The other oligomers that are not active can be thought of as controls for the backbone. The more control oligomers used, the more likely that an observed effect represents true antisense.

4. Demonstrate inhibition of the target protein by Western blotting and of the mRNA by Northern blotting or by reverse transcriptase-polymerase chain reaction. However, it is possible that some antisense activity can occur via steric blockade (28), and thus mRNA levels do not change. This is especially true for 2"-O-methyloligoribonucleotides, which are not substrates for RNase H activity. However, for deoxyribonucleotide oligomers that are all-phosphorothioate, or chimerics (also known as *gap-mer*) containing either phosphorothioate or phosphodiester linkages or both, the general consensus is that target mRNA levels should decrease in the presence of an active antisense oligonucleotide because of RNase-H activity.

Question of Appropriate Controls

5. A sense-oligomer control is not necessary, and a total random-mer (mixture of bases at each position) is not an appropriate control. The other oligonucleotides that are active can be used to determine specificity by examining their effects on proteins that are related to the target (e.g., one with an approximately equal half-life that is in the same family). Do not use actin as a control protein if your target has a half-life of only a few hours. The evaluation of the expression of other genes with significant sequence homology may be important to evaluate the extent of irrelevant cleavage. Remember, the more control oligomers tested, the more assurance that the result is specific (arbitrary minimum of two). The use of oligonucleotides with two different backbones, each producing the identical antisense effect, is usually convincing. An additional control is to attempt to antisense knockout your gene in an over-expressing line. If the cells are rescued from the antisense effect, your case is strengthened, but still not proved.

6. Another useful control is to introduce the target gene with one or more mutations in the region complementary to the antisense molecule. Lack of inhibition suggests a true antisense effect, but does not prove it if the rate of transcription and hence the copy number of the mRNA is high. An additional control is to clone your gene in the antisense orientation into an expression vector. Successful suppression of translation of the transfected gene, with the identical biologic activity as seen with the antisense oligomers, is always convincing. Because of high-order mRNA structure, however, the antisense strand may not be able to invade the sense strand, and the method may fail.

Cellular Delivery of Antisense Oligonucleotides

7. Do not treat cells with naked phosphorothioate oligonucleotides, although exceptions to this rule may exist. As mentioned, phosphorothioates are highly nonspecifically active at the cell membrane, with concentrations as low as 2 μm causing defined effects.

8. Deliver oligonucleotides with a carrier. Many are commercially available, including Lipofectin, LipofectACE, Cytofectin (serum stable), Starburst dendrimers of many generations, cationic porphyrins, and others. Remember that antisense may be caused by the summation of effects of the carrier plus the oligomer, as the carriers dissociate from the oligomer intracellularly. You must optimize the molar ratios and concentrations for each carrier and cell line, and probably oligomer sequence as well.

And Watch Out for…

9. When possible, avoid active oligomers with the CpG motif. Depending on the sequence context, they can be highly immune stimulating (50). This can be a problem in xenograft models (if it is your eventual plan to use them) because of immune-mediated graft rejection. However, methylation at C5 of cytidine eliminates immune stimulation.

10. Do not treat cells with oligonucleotides containing G-quartets until verified by capillary gel-electrophoresis that higher-order structures are not present in solution.

11. Finally, do not attempt to correlate an observed biologic effect with antisense efficacy (e.g., do not say that an antisense effect is causative of inhibition of proliferation or cell death, as especially the phosphorothioates are intrinsically too biologically active. Rather, demonstrate downregulation of protein expression by Western blotting and target mRNA levels by Northern blot, and make no other claims.

12. These rules are subject to change and augmentation as the field advances.

Cellular Uptake of Antisense Oligodeoxynucleotides

Part of "20.5 - Antisense Oligodeoxynucleotides "

The success of oligonucleotides as antisense agents depends on their efficient delivery to the cytoplasm and the nucleus. Phosphorothioate oligonucleotides are taken up by a wide range of cells *in vitro* (51). In many cases, internalization is a calcium-dependent process (52) and is slowed by metabolic inhibitors, such as deoxyglucose, cytochalasin B, and sodium azide (53). Oligonucleotide internalization in tissue culture depends predominantly on the two processes of adsorptive endocytosis and fluid-phase endocytosis (pinocytosis). The adsorptive process has two components; initial binding to the cell surface and internalization (33,53). Supporting the importance of adsorptive endocytosis is the fact that oligonucleotides that adsorb well to the cell surface (e.g., phosphodiesters and phosphorothioates) tend to be internalized to a much higher degree than those that do not (methylphosphonates and peptide nucleic acids) (54). Uptake is also influenced by temperature, cell type, cell culture conditions, media, sequence (to a small extent), and length of the oligonucleotide (55). The existence of an oligonucleotide receptor mediating active transport has been postulated (51,53), but a purified or cloned receptor protein, or both, is still not available to date, except for Mac-1, which has been shown to be an oligonucleotide-binding and -internalization protein in human polymorphonuclear leukocytes (37). The predominant mechanism of uptake is concentration dependent: At an oligomer concentration less than 1 μm, uptake occurs by the relatively efficient process of adsorptive endocytosis (56,57). Uptake occurring via fluid-phase endocytosis is less efficient at higher oligonucleotide concentrations.

Regardless of the mechanism of the uptake, the bulk of the internalized oligomer is trapped, at least initially, in an intracellular vesicle (54). However, this compartment is useless for antisense activity. Here, antisense oligonucleotides are sequestered from their ultimate targets in the nucleus and cytoplasm and are directly exposed to degradative enzymes. If oligonucleotides can escape from the endosomal/lysosomal compartment into cytoplasm, it appears they are rapidly translocated to the nucleus (58).

Delivery Facilitated by Carriers

Enhanced delivery of oligodeoxynucleotides to cells has been achieved by linking them to hydrophobic moieties, such as peptides (59,60 and 61), cholesterol (62), or poly-L-lysine. The targeted transfer of antisense oligonucleotides can also be achieved by using small synthetic peptides that are specific to cellular receptors (63). Additionally, sugar moieties, such as lactose or mannose, can be bound to the polycation poly-L-lysine, forming complexes that can bind to sugar receptors expressed on various target cells (64,65). Covalent linking of hydrophobic molecules to the 3"-position of the oligomer decreases degradation by nucleases and increases intracellular internalization, probably by an interaction between the complex and the cell membrane (66,67). However, the hydrophobic groups may dramatically reduce the melting temperature of the hybrid of oligonucleotide with its target mRNA and may interfere with the intracellular distribution of the oligonucleotide conjugate. Linkers susceptible to cleavage by intracellular internalization have been designed and include disulfide and carboxyester bonds [e.g., acyloxyalkyl esters of phosphorothioate oligodeoxynucleotides (68) and S-alkyl-phosphorothioates (69)].

Delivery by Cationic Lipids and Liposomes

Encapsulation of oligonucleotides into liposomes has been used to increase their delivery across membranes (70). Liposomes are spheric structures consisting of multiple phospholipid bilayers. They are arranged to create hydrophobic layers alternating with hydrophilic layers or can consist of a single phospholipid bilayer encasing an aqueous core. Antisense sequences can either be partitioned into the hydrophobic layers [if a hydrophobic moiety such as cholesterol is conjugated to the oligonucleotide (71)] or be dissolved in the aqueous layers. Additionally, the lipid protects the oligonucleotide from serum or lysosomal nucleases. Liposomes can be targeted by attached antibodies to specific cell surface markers (72).

Alternatively, cationic lipids such as Lipofectin or Cytofectin are frequently used as delivery vectors. This class of transfection agents contains positively charged amine groups that interact directly with the negatively charged phosphate residues of the oligonucleotide. These complexes result in efficient delivery to the cytoplasm and nucleus, presumably via destabilization of endosomal membranes (73,74 and 75). Attempts have been made to modify the lipids by adding ligands of such cellular receptors as folate, providing a targeted delivery to tumor cells (76,77). Other modifications include the use of peptide or protein residues, and antibodies directed against antigens expressed on the target cells (78,79 and 80). However, one disadvantage of the use of cationic lipids is that significant cellular toxicity of the oligonucleotide-lipid complex has been observed.

Another approach is the delivery of oligonucleotides adsorbed to polyalkylcyanoacrylate (81,82), methylmethacrylate (83), or polynanoparticles (D-, L-lactose) (84). However,

cyanoacrylate-based nanoparticles have significant cytotoxicity. Some improvement in toxicity has been achieved using novel polymers, such as methylmethacrylate. Water-soluble macromolecular carrier systems, such as polyamine-poly(ethylene glycol) copolymers (85) and N-(2-hydroxypropyl)methacrylamide polymer (86) have shown great potential for oligonucleotide delivery. They exhibit little or no binding to cell surfaces, little immunogenicity, and are captured by cells via fluid-phase endocytosis. Cationic porphyrins (16,87), and Starburst dendrimers (88) are also efficient for oligonucleotide delivery in tissue culture.

Our ability to specifically inhibit gene expression in tissue culture has dramatically increased because there are several approaches available for the exogenous delivery of oligonucleotides. However, oligonucleotide delivery *in vivo* may not require them. In animal studies, several provocative reports have suggested that oligodeoxynucleotides can penetrate cells in at least some tissues in the absence of cationic lipids (89,90 and 91). More recently, though, these results too have been called into question (92).

Clinical Trials of Antisense Oligonucleotides in Cancer

Part of "20.5 - Antisense Oligodeoxynucleotides "

Despite mechanistic questions and delivery issues, there have been definite successes in antisense technology. Problems have existed with the interpretation of earlier results, and nonantisense effects of oligodeoxynucleotides continue to emerge. However, convincing demonstrations of specific antisense effects have been achieved using highly controlled assays. The first Investigational New Drug application for an antisense oligonucleotide was filed with the U.S. Food and Drug Administration in late 1991 (92). Since that time, antisense oligonucleotides complementary to selected targets, such as *c-Myc* (93), *c-Myb* (94), *c-Raf* (95), PKC-α (96), prekallikrein activator (97,98), *H-ras* (26,99), and bcl-2 (100,111), have been studied extensively in *in vitro* and *in vivo* models and are currently being evaluated in human clinical trials. All antisense oligonucleotides in human clinical trials are phosphorothioates except for that targeting prekallirein activator, which is a mixed-backbone oligonucleotide (phosphorothioate oligodeoxynucleotide containing regions of 2"-O-methyloligoribonucleotides).

Preclinical and Clinical Toxicology

The animal pharmacokinetics and toxicology of the phosphorothioates appear to be a result of the chemical structure of the oligonucleotides and not the specific antisense sequence (101,102 and 103). To date, pharmacokinetic and toxicologic data obtained in animals are surprisingly similar among phosphorothioates of widely differing sequences directed against disparate gene products g. Phosphorothioates appear to be distributed predominantly to liver, kidney, spleen, and lymph nodes, with lesser amounts being found in heart, pancreas, lungs, bone marrow, and virtually none in the central nervous system (105,106 and 107). The elimination half-life of phosphorothioates from tissue compartments may be two- to threefold longer than that found in the plasma, which is 24 to 72 hours (108).

A major toxicity of the phosphorothioates is due to oligonucleotide activation of complement (109). Other problems include their binding to thrombin resulting in a transient coagulopathy. Additionally, the immunostimulatory effects of DNA (bacterial DNA and phosphorothioate oligonucleotides containing the CpG motif are mitogenic to lymphocytes and stimulate cytokine release) should be appreciated (50). These effects are dependent not only on the CpG motif, but on the flanking sequences as well. When optimized, sufficient immunostimulation can be observed in rodents to warrant developing these molecules as vaccine adjuvants.

An antiproliferative effect may require continued exposure to the antisense drug; therefore, antisense drugs might have to be administered orally for maximum effect. However, the compounds presently in trial are not orally bioavailable due to their size, charge, and acid lability.

Therapeutic Applications

Because the ultimate effect of antisense oligonucleotides on the time to disease progression, the time to metastasis, or survival may require months or years to determine, in some cases the evolution of these agents may depend on the measurement of pharmacokinetic, molecular, or biologic end points (110). This has been accomplished with varying degrees of success in the experiments described in the following paragraphs (Table 20.5-1).

Table 20.5-1 Ongoing Clinical Trials (1998) Using Antisense Oligonucleotides (Oligos) in Oncologic Therapeutics

Gene Target	Name of the Oligo	Sponsor	Backbone	Size	Disease/Trial Phase	Method of Delivery	Reference
Bcl-2	G3139	Genta and Memorial Sloan-Kettering Cancer Center	PS	18-mer	Non-Hodgkin's lymphoma/phase 1	Systemic, s.c.	118
					Prostate cancer/phase 1-2a		119
c-myb	LR-3001	A. Gewirtz and Lynx	PS	24-mer	CML/phase 1	Systemic, i.v.	124
					AML/phase 1-2	*Ex vivo* purging of bone marrow	125
bcr-abl	—	Lynx	PS	26-mer	CML advanced phase/pilot	*Ex vivo* purging of bone marrow	133,134
p53 exon	OL(1)p53	J. Armitage and Lynx	PS	20-mer	AML and myelodysplastic syndrome/phase 1	Systemic, i.v.	135 138
						Ex vivo purging of bone marrow and peripheral blood stem cells	
PKC-α	CGP64128A (ISIS 3521)	ISIS/Novartis	PS	20-mer	Variety of solid tumors (ovarian, prostate, breast, brain, colon, lung) and melanoma phase 1-2a	Systemic, i.v.	142,143 and 144
PKA-1	GEM 231	Hybridon	PS with 2"-O-Me modifications of a backbone	18-mer	Refractory solid tumors/phase 1	Systemic, i.v.	99
c-raf kinase	CGP69846A (ISIS 5132)	ISIS/Novartis	PS	20-mer	Variety of solid tumors (ovarian, prostate, breast, pancreas, colon, lung)/phase 1-2	Systemic, i.v.	146,147
Ha-ras	ISIS 2503	ISIS	PS	20-mer	Variety of solid tumors/phase 1	Systemic, i.v.	100

AML, acute monocytic leukemia; CML, chronic myelogenous leukemia; PKA-1, protein kinase A, type 1; PKC-α, protein kinase C-α.

The bcl-2 proto-oncogene is derived from t(14;18) chromosomal translocation (111). Overproduction of bcl-2 protein is seen in one-half or more of human malignancies and has been suggested to be a poor prognostic marker in some cases (112). Increased bcl-2 expression is also known to inhibit apoptosis and to be associated with resistance to multiple chemotherapeutic agents in both cell culture and tumors *in vivo* (113).

Several groups have explored the antitumor activity *in vitro* of oligonucleotides directed against bcl-2 (114,115). G3139, an 18-mer phosphorothioate oligonucleotide directed against the first six codons of the human bcl-2 mRNA, significantly reduced bcl-2 protein expression and cell viability of DoHH2 lymphoma cells. G3139 was administered to severe combined immunodeficiency disease (SCID)-hu mice inoculated with lymphoma xenografts (116). Disease-free survival in treated mice appeared to be related to dose and to the duration of the infusion. G3139 doses of 1, 5, and 10 mg per kg, cured 0%, 50%, and 100% of the mice, respectively.

The preliminary results of a clinical trial G3139 have been published. Nine patients with bcl-2-positive, relapsed, stage-IV non-Hodgkin's lymphoma were treated in the United Kingdom (117). The phosphorothioate oligonucleotide was tolerated in doses up to 73.6 mg per m^2 per day. The authors found that in some treated patients, antisense therapy led to an improvement in symptoms. In two patients, this was accompanied by biochemical and computed transaxial tomography scan evidence of tumor response. In two patients, the number of circulating lymphoma cells decreased during treatment. Bcl-2 protein levels in lymphocyte and bone marrow samples were measured in five patients and

decreased in two. It is possible that at higher doses or with more prolonged administration a more significant molecular response would be seen. In preparation for potential clinical trials in patients with hematologic and solid tumors, the National Cancer Institute is evaluating the combination of G3139 and cytotoxic agents in preclinical systems to improve the activity of the antisense agent (118). However, it is still unclear if the sequence of G3139 is optimal. Based on other *in vitro* studies, a bcl-2–directed phosphorothioate oligonucleotide of different sequence demonstrated higher efficiency in assays of viability in a small-cell lung cancer cell line (119).

Downregulation of the c-myb proto-oncogene with antisense oligonucleotides has been shown to be efficient *in vitro* and *in vivo* (120). However, the data also indicate that some of the results of the inhibition of cellular proliferation by the *c-myb*-directed oligonucleotide are not sequence specific (121,122). A phosphorothioate oligonucleotide targeting the *c-myb* gene was evaluated as a marrow-purging agent for different groups of nine and 18 chronic- or accelerated-phase patients with chronic myelogenous leukemia (CML) or other refractory leukemias (123,124). The clinical benefits of treatment were uncertain, although some patients demonstrated marked, sustained, hematologic improvement with virtual normalization of their blood counts. The toxicity of the oligonucleotide treatment was minimal.

The BCR-ABL fusion gene is found in CML (125). The bcr-abl transcript provides a tumor-specific target potentially susceptible to suppression by antisense oligonucleotides. Inhibition of the growth of antisense-treated leukemic cells was observed in several experiments (126). A 26-mer phosphorothioate oligonucleotide directed against the b2a2 breakpoint junction of the bcr-abl transcript completely inhibited the growth of a Philadelphia chromosome-positive cell line, BV173 (127,128). Treatment with this oligonucleotide also increased duration of life of SCID mice implanted with BV173 cells. However, it is possible that the observed inhibition was due to nonsequence specific interactions (129,130), as the oligonucleotides failed to reduce cellular bcr-abl protein levels (131).

A phosphorothioate oligonucleotide specific for the b2a2 junction has been used for the *in vitro* purging of bone marrow cells. A patient with CML was engrafted with the purged marrow cells and was reported to be in a complete hematologic remission at 9 months posttreatment (132). In another group of patients treated with bcr-abl antisense oligodeoxynucleotides, hematopoietic reconstitution of reinfused cells with low toxicity was observed (133). However, Kirkland et al. have investigated

purging strategies with phosphodiester and phosphorothioate oligomers and have been unable to show specific inhibition of CML chronic phase progenitors (126). Although effective antisense strategies might be developed, perhaps by combining antisense with other purging agents such as mafosfamide, trials of single-agent antisense purging with BCR-ABL oligomers may be premature in light of the currently available data.

A phase 1 trial using an antisense oligonucleotide [(OL(1)p53) targeted to p53 in 16 patients with refractory acute myeloid leukemia] produced no responses, but treatment-related toxicities attributed to the oligonucleotide were minimal (134). The results of this study are difficult to interpret because in eight patients the p53 status was unknown and was wild type in seven of the other eight. Because p53 can be a proapoptotic protein and its elimination may lead to cell proliferation, the rationale for this trial was unclear (135). It is also possible that the suppression of p53 expression by OL(1)p53, as observed in tissue culture, can be explained by the nonspecific, nonantisense, antiproliferative activity of this molecule (107,136). In further experiments, transplantation of autologous bone marrow cells treated with OL(1)p53 resulted in successful recovery of circulating neutrophils after high-dose therapy in patients with acute myelogenous leukemia or myelodysplastic syndrome (137).

Another promising molecular target for inhibitors of protein phosphorylation is represented by the PKC gene family. PKC is a family of serine-threonine kinases that include at least 11 distinct isozymes and regulate a variety of cellular responses, including proliferation, differentiation, and apoptosis (138). Existing inhibitors of PKC either lack selectivity for the enzyme or demonstrate PKC selectivity but lack isoform specificity. The antisense approach offers an opportunity to circumvent these problems and to knock out target gene expression by a highly selective and sequence-specific mechanism. CGP 64128A (ISIS 3521) is a 20-mer phosphorothioate oligodeoxynucleotide targeted against the 3"-UTR of human PKC-α that specifically inhibits the expression of human PKC-α mRNA and protein m (IC_{50} of 150 nm) in human cancer cells (139,140). Most important, CGP 64128A has been demonstrated to be a true isoform-specific inhibitor of PKC-α (140). GSP 64128A caused partial regression of a pelvic mass in a patient with ovarian cancer and stabilization of a rising carcinoembryonic antigen in a patient with colon cancer in a phase 1 trial (141,142). All observed side effects were believed to represent nonspecific phosphorothioate class effects, and no toxic events attributable to sequence-specific effects have been observed in human trials. No molecular correlations of drug action were presented in a published abstract. Currently, ISIS 3521 is in phase 2 clinical trial as an antitumor agent (143).

The raf proto-oncogene encodes a serine-threonine kinase that is activated by the *ras-* protein as part of the mitogen-activated protein-kinase signaling cascade (144). Mutations of *ras* or *raf* genes that result in their constitutive activation have been identified and elevated. Aberrant expression of these gene products has been reported in many human tumors. Monia et al. screened 34 phosphorothioate oligonucleotides against the human c-*raf* mRNA and found a potent sequence-specific inhibitor of c-*raf* mRNA expression *in vitro* and *in vivo* (91). This oligonucleotide, ISIS 5132 (also known as *CGP 69846A*), entered phase 1 clinical trials for solid tumors in early 1996: It is administered as a 2-hour infusion three times weekly or as a 21-day continuous infusion (145,146). However, it has been suggested that the use of c-*raf*-1 antisense oligodeoxynucleotides could be limited by their toxicity to normal cells, as c-*raf*-1 is a critical component for cellular proliferation and differentiation. Despite this potential problem, preliminary results using an antisense oligodeoxynucleotide complementary to murine c-*raf*-1 failed to show any oligodeoxynucleotide-associated toxicities in normal mice, suggesting that oligodeoxynucleotides might be preferentially effective in tumors. It is also possible that other members of the *raf* family might compensate for c-*Raf*-1 activity in normal cells.

Antisense oligonucleotide ISIS 2503 demonstrated potent and specific activity against Ha-ras mRNA, but had no effect on the expression of K-ras or G3PDH in a variety of cell lines (147). On the basis of its isoform selectivity and antitumor activity in xenograft models this oligomer also is entering phase 1 clinical trials for the treatment of solid tumors (100).

In the past 5 years, there has been a dramatic increase in the understanding of the ways in which antisense oligonucleotides function. The first antisense drug has been approved for cytomegalovirus retinitis; several more are currently in clinical trials. The most optimal clinical uses for these molecules are unknown, but for best results in a cancer indication it seems likely that they should be used in association with cytotoxic agents. In this context, they undoubtedly are an important addition to the growing armamentarium of anticancer drugs.

Section VI
Principles and Practice of Antiangiogenic Therapy

21

Antiangiogenesis: Basic Principles and Preclinical Models

Michael S. O'Reilly

Introduction

Part of "21 - Antiangiogenesis: Basic Principles and Preclinical Models "

In 1971, Folkman proposed that tumor growth was dependent on angiogenesis based on his studies of tumor growth in isolated perfused organs (1). Historically, the increased vascularity of malignant tissue as compared to normal tissue had been often noted. However, this hyperemia had been assumed to result from the dilation of preexisting host vessels in response to tumor necrosis and metabolic byproducts from the tumor cells. Neovascularization in association with a tumor was merely assumed to be a byproduct of inflammation and was not considered important. Thus, Folkman's proposal that a tumor was dependent on the endothelial cell was widely criticized. However, numerous lines of direct evidence have now clearly established that the growth and expansion of tumors and their metastases is dependent on angiogenesis (2).

Several factors that stimulate angiogenesis have been identified and described (3). These include the fibroblast growth factors (FGFs) such as acidic and basic FGF (aFGF, bFGF) (4), vascular endothelial cell growth factor/vascular permeability factor (VEGF/VPF) (5,6), hepatocyte growth factor/scatter factor (7), transforming growth factor beta (8,9), proliferin (10), erythropoietin (11), and several others. Numerous inhibitors of angiogenesis have also been described, and the discovery and characterization of these inhibitors has become an area of intense focus. Many of the first angiogenesis inhibitors to be described were substances with other functions whose antiangiogenicity were discovered incidentally. Other substances have been developed that are selective angiogenesis inhibitors. More recently, strategies have been developed that have led to the discovery of highly specific inhibitors of angiogenesis.

With the discovery of angiogenic factors, the field of angiogenesis research has grown rapidly, and new applications of angiogenesis have arisen. This chapter identifies some themes that appear to be emerging based on the discovery and characterization of angiogenesis inhibitors.

Angiogenesis Is Regulated by Both Stimulators and Inhibitors

Part of "21 - Antiangiogenesis: Basic Principles and Preclinical Models "

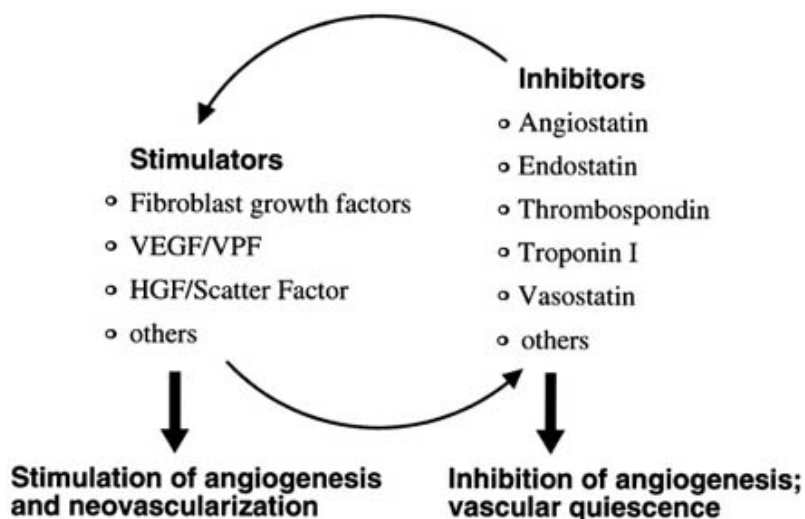
Angiogenesis, the growth of new capillary blood vessels from preexisting vessels, is a fundamental process that is required for a wide variety of physiologic and pathophysiologic processes. Examples of physiologic processes that require angiogenesis include wound healing, tissue repair, reproduction, growth, and development (12). For angiogenesis to occur, an increased production of stimulatory factors and/or a decreased production or generation of inhibitors is necessary. Angiogenesis is therefore regulated by a complex balance (Fig. 21-1) of stimulators and inhibitors (13,14). Endothelial cells are normally quiescent, and years may pass between cell divisions (15). Under physiologic conditions that require neovascularization, angiogenesis is a tightly regulated process, and the balance in favor of stimulation is generally short-lived. However, in malignant angiogenesis the process is sustained and requires the continued production of stimulators by tumor and stromal cells in excess of inhibitors (16,17). Many disease states both arise and are maintained by the persistence of angiogenesis and the loss of normal regulatory mechanisms (17,18). These include cancer; ophthalmologic disorders, such as ocular neovascularization in patients with diabetes or macular degeneration; arthritis and other inflammatory disorders; psoriasis; and many others (17,19). Furthermore, a number of differences between malignant and physiologic angiogenesis are becoming apparent (20). In malignant angiogenesis induced by a cancer, endothelial cells are not returned to their normal state of quiescence, and angiogenic vessels appear markedly disordered relative to their physiologic counterparts (21). Malignant angiogenesis is often characterized by a distorted architecture, the lack of pericytes and other support cells (22), impaired and/or intermittent flow (23,24 and 25), the presence of plasma proteins that function as a neostroma (26,27), and increased permeability (28). Thus, strategies that target angiogenesis have clear clinical implications for a variety of conditions, both neoplastic and nonneoplastic, and the study of angiogenesis helps in the understanding of a number of disease states.


FIGURE 21-1. Angiogenesis is regulated by a balance of stimulators and inhibitors. The capillary endothelial cell is normally maintained in a state of quiescence by a variety of endogenous inhibitors that prevent angiogenesis. However, if factors that stimulate angiogenesis are produced in excess of the inhibitory factors, neovascularization can occur. Under physiologic conditions, this balance is precisely regulated. However, under pathophysiologic conditions, angiogenesis is poorly regulated and disordered due to the continued production of stimulators in excess of the inhibitors. (HGF, human growth factor; VEGF/VPF, vascular endothelial growth factor/vascular permeability factor.)

Before the onset of angiogenesis, tumor growth is limited by perfusion, and preangiogenic tumors remain in an *in situ* stage in which tumor volume is limited to a few cubic millimeters (1,14,29,30). For a tumor to grow beyond this prevascular stage, neovascularization is needed to produce new vessels that are required to perfuse the tumor with nutrients and oxygen and for the removal of metabolic catabolites (Fig. 21-2). However, the endothelial cells also produce a number of paracrine growth factors that are stimulatory for tumor growth (31,32). The tumor

cells also produce or induce the production of factors such as VEGF that prevent apoptosis, induce Bcl-2 expression, and are important for endothelial cell survival (33,34). A tumor's growth is dependent on both its endothelial cells and its malignant cells, each of which produce factors that stimulate the other. Angiogenesis, therefore, provides both a perfusion effect and a paracrine effect to a growing tumor (see Fig. 21-2), and a circuit is established in which tumor cells and endothelial cells continue to drive each other. These observations led Folkman to propose a two-compartment model of malignancy consisting of endothelial cell and tumor cell populations (35).
FIGURE 21-2. The angiogenic response has both a perfusion and a paracrine effect. For a malignancy to grow beyond the size of 1 to 2 mm^3, it must stimulate angiogenesis. The newly formed capillaries provide the growing tumor with nutrients and oxygen and remove catabolites (perfusion effect). For the tumor cell to induce angiogenesis, it must produce and induce factors that can activate the capillary endothelial cell. The activated endothelial cell, in turn, produces a number of paracrine factors that are needed for tumor cell survival. The resultant circuit drives both cell populations (the paracrine effect) and promotes tumor expansion. (EC, endothelial cell.)

Much of the focus of angiogenesis research has centered on the concept that the growth of all solid tumors is dependent on angiogenesis. Neovascularization is critical in the dissemination and progression of both primary and metastatic disease (Fig. 21-3). Leukemia has also been shown to be dependent on angiogenesis (36). As with physiologic angiogenesis, the neovascularization of solid tumors and their metastases is also regulated by the balance of stimulators and inhibitors (see Fig. 21-1). However, tumors require that this imbalance be sustained. The studies of Bouck and her colleagues (37,38) support a model in which the net balance of the stimulators and inhibitors of angiogenesis controls tumor growth. To promote angiogenesis, tumor cells produce a number of stimulatory factors, such as VPF and VEGF, and bFGF and aFGF. However, Bouck and her colleagues have further demonstrated that when hamster cells are transformed to an angiogenic phenotype, they must also downregulate the production of angiogenesis inhibitors during the transition to an angiogenic phenotype. They found that transformed hamster cells upregulate the production of angiogenesis stimulators but must also downregulate the production of thrombospondin, an angiogenesis inhibitor, to form angiogenic lesions. Thrombospondin production is under the regulation of the wild-type p53 tumor-suppressor gene (39).
FIGURE 21-3. Angiogenesis in primary and metastatic tumor growth. Angiogenesis is required for growth of both primary and metastatic tumors. Within a primary tumor, heterogeneity of the angiogenic phenotype may exist, and angiogenesis may initially be limited to distinct regions of the tumor *(black circles)*. As the malignancy of the tumor progresses, angiogenesis and tumor growth and invasion accelerates. Metastatic cells can then escape from the tumor to target organs. Once established, a metastasis must induce angiogenesis to grow *(upper lesion)*. If a metastasis cannot induce angiogenesis in the target tissue, it may persist as a dormant lesion and is limited by perfusion *(lower lesion)*.

Preclinical Models Used in the Evaluation of Angiogenesis Inhibitors

Part of "21 - Antiangiogenesis: Basic Principles and Preclinical Models "

In Vitro Angiogenesis Assays

To prove his hypothesis that tumor growth was dependent on angiogenesis, Folkman developed methods to isolate and grow capillary endothelial cells, which are still in use today (40). Their isolation and characterization allowed the field of angiogenesis to progress and has led to the discovery of a number of inhibitors and stimulators of angiogenesis. The process of angiogenesis requires endothelial cell proliferation, migration, and invasion. Numerous *in vitro* systems that model events critical for angiogenesis *in vivo* using endothelial cells from a variety of species and tissues have been described. Using these assays, compounds can be screened for evidence of angiogenic activity (4,41).

The *in vitro* proliferation of endothelial cells provides a powerful tool for the study of angiogenesis. In our laboratory, we routinely use primary cultures of capillary endothelial cells derived from bovine adrenal tissue. Because angiogenesis typically occurs at the level of the capillary, the use of capillary endothelial cells would seem of more relevance to the study of angiogenesis. However, several groups also study angiogenesis using large vessel endothelial cells derived from human umbilical veins, bovine aorta, and a variety of other sources. Proliferation of endothelial cells can be determined directly by cell count or indirectly by the quantitation of DNA synthesis or mitosis, or

both. Alternatively, the internalization of magnetic microbeads by capillary endothelial cells (42) (the microbead assay) can be used to detect soluble pro- and antiangiogenic factors. If a stimulator of angiogenesis is applied to the cells, the beads are distributed evenly among daughter cells during division. In contrast, the intracellular beads are retained in the presence of inhibitors. Endothelial cell migration is also required for angiogenesis, and a number of migration assays have been developed. Chemokinetic assays that use colloidal gold and chemotactic assays using the modified Boyden chamber have been developed (43). Alternatively, the ability of endothelial cells to grow into a wound made in a monolayer has also been used to assess migration.

Angiogenesis requires multiple coordinated steps, and assays that focus on only one aspect, such as proliferation or migration, may not reflect the whole process. The ability of endothelial cells in culture to form tube-like structures that resemble capillaries has been described as a model of *in vitro* angiogenesis (44). The formation of endothelial tubes or cords allows for the study of angiogenesis in a model that seems to parallel capillary development [reviewed by Montesano (45) and Williams (46)]. For example, endothelial cells form capillary-like structures in type-1 collagen gels (47) that can be dissociated and disrupted by the addition of 16K prolactin (48) or mediated by laminin domains (49). Several different *in vitro* angiogenesis models have been described to assess tube formation in two dimensions on tissue culture plates coated with gelatin or in three dimensions in collagen or fibrin gels (29,47,50,51,52 and 53) or into Matrigel (49). The aortic ring model, in which a circumferential section of a rat aorta is placed in a gel, has also been used and allows for the study of several aspects of angiogenesis (54).

Although useful for the screening of materials for their potential ability to regulate angiogenesis, *in vitro* assays have several limitations. The ability to inhibit endothelial cell proliferation, migration, and tube formation *in vitro* may not reflect the potency of an angiogenesis *in vivo*, and the results obtained in a tube assay may be difficult to interpret. Furthermore, many substances, such as transforming growth factor-beta and tumor necrosis factor-alpha are potent inhibitors of the *in vitro* proliferation of endothelial cells yet stimulate angiogenesis *in vivo* (8,55). Quantitative assays are therefore needed to screen compounds for angiogenic activity. Currently, our laboratory typically uses a variety of *in vitro* assays in combination to characterize angiogenesis inhibitors.

In Vivo Angiogenesis Assays

Chicken Chorioallantoic Membrane Assay

The chicken chorioallantoic membrane (CAM) has been used extensively in the characterization of angiogenic factors (56). Using the CAM assay, some of the first angiogenesis inhibitors, such as protamine (57) and angiostatic steroids (58) were discovered. With the CAM assay, substances can be tested for their ability to regulate spontaneous angiogenesis on the developing 6-day-old CAM or induced angiogenesis on the established 10-day-old CAM. Human angiostatin potently inhibits angiogenesis in the developing CAM, leaving a large avascular zone (Fig. 21-4). Inhibition of angiogenesis on the 6-day-old CAM from human angiostatin was dose-dependent (59). The CAM can also be used to screen for evidence of inflammation or toxicity from the test substance.
FIGURE 21-4. Inhibition of angiogenesis by angiostatin. A: Mouse corneal angiogenesis assay. A pellet (P) containing sucrose octasulfate, Hydron, and basic fibroblast growth factors (80 to 100 ng per pellet) was placed into a corneal micropocket. Mice received subcutaneous injections of human native angiostatin (50 mg per kg) or vehicle every 12 hours starting 48 hours before implantation. In control eyes, neovascularization is evident and vessels have extended into the pellet (P) within 6 days. In contrast, there is a potent inhibition of angiogenesis in mice treated with angiostatin. B: Chick chorioallantoic membrane (CAM) assay. Recombinant mouse angiostatin in a methylcellulose disc was applied to a developing CAM. After 48 hours, a large zone of angiogenesis inhibition that persisted for several days was observed.

One of the limits of the original CAM assay is the lack of quantitation. To allow for more precise quantitation in the CAM assay, Nguyen and her colleagues (60) modified the CAM assay by placing a collagen gel sandwiched between nylon mesh directly onto the developing CAM. The number of vessels into the collagen gel can then be quantitated by counting the number of capillary loops.

In Dr. Folkman's laboratory, the CAM assay typically is used as the first *in vivo* system to test potential angiogenesis inhibitors identified using *in vitro* models. Although it is rare for a substance that does not work in the CAM assay to prove to be

an angiogenesis inhibitor, many substances that inhibit angiogenesis in the CAM assay do not inhibit angiogenesis in more advanced *in vivo* systems. Thus, the CAM assay is used primarily as a first screen in our group.

Disc Angiogenesis Assays

To quantitate angiogenesis in a variety of animal models, techniques have been developed in which a matrix or polymer is injected or implanted, or both, into a test animal. In many cases, a factor that stimulates angiogenesis is added to the disc. Test substances can be added to the disc or the animal can be treated systemically. Several methods have been described, including a polyvinyl alcohol foam surrounded by Millipore filters (61), polyurethane sponges inserted with a pellet containing bFGF or other angiogenesis stimulators (62), gelatin-impregnated sponges, and encapsulated tumor cells.

A tumor-derived extract of basement membrane, called *Matrigel* (63), is liquid at cold temperatures and reconstitutes into a gel when injected into animals. The addition of heparin and angiogenic factors induces angiogenesis *in vivo* that can be quantitated by microvessel count or by hemoglobin content. A variety of inhibitors and stimulators of angiogenesis have been tested in this model using systemic or local delivery.

Corneal Angiogenesis Assays

The cornea is normally avascular and therefore is useful in the study of angiogenesis. Several methods have been developed in which angiogenesis is induced in the cornea. Initially, test tissues, such as a section of tumor, were placed into a corneal micropocket in rabbit (64), rat (65), or mouse (66) eye and tumor-derived angiogenesis stimulators would induce an angiogenic response. More recently, angiogenic factors, such as bFGF or VEGF/VPF, have been placed in sustained-release polymers for implantation into corneal micropockets in the mouse, rat, and rabbit. The mouse corneal assay provides a powerful tool for the screening of angiogenesis inhibitors against a defined angiogenic response (67). Substances can then be screened for the ability to inhibit angiogenesis by adding them to the pellet or by systemic therapy (68). The inhibition of angiogenesis can then be quantitated as a function of the length of the vessels and the circumferential area of the cornea involved. The systemic administration of angiostatin, for example, inhibited angiogenesis

by greater than 90% in a mouse corneal angiogenesis assay using bFGF (see Fig. 21-4A) or VEGF/VPF as a mitogen. In normal mice, new capillary vessels grew from the corneal limbus and across the cornea in response to the sustained-release of bFGF from the pellet within 3 days. Within 6 days of implantation, the new vessels had grown across the cornea and into the pellet. In contrast, in mice treated with angiostatin, there was a virtually complete absence of corneal neovascularization in response to the bFGF pellet.

To provide a more accurate quantitation of angiogenesis in corneal assays, computerized image analysis of the angiogenesis in the cornea has been used to precisely calculate the vessel density.

Primate Model of Ocular Angiogenesis

Rodent models have been used extensively in the study of angiogenesis and allow for substances to be screened for their ability to inhibit angiogenesis by local or systemic administration. However, the use of a primate model offers advantages over the rodent models but is technically more difficult and more costly. A model of iris neovascularization in the monkey that is clinically and histologically similar to human disease was first developed by Virdi and Hayreh (69). The model has since been modified by Miller and her colleagues (70,71) and provides an effective method to screen angiogenesis inhibitors. Using a series of laser bursts directed at the retina of the monkey, the central retinal veins are occluded. Retinal ischemia and hypoxia is produced and results in the expression and production VEGF/VPF that causes both retinal and iris neovascularization within 5 to 10 days of laser treatment (72). The degree of neovascularization can then be assessed by slit-lamp examination and fluorescein angiography. Interferon-α (IFN-α), for example, has been shown to be an inhibitor of angiogenesis in this system (71) and is now being used clinically to treat malignant angiogenesis (73).

Experimental and Spontaneous Metastasis Models

The metastatic process involves multiple steps in which tumors' cells must invade locally, penetrate through stomal tissues and into a vessel wall, enter into the circulation, adhere to the endothelium at a target site, extravasate, and invade into a target tissue. Angiogenesis is critical for the metastatic process to begin and for metastases to grow (74,75) (see Fig. 21-3). To grow, metastatic tumor cells must induce an angiogenic phenotype on the vascular endothelial cells of the tissues they invade. However, metastases that do not induce angiogenesis may persist for prolonged intervals as dormant lesions that cuff preexisting host vessels (O'Reilly et al., *unpublished*). The dependence of the growth of metastases on angiogenesis has led to the development of several assays using experimental, in which tumor cells are delivered to the target organ by intravenous injection, or spontaneous metastases from different tumors.

One model of spontaneous metastatic disease was developed in our laboratory and led to the discovery of angiostatin (59). Metastases of a variant of Lewis lung-carcinoma remain dormant until the primary tumor is removed. Angiogenesis inhibitors can be screened in this system for their ability to prevent the growth of spontaneous metastases.

Tumor Growth on the Chicken Chorioallantoic Membrane

The CAM allows for the growth of a variety of tumors. Typically, 10-day-old embryos in which the CAM is fully developed are used, and tumor fragments or suspensions are implanted. This system has been used extensively in several laboratories for the characterization of antiangiogenic and antivascular agents. For example, in the Cheresh laboratory, this model was used to demonstrate that antagonists of the integrin αvß3 could disrupt angiogenesis and induce tumor regression (76) and that PEX, a metalloproteinase fragment, can potently inhibit tumor angiogenesis (77).

Primary Tumor Growth (Transplantable Models)

The dependence of the growth of solid tumors on angiogenesis allows for the study of the efficacy for angiogenesis inhibitors. The use of microvascular corrosion casting provides a method to determine the vascular patterns of transplantable tumors (78). This method has been used for several different tumor xenografts in mice and demonstrated that tumor cells may induce characteristic vascular networks (21).

By determining the ratio of the volume of treated over control tumors, different inhibitors can be compared for their ability to inhibit the growth of transplantable rodent tumors in syngeneic mice. TNP-470, which was first named AGM-1470 and is a synthetic analogue of the antibiotic fumagillin (41), has been used to treat a wide variety of transplantable tumors in animal models and potently inhibits tumor growth and angiogenesis. However, TNP-470 only selectively inhibits angiogenesis, is generally only cytostatic, and only rarely leads to tumor regressions (79). In a compelling series of experiments, Christofferson and his colleagues found that treatment with TNP-470 *in vivo* induced differentiation of neuroblastoma xenografts (80). TNP-470, like IFN-α, has also been shown to inhibit the growth of hemangiomas (81,82). In fact, TNP-470 has now been tested on more than 60 different transplantable tumors in rodents (Folkman, *personal communication*, 1999) and, as of this writing, all tumors tested thus far respond to therapy with TNP-470.

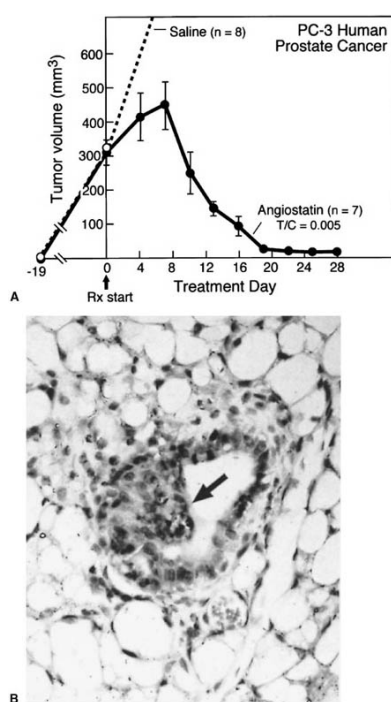
Systemic therapy with angiostatin has also been shown to inhibit the growth of subcutaneous and orthotopic malignant gliomas (83); hemangioendotheliomas (84); lung carcinomas (85); and human breast, colon, and prostate (Fig. 21-5) xenografts (86) in mice. As with TNP-470, a tumor that does not respond to angiostatin therapy has not been identified, suggesting that strategies that target the endothelial cell directly may be useful against a wide variety of neoplasms.


FIGURE 21-5. Treatment of PC-3 human prostate carcinoma in mice with human angiostatin. A: Severe combined immunodeficiency mice were implanted with human prostate carcinoma and treated with human angiostatin (50 mg per kg every 12 hours) or vehicle alone. All of the mice treated with vehicle alone *(dotted line)* had rapidly growing tumors. Tumors in mice treated with angiostatin *(solid line)* were inhibited but still grew for the first 8 days of therapy. However, with continued angiostatin therapy, all tumors regressed to small and pale lesions that did not grow for as long as angiostatin was administered. B: Histology of PC-3 human prostate carcinoma treated with angiostatin. Sections were stained with hematoxylin and eosin. The angiostatin-treated tumor regressed to a lesion *(arrow)* limited to four to eight cell layers in diameter surrounded by fat and fibrotic tissue. Immunohistochemistry revealed blocked angiogenesis and a high proliferation of the tumor cells balanced by high apoptosis.

Stable Transfection of Angiogenesis Inhibitors into Tumor Cell Lines

As an alternative to systemic therapy, tumor cells can be transfected with the gene corresponding to an angiogenesis inhibitor and the cells then injected into mice. Tumor growth can then be

compared to the appropriate vector controls. Cao and his colleagues transfected an aggressive murine fibrosarcoma (T241) with a complementary DNA of murine angiostatin and observed an 80% inhibition of primary tumor growth (87). Furthermore, metastases in 70% of mice implanted with the angiostatin-transfected tumors remained in a state of dormancy after primary tumor resection. The dormant metastases appeared as avascular cuffs around the normal lung capillaries and exhibited a high rate of proliferation balanced by apoptosis. The pattern was similar to the pattern seen in tumors treated systemically with angiostatin (59) and defines the dormant state that can be induced by angiogenesis inhibition (30). Steeg and her colleagues transfected human breast carcinoma cells with thrombospondin-1 (88) and saw a significant inhibition of tumor growth in immunocompromised mice and a decreased microvessel density. The stable transfection of thrombospondin-1 into transformed endothelial cells restored a normal phenotype to these cells *in vitro* and suppressed tumorigenesis *in vivo* (89). Furthermore, thrombospondin-1 transfection almost completely blocked angiogenesis and tumor growth of human skin carcinomas injected subcutaneously in mice (90). In this study, thrombospondin deposition in the matrix around the transfected tumors hindered blood vessel penetration into the tumor. The authors also noted that proliferation of growing and suppressed tumors was virtually identical. Although they did not measure tumor cell apoptosis, they did note increased necrotic cell death in the dormant tumors that were overexpressing thrombospondin. Thus, the induction of tumor dormancy by thrombospondin may be similar to the pattern of dormancy seen with angiostatin, endostatin, and other angiogenesis inhibitors.

Mouse and Human Chimeric Models of Tumor Growth

In an attempt to study the effect of angiogenesis inhibitors on human endothelium in an *in vivo* tumor model, human skin can be grafted onto an immunocompromised mouse. Human tumors implanted onto the skin graft induce an angiogenic phenotype of the dermal microvascular endothelial cells in the graft (91). The growth of human tumors with angiogenic vessels made up of human endothelial cells in a murine model can then be studied. For example, LM609 antibodies directed against the integrin αvβ3 were able to block angiogenesis and tumor growth of a human breast cancer implanted into a human skin graft in a severe combined immunodeficiency mouse/human chimeric model (91). Analysis of the neovessels in the tumors showed that they were made up of human endothelial cells.

Transgenic Models

Although useful in the study of angiogenesis inhibitors in the treatment of malignancy, transplantable tumor models, even with orthotopic implantation, are somewhat limited. In an attempt to develop models of tumor growth that would be more analogous to the development of cancer in patients, transgenic models were developed in which animals develop spontaneous tumors. Transgenic

models allow for the study of cancer arising from physiologically normal cells that progress through multiple stages of carcinogenesis [reviewed by Hanahan and Folkman (14)]. Transgenic mice that carry knockouts of tumor suppressor genes or dominant oncogenes have been developed and are being used widely. In addition to allowing for the study of the effect of angiogenesis inhibitors and other therapies on both the development and growth of malignancy, such models have allowed the switch to the angiogenic phenotype to be studied. In these models, tumors develop in distinct stages that are substantially similar to the development of human cancer. Using oncogenes with tissue-specific promoters, Hanahan and his colleagues have developed three distinct transgenic mouse models of tumor development and have extensively characterized the angiogenic switch (14). In one model, referred to as the *RIP-Tag transgenic mouse*, the SV40-T antigen oncogene is expressed by pancreatic-islet beta cells and induces the formation of solid tumors by 12 to 16 weeks of age. Angiogenesis appears in a subset of hyperplastic islets before the onset of tumor formation (29). In other transgenic models, bovine papillomavirus oncogenes induce the multistage development of fibrosarcomas from dermal cells (92) or targeted expression of human papillomavirus type 16 oncogenes to epidermal basal cells induces the development of squamous cell carcinomas (93). Studies of these and other transgenic models have defined angiogenesis as a rate-limiting step in tumor development (14).

The RIP-Tag transgenic mouse has been used to test the efficacy of several angiogenesis inhibitors in the prevention of tumor development and progression after the switch to the angiogenic phenotype. Mice were treated with a combination of the angiogenesis inhibitors TNP-470, minocycline, and IFN-α and IFN-β before the development of malignant tumors. Although tumor formation was not prevented, pancreatic islet tumor volume and capillary density was reduced by 90% and 40%, respectively (94). Tumor-cell proliferation was not substantially different between treated and control tumors, but tumor cell apoptosis was doubled in the treated tumors. The effect of monotherapy with the angiogenesis inhibitors TNP-470 (AGM-1470), BB-94 (batimastat), angiostatin, or endostatin was studied in the RIP1-TAG2 model of pancreatic islet cell carcinogenesis (95). The experiments were designed to study the effect of angiogenesis suppression in the prevention of the switch to the angiogenic phenotype, in the growth of small tumors, or in the treatment of large end-stage lesions. The different angiogenesis inhibitors had varying efficacy depending on the stage of carcinogenesis being targeted. BB-94, angiostatin, and endostatin significantly prevented the angiogenic switch, whereas TNP-470 did not. However, only TNP-470 or angiostatin and endostatin administered in combination was able to induce significant tumor regression. All of the compounds were efficacious in the intervention trial. These results suggest that combinations of angiogenesis inhibitors that target different angiogenic pathways may have improved efficacy as compared to monotherapy.

Immunohistochemistry of Tumors and Microvessel Density

Tumor tissue can be analyzed by immunohistochemistry to quantitate the microvessel density of the treated and control tumors. A variety of antibodies, such as antifactor-VIII–related antigen and von Willebrand's factor or anti-PECAM-1/CD31, directed against the endothelial cell have been used (96,97 and 98). Clinically, microvessel density has been studied extensively and has been shown to have prognostic value for a wide variety of tumors (99). In animal models, a decrease in microvessel density can often be seen in tumors treated with angiogenesis inhibitors. However, the results can be difficult to interpret. In some cases, if the tumor shrinks in direct proportion to the number of endothelial cells, there would not be an apparent difference in the microvessel density of the tumor.

The studies of Holmgren et al. (30) demonstrated a new mechanism to explain tumor dormancy brought about by angiogenesis suppression. Dormancy was the result of a balance of apoptosis to proliferation of tumor cells, which arises after the suppression of angiogenesis. Treatment with an angiogenesis inhibitor is not only associated with decreased neovascularization, but also with a three- to fivefold increase in apoptosis, and an increase in tumor cell apoptosis may be a hallmark of angiogenesis suppression. Thus, immunohistochemistry to study microvessel density, tumor-cell proliferation, and apoptosis of tumor and endothelial cells can be useful to define an antiangiogenic effect.

Angiogenesis Inhibitors Can be Mobilized by Malignant Tumors

Part of "21 - Antiangiogenesis: Basic Principles and Preclinical Models "

Angiostatin Provides a Mechanism for Concomitant Resistance

A new class of endogenous-specific angiogenesis inhibitors has been discovered by studying the different patterns of metastatic presentation. Fifty percent of all cancer patients have metastases (74). These patients can be grouped into five clinical presentations (17) based on the pattern of growth of metastases in relation to the primary tumor. In one of these metastatic patterns, a primary tumor can inhibit the growth of its metastases. For example, the resection of a primary tumor can, in up to 10% of cases (Brem, *personal communication*, 1999), lead to the rapid growth of previously undetected distant metastases. A number of experimental models (in animals) of the inhibition of tumor growth by tumor mass have been described [reviewed by Gorelik (100,101)] and the phenomenon has been referred to as *concomitant resistance* [reviewed by Prehn (102,103)]. In the laboratory of Judah Folkman, I developed a model of the concomitant resistance in which a variant of Lewis lung carcinoma completely suppresses the growth of its metastases (59). We proposed that a primary tumor produces an excess of stimulators of angiogenesis that result in neovascularization in its own vascular bed. As a result, the primary tumor can grow. However, we further proposed that some primary tumors might also produce inhibitors of angiogenesis that accumulate in the circulation in excess of the stimulators and thereby inhibit angiogenesis in the vascular bed of a metastasis or secondary tumor. Angiostatin, a fragment of plasminogen, was purified from the urine of these tumor-bearing mice (59). Angiostatin potently inhibits endothelial cell proliferation and migration *in vitro* and induces endothelial cell apoptosis (104,105) on a variety of endothelial

cell types and induces the activation of focal adhesion kinase (105). Adenosine triphosphate synthase on the surface of endothelial cells has been described as a receptor for angiostatin (106). *In vivo* (see Fig. 21-4 and Fig. 21-5), angiostatin potently inhibits angiogenesis and tumor growth (59,86). Fragments of plasminogen that include at least the first three kringles and up to all five of the kringles have angiostatin activity (85,107,108,109,110 and 111). Angiostatin therapy induces a state of harmless dormancy of malignant tumors without toxicity.

The Discovery of Endostatin

In other models of concomitant resistance, a primary tumor suppresses the growth of one or several secondary tumors (101,112,113). We noted that a murine hemangioendothelioma inhibits the growth of satellite nodules by endostatin (114), a 20-kd carboxyl-terminal fragment of collagen XVIII. Endostatin is a specific inhibitor of endothelial cell proliferation and has no obvious effect on resting endothelial cells or on a variety of nonendothelial cells (114). The crystal structure of human and mouse endostatin have been determined (115,116). Endostatin was shown to induce endothelial cell apoptosis and a marked reduction in Bcl-2 and Bcl-XI antiapoptotic protein (117) and to inhibit migration and proliferation and cause G1 arrest of endothelial cells stimulated with bFGF or VEGF (118). In our report of the discovery of endostatin, we showed that systemic administration of endostatin to tumor-bearing mice resulted in regression of tumors to a microscopic size (114). A dormant state, defined by a balance of proliferation and apoptosis of the tumor cells without evidence of toxicity, can be maintained for as long as endostatin is administered. Using several recombinant endostatins, Sukhatme's laboratory has since shown similar efficacy against human renal cancer xenografts in mice (119).

Restin, a C-terminal fragment of collagen XV that is homologous to collagen XVIII, has also been shown to be antiangiogenic (120). As with endostatin (119), restin was able to potently inhibit the growth of human renal cell carcinoma xenografts. Currently, several groups are studying fragments derived from other collagens to elucidate their role in angiogenesis.

Vasostatin, a potent and specific angiogenesis inhibitor, is an N-terminal fragment of calreticulin that was purified from the supernatant of Epstein-Barr virus-immortalized cell lines. The generation of vasostatin, along with IP-10 and Mig, is in part responsible for angiogenesis suppression and tumor regression induced by Epstein-Barr virus-immortalized cells.

A Method to Detect Angiogenesis Inhibitors Produced by Human Tumors

To determine if human tumors might also produce inhibitors of angiogenesis, a corneal angiogenesis assay in mice bearing human tumor xenografts has been used. Several human tumors inhibited angiogenesis in this assay (121). Evidence of a circulating inhibitor of angiogenesis associated with human prostate cancer has also been described in an intravital microscope study in mice (122). Furthermore, the inhibition of the growth of experimental B16F10 melanoma metastases by a human fibrosarcoma (HT1080) was shown to be due to the inhibition of angiogenesis by thrombospondin-1 derived from the primary tumor cells (123).

We have developed a method to screen human tumors for the production of angiogenesis inhibitors. The ability of a primary tumor on the flank of an immunocompromised mouse to inhibit the growth of a similar implant on the opposite flank suggests that a tumor might be generating an angiogenesis inhibitor (124a). While studying the inhibition by a human small cell lung cancer model in this model system, we discovered that the cleaved conformation of antithrombin III has potent antiangiogenic and antitumor activity. The intact native molecule did not have this effect. As with angiostatin and endostatin, the inhibitory activity was specific for endothelial cells.

Angiogenesis Inhibitors

Part of "21 - Antiangiogenesis: Basic Principles and Preclinical Models "

A number of factors that inhibit angiogenesis have been discovered [reviewed by Auerbach and Auerbach (124)], and the specificity of these agents is becoming an important distinction. Thrombospondin, an endogenous inhibitor of angiogenesis, has already been discussed earlier in this chapter. Many of the first angiogenesis inhibitors were discovered incidentally. Fumagillin, whose analogue TNP-470 is in clinical trial, for example, was discovered from a fungal contaminant that was noted to inhibit endothelial cells (41). More recently, Robert D'Amato developed a profile of potential side effects of angiogenesis inhibition and screened known drugs for these characteristics. In this fashion, the antiangiogenic potentials of thalidomide (125) and 2-methoxyestradiol (126) were discovered. For thalidomide, the drug must be metabolized to become antiangiogenic (68,125,127). A long list of agents that inhibit angiogenesis, including somatostatin analogues, such as octreotide (128), carboxyaminotriazole (129), spironolactone (130), and captopril (131), have since been identified. The goal of this section, however, is not to provide a list of all of the substances that have been described as angiogenesis inhibitors in the literature. Rather, I attempt to give examples of different classes of angiogenesis inhibitors and to develop the concept of angiogenesis inhibition.

Proteolytic Fragments That Inhibit Angiogenesis

Several endogenous inhibitors have been described that are fragments of proteins with distinct functions. One of the first such fragments to be described is a 16-kd fragment of the hormone prolactin (48,132) produced from intact prolactin in the pituitary. Native and recombinant 16K prolactin maintain biologic activity as prolactin agonists but, unlike intact prolactin, also inhibit endothelial proliferation and capillary tube formation *in vitro* and angiogenesis *in vivo.* N-terminal fragments of the human prolactin and growth hormone family and the intact molecules have been found to have opposing effects on angiogenesis (133). Recombinant N-terminal fragments of prolactin, growth hormone, placental lactogen, and growth hormone variant all inhibit angiogenesis possibly by blocking the activation

of MAPK downstream of bFGF and VEGF (134) or by increased expression of plasminogen activator inhibitor-1 in capillary endothelial cells. A dual role in angiogenesis has also been described for proliferin, which is angiogenic, and proliferin-related peptide, which is antiangiogenic, in the placenta (10). The association between stimulatory and inhibitory effects on angiogenesis within the same molecules may provide an efficient means of regulating physiologic angiogenesis.

Furthermore, a plasmin-derived internal fragment of the angiogenesis-inhibitor platelet factor 4 (135) is up to 50-fold more potent than the intact molecule (136). Synthetic fragments of murine epidermal growth factor (137), fragments of laminin (49,138), and peptides derived from thrombospondin (37,139,140) all inhibit endothelial cell proliferation and angiogenesis. A 29-kd plasmin-derived fragment of fibronectin (141), the prothrombin kringle-2 domain (142), and a fragment of SPARC (143) can inhibit the proliferation of endothelial cells *in vitro.*

When taken together with the discovery of angiostatin (59), fragments of plasminogen, and endostatin (114) (a fragment of collagen XVIII), a theme has emerged in which endogenous inhibitors of angiogenesis arise from larger proteins with distinct and varied functions. If common proteases or similar cleavage patterns, or both, are found, a new general mechanism of proteolytic events regulating the vascular system may be revealed.

Protease Inhibitors Can Be Antiangiogenic

Increased protease activity is a critical step in both angiogenesis and tumor progression. Furthermore, the extracellular matrix and its components play a critical role in angiogenesis (144,145). Matrix metalloproteinases (MMPs) have a prominent role in the progression of malignancy [reviewed by Liotta (146), Stetler-Stevenson (147), and Moses (148)]. Furthermore, the activity of MMPs in the urine of cancer patients may have prognostic value (149). The presence of metalloproteinases in cartilage may in part explain its resistance to angiogenesis (150). Troponin I has been identified as a potent inhibitor of angiogenesis found in cartilage (151).

A family of endogenous proteins, the tissue inhibitors of the metalloproteinase family, has been shown to inhibit angiogenesis (150,152,153). However, the difficulties associated with the development of proteins for clinical use have led to the discovery of small molecules that can inhibit MMP activity. Many of the first agents used were tetracycline derived and include minocycline and, more recently, COL-3. Other agents, such as marimastat and batimastat, target the incorporation of zinc into the MMP catalytic site of MMPs (154). More recently, selective inhibitors, such as BAY 12-9566 and AG3340 and several others (155,156), have been developed to selectively target only those MMPs that are important for tumor growth and angiogenesis.

Plasmin is also important in the outgrowth of capillaries in the angiogenic response (157). The serpin plasminogen activator inhibitor-1 has been shown to inhibit angiogenesis, possibly by blocking the interaction of αvß3 with vitronectin (158). Taken together with our discovery that antithrombin III, another serpin, can also inhibit angiogenesis (O'Reilly et al., submitted), these findings suggest that other serpins involved in the coagulation system may have effects on the endothelial cell. Furthermore, the degradation of plasminogen by plasminogen activators in the presence of sulfhydryl donors can mobilize angiostatin (110,159). Thus, the regulation of plasminogen activation has both a stimulatory and inhibitory role in angiogenesis (Table 21-1).

Table 21-1 Regulation of Angiogenesis by Factors Derived from the Clotting System[a]

Coagulation-derived factors

  Antiangiogenic

    Kininogen fragment

    Prothrombin kringle 2

    Plasminogen kringles (angiostatin)

    Antithrombin (antiangiogenic conformation)

    Plasminogen activator inhibitor-1

    Thrombin

    Plasmin

    Tissue factor

    Urokinase

    Tissue-type plasminogen activator

Platelet-derived factors

  Antiangiogenic

    Platelet factor 4

    Thrombospondin

    Fibronectin fragments

  Proangiogenic

    Vascular endothelial cell growth factor/vascular permeability factor

    Platelet-derived growth factor

    Transforming growth factor-ß

    Platelet-derived endothelial cell growth factor

[a]A number of factors derived from the coagulation and fibrinolytic systems can stimulate or inhibit angiogenesis. Many of the endogenous inhibitors are generated by the proteolytic degradation of these factors. Furthermore, many clotting factors have direct and indirect roles in the stimulation of angiogenesis and are involved with the capillary endothelial cell sprouting and invasion. Platelets also function to regulate angiogenesis, and their activation can lead to the release of both stimulators and inhibitors of angiogenesis.

The inhibition of protease activity may therefore offer both a direct antitumor effect and an antiangiogenic effect in the treatment of cancer. However, in a small population of cancer patients there may be a potential disadvantage to administering a metalloproteinase inhibitor. As has been described, many of the endogenous inhibitors of angiogenesis are generated by the cleavage of other proteins by metalloproteinases and other enzymes (109,159,160,161,162 and 163). In these patients, the level of endogenous angiogenesis inhibitors could potentially decrease and need to be replaced.

Agents That Target Angiogenic Factors and Their Receptors

Most of the known angiogenesis factors bind to and are regulated by heparin, and many of the first agents designed to target these factors were heparin-like. Examples include pentosan polysulfate, tecogalan sodium, suramin derivatives (164), squalamine, and several others. However, the disadvantage of this strategy is the lack of specificity of these agents.

Angiogenesis is regulated by a variety of stimulators of the process that interact with growth factor receptors. Strategies that target these receptors, either directly or indirectly, have been

developed. One strategy involves directly blocking the binding of the growth factor to its target receptor using antibodies or small molecule inhibitors. Alternatively, the signaling of the growth factor receptor can be blocked. These strategies offer great potential. However, one theoretical concern is the development of resistance by the tumor by the production of multiple stimulators of angiogenesis.

IFN-α and IFN-β (165) have been shown to inhibit angiogenesis and work by downregulation of the expression of bFGF (166). The antiangiogenic activity of IFN requires sustained levels of the drug, and its use is limited by the toxicity seen when it is given in high dose. However, Fidler and colleagues have demonstrated that human prostate cancer cells transfected with IFN-β were significantly inhibited when implanted orthotopically and subcutaneously *in vivo* due to angiogenesis inhibition and activation of host effector cells (167).

Soluble receptors for angiogenic factors may play a role in the regulation of angiogenesis. Circulating soluble receptors for Flt-1 (168), a receptor for VEGF, and binding proteins for fibroblast growth factors (169) have been described. Their function is not known, but they may serve to limit the levels of angiogenic factors in the circulation and counteract the elevated levels of angiogenic factors seen in cancer patients (170).

Antisense targeting of angiogenic factors or their receptors, such as VEGF/VPF (171) and bFGF (172), can be used to inhibit angiogenesis and tumor growth. Furthermore, strategies that use monoclonal antibodies or soluble receptors to angiogenic factors, such as bFGF (173), VEGF/VPF (174,175,176,177 and 178), and Tie2 (179), can potently inhibit a wide variety of tumors and angiogenesis. A variety of agents have also been produced that target autophosphorylation or the downstream signals of receptor tyrosine-kinase activity (180). By selectively targeting the endothelial cell, these strategies have shown significant antitumor efficacy.

The interaction of endothelial cells with the extracellular matrix is critical for angiogenesis. Agents that target the binding of endothelial integrins have been studied (181). Integrin αvβ3, for example, was shown to be preferentially expressed by angiogenic blood vessels (76), and antagonists trigger endothelial cell apoptosis, are anti-vascular, and potently inhibit angiogenesis and tumor growth (76,91). Strategies that target αvβ3 and other related integrins, including antibodies and small molecules, are currently the focus of intense research.

A new class of ligands for the receptor tyrosine-kinase Tie2, which is expressed almost exclusively by endothelial cells, have been described (182,183). These molecules, angiopoietin-1 and angiopoietin-2, function in the regulation of angiogenesis and vascular development (184). Angiopoietin-1 recruits pericytes to newly formed capillary sprouts and may help stabilize newly formed capillaries (185), whereas angiopoietin-2 may antagonize the process.

Use of Angiogenesis Inhibitors in Combination with Other Modalities

Part of "21 - Antiangiogenesis: Basic Principles and Preclinical Models "

A malignant tumor has been described as having at least two distinct cell populations (35). Classically, therapies have primarily targeted the tumor cell component, and strategies have been optimized for the delivery of these agents to target only the tumor cells. Thus, although cytotoxic agents can inhibit angiogenesis, when they are given at their maximal tolerated dose, their antiangiogenic effect may not be sustained. By targeting both the endothelial cell population of a tumor and the tumor cell population, improved efficacy should be possible.

Angiogenesis Inhibitors Combined with Chemotherapeutics

Teicher and her colleagues were among the first to show a synergistic effect between cytotoxic agents and antiangiogenic therapy. A combination of the angiogenesis inhibitors tetrahydrocortisol (186), beta-cyclodextrin tetradecasulfate (187), and minocycline (188) given with a variety of cytotoxic agents significantly increased the growth delay of Lewis lung carcinoma xenografts as compared to antiangiogenic or cytotoxic monotherapy (189). Furthermore, the formation and growth of lung metastasis was reduced in all mice, and 40% of the mice treated with combination therapy remained clinically disease-free for longer than 120 days. In a similar set of experiments, a combination of TNP-470 (AGM-1470) and minocycline were given to mice bearing Lewis lung carcinoma (190). A similar improvement in efficacy when angiogenesis inhibitors and cytotoxic agents were combined was demonstrated. A synergistic effect between the combination of TNP-470 with chemotherapy was also seen for murine mammary carcinomas (191) and human pancreatic carcinoma (192). Other angiogenesis inhibitors, such as protamine, when combined with carmustine in the treatment of rat gliomas (193) improved efficacy. Furthermore, by targeting a chemotherapeutic agent directly to the tumor endothelium using homing peptides identified by phage display (20), antitumor efficacy was markedly enhanced.

Angiogenesis Inhibitors and Ionizing Radiation

It had long been assumed that an angiogenesis inhibitor would impair the effect of ionizing radiation by inducing tumor hypoxia. However, Teicher and her colleagues observed that antiangiogenic therapy with a combination of TNP-470 (41) and minocycline improved tumor oxygenation and the antitumor effect of radiation therapy (194). More recently, Weichselbaum and colleagues demonstrated a synergistic effect when angiostatin and ionizing radiation were combined for a variety of transplantable tumors in mice (195,196). The studies were designed using low doses of both modalities and large established murine Lewis lung carcinoma or human glioblastomas, squamous cell carcinomas, or prostate carcinomas. The sequencing of the two modalities was also critical, and the concurrent administration of the radiation and antiangiogenic therapies produced the best efficacy (196). The antitumor effect of hyperthermia is also enhanced by the combination with antiangiogenic therapy with TNP-470 (197,198).

Gene Therapy

Angiogenesis inhibitors often require extended time to begin to work and can induce stasis of tumor growth followed by dormancy

after prolonged therapy. They may also require extended therapy for maximal efficacy. Thus, gene therapy may be an attractive strategy for the delivery of an angiogenesis inhibitor [reviewed by Folkman (199), and Kong and Crystal (200)]. Several angiogenesis inhibitors, including angiostatin (201,202 and 203), endostatin (204), a truncated VEGF receptor (205), and Tie2 (206), have been delivered using gene therapy. In these studies, a potent inhibition of angiogenesis and tumor growth without evidence was observed. These studies suggest that gene therapy may provide a platform for the therapeutic delivery of angiogenesis factors.

Angiogenesis Inhibition and Immunotherapy

The use of angiogenesis inhibitors may also provide a platform for immunotherapy. The combination of angiogenesis suppression by an alpha-v antagonist and an antibody-cytokine fusion protein induced the complete regression of spontaneous metastases (207). Regressions were not seen with the two modalities when they were administered separately. Furthermore, some molecules may induce both an antiangiogenic and an immunomodulatory response. This is true of interleukin-12, which inhibits angiogenesis indirectly by up regulating IFN-γ (208) that then induces IFN-inducible protein 10 and MIG-1. IFN-γ has since been found to inhibit angiogenesis by the upregulation of IP-10 and MIG. Both are potent inhibitors of angiogenesis and tumor growth (209,210 and 211). The potent efficacy of interleukin-12 against a wide variety of tumors may be explained by the combination of its effects on the immune system to induce a tumoricidal effect and its antiangiogenic effect.

Tumor Dormancy by Angiogenesis Suppression

Part of "21 - Antiangiogenesis: Basic Principles and Preclinical Models "

Initially, angiogenesis inhibitors were expected to be cytostatic only in the treatment of malignant tumors. However, studies of concomitant resistance that led to the discovery of angiostatin and endostatin showed that angiogenesis inhibitors could maintain metastases in a state of dormancy (30,59,114). The mechanism of tumor dormancy induced by angiogenesis suppression was studied by Holmgren et al. and is defined by a dynamic equilibrium between proliferation and apoptosis of tumor cells regulated by the capillary endothelial cell (30). Subsequently, angiostatin has caused regression of established human primary carcinomas (see Fig. 21-5), growing in mice to microscopic dormant foci in which tumor-cell proliferation was balanced by apoptosis in the presence of blocked angiogenesis (86). This pattern has since been termed *dormancy therapy* and constitutes a novel anticancer strategy in which malignant tumors are regressed by prolonged blockade of angiogenesis. The mechanism of the induction of dormancy and increased tumor-cell apoptosis by angiogenesis suppression remains unknown. Angiogenesis blockade may result in a loss of endothelial-derived paracrine factors needed by the tumor cells. The lack of toxicity seen with angiogenesis inhibition demonstrates the advantage of antitumor therapy directed against the endothelial compartment.

Use of Angiogenesis Inhibitors to Bypass Drug Resistance

Part of "21 - Antiangiogenesis: Basic Principles and Preclinical Models "

Acquired drug resistance is a major problem in the treatment of cancer, and the emergence of resistance depends in part on the genetic instability and heterogeneity of tumor cells. In contrast, endothelial cells are genetically stable, homogenous, and have a low mutation rate. Therefore, antiangiogenic therapy that is directed against angiogenic endothelial cells should not induce significant drug resistance. Kerbel first proposed the hypothesis that antiangiogenic therapy could be a strategy to circumvent acquired drug resistance in cancer therapy (212). In a series of preliminary studies, drug resistance was not seen in mice bearing Lewis lung carcinomas treated with TNP-470, a selective angiogenesis inhibitor that inhibits tumor growth (213). However, these studies were limited by the lack of specificity of the agents being tested.

We therefore treated mice bearing Lewis lung carcinoma, T241 fibrosarcoma, or B16F10 melanoma with endostatin, a potent angiogenesis inhibitor (214). Mice were treated with cycled endostatin therapy, and mice were treated systemically with endostatin until tumors had regressed for each cycle. Tumors were then allowed to regrow, and endostatin therapy was resumed. The rate of tumor regression induced by endostatin was essentially the same in all cycles with endostatin. No resistance to therapy was seen even after repeated cycles. We have since observed a similar lack of resistance with other tumors. These experiments show that drug resistance does not develop in response to treatment with a specific inhibitor of angiogenesis.

In a surprising finding, after repeated treatment cycles of endostatin, tumors entered a state of self-sustained dormancy and did not recur after discontinuation of therapy. An unexpected finding is that repeated cycles of antiangiogenic therapy are followed by prolonged tumor dormancy without further therapy. Histologic sections of the primary site revealed a residual tumor of microscopic size that has the same pattern of dormancy as was first defined by Holmgren et al. (30), and the tumors were hypovascular. Some microscopic tumors were mildly infiltrated by leukocytes, and others contained focal necrosis. Although the mechanism of self-sustained dormancy is unknown, it illustrates the powerful control exerted by the vascular endothelial cell population over the tumor cell population. Furthermore, the self-sustained dormancy may be analogous to the cancer patient who has recurrent diseases after a prolonged period of disease-free survival.

Drug resistance may not be a general property of angiogenesis inhibitors. It may be reasonable to assume that angiogenesis inhibitors that specifically or selectively target vascular endothelial cells are less likely to induce resistance than inhibitors that target a tumor-derived mediator of angiogenesis (214). As cells arise that produce other angiogenic factors, the tumor itself may acquire resistance. However, tumors could potentially become resistant to a specific angiogenesis inhibitor should they generate a degrading enzyme. Given that resistance to an angiogenesis inhibitor has not been observed, however, these concerns may not be realized.

Integration of Angiogenesis and Other Physiologic Processes

Part of "21 - Antiangiogenesis: Basic Principles and Preclinical Models "

As discussed in this chapter, angiogenesis is a complex process dependent on the balance of inhibitors and stimulators of the process. Numerous lines of evidence now suggest that angiogenesis is regulated in synchrony with other physiologic processes. For example, several factors involved in the coagulation cascade are also critical in the induction and maintenance of the angiogenic response (see Table 21-1). Tissue factor, for example, can induce angiogenesis by upregulating VEGF/VPF and downregulating the angiogenesis inhibitor thrombospondin-2 (215). Furthermore, platelets sequester VEGF, and their activation may induce angiogenesis by its release (216). Plasma protein forms a neostroma for tumor growth, but these same factors may provide a substrate for the enzymatic mobilization of angiogenesis inhibitors. A general process in which components of the clotting system play a major role in the regulation of angiogenesis has been proposed by Judah Folkman (35). This hypothesis is supported by the presence of potent inhibitors of angiogenesis within proteins such as plasminogen (59), thrombospondin, platelet factor 4 (135), kininogen (217), prothrombin, and antithrombin III (O'Reilly et al., *submitted*). Furthermore, several associations between angiogenesis and the nervous system have emerged. Human neourpilin-1, a receptor for the collapsin and semaphorin family of proteins that mediates neuronal cell guidance, has been found to also be an isoform specific receptor for VEGF165 (218). Furthermore, the ephrin-B2 and its receptor Eph-B4 (219), which are involved in neuronal development, have been shown to play a major role in the embryonic development of arteries and veins. A close association between angiogenesis and other systems may allow for the precise regulation and integration of angiogenesis with physiologic processes.

Summary and Future Directions

Part of "21 - Antiangiogenesis: Basic Principles and Preclinical Models "

Since its beginning in the 1970s, the field of angiogenesis research has grown dramatically and has broadened the understanding of a number of physiologic and pathophysiologic processes. In addition to cancer, a number of other pathologic conditions, including atherosclerosis (220), arthritis (221), ectopic bone formation (222), and ocular neovascularization (71), can also be treated with angiogenesis inhibitors. Antiangiogenic agents should have far-reaching applications in a variety of clinical settings and have the potential to improve efficacy and diminish toxicity in a variety of diseases. In the future, it may be reasonable to combine chemotherapy, radiation therapy, immunotherapy, and emerging modalities with antiangiogenic therapy and to then continue antiangiogenic therapy if needed. If tumor eradication is not possible, then angiogenesis inhibitors may be able to serve as gate keepers to induce and maintain tumors in a state of harmless dormancy and prevent tumor expansion. Clinical trials with a number of antiangiogenic agents have begun or are due to begin shortly. However, a great deal of effort is still required even after antiangiogenic agents become available to learn how to use them to their full potential.

Antiangiogenesis: Clinical Applications

Steven K. Libutti

James M. Pluda

Introduction

Part of "22 - Antiangiogenesis: Clinical Applications "

The concept of treating cancer by attacking the tumor's blood supply is one that has recently received increased attention. However, the observation that growing tumors are critically dependent on the in-growth of host neovasculature is one that was made in the 1940s. In a series of elegant experiments using transparent chambers made in tissue flaps, Drs. Algire and Chalkley, working at the National Cancer Institute, demonstrated that the tumor vasculature originated from the host and was required by the tumor for it to grow larger than a few millimeters (1). The importance of this observation and its therapeutic implications was elucidated by Judah Folkman over 25 years later, when he recognized that tumors secrete molecules, which he termed *tumor angiogenesis factors*, that recruited blood vessels into the growing tumor (2). In this landmark paper, the concept of tumor dormancy—that is, arresting the tumor at the size of several millimeters by blocking its ability to recruit blood vessels—was born.

Antiangiogenesis as a therapeutic modality is directed at preventing the recruitment or growth of a vascular supply, which is critical for continued tumor enlargement, invasion, and metastasis. This chapter describes some of the evidence supporting the notion that tumor growth is angiogenesis dependent. Additionally, it outlines issues related to the selection of angiogenesis inhibitors for clinical use. It also describes novel clinical trial designs for angiogenesis inhibitors and emerging methods for measuring end points of response. Last, it discusses the agents that are currently in clinical trials, the agents that are in preclinical development, and the clinical development of antiangiogenic gene therapy.

Background

Part of "22 - Antiangiogenesis: Clinical Applications "

Several clinical observations have supported the importance of tumor vascularity to the malignant phenotype. Weidner and colleagues were the first to report that tumor vascular density may be predictive for the risk of metastases, disease-free survival, and overall survival (3). Since then, there have been an increasing number of reports of similar observations in a growing number of tumors, including breast cancer, prostate cancer, gastric cancer, and colon cancer (3,4). Lu and colleagues have also reported that there may be an inverse relationship between tumor microvascular density and the rate of tumor-cell apoptosis (5). Circulating factors known to induce angiogenesis, such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF), have also been reported to correlate with extent of disease, clinical status, and survival (6,7). Inhibitors of angiogenesis have been shown to suppress tumor growth *in vivo* but have little or no effect on tumor cell proliferation *in vitro* (8,9,10 and 11). Thus, it appears that the development of a blood supply is important not only for the growth of the primary tumor but also for invasion and distant spread.

During the growth of a tumor mass, tumor cells are rarely shed into the circulation before the onset of active neovessel formation (12). However, once angiogenesis commences, the number of tumor cells shed into the circulation correlates directly with the density of tumor blood vessels. These tumor cells access the circulation based on an important property of tumor neovessels. Newly forming vessels in the tumor bed are "leaky" and contain fragmented basement membranes (13). This disruption in endothelial cell barrier function allows malignant cells to more easily enter the circulation, where they can travel to distant sites and establish metastatic deposits. Their growth at these distant sites is also critically dependent on angiogenic activity. The action of collagenases is necessary for both angiogenesis and the invasion of tumor cells (14). Several stages are important for tumor growth and metastases, and many of these are reliant on the formation of tumor vessels. Thus, attacking the formation of tumor vasculature can theoretically inhibit both the growth of the primary tumor and the ability of that tumor to metastasize.

The endothelial cell is an attractive target for anticancer therapy. Unlike tumor cells, which are transformed and rapidly dividing, host endothelial cells are normal and respond to mitogens secreted by the tumor. Therefore, endothelial cells are not dividing at as rapid a rate as tumor cells and do not possess the genetic instability of tumor cells. This is important, as this makes it extremely difficult for endothelial cells to develop genetic mutations associated with resistance to the therapies directed against them. This phenomenon makes antiangiogenic therapy particularly

attractive, because theoretically it would be extremely difficult for tumors to generate escape mechanisms.

The environment in which it is growing can dramatically alter the endothelial cell's phenotype. The expression of surface molecules such as receptors and integrins can change in response to various cytokines or environmental changes such as hypoxia (15,16). To develop therapies directed against tumor vasculature, it is critical to understand the unique features of the endothelial cell.

Endothelial cells lining the vasculature of normal tissues exist in a quiescent or resting state. They provide a homeostatic barrier, which prevents the uncontrolled extravasation of intravascular components and inhibits coagulation (17). When a tumor begins to grow in a region of normal tissue, factors are released from the tumor cells, which elicit responses from the surrounding endothelium and result in vascular invasion into the tumor (18). Not all tumor cells, however, are capable of stimulating this response. The ability to release these important angiogenic factors and the conversion within the tumor cell from a nonangiogenic to an angiogenic inducer has been referred to as the *angiogenic switch* (19).

Most tumors arise without angiogenic activity and switch when a critical subset of cells acquires the angiogenic phenotype (19). The switch is associated with increased production of angiogenic factors by the tumor such as VEGF and bFGF. Avascular tumors, which are in a dormant or inactive state, have a balance between tumor cell proliferation and apoptotic cell death (20,21). As tumor cells begin to induce angiogenesis, there is a decrease in the incidence of cell death by apoptosis within the tumor itself (21). The factors involved in the regulation of the angiogenic switch are being elucidated. An understanding of these mechanisms is critical in the further development of antiangiogenic therapies for use in the clinic.

A careful balance exists between those stimulatory factors that potentiate neovessel development and those factors that serve to suppress the angiogenic response. Several potential stimulatory mechanisms, which may lead to the potentiation of tumor-associated angiogenesis, have been described previously (19,20 and 21). However, there are also events that lead to a loss of inhibition that can shift the balance in favor of angiogenesis. The loss of tumor-suppressor gene function, such as mutations in p53, can lead to a decreased production of angiogenesis inhibitors like thrombospondin (22). Mutations in the von Hippel-Lindau tumor-suppressor gene may lead to a loss of control of VEGF expression, resulting in increased VEGF production (23,24). Tumors arising in this familial cancer syndrome are notable for their increased vascularity and increased production of VEGF by both Northern and Western blot analysis. Studies have further demonstrated that mutations in the ras oncogene may also upregulate VEGF expression (25). Taken as a whole, the important factors involved in the angiogenic switch can be grouped by those that activate angiogenesis and those that inhibit it. To maintain equilibrium between new vessel development and growth and control of pathologic or neoplastic vascular invasion, these activators and inhibitors must be carefully balanced. With respect to tumor growth, invasion, and metastasis, it may be possible to exploit this balance and tip it in favor of angiogenesis inhibition.

Selection of Angiogenesis Inhibitors for Clinical Development

Part of "22 - Antiangiogenesis: Clinical Applications "

Ideally, an antiangiogenic agent should possess several properties. It is important to keep these properties in mind when planning strategies for the development of this class of agent. The angiogenesis inhibitor should have specificity for a particular step, aspect, or component of the neovascularization process. By selecting critical steps important for neovascular formation, a broad spectrum of antitumor activity can be achieved. The ideal agent should demonstrate a lack of resistance developed by the tumor. Therapies directed against the endothelial cell might have advantages over therapies directed against the tumor cell due to the inability of the endothelial cell to develop resistant clones. However, agents directed against a single angiogenic molecule or isolated step in the angiogenic process may potentially be defeated by the tumor if the tumor cells are able to produce another factor that achieves the same result but circumvents the block by the agent. The ideal agent should be relatively nontoxic, particularly because these agents may need to be administered for a prolonged period (26). They should also be able to synergize with other cancer therapies. Because the target of antiangiogenic therapy is the tumor vasculature, combining these agents with more traditional chemotherapies or radiation directed against the tumor cell might be a strategy that maximizes the efficacy of each therapy (27,28 and 29).

The selection of agents for further clinical development is based on the preclinical data generated in the laboratory. This makes it important to understand the mechanism of action of the agent and whether the assay that is chosen to determine the activity of a compound is appropriate for the agent being tested. Several assays are routinely used in the laboratory to assess the degree of antiangiogenic activity of a given compound (Table 22-1). Endothelial cell functional assays generally measure proliferation, migration, invasion, and capillary tube formation (30). Bovine capillary endothelial cells are commonly used in proliferation assays as are human umbilical vein endothelial cells, lung microvascular endothelial cells, and dermal microvascular endothelial cells. These same cells can be used in migration, invasion, and capillary tube formation assays. By making use of the basement membrane material Matrigel as an artificial extracellular matrix, cells can grow and organize as they might *in vivo.* One must be careful, however, in the interpretation of the results of these assays, as there are

differences between the types of endothelial cells and the individual endothelial cells' behavior on various extracellular matrixes (Berger et al., *manuscript in preparation*). Additionally, there may be species specificity for the activity of a compound. Also, a compound may require metabolic activation. In this circumstance, the parent compound may be inactive in *in vitro* assays but extremely active *in vivo.*

Table 22-1 Preclinical Angiogenesis Assays

In vitro

    Endothelial cell proliferation

    Endothelial cell migration

    Endothelial cell invasion

    Capillary tube formation

    Rat aortic ring assay

In vivo

    Corneal micropocket

    Chicken chorioallantoic membrane

    Matrigel implantation

    Sponge implantation

    Rat dorsal air sac

The rat aortic ring assay is a useful *in vitro* assay for measuring the inhibition of angiogenesis (31). Circular sections of the rat aorta are placed in Matrigel with or without an angiogenic stimulus such as bFGF. Over 5 to 8 days, an arborization of vessels can be seen emanating from the central aortic disc. In the presence of an inhibitor of angiogenesis, this arborization of vessels is impaired to varying degrees (Fig. 22-1). This assay is readily reproducible and easy to interpret. However, one must be certain of the species specificity and metabolic activation of the compound being tested.

A Media   CAI   EMAP-II

B Media   CAI   EMAP-II
FIGURE 22-1. Several *in vitro* assays are available that allow for the assessment of antiangiogenic activity of agents as they are being evaluated for further development. Panel (A) illustrates the use of the rat aortic ring assay, which is used to measure angiogenic activity. Rat aorta is sectioned and placed in Matrigel containing either media alone or media containing various inhibitors of angiogenesis. The amount of vessel outgrowth from the aortic ring can be determined. Panel (B) illustrates the use of a tube-forming assay. Endothelial cells are plated on Matrigel and assayed for their ability to form tubes, which appear as a lattice or matrix on phase-contrast microscopy. Agents, which perturb this tube formation, can be analyzed. Both of these assays can be semi-quantified using image-processing software. (CAI, carboxyamido-triazole; EMAP-II, endothelial monocyte-activating polypeptide II.)

For example, thalidomide has been shown to inhibit angiogenesis in preclinical models (32). However, when thalidomide was administered at similar doses orally in mice it had no antiangiogenic activity. Furthermore, when thalidomide is placed on rat aortic rings, there is no inhibition of neovessel formation. In contrast, when thalidomide was mixed with a preparation of human hepatocytes, there was potent activity in the rat aortic ring assay. Combining thalidomide with murine hepatocytes demonstrated no effect (33). This observation underscores the importance of species specificity and metabolism in the activation and subsequent efficacy of various agents.

Several *in vivo* angiogenesis assays exist for preclinical use. The corneal micropocket assay and the chicken chorioallantoic membrane (CAM) assay are standard screening assays that can demonstrate potent inhibition of neovessel formation (34,35,36,37 and 38). Matrigel can also be implanted in subcutaneous pockets in mice with or without angiogenic stimulatory molecules. Animals can then be given systemic treatment with putative antiangiogenic agents, and the degree of vascular invasion into the Matrigel can be assessed. These assays rely on either microscopic examination of explanted Matrigel or on actual hemoglobin content determinations from the Matrigel. The level of hemoglobin directly correlates with the amount of vascular ingrowth into the Matrigel implant.

Once an agent has demonstrated activity consistent with the inhibition of vascular growth, the next step is to ascertain whether the agent has an effect on tumor growth. A variety of models exist for measuring the antitumor effects of antiangiogenic agents in the preclinical setting. Tumor xenograft models

may be used involving human tumors grown in immunodeficient mice. Alternatively, mouse tumors may be implanted into syngeneic mice. Additionally, a number of models for tumor metastases in either the liver or lung have been characterized. However, a growing body of literature suggests that there are differences in the microvasculature in various models and that testing an agent for activity against subcutaneously implanted tumors may not be a true representation of whether that agent inhibits tumor growth in the tissue of origin. In an attempt to examine more potentially relevant models, researchers are using orthotopic tumor models, in which the tumor cells are placed directly into the organ of origin. An example would be colon cancer cells injected into the colon (39). Another approach uses spontaneous tumor models based on the formation of organ-specific tumors in transgenic mice (40,41 and 42).

Once an agent has demonstrated antitumor activity, experiments exploring the appropriate route and schedule of administration should be performed. The route of administration often depends on the physical properties of the agent. Oral dosing is preferable, but many agents are not orally bioavailable. The solubility of a compound may have an effect on whether it can be administered intravenously or via a subcutaneous injection. The pharmacokinetics of a compound also influence the schedule of administration. However, it is important to keep in mind that the biologic half-life of a compound may in fact have a greater effect on schedule than its pharmacologic half-life. For example, a compound with a pharmacologic half-life measured in minutes need not be administered on a frequent or continuous schedule if its biologic half-life is several days. Finally, the toxicity of a compound must be ascertained. This can have a profound influence on the route and schedule of administration.

Clinical Trial Designs for Angiogenesis Inhibitors

Part of "22 - Antiangiogenesis: Clinical Applications "

Antiangiogenic agents currently under development have been thought to be static drugs inhibiting tumor growth rather than causing tumors to regress. Many have had relatively little toxicity, which is important given the potential need for long-term administration. The end points typically used in early clinical trial designs evaluating cytotoxic agents may not apply to antiangiogenic agents. New paradigms for the clinical development of antiangiogenic agents need to be developed. This includes end points other than toxicity as the determinant of drug doses and schedules from phase 1 trials. This may influence the way in which decisions are made to move drugs on to phase 2 and phase 3 clinical trials.

Trial designs analyzing various routes of administration, including oral, subcutaneous injection, and intravenous delivery, are important. Whether these agents should be given as a bolus or more likely as continuous low-dose therapy can be determined by measuring pharmacologic end points as well as early biologic and clinical responses. Given the potential for prolonged administration, traditional end points such as toxicology should be examined and expanded to include long-term toxicity data.

Route of administration and pharmacokinetics are determined for an agent in phase 1 trials. Traditional phase 2 trials generally occur after the maximum tolerated dose. The phase 2 trial is generally directed at a single histologic type of cancer with the end point being tumor response. Given the theoretical possibility that antiangiogenic agents work across a variety of tumor histologies, because the endothelium is the target, certain modifications of the traditional phase 2 trial may be necessary.

A modified phase 2 trial may take a variety of forms. Because appropriate historical controls for cytotoxic agents may not be available, trials with a concurrent control arm may be useful. For example, one could conduct a two-armed randomized trial between an antiangiogenic agent and either no therapy or standard therapy. These trials may not be empowered to give a definitive answer with regard to the superiority of one agent over another as would be derived from a large-scale phase 3 trial. However, a carefully designed randomized phase 2 trial may allow one to eliminate agents as being less than promising. Alternatively, various doses or routes of administration could be randomized against each other with the same agent to better delineate the most efficacious regimen for use in larger phase 3 studies. The end points to these trials can also vary from the traditional measures of response.

Time to progression and progression-free survival as well as prolongation of survival can be determined by randomizing an agent against an appropriate concurrent control arm. In some cases, a decreased rate of progression may be strong enough evidence to suggest moving a particular agent into further study. Once promising agents have been selected from these phase 2 designs, definitive phase 3 studies can be performed. These studies can be random assignment trials comparing antiangiogenic agents to placebo controls using prolongation of survival, time to progression, progression-free survival, and overall response rate as end points. Trials may also compare standard chemotherapeutic agents with chemotherapy plus the antiangiogenic agent. These combination therapy trials may demonstrate synergy that was predicted from preclinical data. The overall goal of the design of clinical trials for antiangiogenic agents should be to exploit the fact that the agents studied to date have relatively mild side effects and, therefore, modified phase 1 and phase 2 trials may be the most efficient for early clinical evaluations.

End Point Measures

Part of "22 - Antiangiogenesis: Clinical Applications "

The traditional end points used to define the efficacy of anticancer therapies in clinical trials have been response rate, time to progression, disease-free survival, and overall survival. Response rates are generally determined by standard established criteria based on the measurements of the perpendicular diameters of index-tumor lesions. The most commonly used imaging modalities are computed tomography and magnetic resonance imaging (MRI). These radiographic measures of the changes in tumors are limited to an assessment of the tumor's physical dimensions. In their most often used formats, these imaging modalities give no information on the physiologic changes that are occurring within the tumor and the tumor microenvironment.

Several early clinical trials of antiangiogenic agents relied on these standard radiographic imaging techniques that have become commonplace in the evaluation of chemotherapeutics. Many of these antiangiogenic agents demonstrated static activity in that their use resulted in the stabilization of disease with few documented tumor regressions. These results, however, may hide some important effects of these novel treatment strategies and may result in the loss of important information regarding the biology of the tumor's response. To address this issue, several functional imaging modalities are being developed.

Functional imaging attempts to visualize changes in aspects of tumor metabolism, oxygen consumption, blood flow, and receptor expression. With respect to antiangiogenic imaging, several challenges must be overcome. Methods that allow for the quantification of changes in tumor vasculature must be identified. These methods must be validated against standard methods of measuring vascular density such as microvessel counting. They also must be shown to have a meaningful correlation with actual clinical activity of the agents being tested. Finally, one must be able to compare the results of these functional imaging studies with the more traditional scans and the patient's ultimate outcome. A variety of imaging techniques are under study as possible functional measures for antiangiogenic therapies (43).

Positron emission tomography (PET) can be used to assess a variety of aspects of the biologic response to antiangiogenic agents. Depending on the radiopharmaceutical used, assessments of changes in tumor metabolism, tumor blood flow, and tumor blood volume can be made before, during, and after therapy with antiangiogenic agents (Fig. 22-2). Several studies have shown that malignant lesions demonstrate elevated glycolysis when compared to normal tissues (44,45). By using the radiolabeled glucose analog (18-F) fluorodeoxyglucose (FDG) investigators have documented increased uptake of FDG in cancer tissues (46,47). PET scanning with [18]FDG has been used to image a variety of malignant neoplasms, including breast cancer, head and neck tumors, lung cancer, lymphoma, melanoma, ovarian tumors, bone cancers, and colorectal carcinomas.

CT SCAN Dynamic MRI

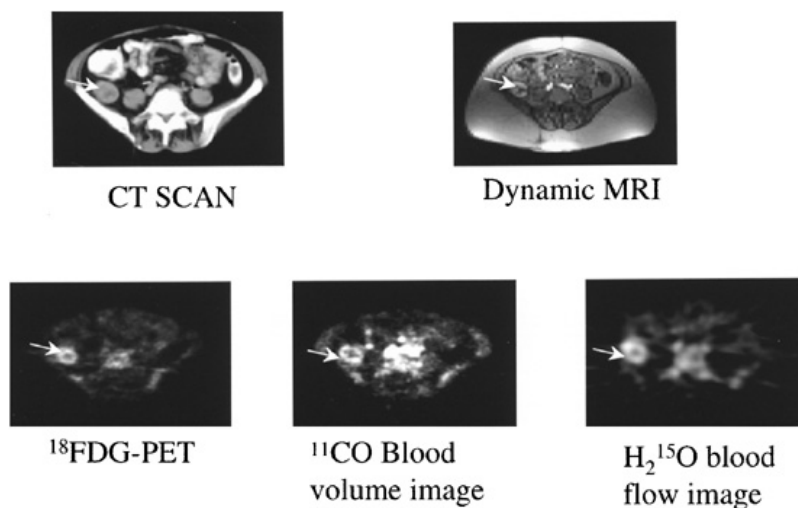
[18]FDG-PET [11]CO Blood volume image $H_2{}^{15}O$ blood flow image


FIGURE 22-2. A variety of functional imaging studies are available to assess the degree of vascularity of tumors as well as changes in tumor metabolism. Illustrated here are five images obtained from a patient with a retroperitoneal mass *(arrow)* using a variety of imaging modalities. ([11]CO, radiolabeled carbon monoxide; CT, computed tomography; [18]FDG-PET, radiolabeled fluorodeoxyglucose positron emission tomography; $H_2{}^{15}O$, radiolabeled water; MRI, magnetic resonance imaging.)

The mechanism whereby [18]FDG is selectively accumulated in neoplastic tissue is based not only on increased uptake of FDG and conversion to FDG-6-phosphate, but also on the inability of neoplastic cells to further metabolize FDG-6-phosphate. This molecule is therefore trapped in the cells, facilitating accurate imaging. As the blood flow to a tumor is decreased, the supply of oxygen and nutrients should be decreased as well. This may result in a shift from aerobic to anaerobic metabolism, and this also may impact on glucose metabolism of the tumor cells. Therefore, [18]FDG-PET may demonstrate changes in the tumor during the course of antiangiogenic therapy that may not be appreciated on conventional imaging (43).

If an agent is designed to inhibit new vessel formation and to decrease the overall vascularity of a tumor, it follows that the blood flow to the tumor and the total blood volume in the tumor

should change. PET has been used in a variety of clinical settings to measure both blood flow and blood volume (48,49 and 50). Much of this work has been done in the heart and the brain to measure normal physiologic parameters. These techniques have been applied to the study of neoplastic tissue (51,52,53,54 and 55). Using the radiopharmaceuticals $H_2^{15}O$ (radiolabeled water) and ^{11}CO (radiolabeled carbon monoxide), assessments of blood flow and blood volume can be made. Accurate quantification of myocardial blood flow (in absolute units of mL per minute per g of tissue) has been performed as well as quantification of blood flow to the liver, cerebral blood flow, and metabolism. With regard to neoplasms, investigators have shown changes in the blood flow to tumors in the brain in response to angiotensin-2 using such techniques (54).

Use of ^{11}CO, which is an excellent red blood cell label (attaching to hemoglobin), permits quantitative measurement of red blood cell volume in tissues. Both radiolabeled water and radiolabeled carbon monoxide can be easily administered. Radiolabeled water can be delivered intravenously, and its short half-life and rapid clearance allows for short imaging times. Radiolabeled carbon monoxide is administered by inhalation and, although it binds tightly to red cells, it, too, has a relatively short half-life. By combining the information obtained using these two agents, accurate assessments of blood flow and blood volume have been obtained (56,57,58,59,60,61,62,63 and 64). Both of these agents are well tolerated, and the small volume of water (<10 cc per injection) has little physiologic effect. The sensitivity of the PET scanner is such that the amount of radiolabeled carbon monoxide that is administered is many orders of magnitude below that needed to produce any deleterious physiologic effect.

In addition to PET scanning, dynamic MRI is also a promising new technique (43,65). Dynamic enhanced MRI involves the rapid administration of a gadolinium-based contrast agent followed by ultrafast analysis of signal intensity. Patterns of MRI contrast uptake within tumors correlate within microvascular density (66). Some variability has been noted in the strength of this correlation, but it should be possible in individual subjects to monitor changes in microvascular density using dynamic enhanced MRI. This is particularly true for the early phases of enhancement after injection when the agent is principally intravascular and has not yet leaked into the interstitial space. Early studies have concentrated on MRI mammography in which differences in enhancement patterns have been shown to be predictors of the malignancy of a lesion (67,68,69,70 and 71). Still others have investigated the role of dynamic contrast-enhanced MRI in uterine cervical cancer, myocardium, and liver metastases (72,73 and 74). The development of contrast agents that remain in the intravascular space and do not leak into interstitial tissues may further improve the sensitivity of dynamic MRI for the quantification of microvascular density.

Using image-processing algorithms established for the detection of malignancy for MRI, it may be possible to assess changes in perfusion and microvessel density over time in lesions being treated with agents that inhibit angiogenesis. Comparative quantification can be used to assess changes in tumor microvascular density. Diffusion-weighted MRI allows an assessment of net perfusion and diffusion and is widely used in the assessment of cerebrovascular accidents. This technique may also reflect tumor perfusion, as diffusion would be expected to decrease as the flow decreases. Therefore, the activity of antiangiogenic agents as measured by their ability to decrease microvascular density and therefore tumor blood flow and blood volume may be accurately assessed by these advanced functional imaging techniques.

There are several potential biologic markers that can also be used as end points in assessing the efficacy of antiangiogenic agents. Circulating angiogenic-related factors, such as VEGF and bFGF, can be measured in the urine, serum, and plasma of patients before and during therapy. Changes in these levels may be predictive of ultimate tumor responses (75,76). If tumor tissue is accessible for biopsy, a variety of assays can be performed.

Microvessel density as a determinant of the angiogenic index can be followed while patients are on therapy. Proliferation and migration assays can be performed on tumor cells, tumor-associated endothelial cells, or both (30). Apoptosis assays [TUNEL (*in situ* DNA nick end labeling)] can be performed on fresh tissues and interpreted for both the tumor cells and the endothelial cells. The production and subsequent activity of angiogenesis-associated factors, whether they are stimulatory or inhibitory, can be measured (77,78). The expression of endothelial cell surface receptors can also be determined as can their level of phosphorylation or activation, or both (15,79).

With the advent of DNA microarray technology, the upregulation or downregulation of important genes related to tumor growth or vascular development can be rapidly screened for from small quantities of biopsy material (80). Using laser-capture microdissection, tumor cells and endothelial cells can be separated and analyzed independently (81). These powerful new techniques can be used to ascertain the processes involved in the mechanism of antiangiogenic action. Newer automated systems can screen thousands of genes at a time.

Although the ultimate end point desired is the prolongation of survival and inhibition of tumor progression, the trials needed to assess these end points often require hundreds of patients, taking years to accomplish. In the early development of antiangiogenic agents, these end points, although an important ultimate goal, may represent an unrealistic challenge. Using surrogate end points and advanced imaging techniques, more rapid screening of novel antiangiogenic agents may be accomplished.

Antiangiogenic Agents Currently in Clinical Trials

Part of "22 - Antiangiogenesis: Clinical Applications"
The number of clinical trials evaluating antiangiogenic agents increased significantly in the late 1990s. Table 22-2 lists the agents currently being evaluated in the clinic along with their putative mechanism of action, the trial type, and the tumor histologies being accrued. This list is evolving and may not be complete. We discuss several of these agents in detail to provide examples of the different types of compounds currently under clinical investigation.

Table 22-2 Antiangiogenic Agents Currently in Clinical Trials

Agent	Mechanism of Action	Trial Type	Histologies	Sponsor
TNP-470	Inhibits endothelial cell growth; synthetic analogue of fumagillin	Phase 1, 2	Adult cancers, pediatric solid tumors, lymphomas, leukemias	TAP Pharmaceuticals, Deerfield, IL
Thalidomide	Unknown, possible modulation of TNF-α VEGF	Phase 1, 2, 3	Kaposi's sarcoma, prostate, lung, breast, glioblastoma, colon, renal, myeloma	Celgene, Warren, NJ
CAI	Inhibitor of calcium influx	Phase 1, 2, 3	Ovarian, non-small-cell lung, renal cancer	NCI, Bethesda, MD
Suramin	Unknown, effects are at multiple sites	Phase 1, 2, 3	Prostate	Parke-Davis, Morris Plains, NJ
Squalamine lactate, MSI-1256F	Inhibits sodium-hydrogen exchange; extracted from dogfish shark liver	Phase 1	Adult cancers	Magainin Pharmaceuticals, Plymouth Meeting, PA
Combretastatin A-4 (CA4P)	Induces apoptosis in proliferating endothelial cells	Phase 1, 2, 3	Adult cancers	Oxigene, Boston, MA
Neovastat	Naturally occurring MMP inhibitor	Phase 1, 2, 3	Adult solid tumors, non-small-cell lung cancer	Aeterna, Sainte-Foy, Quebec
COL-3	Derivative of tetracycline, synthetic MMP inhibitor	Phase 1, 2	Solid tumors	Novartis, East Hanover, NJ
Marimastat	Synthetic MMP inhibitor	Phase 3	Pancreas, non-small-cell lung, breast	British Biotech, Annapolis, MD
AG3340	Synthetic MMP inhibitor	Phase 3	non-small-cell lung, prostate	Agovron, La Jolla, CA
Bay 12-9566	Synthetic MMP inhibitor	Phase 3	Lung and pancreatic	Bayer, West Haven, CT
Vitaxin	Humanized antibody to αvB3 integrin on ECs	Phase 1	Adult solid tumors	Ixsys, Inc., La Jolla, CA
EMD121974	Inhibits/blocks αvB3 and αvB5	Phase 1	Adult solid tumors	Merke KCgaA, Darmstadt, Germany
Anti-VEGF antibody	Monoclonal humanized antibody to VEGF	Phase 1, 2, 3	Lung, breast, prostate, colorectal, renal cell	Genentech, South San Francisco, CA
Interferon-α	Inhibits production of bFGF and VEGF	Phase 1, 2	Solid tumors	Available commercially
SU5416	Blocks signaling of VEGF receptor	Phase 1	Adult solid tumors and Kaposi's sarcoma	Sugen, Redwood City, CA
SU6668	Blocks signaling of VEGF, FGF, and EGF receptors	Phase 1	Adult solid tumors	Sugen, Redwood City, CA
PTK 787/ZK 22584	Blocks VEGF receptor signaling	Phase 1, 2	Glioblastoma, Kaposi's sarcoma, von Hippel-Lindau's	Novartis, East Hanover, NJ
Interleukin-12	Upregulates expression of interferon-g and IP10	Phase 1, 2	Solid tumors and Kaposi's sarcoma	Genetics Institute, Cambridge, MA
IM862	Unknown	Phase 3	Kaposi's sarcoma	Cytran, Kirkland, WA
Platelet factor 4	Inhibits endothelial cell growth	Phase 2	Adult solid tumors	Repligen, Cambridge, MA
ZD0101	Bacterial toxin that binds new blood vessels and induces inflammation	Phase 2	Adult solid tumors	Zeneca Pharmaceuticals, Wilmington, DE
CM 101	Induction of host response to tumor vasculature	Phase 1	Solid tumors	Carbomed, Brentwood, TN
AE-941	Inhibits MMPs and angiogenesis (mechanism unknown)	Phase 1, 2	Lung cancer, solid tumors	Aeterna, Sainte-Foy, Quebec
PNU-145156E-a	Sulfonated distamycine A derivative lowers AT III levels	Phase 1	Solid tumors	Pharmacia & Upjohn, Milan, Italy
Endostatin	Unknown	Phase 1	Solid tumors	NLI, Bethesda, MD and Eutremed, Rockville, MD

AT, Antithrombin III; bFGF, basic fibroblast growth factor; CAI, carboxyamido-triazole; ECs, Endothelial cells; EGF, epidermal growth factor; FGF, fibroblast growth factor; IP10, interferon inducible protein 10; MMPs, matrix metalloproteinases; TNF-α, tumor necrosis factor-α; TNP-470, trinitrophenyl-470; VEGF, vascular endothelial growth factor.

Trinitrophenyl-470

Fumagillin is an antibiotic derived from the fungus *Aspergillus fumigatus Fresenius.* Fumagillin was initially shown to be an inhibitor of angiogenesis in a variety of assays, including the CAM assay and the dorsal, air-sac assay in the mouse. However, fumagillin is extremely toxic, and, therefore, potent nontoxic analogues were sought. Trinitrophenyl-470 (TNP-470) is one such analogue of this natural product (82,83). A variety of preclinical studies were performed using TNP-470 *in vivo* with tumor-bearing animals. These studies demonstrated reductions in the size and number of both primary tumors as well as experimentally induced metastases (84). Based on favorable preclinical data, TNP-470 entered into clinical trials.

Early phase 1 trials were conducted in patients with recurrent squamous cell carcinoma of the cervix, androgen-independent prostate cancer, and human immunodeficiency virus (HIV)-associated Kaposi's sarcoma (82,85,86 and 87). Taken as a whole, the results of these phase 1 trials indicated that when the drug was given as a 1-hour infusion every other day or on a Monday, Wednesday, and Friday schedule, the dose-limiting toxicity was neurocerebellar, and the maximum tolerated dose was 50 to 60 mg per m^2 per dose. A 4-hour infusion weekly also had as its dose-limiting toxicity neurocerebellar manifestations. The 120-hour (5-day) continuous infusion every 3 weeks is still an ongoing study. Based on the tolerated doses demonstrated in the phase 1 trials, phase 2 trials were performed in glioblastoma multiforme, advanced pancreatic carcinoma, cervical cancer, and renal cell carcinoma. The trial

performed for renal cell carcinoma used a dose of 60 mg per m^2 as a 1-hour infusion given three times per week. Thirty-three patients were enrolled in this trial, of which 20 were evaluable. There was one partial response (PR), five (25%) patients had stable disease for longer than 16 weeks, and the dose-limiting toxicity included two patients with central nervous system toxicity, one patient with fatigue, and one death from gastrointestinal hemorrhage after only one dose (88). TNP-470 may be limited in its efficacy as a single agent. Ongoing studies are evaluating extended duration of infusion and alternate formulations. Combination studies with cytotoxic agents are currently under way. Preclinical data has demonstrated that the addition of TNP-470 to paclitaxel and carboplatin results in increased antitumor activity and efficacy (89).

Thalidomide

Thalidomide was first developed in the 1950s as an oral sedative. It had been extensively studied in preclinical animal models and showed little or no toxicity (82). In 1961, a connection was made between thalidomide and babies born with malformed limbs to mothers using the drug as a sleeping pill (90). Further clinical use of the drug was halted at that time. The experience with thalidomide is an important example of the differences across species in the metabolism of various agents. Mice lack the enzymes necessary in their livers to metabolize thalidomide down to its derivative products, which are metabolically active. The absence of toxicity in the preclinical models is therefore understandable.

Thalidomide is an immunomodulatory drug that has the ability to downregulate the expression of tumor necrosis factor-α (TNF-α) messenger RNA (91). Thalidomide's immunomodulatory properties led to its use in the treatment of patients with erythema nodosum leprosum that is a complication of lepromatous leprosy. Thalidomide is currently U.S. Food and Drug Administration approved for this use. Treatment of severe ulcers associated with Behçet's disease and HIV infection as well as chronic graft-versus-host disease and tuberculosis with thalidomide is also under evaluation (92).

Thalidomide has been shown in preclinical models to prevent the development of neovascularization (93,94). The exact mechanism of this action is not yet known. Several metabolites of thalidomide are active. There is some speculation that modulation of VEGF levels as well as TNF-α may be the important targets. Preclinical models have also demonstrated that thalidomide can result in antitumor activity against murine colon cancer (95). The observation that thalidomide inhibits neovessel formation may, in fact, be related to the mechanism of teratogenicity that was seen in children born with malformed limbs (32). Based on the preclinical data indicating the effectiveness of thalidomide at inhibiting tumor neovessel formation and based on its ease of dosing as an oral agent, thalidomide was moved into clinical trials.

A phase 1 trial has been conducted in patients with acquired immunodeficiency syndrome (AIDS)-associated Kaposi's sarcoma (96). The trial accrued 12 patients (all homosexual or bisexual males) with a mean age of 31 years. Four dose levels were evaluated: 200, 300, 400, and 600 mg per day. Thalidomide was continued until toxicity or disease progression. Dose-dependent somnolence developed in all patients, and resulted in therapy being discontinued in two of three patients at the 600-mg per day dose. Other toxicities consisted of skin rash (one patient receiving 300 mg), fever (one patient receiving 300 mg), headache (one patient receiving 600 mg), dry mouth (one patient receiving 300 mg), and peripheral neuropathy (one patient receiving 400 mg per day after 4 months). Although the main end point was toxicity, all patients were evaluable for response. Two PRs were seen, and seven patients had stable disease. Median time to progression was 4 months, and survival was 4 to 18 months. The maximum tolerated dose was defined as 600 mg per day in this patient population (96)Ro022r001.

Similar results were seen in a phase 1 and 2 trial of thalidomide in patients with advanced cancers (97). This trial accrued 60 patients with a variety of histologies, including melanoma, breast, colon, mesothelioma, renal cell, and glioblastoma. The maximum tolerated dose was 500 mg per day. Overall, two patients had a PR, with ten patients having stable disease (97).

In a phase 2 trial of patients with metastatic melanoma, renal cell, ovarian, and breast cancers, thalidomide was given at a dose of 100 mg per day and was well tolerated. Of the 48 patients enrolled, ten had stable disease whereas three had differential responses (98). In this trial, stable disease was associated with stable or falling serum and urine VEGF levels. Those patients who progressed had rising VEGF levels detected in the urine and serum (98). This study illustrates the potential utility of secondary end point measures in evaluating the activity of antiangiogenic agents.

A randomized two-arm phase 2 study examining two doses of thalidomide, 200 mg per day versus 600 mg per day, has been conducted in patients with androgen-independent prostate cancer. This study has been completed, and it appears that the 200 mg per day dose may have equal efficacy to the 600 mg per day dose and fewer side effects (WD Figg, *personal communication*, 1999). The response rates and pharmacokinetic data are pending.

A trial has opened at the National Cancer Institute studying thalidomide in doses up to 300 mg per day randomized against a placebo for the treatment of patients after the resection of colorectal cancer metastases. The end point for this trial is disease-free survival. Other trials looking at glioblastoma multiforme, recurrent head and neck carcinoma, multiple myeloma, and hormone-sensitive prostate carcinoma are under way.

Squalamine Lactate

Squalamine lactate (MSI-1256F) is an amino sterol isolated from the dogfish shark liver. Its mechanism of action appears to be the inhibition of the sodium-hydrogen exchanger NHE3. Preclinical data demonstrated inhibition of endothelial cell proliferation. Two phase 1 clinical trials have been conducted (99,100).

A 5-day continuous infusion every 3 weeks was evaluated using the continual reassessment method of dose escalation and the accrual of a single patient at dose levels with minimal toxicity (99). To date, 12 patients received 26 courses at doses ranging from 6 to 255 mg per m^2 per day. No dose-limiting toxicities have occurred. Toxicities that were not dose limiting included nausea, fatigue, and anorexia. No response data were reported (99).

A second continuous-infusion trial was performed in 16 patients with a variety of tumor types, including lung, ovarian, melanoma, breast, colon, renal cell and soft tissue sarcoma (100). Doses were escalated from 6 to 538 mg per m^2 per day. Dose-limiting toxicity was encountered in the two patients who received 538 mg

per m^2 per day and consisted of grade 3 elevations of transaminases. Other non-dose-limiting toxicities included fatigue, nausea, anorexia, myalgia, and lip numbness. No objective tumor responses were noted, and 14 patients have had disease progression (100).

Carboxyamido-Triazole

Carboxyamido-triazole (CAI) is an agent with cytostatic and antiproliferative properties. It has been shown to have antiinvasive and antiangiogenic activity (101,102 and 103). CAI selectively inhibits non-voltage-gated calcium influx and thereby modulates the elements involved in invasion and angiogenesis (104). As endothelial cells adhere to and spread on extracellular matrix proteins, an increase in intracellular calcium is seen. This can be inhibited by CAI exposure (104). CAI was evaluated in clinical trials using two formulations administered orally.

A polyethylene glycol (PEG)-400 solution or gelatin capsule containing the PEG-400 CAI solution was used (105). Patients with advanced refractory cancers were entered on the study and assessed for toxicity, pharmacokinetics, and response (105,106 and 107). Patients experienced mild or moderate nausea and vomiting that became compliance limiting in these trials. Using an every-other-day dosing schedule, one patient experienced reversible grade 3 sensory neuropathy, and one patient developed neutropenia (105). Based on these phase 1 data, the recommended phase 2 dose and formulation was 150 mg per m^2 per day in the PEG-400 liquid formulation. Disease stabilization was observed in 49% of the patient cohort, which lasted from 2 to 7 months. Patients had ovarian cancer, melanoma, colorectal cancer, pancreatic or biliary cancer, and lung cancer (105). To improve the tolerance to the agent, a phase 1 trial was conducted using a micronized formulation of CAI in patients with refractory solid tumors (105).

Twenty-one patients with refractory solid tumors were enrolled in this study. Patients received a test dose followed 1 week later by daily administration of CAI and the encapsulated-micronized formulation at doses of 100 to 350 mg per m^2. Patients remained on CAI until disease progression or dose-limiting toxicity. All 21 patients were assessed for toxicity, and 18 were evaluable for pharmacokinetics and response. Fifty percent of the patients demonstrated grade I and II gastrointestinal side effects. Dose-limiting toxicity was observed at the dose of 350 mg per m^2 per day, which consisted of reversible grade 2 and 3 cerebellar ataxia and confusion. One minor response was observed in a patient with renal cell carcinoma, and another nine patients had disease stabilization. The micronized formulation was thought to have a better toxicity profile and a similar frequency of disease stabilization. It was easier to administer, and the dose of 350 mg per m^2 per day was selected for further phase 2 investigations (105). Currently, a phase 2 trial evaluating orally administered CAI for patients with persistent or refractory epithelial-ovarian cancer or primary peritoneal cancers is under way as well as a phase 3 trial for non-small-cell lung cancer (NSCLC).

Inhibitors of Vascular Endothelial Growth Factor and Basic Fibroblast Growth Factor

VEGF and bFGF are important endothelial cell mitogens. The influence of these factors on the host vasculature leads to the invasion of vessels into the tumor and the formation of tumor neovasculature. This allows for tumor growth, invasion, and metastases. Therefore, inhibition of these cytokines either by preventing their production or interfering with their binding to receptors may have an impact on inhibiting tumor angiogenesis. Several strategies are being evaluated in clinical trials specifically directed against VEGF and bFGF.

Rhu Monoclonal Antibody Against Vascular Endothelial Growth Factor

A humanized, murine, monoclonal antibody (MAb) against VEGF has been developed and is currently being evaluated in a variety of clinical studies. RhuMAb VEGF has been designed to bind free-circulating VEGF and, therefore, decrease the levels of VEGF available to initiate the neovascular process. A phase 1 trial was conducted using RhuMAb VEGF as a single agent in adult patients (108). Doses were escalated from 0.1 to 10 mg per kg intravenously delivered over 90 minutes. Patients were treated on day 0, day 28, day 35, and day 42. Twenty-five patients were enrolled in the trial, 24 of whom completed all four doses. Toxicity was evaluated and grade 1 or 2 toxicity was seen in more than 20% of the patients. Three patients experienced tumor-related hemorrhage. Other toxicities noted were headache, asthenia, fever, nausea and vomiting, cough and dyspnea, and skin rash. Thirteen patients demonstrated stabilization of disease at 72 days after therapy. Pharmacokinetic analysis demonstrated linear pharmacokinetics at doses greater than or equal to 0.3 mg per kg with a mean terminal half-life of 17 days. No neutralizing antibodies to RhuMAb VEGF were seen (108).

Based on these results, several phase 2 trials have been initiated using RhuMAb VEGF as either a single agent or in combination with chemotherapy. Currently, there are trials with RhuMAb VEGF as a single agent for metastatic breast cancer, hormone-refractory prostate cancer, and renal cell carcinoma. RhuMAb VEGF is also being evaluated in combination with chemotherapy in patients with stage III and IV NSCLC and patients with previously untreated metastatic colon cancer.

Interferon-α

Interferon-α (IFN-α) decreases the production of proangiogenic cytokines such as bFGF (109). It has been gaining increasing popularity as an antiangiogenic agent, having been used successfully to treat life-threatening pulmonary hemangioma (18,110). Chronic low-dose administration of IFN-α was used to induce remission in 10 of 20 patients with life- or sight-threatening hemangiomas or tissue-destructive hemangiomas (111). IFN-α has been evaluated as a single agent in trials for hairy cell leukemia, chronic myelogenous leukemia, Kaposi's sarcoma, and squamous cell carcinoma (82). IFN-α has been used in combination with interleukin-2 (IL-2) and 5-fluorouracil (5-FU) in the treatment of metastatic renal cell cancer.

Forty-seven patients with metastatic renal cell cancer were treated using recombinant IL-2 and recombinant IFN-α subcutaneously in combination with intravenous 5-FU. Patients received an average of 2.4 cycles, and toxicity of grades 2 to 3

were observed in 24 and 17 patients, respectively. Nine major responses (seven complete and two partial) for an objective response rate of 19.1% were seen (112).

Clearly, an evaluation of a triple-drug combination such as this cannot discern the contribution of each individual agent because there was no randomization against a comparative arm. However, toxicity appeared to be acceptable. IFN-α has also been used in combination with TNP-470 in preclinical models and has shown an additive effect (82). IFN-α is being evaluated in a phase 2 pilot study for patients with progressive hairy cell leukemia after splenectomy. Additionally, this agent is being used in a trial treating recurrent unresectable meningiomas and malignant meningiomas. A pegulated formulation of IFN-α is being used in a phase 1 and 2 study in patients with solid tumors (113). In addition to measuring response, the ability to measure circulating serum levels of bFGF as well as levels of bFGF in the urine of patients on IFN-α represents a potentially important surrogate end point for these trials.

SU-5416

The agent SU-5416 is a synthetic compound that selectively inhibits the signaling of the VEGF receptor 2 (KDR) receptor tyrosine kinase (114). SU-5416 was shown to inhibit VEGF-dependent mitogenesis of human endothelial cells without having an effect on a variety of tumor cells *in vitro*. In mouse models, systemic administration of SU-5416 at nontoxic doses led to the inhibition of growth of subcutaneously implanted tumors. Furthermore, this antitumor effect was accompanied by a pale appearance of the tumors consistent with antiangiogenic activity (114).

A phase 1 single-agent trial was conducted in 12 patients using a biweekly infusion of doses ranging from 4.4 to 15 mg per m^2 per day. Tumor types included colon, breast, lung, prostate, and Kaposi's sarcoma. Toxicities have included pain and burning at the injection site, shortness of breath, cough, fatigue, and allergic reaction (115). No response data were reported in this study.

Several phase 2 and phase 3 trials are planned in a variety of tumor histologies, including Kaposi's sarcoma, colorectal, renal cell, prostate, head and neck, glioma, melanoma, and myeloma. Some of these trials plan to evaluate combination therapy with other antiangiogenic agents, such as thalidomide and IFN-α, or chemotherapy with 5-FU, leucovorin, cisplatin, and doxorubicin.

Vitaxin

Although VEGF and bFGF are important angiogenic stimulatory molecules and appear to be critical in the angiogenic response, there are other potential targets on endothelial cells for which novel therapeutic strategies have been developed. The endothelial cell-surface integrin αvß3 has been shown to be important for endothelial cell attachment to the basement membrane and inhibition of endothelial cell apoptosis (18,116). By targeting αvß3 and preventing its binding to the extracellular matrix, it is hypothesized that endothelial cells are not able to properly adhere and align themselves. The cells then undergo programmed cell death. Evidence supporting this hypothesis has been demonstrated in preclinical studies. Based on these data, a recombinant humanized murine monoclonal antibody has been developed against αvß3. This agent, vitaxin, is currently being evaluated in a phase 1 trial for adult solid tumors.

Twelve patients have been enrolled in this phase 1 trial and have received doses ranging from 0.1 to 2 mg per kg given once a week for 6 weeks. Several patients had infusion-associated fever, but no other significant side effects were noted. Of 12 evaluable patients, there was one PR (sarcoma), six patients with stabilization of disease, and five patients with progressive disease (116). Based on its favorable toxicity profile, vitaxin is being readied for a phase 2 trial.

Interleukin-12

IL-12 has been shown to interfere with neovascularization by its induction of IFN-γ and IFN inducible protein 10 (IP10) (117). IP10 has inhibitory effects on tumor vasculature. IP10 does not act on cell growth or on migration and attachment but rather it acts to interfere with formation of tube-like structures and may inhibit bFGF-induced neovascularization *in vivo* (18,118). In a study performed *in vivo* using a NSCLC model, intratumor injection of IP10 for a period of 8 weeks resulted in significant inhibition of tumor growth, tumor-associated angiogenic activity, and neovascularization. IP10 may prove to be a useful antiangiogenic agent in its own right.

A phase 1 trial of intravenous, recombinant, human IL-12 was conducted in patients with advanced malignancies. Patients were eligible for the trial if they had refractory tumors, normal organ function, and a Karnovsky performance status of greater than 70%. Recombinant IL-12 was given by intravenous bolus once as an inpatient and then after a 2-week rest period once daily for 5 days every 3 weeks as an outpatient. Forty patients were enrolled in the trial, including 20 with renal cancer, 12 with melanoma, and five with colon cancer. Twenty-five patients had received earlier systemic therapy. Common toxicities were fever and chills, fatigue, nausea, vomiting, and headache. Dose-limiting toxicity included oral stomatitis and liver function test abnormalities that occurred in three of four patients at the 1 µg per kg dose level. The 500 ng per kg dose level was determined to be the maximum tolerated dose. Biologic effects included dose-dependent increases in circulating IFN-γ without any detectable changes in other factors such as TNF-α. An objective tumor response was observed in two patients, one with metastatic renal cell carcinoma and one with melanoma. Four additional patients completed six 21-day treatment cycles with stable disease. Of note, of the 14 patients treated at the maximum tolerated dose (six renal, four melanoma) no responses were seen (119).

A pilot dose-finding trial was conducted in patients with AIDS-associated Kaposi's sarcoma (120). Doses of 100 ng per kg (five patients), 300 ng per kg (six patients), and 500 ng per kg (four patients) of subcutaneous IL-12 were administered twice a week. The main toxicities noted were reversible neutropenia, hepatotoxicity, and constitutional symptoms at the initiation of dosing. Only three patients were removed from the trial for toxicity. No responses were seen at the 100 ng per kg dose. Of the nine remaining patients with evaluable disease, four had PRs (three patients at the 300 ng per kg dose and one patient at

the 500 ng per kg dose). Overall, the drug appeared to be well tolerated in this patient population.

Matrix Metalloproteinase Inhibitors

Tumor angiogenesis and tumor invasion are two critically interdependent activities. Factors important to each may be critical targets for anticancer therapy. For tumor cells to spread through tissues, gain access to the circulation, and establish distant sites of metastases, they must be able to digest the substance present in the basement membrane and extracellular matrix. Matrix metalloproteinases (MMPs) are therefore extremely important to the tumor's ability to invade and spread. Inhibitors of MMPs may have activity not only on the growth of the primary tumor but also on its ability to metastasize.

MMPs are a family of stromal proteases that have a zinc ion within their active site and share strong structural and sequence homology. They are involved in the normal remodeling of the supporting interstitium during tissue morphogenesis and wound healing (18). MMPs are secreted by tumor cells and endothelial cells and are involved in extracellular matrix degradation. Tumor cells use MMPs to break down and remodel tissue matrices during metastatic spread, and endothelial cells use MMPs for vascular invasion into surrounding tissue, including the tumor. Several inhibitors of MMPs have been developed and are entering clinical trials.

Marimastat

Marimastat is a synthetic inhibitor of MMPs that specifically inhibits MMP-1, MMP-2, MMP-7, and MMP-9 (121). A pilot escalating dose study of oral marimastat has been performed in patients with recurrent colorectal cancer. In these patients, an examination of serologic response was made by measurement of carcinoembryonic antigen (CEA) levels. This study assessed the safety and tolerability of 4 weeks of administration of marimastat and determined a dose range that produced detectable serologic effects (121). Patients were recruited by the criteria of a serum CEA level greater than 5 ng per mL and rising by more than 25% over a 4-week screening period. Patients were treated for 28 days and entered into a continuation protocol if a serologic response or clinical benefit was observed. A biologic effect was defined as a CEA value on day 28, no greater than on day 0; a partial biologic effect was defined as a rise in CEA over the 28-day treatment period of less than 25%.

Of the patients recruited, 63 completed the 28-day treatment period and 55 were eligible for CEA analysis. The median rates of rise of CEA fell significantly during the treatment period when patients received twice-daily marimastat. No effect was seen with the once-daily regimen. Toxicities were mainly musculoskeletal and occurred in a dose- and time-dependent fashion. The occurrence of musculoskeletal side effects defined 25 mg twice a day as the upper-limit dose range for continuous use (121). This trial used a surrogate marker (CEA levels) as a means of rapidly evaluating the potential efficacy of an agent in a relatively short period.

A phase 1 and 2 study of marimastat combined with captopril and dalteparin (Fragmin) has been completed (122). Seventeen patients were enrolled representing a variety of tumor types, including renal, colorectal and prostate cancer. The dose of marimastat administered was 10 mg orally twice a day. In addition to toxicity, the trial assessed response rates and changes in circulating cytokines such as VEGF (122). Toxicities attributed to marimastat included altered taste, musculoskeletal pain, and myalgia or arthralgia. One patient had a PR. VEGF levels fell in five patients (122).

A dose-finding study using marimastat for patients with pancreatic cancer has been performed (123). A total of 64 patients were enrolled in the trial; all had advanced pancreatic cancer that had failed earlier therapy. Patients received doses of marimastat ranging from 10 to 150 mg daily administered orally. The end points of the trial were safety, tolerance, and changes in the rate of rise of CA 19-9 (a tumor marker) as a surrogate marker for disease progression (123). Overall, marimastat was well tolerated. Dose-limiting toxicity included joint pain and stiffness; doses of 5, 10, and 25 mg twice a day were found to be acceptable. A reduced rate of rise in CA 19-9 was found at all three of these doses, and the median survival was 160 days with a 1-year survival of 21% (123).

Marimastat was evaluated in combination with carboplatin and paclitaxel and was well tolerated (124). In this study, 22 patients with NSCLC were treated, and 50% achieved a PR (124). Several other trials are ongoing evaluating marimastat alone or in combination with chemotherapy or radiation therapy (125,126). Of particular note are two randomized phase 3 trials, one evaluating marimastat in patients with breast cancer and the other in patients with small-cell lung cancer. As these trials mature, the potential role for marimastat may become more fully elucidated.

AG3340

The compound AG3340 is a selective inhibitor of MMPs 2, 3, 9, and 14 (29). MMPs 2, 3, 9, and 14 are associated with tumor angiogenesis, invasion, and metastasis. AG3340 has been evaluated in a human malignant glioma model in severe combined immunodeficient (SCID) mice (127). Animals were treated with daily intraperitoneal injections of AG3340 or a control and tumor volumes were measured over 31 days. Animals receiving AG3340 had a 78% reduction in tumor volume and survived 40 days longer (71 versus 31 days) than animals receiving a negative control (127). No significant toxicity was appreciated.

A phase 1 study of AG3340 in combination with paclitaxel and carboplatin for patients with advanced solid tumors has been completed (29). Fifteen patients were enrolled and received a regimen consisting of chemotherapy administered on day 1 of a 21-day cycle (carboplatin AUC = 5 mg per minute per mL and paclitaxel 200 mg per m^2) and AG3340 administered at a dose of 25 mg orally twice a day starting on day 15 and continuing thereafter. The majority of toxicities seen were attributable to one or the other chemotherapeutic agents. Toxicities specific to AG3340 were seen in two patients and were notable for one case of an alteration in taste and a grade 2 myalgia. Overall, the regimen was well tolerated. Of the 15 patients enrolled, 13 remain on study with stable disease

while two have terminated the treatment due to disease progression (29). Further follow-up is needed to evaluate patients for response.

COL-3

Another synthetic MMP inhibitor is the derivative of tetracycline designated COL-3 (128). COL-3 has been shown to downregulate MMP-2 and MMP-9 expression. Several phase 1 studies of COL-3 are ongoing. One is a phase 1 trial of COL-3 in patients with advanced solid tumors being conducted at the San Antonio Cancer Institute with end points being the definition of maximum tolerated dose, identification of dose-limiting toxicity, and definition of pharmacokinetics and pharmacodynamics. A phase 1 study of COL-3 in patients with HIV-related Kaposi's sarcoma is being conducted by the AIDS-Associated Malignancies Clinical Trials Consortium. In addition to standard phase 1 end points, this trial is also designed to evaluate the effect of COL-3 on CD4 and CD8 cell counts and on serum levels of MMP-2 and MMP-9 as surrogate markers. Serum from these patients is also being evaluated for antiangiogenic activity using *in vitro* assays. A phase 1 study of oral COL-3 in patients with refractory-metastatic solid tumors or lymphoma is also being conducted at the National Cancer Institute. This trial is designed to assess the effects of serum from patients being treated with COL-3 on bioassays designed to measure antiangiogenic activity, as well as toxicity and pharmacolcinetics.

Bay 12-9566

Bay 12-9566 is a nonpeptide biphenyl compound that inhibits MMP-2 and MMP-9 predominantly (129). Preclinical studies demonstrated inhibition of tumor growth, invasion, and metastasis with prolonged administration and led to the initiation of several clinical trials (129,130,131 and 132). In a phase 1 trial, 20 patients with solid tumors received daily doses ranging from 100 to 1,600 mg per day. A variety of schedules were used, including once a day, twice a day, three times a day, and four times a day dosing. Doses of 400 mg three times a day and 400 mg four times a day were notable for toxicities, including grade 3 hyperbilirubinemia, grade 2 thrombocytopenia, and grade 2 nausea each leading to dose reductions. Overall, the agent was well tolerated (129).

In another phase 1 study, 29 patients were treated with doses up to 1,200 mg per day (131). The tumor types were varied and included colon, ovarian, breast, renal, and soft tissue sarcoma. The main toxicities were dose-related thrombocytopenia and transient elevations of transaminases. These were for the most part mild and not dose limiting. No significant musculoskeletal toxicities occurred. No response data were noted; however, patients tolerated therapy for up to 10 months, indicating that chronic administration may be possible (131).

Bay 12-9566 has also been studied in combination with paclitaxel and carboplatin (132). A total of 19 patients were treated in one of three cohorts: (a) paclitaxel + Bay 12-9566, (b) paclitaxel + carboplatin + Bay 12-9566, and (c) carboplatin + Bay 12-9566. All patients received Bay 12-9566 at a dose of 800 mg orally twice a day starting on day 8 of therapy. Toxicities were seen mainly in patients who had been heavily pretreated with chemotherapy. Most toxicity was attributable to carboplatin or paclitaxel. Overall, the regimen was well tolerated. Pharmacokinetic data indicated that Bay 12-9566 did not significantly alter the plasma concentration or clearance of the chemotherapeutic agents (132). Based on these initial studies, several phase 3 trials have opened utilizing Bay 12-9566 alone or in combination with chemotherapy.

Antiangiogenic Agents on the Verge of Clinical Trials

Part of "22 - Antiangiogenesis: Clinical Applications "

Given the rapidity with which the field of angiogenesis research is growing, there is no doubt that by the time this chapter appears in print, several more agents will be added to those currently being evaluated in clinical trials. There are some notable ones, for which preclinical data has matured enough that they are likely to appear in clinics in the near future. This section briefly describes these agents, the targets of their action, and their likelihood for further clinical development.

Angiostatin

Angiostatin was isolated from the urine of mice bearing the murine Lewis lung carcinoma based on its ability to inhibit endothelial cell proliferation *in vitro* (10). It was further characterized by its ability to inhibit metastatic lesions from Lewis lung carcinoma when exogenously administered. Structural analysis of angiostatin demonstrated that it comprises the first four kringles of plasminogen (10). Some reports indicate that smaller fragments of the molecule may be all that are required for its antiangiogenic effect (133). Angiostatin can act in a paracrine or endocrine manner and is generated by tumor media proteolysis of plasminogen.

Although the mechanism of action of angiostatin is not completely understood, some work has demonstrated that angiostatin binds to the cell surface of endothelial cells and may, in fact, bind the alpha subunit of adenosine triphosphate synthase (134). This binding may inhibit adenosine triphosphate synthase, which may be an important mediator of endothelial cell proliferation. Angiostatin has also been shown to induce apoptosis in endothelial cells (135).

Several preclinical studies of angiostatin have demonstrated the effectiveness of this agent in inhibiting the growth of tumors across a variety of histologies and in a variety of models. No significant toxicity has been seen to date (136). Given its broad spectrum of activity and favorable toxicity profile, angiostatin is currently being readied for phase 1 clinical trials.

Endostatin

Endostatin is another antiangiogenic molecule identified by Folkman and his coworkers using a similar strategy to that used for the isolation of angiostatin (11). Endostatin was purified from the urine of mice bearing a murine hemangioendothelioma and was found to be a 20-kd protein identical to the C-terminal fragment of collagen XVIII (11). Systemic administration of

endostatin specifically inhibits endothelial cell proliferation and is a potent inhibitor of angiogenesis. Endostatin has been shown to induce apoptosis selectively in endothelial cells. *In vivo* animal studies have shown that endostatin is able to inhibit the growth of metastases. It also results in regression or almost total obliteration of primary tumors with repeated treatment (11). Furthermore, it has been shown that mice bearing Lewis lung carcinoma, T241 fibrosarcoma, or B16 410 melanoma, did not develop resistance with multiple administrations of endostatin (137). Like angiostatin, endostatin has been shown to have broad activity against a variety of histologies in a number of different tumor models. None of these early preclinical models have demonstrated toxicity from repeat administrations of endostatin. Given its favorable toxicity profile and efficacy in preclinical models, three phase 1 clinical trials are in progress.

2-Methoxyestradiol

The endogenous estrogen metabolite 2-methoxyestradiol (2-ME) is a potent inhibitor of endothelial cell proliferation and invasion *in vitro* (138,139 and 140). Although its mechanism of action has not been completely elucidated, it does not appear to exert its effects through the estrogen receptor (139). Furthermore, it does not require heparin or sulfated cyclodextrins for its activity, unlike the angiostatic steroids of corticoid structure (141). The compound may interfere with a basic proliferation-associated cellular event, as its antiproliferative effects are not restricted to endothelial cells (139). Inhibition of cell growth was seen in several normal lines as well as a variety of tumor lines (139). Oral administration of 2-ME, 100 mg per kg per day, to mice bearing subcutaneous Meth-A sarcoma or B16 melanoma resulted in the inhibition of tumor growth with no apparent signs of toxicity (139). Quantification of tumor neovasculature demonstrated a marked reduction in the treated animals compared to controls (139).

The antiangiogenic effects of 2-ME were also evaluated in a corneal neovascularization assay (138). An oral dose of 150 mg per kg inhibited bFGF- and VEGF-induced neovascularization in mice by 39% and 54%, respectively (138). In a mouse model of human breast cancer, severe combined immunodeficient (SCID) mice bearing a subcutaneously implanted estrogen receptor–negative human breast cancer were treated with 75 mg per kg per day of 2-ME for 29 days (138). This resulted in a 65% reduction in tumor volume compared to controls without significant toxicity (138).

The activity of 2-ME against endothelial cells and tumor cells may involve an initiation of apoptotic cell death (140). Human pancreatic carcinoma cells when exposed to 2-ME demonstrated an increase in apoptotic cell death as well as a prolonged S phase after 48 hours of exposure (140). An inhibition of lung metastases was also demonstrated using this same cell line in nude mice (140). The ability to administer 2-ME orally as well as its low toxicity and broad activity make it an attractive agent for further clinical development.

RGD Peptides

RGD peptides, an exciting group of agents that bind specifically to receptors or integrins expressed on the endothelial cell surface, are being readied for use in clinical trials. These are peptides that contain an arginine, glycine, and aspartic acid residue. One such class of agents has a specific amino acid motif that selectively binds to the αvβ3 subunit, which is expressed on the antiluminal surface of endothelial cells. Using a phage display library, Arup and coworkers identified a 3-amino acid motif (RGD) which binds avidly to αvβ3 (142). Preclinical data demonstrated that conjugating chemotherapeutics, such as doxorubicin, to an RGD-containing peptide motif resulted in targeted delivery of a chemotherapeutic agent to tumor neovasculature (142). This type of targeted delivery to neovasculature can be exploited not only for therapeutic agents but also for the imaging of developing vessels. One could either radiolabel RGD-containing peptides or conjugate contrast agents, such as gadolinium, to these motifs, allowing the use of gamma cameras or MRI to visualize tumor vasculature. Other potential targets for surface binding on endothelial cells include the Tie receptors (Tie 1 and Tie 2), tissue factor, and VEGF receptors (18).

Thrombospondin

Thrombospondin is a 420-kd glycoprotein, which binds the CD36 receptor (143,144). Thrombospondin is a multifunctional matrix protein released from alpha granules of activated platelets in response to thrombin and influences the growth and function of a variety of normal and neoplastic epithelial and mesenchymal cell types (18). Thrombospondin is a binding inhibitor of plasmin as determined by loss of amidolytic activity, loss of ability to degrade fibrinogen, and decreased lysosomes in fibrin plate assays (145). Thrombospondin may be involved in tumor inhibition through a vascular means, as studies have shown that it functions by overriding the effects of VEGF (146). It has also been shown to inhibit bFGF-induced angiogenesis in the rat cornea model (147). Preclinical models are still being studied to determine the role of thrombospondin in the inhibition of tumor growth and metastases.

Endothelial Monocyte-Activating Polypeptide II

Endothelial monocyte-activating polypeptide II (EMAP-II) was isolated from the supernatant of the Meth-A fibrosarcoma based on its ability to induce tissue factor upregulation on the surface of endothelial cells (148,149). EMAP-II is a processed protein that is first synthesized in a pro-form of 34 kd and then cleaved at an interleukin converting enzyme-like cleavage site to a mature 22-kd form. Purified, recombinant, mature EMAP-II activates endothelial cells and results in elevation of cytosolic-free calcium concentrations, release of von Willebrand's factor, induction of tissue factor, and expression of E-selectin and P-selection (150).

EMAP-II was first studied with regard to its ability to render previously resistant tumors sensitive to the antitumor effects of TNF-α. Intratumoral injection of recombinant EMAP-II into a resistant mouse-mammary carcinoma (as well as B16 melanoma and a human fibrosarcoma) rendered these tumors sensitive to subsequent systemic injections of TNF (17). Further studies demonstrated that retroviral transduction of a human melanoma resistant to TNF, with the complementary DNA (cDNA) for EMAP-II, resulted in a conversion of the phenotype to a TNF-sensitive one (151).

The mechanism by which EMAP-II renders tumor vasculature sensitive to TNF-α appears to be through the upregulation of TNF-receptor I on endothelial cells (152,153). Cell lines transduced with EMAP-II are sensitive to TNF *in vivo,* although their *in vitro* sensitivity to TNF is unchanged. All of this evidence taken as a whole points to EMAP-II as a potent inducer of endothelial cell functions.

In addition to its upregulation of E-selectin, P-selectin, tissue factor, and TNF-receptor 1 on endothelial cells, EMAP-II appears to be a potent inhibitor of endothelial cell proliferation and neovascular formation. Early work demonstrated that recombinant EMAP-II inhibited neovessel formation in the CAM assay (ML Kayton, SK Libutti, *unpublished data*). Preliminary data using recombinant EMAP-II suggested that it might have an effect on endothelial cell apoptosis and neovessel growth in a subcutaneous Matrigel assay (154). Recombinant EMAP-II is being evaluated in preclinical animal models studying its antitumor effects as well as its toxicity.

Development of Antiangiogenic Gene Therapy

Part of "22 - Antiangiogenesis: Clinical Applications "

A number of the antiangiogenic agents described thus far are naturally occurring proteins or cleavage products thereof. These proteins can be difficult to produce recombinantly due to instability and sensitivity to changes in environmental factors such as freezing and thawing. Preclinical and clinical studies have indicated that it may be necessary to deliver antiangiogenic agents chronically to maintain long-term inhibition of primary tumor growth as well as to prevent the growth of micrometastases. Thus, to achieve adequate local tissue levels, high doses may need to be delivered systemically for prolonged periods. For example, effective doses of endostatin in murine models range from 10 to 100 mg per kg per day depending on whether murine or human recombinant endostatin is used (155). It may be difficult to produce large enough quantities of these recombinant materials to keep up with demand if they prove to be efficacious antitumor agents. Gene delivery strategies are an attractive alternative to exogenous dosing.

By engineering vectors that carry the coding sequence for an antiangiogenic protein, one can target specific sites in the host and allow the host to produce chronic levels of the antiangiogenic agent either regionally, where the tumor is growing, or systemically to prevent the growth of distant microscopic disease. This strategy has been attempted using several different gene-delivery vectors as well as a variety of genes encoding antiangiogenic agents (156,157,158,159 and 160). The approach has been to select a vector, such as an adenovirus, retrovirus, or liposome; construct an expression system carrying the gene of interest; and deliver that gene to the host.

Using an adenoviral vector to deliver a recombinant Tie 2-soluble receptor that blocked activation of the Tie 2 receptor on endothelial cells, Lin and his colleagues demonstrated that a single intravenous injection of this construct resulted in high circulating levels of the soluble receptor protein for up to 8 days (157). Growth of two different primary tumors was inhibited, and neovascularization and growth of lung metastases were almost completely abrogated (157). Using a cDNA coding for DNA complementary to angiostatin, Tanaka and associates demonstrated that retroviral and adenoviral vectors could be used to inhibit endothelial cell growth *in vitro* and angiogenesis *in vivo.* This technique mediated the inhibition of tumor-associated angiogenesis, resulting in increased apoptotic tumor cell death, leading to inhibition of tumor growth (158).

Plasminogen activator inhibitor type I has been used in an adenovirus-mediated gene-transfer model and demonstrated the *in vivo* inhibition of metastasis of an intraocular melanoma in a murine model (159). The use of this adenoviral vector resulted in transduction of more than 95% of human and murine uveal melanoma cells in the eyes of nude mice. A 50% reduction in the number of animals developing liver metastases was seen. Intravenous injection of the adenovirus plasminogen activator inhibitor type I construct resulted in transduction of normal liver cells, culminating in the reduction in the incidence of metastases and prolongation of survival (159).

The cDNA coding for angiostatin, endostatin, and an antisense messenger RNA species against VEGF have been used to create a recombinant adenoassociated virus by Nguyen and his colleagues at the Beth Israel Deaconess Medical Center (160). Although this study was an *in vitro* study, they were able to demonstrate measurable levels of antiangiogenic protein production in the supernatant of transfected cells. Concentrated supernatant demonstrated antiangiogenic activity in an endothelial cell proliferation assay.

Using a unique signal sequence attached to the cDNA coding for endostatin, an adenoviral vector was created that efficiently transfected cells in culture. Measurements of endostatin in the cell supernatant from cells infected with signal-sequence endostatin had detectable levels, whereas the endostatin construct without a signal sequence showed only intracellular levels of the molecule without secretion into the supernatant (161). Furthermore, when this adenoviral construct was injected systemically into immunocompromised mice, significantly increased circulating levels of endostatin could be detected in the serum up to 3 μg per mL at 4 days. Tumor growth was inhibited in nude mice bearing a subcutaneous colon cancer (162).

The main hurdle to antiangiogenic gene therapy is finding vector systems that deliver the gene efficiently, resulting in sustained and effective levels of gene production without toxicity to the host from either the vector itself or the protein being produced. To date, viral vectors have been limited by their immunogenicity, often resulting in neutralization of the virus (163). With the introduction of new vector systems, such as liposomes and other synthetic carriers, effective clinical gene therapy may become a reality.

Although there are currently no open clinical trials utilizing antiangiogenic gene therapy, the number of preclinical studies is increasing rapidly. As the hurdles to gene therapy are overcome, many of these strategies become viable ones for evaluation in the clinic.

Summary and Conclusions

Part of "22 - Antiangiogenesis: Clinical Applications "

The focus of anticancer therapies has, for the better part of this century, been on attacking the tumor cell directly. Since the

1970s, this has been shifting to other aspects of the tumor host interaction. The relationship between tumors and their vasculature is a prime example of the tumor-host interface that can be an important target for antitumor strategies. The interest in antiangiogenic therapy has increased dramatically.

We have summarized the strategies for bringing agents from the bench to the bedside and highlighted those agents that are currently being evaluated in clinical trials. Emerging techniques in noninvasive imaging and in the ability to measure surrogate end points dramatically improves the ability to assess the biologic activity of this novel class of therapeutics and aid in their development. By using novel methods of gene therapy, exciting new advances may be on the horizon. Through the study of the relationship between the tumor and its blood supply, more is learned about how tumors invade and spread, helping to develop new methods to combat them.

Introduction

Part of "23 - Delivery of Biologic Molecules and Cells to Tumors "

To be successful, a therapeutic agent must satisfy two requirements: It must be effective in the *in vivo* microenvironment, and it must reach target cells *in vivo* in optimal quantities (1). Extraordinary advances in molecular biology and biotechnology have helped researchers identify novel targets and develop a vast array of therapeutic agents including the biologic agents described in this book.

These agents can be divided into three categories: molecules, particles, and cells. In chemotherapy, the therapeutic agent can be injected as a molecule or incorporated in a particle (e.g., a liposome). In gene therapy, it can be a molecule, a viral or nonviral particle, or a genetically engineered cell. Similarly, for immunotherapy, molecules such as antibodies, particles such as liposomes, or cells such as activated lymphocytes can be used.

When any of these agents is injected into a patient, the material is distributed throughout the body via the circulatory system. It then arrives in the blood vessels of the tumor and moves across the vessel walls and through the interstitial compartment to reach the cancer cells. To be effective, the therapeutic agent must cross these barriers and successfully reach targets in optimal quantities. Unfortunately, tumors develop in ways that hinder each of these steps (Fig. 23-1) (2,3).
FIGURE 23-1. Physiologic barriers that a blood-borne molecule encounters before it reaches a cancer cell in a solid tumor. A: Schematic of a heterogeneously perfused tumor showing well-vascularized periphery; a seminecrotic intermediate zone; and an avascular, necrotic central region. Note that immediately after intravenous injection, the molecules are delivered to perfused regions only. B: Low interstitial pressure in the periphery permits adequate extravasation of fluid and macromolecules. C: These macromolecules move toward the center by the slow process of diffusion. In addition, interstitial fluid oozing from tumor carries macromolecules with it by convection into the normal tissue. Note that the interstitial movement may be further retarded by binding. Products of metabolism may be cleared rapidly by blood. (Adapted from Jain RK. Delivery of novel therapeutic agents in tumors: physiological barriers and strategies. *J Natl Cancer Inst* 1989;81:570-576.)

This chapter explores the current understanding of these physiologic barriers to delivery and effectiveness, as well as some strategies to overcome or exploit them.

Distribution through Vascular Space

Part of "23 - Delivery of Biologic Molecules and Cells to Tumors "

The chaotic blood supply of tumors is the first barrier encountered by a blood-borne agent. The tumor blood supply consists of vessels recruited from the preexisting network of the host vasculature and vessels resulting from the angiogenic response of host vessels to cancer cells (4,5). Movement of molecules and cells through the vasculature is governed by the vascular morphology (i.e., the number, length, diameter, and geometric arrangement of various blood vessels) and the rate of blood flow (6,7,8,9 and 10).

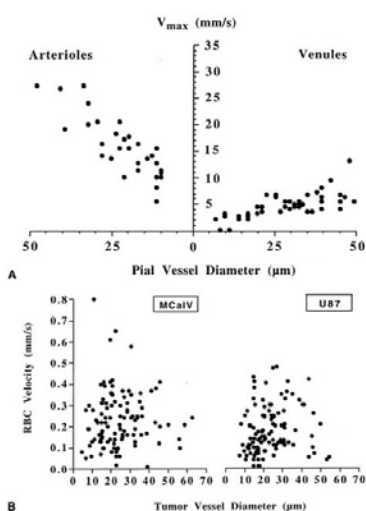
Although the tumor vasculature originates from the host vasculature and the mechanisms of angiogenesis are similar (4,10,11 and 12), its organization may be completely different depending on the tumor type, its growth rate, and its location. The fractal dimensions and minimum path lengths of tumor vasculature are different from those of normal host vessels (7,9,12,13). The architecture and blood flow are different not only among various tumor types but also among a tumor and its metastases (5,14). For example, unlike normal tissue, in which red blood cell velocity depends on vessel diameter, no such dependence is seen in tumors (15,16 and 17). Furthermore, the red blood cell velocity may be an order of magnitude lower in some tumors compared to the host vessels (Fig. 23-2). The temporal and spatial heterogeneity in tumor blood flow may, in part, be a result of elevated geometric and viscous resistance in tumor vessels (18,19,20 and 21), coupling between high vascular permeability and elevated interstitial fluid pressure (8,22), vascular remodeling by intussusception (11), and solid stress generated by proliferating cancer cells (23,24).


FIGURE 23-2. Blood velocity as a function of vessel diameter in normal pial vessels (A) a murine mammary carcinoma (MCaIV) and a human glioma (*U87*) xenograft on the pial surface (B). Note that in normal microcirculation, blood velocity depends on vessel diameter, whereas in tumors no such dependence exists. Furthermore, the blood velocity in tumor vessels is about an order of magnitude lower than in host vessels. (RBC, red blood cell; V_{max}, maximal velocity.) (Adapted from Yuan F, Salehi HA, Boucher Y, et al. Vascular permeability and microcirculation of gliomas and mammary carcinomas transplanted in rat and mouse cranial windows. *Cancer Res* 1994;54:4564-4568.)

Based on perfusion rates, four regions can be recognized in a tumor: (a) an avascular, necrotic region; (b) a seminecrotic region; (c) a stabilized microcirculation region; and (d) an advancing front (25) (see Fig. 23-1A). Intratumoral blood flow distributions in spontaneous animal and human tumors are now being investigated using nuclear magnetic resonance, positron emission tomography, and functional computed tomography (26,27,28 and 29). Although limited, these results are in concert with the transplanted tumor studies: Blood flow rates in necrotic and seminecrotic regions of tumors are low, whereas those in nonnecrotic regions are variable and can be substantially higher than in surrounding (contralateral) host normal tissues (30). Considering these spatial and temporal heterogeneities in blood supply along with variations in the vascular morphology at both microscopic and macroscopic levels, it is not surprising that the spatial distribution of therapeutic agents in tumors is heterogeneous and that the average uptake decreases, in general, with an increase in tumor weight.

Metabolic Microenvironment

Part of "23 - Delivery of Biologic Molecules and Cells to Tumors "

The temporal and spatial heterogeneities in blood flow lead to a compromised metabolic microenvironment in tumors, which decreases the effectiveness of some therapies. To quantify the spatial gradients of key metabolites, two optical techniques have been adapted: fluorescence ratio-imaging microscopy and phosphorescence quenching microscopy (31,32,33,34 and 35). As shown in Figure 23-3, pH and PO_2 decrease as the distance increases from tumor vessels leading to acidic and hypoxic regions in tumors. Coupled with the use of cells selected for impaired glycolytic and oxidative pathways, these methods have provided novel insight into pH regulation in tumors (36). Although low PO_2 and pH are detrimental to some therapies (e.g., radiation), they might enhance the effect of certain drugs, if the drug could be delivered in adequate quantities in those regions (37,38 and 39).
FIGURE 23-3. Spatial gradients of metabolites in tumors: pH (□) and PO_2 (▲). Distance from the vessel wall, in microns, is shown on the x-axis, with zero being the vessel wall. (Adapted from Helmlinger G, Yuan F, Dellican M, Jain RK. Interstitial pH and pO_2 gradients in solid tumors *in vivo:* simultaneous high-resolution measurements reveal a lack of correlation. *Nat Med* 1997;3:177–182.)

To gain further insight into tumor metabolism, two powerful approaches have been combined: magnetic resonance spectroscopy and tissue-isolated tumors. The former allows measurement of the energy level in tumors, whereas the latter allows control of the supply of individual substrates (e.g., glucose, oxygen) to the tumor. Using this combined approach, it has been shown that solid tumors depend more on glucose than oxygen to maintain their adenosine triphosphate level (40).

Transport Across the Microvascular Wall

Part of "23 - Delivery of Biologic Molecules and Cells to Tumors "

The vessel wall is the second barrier to therapeutic agents. Once a blood-borne molecule has reached an exchange vessel, it extravasates, by diffusion, convection, and—to some extent—presumably by transcytosis (41). Diffusive flux is proportional to the vascular permeability [P (measured in centimeters per second)], surface area of the exchange vessel [S (measured in square centimeters)], and the difference between the plasma and interstitial concentrations. Convection is proportional to the rate of fluid leakage from the vessel. Fluid flux, in turn, is proportional to the hydraulic conductivity [L_p (measured in centimeters per milligrams of mercury)], surface area of the exchange vessel, and the difference between the vascular and interstitial hydrostatic pressures. Thus, the transport of a molecule across tumor vessels is governed by two transport parameters (vascular permeability and hydraulic conductivity), the surface area for exchange, and the transvascular concentration and pressure gradients.

Vascular permeability and hydraulic conductivity of tumors in general are significantly higher than that of various normal tissues (16,41,42,43,44,45,46 and 47), and hence, these vessels may lack permselectivity (48) (Fig. 23-4). Positively charged molecules have a higher permeability (49). Despite increased overall permeability, not all blood vessels of a tumor are leaky (see Fig. 23-4). Even the leaky vessels have a finite pore size, which has been measured in a variety of human and rodent tumors (50). Our hypothesis is that the large pore size in tumors represents wide interendothelial junctions (50,51). Not only does the vascular permeability vary from one tumor to the

next, but within the same tumor it varies both spatially and temporally, and during tumor growth, regression, and relapse (41,52). The local microenvironment plays an important role in controlling vascular permeability. For example, a human glioma (HGL21) is fairly leaky when grown subcutaneously in immunodeficient mice, but it exhibits blood-brain barrier properties in the cranium. Such site-dependent differences have been noted for other tumors in other orthotopic sites (17). Our working hypothesis is that the host-tumor interactions control the production and secretion of cytokines associated with permeability changes [e.g., vascular permeability factor (VPF)/vascular endothelium growth factor (VEGF) and its inhibitors] (53,54). A better understanding of the molecular mechanisms of permeability regulation in tumors is likely to yield strategies for improved drug delivery (55).
FIGURE 23-4. Heterogeneous extravasation of 90-nm diameter liposomes from LS174T tumor vessels, 48 hours after injection. Note that some vessels are leaky, indicated by the brighter fluorescence for rhodamine, while others are not. Extravasated liposomes do not diffuse far from blood vessels. (Adapted from Yuan F, Salehi HA, Boucher Y, et al. Vascular permeability and microcirculation of gliomas and mammary carcinomas transplanted in rat and mouse cranial windows. *Cancer Res* 1994;54:4564-4568.)

If tumor vessels are indeed leaky to fluid and macromolecules, then what leads to the poor extravasation of these agents in various regions of tumors? As shown by us and others (56,57,58,59,60,61,62,63,64,65,66,67,68 and 69), experimental and human tumors exhibit high interstitial fluid pressure (Table 23-1). Furthermore, the uniformly high pressure drops precipitously to normal values in the tumor's periphery or in the peritumor region (57,70,71). This may lower fluid extravasation in the high-pressure regions, especially because the osmotic and hydrostatic pressures are also equal between the intravascular and extravascular spaces (58,72,73). Because the transvascular transport of macromolecules in normal tissues occurs primarily by convection (41,74), convective transport of macromolecules in the center of tumors may be less than in the tumor periphery (42,70,71). Additionally, the average vascular surface area per unit of tissue weight decreases with tumor growth; hence, reduced transvascular exchange would be expected in large tumors compared with small tumors (6,70).

Table 23-1 Interstitial Fluid Pressure in Normal and Neoplastic Tissues

Tissue Type	N	Mean (mm Hg)	Range (mm Hg)
Normal skin	5	0.4	-1.0-3.0
Normal breast	8	0.0	-0.5-3.0
Head and neck carcinomas	27	19.0	1.5-79.0
Cervical carcinomas	26	23.0	6.0-94.0
Lung carcinomas	26	10.0	1.0-27.0
Metastatic melanomas	14	21.0	0.0-60.0
Metastatic melanomas	12	14.5	2.0-41.0
Breast carcinomas	13	29.0	5.0-53.0
Breast carcinomas	8	15.0	4.0-33.0
Brain tumors[a]	17	7.0	2.0-15.0
Brain tumors[a]	11	1.0	-0.5-8.0
Colorectal liver metastasis	8	21.0	6.0-45.0
Lymphomas	7	4.5	1.0-12.5
Renal cell carcinoma	1	38.0	—

[a]Patients were treated with antiedema therapy.

Transport Through Interstitial Space and Lymphatics

Part of "23 - Delivery of Biologic Molecules and Cells to Tumors "

Once a molecule has extravasated, it moves through the third barrier—the interstitial space—by diffusion and convection (64). Diffusion is proportional to the concentration gradient in the interstitium, and convection is proportional to the interstitial fluid velocity (u_i, measured in centimeters per second). The latter, in turn, is proportional to the pressure gradient in the interstitium. Just as the interstitial diffusion coefficient (D, measured in square centimeters per second) relates the diffusive flux to the concentration gradient, the interstitial hydraulic conductivity (K, measured in square centimeters per millimeter of mercury times seconds) relates the interstitial velocity to the pressure gradient (64). Values of these transport coefficients are determined by the structure and composition of the interstitial compartment as well as by the physicochemical properties of the solute molecule (75,76,77,78,79,80,81 and 82).

Using fluorescence recovery after photobleaching, we have found D of various molecules to be about one-third that in water (83) and similar to that in the host tissue (76). Similarly, the value of K for a human colon carcinoma xenograft (LS174T) measured using two different methods (69,84) was found to be higher than that of a hepatoma (81), which in turn was higher than that of the liver. Given these relatively high values of D and K, why do exogenously injected macromolecules not distribute uniformly in tumors? Two reasons exist for this apparent paradox.

The time constant for a molecule with diffusion coefficient D to diffuse across distance L is approximately $L^2/4D$. For diffusion of immunoglobulin G (IgG) in tumors, this time constant is approximately 1 hour for a 100-µm distance, days for a 1-mm distance, and months for a 1-cm distance. So, for a 1-mm tumor, diffusional transport would take days, and for a 1-cm tumor, it would take months. If the central vessels have collapsed completely owing to cellular proliferation (23) and interstitial matrix rearrangement, no delivery of macromolecules by blood flow to this necrotic center will occur (24). Binding may further retard the transport in tumors (83,85,86,87,88,89,90 and 91). The role of binding-site-barrier is clearly illustrated in Figure 23-5, which compares the rate of fluorescence recovery of a photobleached spot in tumor tissue injected with a nonspecific versus specific IgG. In addition to the heterogeneity in D in tumors, the most unexpected result of these photobleaching studies was the large extent (30% to 40%) of nonspecific binding (83).
FIGURE 23-5. Role of binding in the interstitial transport in tumors, measured using fluorescence recovery after photobleaching. A: Recovery of a photobleached spot is complete in approximately 100 seconds for a nonspecific monoclonal antibody. B: Recovery is incomplete for an antibody against carcinoembryonic antigen, present on the surface of many carcinoma cells. (Adapted from Berk DA, Yuan F, Leunig M, Jain RK. Direct *in vivo* measurement of targeted binding in a human tumor xenograft. *Proc Natl Acad Sci U S A* 1997;94:1785–1790.)

As mentioned, interstitial fluid pressure is high in the center of tumors and low in the periphery and surrounding tissue (57,70,71). Therefore, one would expect interstitial fluid motion from the tumor's periphery into the surrounding normal tissue (see Fig. 23-1). In various animal and human (xenograft) tumors studied to date, 6% to 14% of plasma entering the tumor has been found to leave from the tumor's periphery (41,92). This fluid leakage leads to a radial outward interstitial fluid velocity of 0.1 to 0.2 µm per second at the periphery of 1 cm tissue-isolated tumor (41). [The radial outward velocity is likely to be an order of magnitude lower in a tumor grown in the subcutaneous tissue or muscle (70).] A macromolecule at the tumor periphery has to overcome this outward convection to diffuse into the tumor. The relative contribution of this mechanism of heterogeneous distribution of antibodies in tumors may be smaller than the contribution of heterogeneous extravasation owing to elevated pressure and necrosis (70).

In most normal tissues, extravasated macromolecules are taken up by the lymphatics and brought back to the central circulation. Because of the lack of functional lymphatics within the tumor, the fluid and macromolecules oozing from the tumor surface must be picked up by the peritumor host lymphatics (6). To characterize the transport into and within the lymphatic capillaries, we have developed a mouse tail model (93). We have measured uptake and transport in this model using a macroscopic approach (residence time distribution analysis) and a microscopic approach (fluorescence recovery after photobleaching) (94,95). Concerted efforts towards uncovering mechanisms of lymphangiogenesis (96) and understanding changes in lymphatic transport in the presence of a tumor (97) are needed. Preliminary studies suggest that lymphatics are collapsed in tumors owing to stress exerted on them by proliferating cancer cells (97).

Transport of Cells

Part of "23 - Delivery of Biologic Molecules and Cells to Tumors "

Cells may face additional barriers beyond those encountered by molecules and particles (e.g., liposomes) in tumors. When a cell enters a blood vessel, it may continue to move with flowing blood, collide with the vessel wall, adhere transiently or stably, and finally extravasate. These interactions are governed by local hydrodynamic forces and adhesive forces. The former are determined by the vessel diameter and blood velocity, and the latter by the expression, strength, and kinetics of bond formation between adhesion molecules and by surface area of contact (98,99). Deformability of cells affects both types of forces. Despite their importance in cell-based immunotherapy and gene therapy, the determinants of cell transport in tumors have not been examined extensively.

Using intravital microscopy, rolling of endogenous leukocytes has been shown to be generally low in tumor vessels, whereas stable adhesion (≥30 seconds) is comparable between normal and tumor vessels (100). On the other hand, both rolling and stable adhesion are nearly zero in angiogenic vessels induced in collagen gels by basic fibroblast growth factor (bFGF) or VEGF/VPF, two of the most potent angiogenic factors (101). Whether the latter is due to a low flux of leukocytes into angiogenic vessels, downregulation of adhesion molecules in these immature vessels, or both is currently under investigation. The age of the animal also plays an important role in leukocyte-endothelium interactions (102).

To gain further insight into the type of cells that adhere to tumor vessels, the localization of interleukin-2 (IL-2) activated natural killer (A-NK) cells was examined in normal and tumor tissues in mice using positron emission tomography (103,104). After systemic injection, these cells localized primarily in the lungs immediately after injection, and an undetectable number of cells arrived in the tumor (103). These findings were consistent with previous work on the deformability of these cells using micropipet aspiration technique, in which IL-2 activation was demonstrated to make these cells rigid and predict their mechanical entrapment in the lung microcirculation (105,106). Constitutive expression of certain adhesion molecules in the lung vasculature also facilitates their localization in the lungs (107).

One approach to reduce lung entrapment is to reduce the rigidity of these cells (108). Instead, to circumvent the lung, A-NK cells were injected into the blood supply of tumors, and A-NK cells, both xenogenic and syngeneic, adhered to blood vessels in three different tumor models (104,109,110). These results also supported the hypothesis that the endogenous cells that adhere to tumor vessels after systemic IL-2 injection are mostly activated lymphocytes (111).

To determine the adhesion molecules involved in the A-NK cell adhesion to tumor vessels, two *in vitro* approaches were used. In the first approach, the tumor vasculature was simulated *in vitro* by incubating human umbilical vein endothelial cells (HUVECs) in the tumor interstitial fluid (collected using a micropore chamber) (37,112,113 and 114). Using fluorometry, the expression of relevant adhesion molecules on the HUVEC monolayers was quantified (115). To determine the relative contributions of these molecules in adhesion under physiologic flow conditions, the flow chamber was used (116). Using appropriate antibodies, it was found that molecules upregulated on HUVECs include intercellular adhesion molecule-1 and vascular cell adhesion molecule-1, which bind to CD18 and VLA-4 on A-NK cells. Sporadic upregulation of E-selectin was also observed. The role of these molecules *in vivo* was confirmed by treating A-NK cells with antibodies against CD18 and VLA-4 before injecting them into the arterial supply of tumors. As in *in vitro* studies, blocking these adhesion molecules nearly eliminated the adhesion of A-NK cells to tumor vessels (114).

What leads to the upregulation of these molecules in the tumor vasculature? It was already known that these molecules can be upregulated by tumor necrosis factor-α and a protein of 90-kd molecular weight (p90) secreted by some neoplastic cells (98,117,118) and downregulated by transforming growth factor-β (119,120 and 121). What was unknown was whether other molecules present in the tumor milieu also induce this upregulation. Because tumor growth and metastasis are angiogenesis dependent, the two most potent angiogenic molecules—bFGF and VEGF/VPF—were investigated (4,107,122). It was found that VEGF can mimic tumor interstitial fluid and upregulate these molecules (123,124). bFGF, on the other hand, exhibited no effect when used alone, but abrogated the upregulation induced by VEGF or tumor necrosis factor-α (114). These findings were in concert with earlier reports that bFGF retards the transmigration

of lymphocytes across endothelial monolayer (125) and reduces adhesion of endothelial cells to collagen at low cell density (126). The findings also offer a possible explanation for heterogeneous leukocyte-endothelium interactions in tumors: bFGF may have downregulated adhesion molecules in these tumors (Fig. 23-6). Further efforts are now needed to defining interactions between angiogenic and adhesion molecules using various *in vitro* and *in vivo* approaches, including genetically engineered mice (107,123,127,128).

Pharmacokinetic Modeling: Scale-Up from Mouse to Human

Part of "23 - Delivery of Biologic Molecules and Cells to Tumors "

Thus far, each of the steps in the delivery of molecules and cells to and within solid tumors has been analyzed. Can this information be integrated into a unified framework? Some success has been realized in this endeavor, using physiologically based pharmacokinetic modeling. This approach, pioneered by two chemical engineers—K. Bischoff and R. L. Dedrick—in the 1960s, has been applied successfully to describe and scale up the biodistribution of low-molecular-weight agents (129,130 and 131). This approach has been extended to macromolecules and cells (132,133,134,135 and 136).

In this approach, a mammalian body is represented by a number of physiologic compartments that are interconnected anatomically. The volume and rate of blood flow to each of these compartments, or organs, are known or can be measured. The parameters that characterize transport across the subcompartments (i.e., vascular, interstitial, and cellular) and the metabolism of various agents are not generally known and cannot be easily measured. Our philosophy has been to use as many measured parameters as possible and estimate the remaining parameters by fitting the model to the murine biodistribution data. By scaling up the parameters using well-defined scale-up laws (130), the biodistribution in human patients is predicted and compared with clinical data. Discrepancies between predictions and actual data assist in identification of interspecies differences and force reevaluation of the model assumptions. This is an evolutionary process: As the understanding of underlying physiology and biochemistry improves, the relevant parameters are modified and the model is refined further. The model is useful not only for designing murine experiments and clinical trials but also in identifying the sensitive parameters that need careful measurement and analysis. If detailed spatial information about a tissue or organ is needed, researchers develop a distributed parameter model for that organ (e.g., tumor) (6,70,85,86,132,133,137,38 and 139). Although simple in principle, this cyclic approach of analysis and synthesis has served as a useful paradigm for developing a deeper understanding of drug and cell distribution in normal and malignant tissues. The sophistication of these models is likely to improve with the understanding of underlying principles (7).

Bench to Bedside

Part of "23 - Delivery of Biologic Molecules and Cells to Tumors "

The physiologic factors that contribute to the heterogeneous delivery of therapeutic agents to tumors include heterogeneous blood supply, interstitial hypertension, relatively long transport distances in the interstitium, and cellular heterogeneities (see Fig. 23-1). How can these physiologic barriers be exploited or overcome? Can the findings about these barriers move from the bench to the bedside? Two strategies with the potential to improve the detection and treatment of solid tumors in patients are described here.

As mentioned, all solid tumors in patients exhibit interstitial hypertension (see Table 23-1), provided the patient has not received any antiedema treatment (61). It has been confirmed that interstitial fluid pressure rises quite steeply in the tumor boundary (55,71). This knowledge has been used to improve the design of the needle used by radiologists to localize tumors for surgical excision (140). Needle placement in a tumor can be facilitated by placing a pressure sensor in the needle. Because tumors begin to exhibit interstitial hypertension almost from the onset of angiogenesis (73), this needle may be able to help in localizing early disease. The same concept may be useful in optimizing location and infusion pressure of needles used in intratumoral infusion of therapeutic agents (84) and for monitoring response to therapy (68).

Several physical (e.g., radiation, heat) and chemical (e.g., vasoactive drugs) agents may lead to an increase in tumor blood flow or vascular permeability (14,24,41,141,142,143,144,145 and 146) or lower pH (37,39). Another approach may be based on increasing the interstitial transport rate of molecules by increasing K or D enzymatically (81,84,92) or using multistep approaches (133,147,148 and 149). Several physical and chemical agents have been used to lower interstitial fluid pressure in tumors (15,24,150,151,152,153,154,155 and 156). Because microvascular and interstitial pressures in tumors are approximately equal, any change in one is rapidly followed by a similar change in the other, and thus the convective enhancement disappears rapidly (58,157,158 and 159). By developing a mathematical model for solid tumors, we have calculated theoretically and confirmed experimentally that the time constant of pressure transmission across the tumor vasculature is approximately 10 seconds (157). During such a short time, the convective

enhancement is calculated to be very small (approximately 1%). However, if the vascular pressure is increased repeatedly and the transvascular transport is unidirectional or if the molecule binds avidly in the extravascular region, then in principle, drug delivery to solid tumors can be increased significantly (160).

In contrast, the physiologic barriers discussed here may be less of a problem for (a) radioimmunodetection; (b) treating leukemias, lymphomas, and small tumors (e.g., micrometastases) in which the physiologic barriers are not yet fully established; (c) treatment of adequately perfused, low-pressure regions of large tumors for debulking; and (d) treatment with antibodies or other agents directed against the host cells (e.g., tumor endothelial cells, fibroblasts) or the subendothelial matrix. These physiologic barriers may also pose fewer problems for treatment with a molecule or cell that has nearly 100% specificity for cells in the tumor. Until such selective molecules or cells are developed, methods are urgently needed to overcome or exploit these physiologic barriers in tumors. It is hoped that an improved understanding of transport in tumors will contribute to the development of such strategies (1,3,161).

Introduction

Part of "24 - Flt-3 and Flt-3 Ligand "

Interaction of cell surface receptors with their specific protein ligands is the major mechanism by which cells communicate with, and respond in a coordinated fashion to, their immediate microenvironment. For instance, cytokines and related growth factors such as the interleukins (ILs) and colony-stimulating factors (CSFs) bind to distinct families of receptors and elicit unique patterns of biologic activities. The receptor tyrosine kinases represent a family of cell surface receptors that play an important role in regulating the survival, growth, and differentiation of hematopoietic cells. In this chapter, we focus on one such receptor, tyrosine kinase, *fms*-like tyrosine kinase 3 (Flt-3), and the biologic effects of interactions with its cognate ligand, Flt-3 ligand (FL).

Discovery and Characterization of the Flt-3 Tyrosine Kinase Receptor

Part of "24 - Flt-3 and Flt-3 Ligand "

Flt-3 was isolated independently by two groups looking for novel members of the tyrosine kinase receptor family (1,2 and 3). The name is derived from the fact that the receptor is structurally related to another tyrosine kinase receptor known as *c-fms* (1). The receptor has also been referred to as *fetal liver kinase 2* (flk-2) (3) and *stem cell kinase-1* (Stk-1) (4).

Both mouse (1,000 amino acids) and human (993 amino acids) Flt-3 contain numerous potential sites for N-linked glycosylation in their extracellular domains (2,3,4 and 5), and carbohydrates are attached at one or more of these sites (6). The predicted size of the protein backbone is approximately 110 kd; however, anti-Flt-3 antibodies immunoprecipitate two proteins of 130 to 143 kd and 155 to 160 kd (6,7 and 8). Pulse-chase analysis showed that the larger protein arises from the smaller protein (6), most likely as a result of glycosylation processing. Consistent with this interpretation is the finding that only the 158-kd species is found on the cell surface (6). There do not appear to be any O-linked sugars on the protein (9). The binding affinity of human FL for Flt-3 on human myeloid leukemia cells has been estimated to be kd = 200 to 500 pm (10), and only high-affinity binding sites are seen. Although the mechanistic details are unknown, it is thought that a dimer of FL causes dimerization of Flt-3, which results in signal transduction.

The human Flt-3 genomic locus is approximately 100 kilobases (kb) in size (11). The exon:intron structure of the entire receptor has been reported to contain 24 exons (12), but only the portion of the gene encoding the C-terminal domain has been published (13). The gene encoding human Flt-3 maps to chromosome 13q12 (1), near the Flt tyrosine-kinase receptor locus. The Flt-3 and Flt genes are linked (1) in a head-to-tail fashion and are separated by approximately 150 kb (11). There have been no reports of any genetic defects associated with either Flt-3 or its ligand.

The mouse Flt-3 gene maps to chromosome 5 at the G region (1). The mouse Flt-3 gene (14) is located less than 350 kb from the mouse Flt tyrosine-kinase receptor (15) but is separated from the clustered c-*kit*, platelet-derived growth factor A, and Flf-1/KDR receptors, which are also on chromosome 5.

In addition to the full-length species, only one other isoform of Flt-3 has been described. This isoform is missing the fifth of the five immunoglobulin-like regions in the extracellular domain of the protein. This isoform results from the skipping of two exons during transcription (16). This alternative isoform is present at lower levels than the wild-type receptor, although it binds FL and is phosphorylated as a result of this binding. The fifth immunoglobulin-like domain of Flt-3 is therefore apparently not required for either ligand binding or receptor phosphorylation. The physiologic significance of this isoform of Flt-3 is presently unknown. A soluble version of Flt-3 has not yet been identified in human serum.

Cloning of the Ligand for the Flt-3

Part of "24 - Flt-3 and Flt-3 Ligand "

A soluble form of mouse Flt-3 was used by two groups to clone its cognate mouse ligand via expression cloning (17) or protein purification strategy (18). Once the mouse FL complementary DNA (cDNA) had been isolated, it was used in cross-species hybridization experiments to isolate cDNA encoding the human gene (18,19). The mouse and human FL proteins are 72% identical at the amino acid level. No restriction in species specificity has been observed with regard to the biologic activities of FL. The mouse and human FL proteins are both fully

active on cells bearing either the mouse or human receptor (20). Furthermore, the human FL protein has been found to stimulate mouse, cat, rabbit, and nonhuman primate cells.

The FL protein is clearly ancestrally related to both macrophage CSF (M-CSF) (also known as *CSF-1*) as well as the c-*kit* ligand (KL) (17,18). All three proteins are type 1 transmembrane proteins with short cytoplasmic domains. They share a number of conserved cysteine residues, and all three proteins bind to tyrosine kinase receptors with five immunoglobulin-like domains in their extracellular region (the receptors are also ancestrally related). Finally, their genomic exon:intron structures are similar (21), and all three proteins are involved in regulating hematopoiesis. An extensive comparison of the biologic activities of FL and KL has been published (22).

The genomic loci encompassing the coding regions of mouse and human FL are approximately 4.0 kb and 5.9 kb, respectively, and comprise eight exons (21) (Fig. 24-1). The sizes of the individual FL exons are well conserved between species, whereas the intron sizes are much more variable. The human FL gene maps to chromosome 19q13.3–13.4 (23,24). This region is syntenic with mouse chromosome 7, which is where the mouse FL gene maps (17).
FIGURE 24-1. Structure of mouse and human Flt-3 ligand (FL) genomic locus and the encoded proteins. Exons and introns are drawn to the same scale for both mouse and human loci. The human FL locus is larger than the mouse locus as a result of having larger introns (23). The sequence information encoding the transmembrane form of FL is contained within exons 1 to 5 plus 7 and 8; an alternatively spliced exon 6 is used to generate a soluble form of FL protein. (AA, amino acids; kb, kilobase; TM, transmembrane.)

The primary translation product of the FL gene is a type 1 transmembrane protein (see Fig. 24-1). The mouse and human proteins contain 231 and 235 amino acids, respectively. The first 27 (mouse) or 26 (human) amino acids constitute a signal sequence, followed by a 161 (mouse) or 156 (human) amino acid extracellular domain, a 22 (mouse) or 23 (human) amino acid transmembrane domain, and a 21 (mouse) or 30 (human) amino acid cytoplasmic tail. The cytoplasmic domains of mouse and human FL are only 52% identical, and therefore are much more divergent than the extracellular domains. The mouse and human FL proteins each contain two potential sites for N-linked glycosylation.

Multiple isoforms of both mouse and human FL have been identified by analysis of cDNA clones and by polymerase chain reaction (17,18 and 19,23). The biologic significance of these isoforms is presently unknown. The predominant isoform of human FL is the transmembrane protein, which is biologically active on the cell surface (17,18 and 19). This isoform is also found in the mouse, but it is not the most abundant isoform in that species (see below). The transmembrane FL protein can be proteolytically cleaved to generate a soluble form of the protein that is also biologically active (17). The exact site in the FL amino acid sequence where cleavage takes place has not been identified, and the protease responsible for this cleavage is also unknown.

The most abundant isoform of mouse FL (21) is a 220 amino acid form that is membrane associated, but is not a transmembrane protein (18,23). This isoform results from a failure to splice an intron out of the messenger RNA (mRNA). This leads to a change in the reading frame, which terminates in a stretch of hydrophobic amino acids that serve to anchor the protein in the membrane (19). This isoform is also missing the spacer and tether regions that contain the proteolytic cleavage site present in the transmembrane isoform. As a result, the membrane-associated isoform is resistant to proteolytic cleavage, although it is biologically active on the cell surface (23). This membrane-associated isoform has not been identified in any human FL cDNA examined.

A third FL isoform identified in both mouse (23) and human (21) tissues arises as the result of an alternatively spliced sixth exon. This exon introduces a stop codon near the end of the extracellular domain, and thereby generates a soluble, biologically active protein, which appears to be relatively rare compared to other isoforms (21). Another method of generating soluble FL in humans is to splice out the transmembrane domain (19), but the relative abundance of this isoform has not been quantitated in any species.

As noted above, a soluble, biologically active form of FL can also be generated by proteolytic cleavage of the transmembrane protein. It is unclear what factors regulate the proteolytic cleavage of FL, and what, if any, physiologic processes are affected by this

form of the protein. It is unknown if the protease that generates a soluble, biologically active form of FL is the same one that generates soluble forms of M-CSF and KL (17,18,25).

Expression of Flt-3 on Cell Lines, Primary Cells, and Leukemias

Part of "24 - Flt-3 and Flt-3 Ligand "

Knowing the expression pattern of Flt-3 is one of the keys to understanding the function of FL. Flt-3 is expressed on only a limited number of cell types. In contrast, numerous studies have shown that FL is widely expressed in a variety of tissues. Among mouse cell lines examined, no Flt-3 expression is seen on myeloid, macrophage, erythroid, megakaryocyte, or mast cell lines (26,27), nor on most early B cell lines, but it has been reported on several mature B cell lines (27). In contrast, most human pre-B cell lines do express Flt-3 (28,29). Additionally, Flt-3 expression has been seen on only one mouse pro-T cell line, but not on any mature mouse T cell lines (26,27).

Numerous studies have been published demonstrating expression of Flt-3 on a limited range of human cell lines. Flt-3 is found on a high percentage of human myeloid and monocytic cell lines (27,28 and 29), in contrast to what is observed among mouse cell lines (26,27). Although a few megakaryocytic cell lines are positive, no Flt-3 expression has been detected on myeloma, erythroid, or erythroblastic cell lines (27,28 and 29). Among lymphoid cell lines, pro-B as well as pre-B lines are Flt-3 positive, whereas natural killer (NK) cells, Hodgkin's, and T cell lines are negative (27,28 and 29).

Flt-3 expression in the hematopoietic system appears to be predominantly restricted to the progenitor/stem cell compartment. Flt-3 expression in mouse bone marrow (BM) is restricted to blast cells, monocytes, and a small fraction of lymphocytes (30). Nucleated mouse erythroid cells lack Flt-3 expression (30). Initial studies indicated that Flt-3 mRNA is expressed by mouse B and T cells from thymus, spleen, and peripheral blood (PB) (2). However, later studies of mature mouse B and T cells suggest that these do not express Flt-3 (30,31). Thus, the initial findings were likely due to a small fraction of contaminating Flt-3-positive cells, such as more primitive B- and T-cell progenitors.

No expression of Flt-3 mRNA has been reported on mature lymphohematopoietic cells fractionated from human PB (4), on B cells, T cells, monocytes, or granulocytes (32), or on megakaryocytes (33). However, in other studies, monocytes and granulocytes have been shown as weakly positive at the mRNA and cell surface expression level (5,34).

Expression of Flt-3 in primary leukemias has also been widely investigated (35). Most adult acute myelogenous leukemia (AML) samples from all French-American-British (leukemia classification system) (FAB) classes are positive for Flt-3 expression (7,32,36,37,38 and 39). All B-lineage acute lymphoid leukemia (ALL) samples examined are Flt-3 positive (32,36,37), as are most hybrid (also known as *mixed* or *biphenotypic*) leukemia samples (32). The greatest variability reported in Flt-3 expression is on T-lineage ALL, which have been reported as being all negative (36), having a small percentage positive (37), or having approximately one-half of the samples positive (32). In contrast, both T-cell and B-cell lymphomas are negative for Flt-3 expression (32). Tandem in-frame duplications in the juxtamembrane region of human Flt-3 have been reported to be associated with leukocytosis (40), leukemic transformation (41), and shorter disease-free survival in childhood AML (42). Almost all chronic or accelerated phase chronic myelogenous leukemia (CML) samples are negative for Flt-3 expression (32,37). However, approximately two thirds of the samples from CML patients in blast crisis are Flt-3 positive (32,37).

Responsiveness of Primary Leukemia Cells to Flt-3 Ligand

Part of "24 - Flt-3 and Flt-3 Ligand "

Whether Flt-3 or its ligand plays a causal role in the development of human leukemias has not been determined. A large percentage of AML cells from children (36) and adults (38,39) proliferate in response to FL. To put this in context, however, it should be noted that these same AML samples proliferate in response to a number of other growth factors as well. Within groups of children or adults, some FAB subtypes show a greater response compared to others (36,39). Because not enough samples of each FAB subtype have been analyzed, it is unclear whether there is a difference in the FL responsiveness of Flt-3-positive AML samples from children and adults. As a result, Flt-3 expression on AML samples is simply not predictive of FL responsiveness.

As mentioned previously, all B-lineage ALL and some T-lineage ALL samples express Flt-3. However, only a small percentage of B-lineage ALL samples proliferates in response to FL (36). One study showed that pediatric T-lineage ALL samples did not proliferate in response to FL, but these samples were all negative for Flt-3 expression (36). In a separate study on a variety of ALLs, several Flt-3-positive samples proliferated in FL (43). However, the majority of samples failed to proliferate in FL, even though they were Flt-3 positive (43). Flt-3 expression is therefore not predictive for proliferation of ALL cells to FL *in vitro.*

Expression of Flt-3 Ligand

Part of "24 - Flt-3 and Flt-3 Ligand "

The FL gene is widely expressed in mouse and human tissues, including both hematopoietic and nonhematopoietic tissue types (18,19,23). Highest levels of FL mRNA on human tissue Northern blots are in PB mononuclear cells, but the ligand is also expressed in almost every tissue that has been examined (17,18 and 19). However, it should be pointed out that similar studies of FL protein expression have not been performed. Mouse developmental *in situ* hybridization studies have not yet been done with FL, although it would be interesting to see how the distribution of FL would compare to Flt-3 (44).

Human Serum and Plasma Levels of Flt-3 Ligand

Part of "24 - Flt-3 and Flt-3 Ligand "

Serum levels of FL in normal individuals average less than 100 pg per mL, which is the limit of detection of the enzyme-linked immunosorbent assay (45). FL levels are not elevated in a variety

of anemias that predominantly affect only the erythroid lineage (45). In contrast, serum levels of FL are highly elevated in patients with hematopoietic disorders that specifically affect the stem cell compartment. Thus, a majority of patients with Fanconi anemia or acquired aplastic anemia have highly elevated levels of FL (up to 10 ng per mL) (45). Cancer patients treated with chemotherapy or radiation, or both, also have elevated levels of FL (46).

The simplest interpretation of these data is that the loss of functional stem/progenitor cells leads to the loss of a negative regulator of FL production that is made by the stem and progenitor cells. FL concentrations in blood then become elevated (to a physiologically relevant level) as part of a compensatory hematopoietic response to drive the proliferation of the remaining stem and progenitor cells. In this regard, serum concentrations of FL were found to return to normal levels in a Fanconi anemia patient treated with a cord blood transplant (45). A similar outcome has also been achieved in patients with acquired aplastic anemia after either BM transplant or immunosuppressive therapy (46). These data suggest that restoration of stem cells in these patients is associated with a return of FL serum concentrations to those measured in normal, healthy individuals, and that FL serum levels may be a surrogate marker for stem cell activity or content in BM.

Flt-3 Ligand is a Regulator of Hematopoietic Cell Development

Part of "24 - Flt-3 and Flt-3 Ligand "

The restricted expression of Flt-3 on primitive hematopoietic stem and progenitor cells suggested that the ligand (FL) might play a role in hematopoietic cell development. FL weakly stimulates proliferation or colony formation of hematopoietic progenitor cells (HPCs) when used as a single cytokine *in vitro* (17,18). In addition, FL weakly supports the survival of primitive HPCs, which remain responsive to cytokines, which can induce growth and differentiation (30,47,48 and 49). In contrast, FL displays synergistic effects on hematopoietic cell growth and differentiation when combined with other ILs and CSFs (30,50,51 and 52), as well as with receptors for thrombopoietin and granulocyte CSF (G-CSF) receptor (53), in promoting the colony growth of both primitive and committed progenitors. The use of *in vitro* assays has demonstrated that FL affects the growth of primitive multipotent HPCs as well as myeloid and lymphoid-committed progenitors (54). FL alone does not significantly support the *ex vivo* expansion of progenitor cells but does increase their survival *in vitro* (55). It also synergizes with several growth factors, including various combinations of IL-1, IL-3, IL-6, IL-11, G-CSF, KL, or erythropoietin, to potentiate the *ex vivo* expansion of colony forming units (22,50,51,55,56). However, long-term culture-initiating cells, which represent the most primitive human progenitors, can be expanded with FL alone (47,57), and this can be further augmented when combined with IL-3 and KL (57). Mackarechtschian and colleagues (58) also demonstrated a major effect of FL on the most primitive HPCs when examining mice deficient in Flt-3. Although these animals were viable and healthy, they displayed a defect in their primitive stem cells as measured in long-term competitive repopulation assays and by their potential to reconstitute both the lymphoid and myeloid compartments when transferred to irradiated recipients (58).

Ontogeny and Function of Dendritic Cells

Part of "24 - Flt-3 and Flt-3 Ligand "

Dendritic cells (DCs) are rare, hematopoietically derived leukocytes that form a cellular network involved in immune surveillance, antigen (Ag) capture, and presentation (59). DCs are predominantly found in the T-cell dependent areas of lymphoid tissue (59), as well as in other tissues and organs. Immature processing-type DCs are located at body surfaces and in the interstitial spaces of most tissues where they can acquire Ags in the local microenvironment. In the presence of maturation-inducing stimuli, such as cellular necrosis due to tissue damage, proinflammatory cytokines [e.g., IL-1β, tumor necrosis factor-α (TNF-α), IL-6, and interferon-α (IFN-α)], or bacterial products, DCs exhibit elevated expression of adhesion (e.g., LFA-1, -2, -3, and intercellular adhesion molecule-1, -2, -3) and costimulatory molecules (e.g., CD40, CD80, and CD86) and begin the transformation from cells specializing in Ag capture and processing to more potent, terminally differentiated, stimulators of T-cell immunity (60,61,62,63 and 64). During this process, DCs migrate to the T-cell areas in draining lymphoid tissues under the influence of chemokines and other homing interactions, where they present captured Ags as processed peptides [in association with major histocompatibility complex (MHC)–encoded molecules] to rare Ag-specific T cells (65). On activation by DCs, T cells upregulate expression of CD40L, which in turn binds to CD40 on DCs and ultimately results in the augmentation of their Ag-presenting function. CD40L also induces DCs to secrete IL-12 (66,67), which has been shown to regulate IFN-γ production by T cells (68).

In addition to their localization in T-cell areas, a subset of DCs has also been identified in the B-cell–dependent germinal centers (69) and suggests a role for germinal center DCs in B-cell maturation (70). In addition to their capacity for processing and presenting foreign or altered self-Ags to induce immunity (59), certain DC subsets are believed to negatively regulate T-cell immunity (71,72,73 and 74). Furthermore, there is emerging evidence that DCs may regulate the cytokine repertoire of T cells during the induction of immunity (75,76,77 and 78). Thus, DCs are emerging as key regulators of lymphocyte-mediated immune responses.

The most rapidly evolving aspect of DC biology is the striking diversity of phenotypes that have been described from *in vitro* and *in vivo* studies in both mouse and humans. Although the number of seemingly distinct DC subsets appear to be growing, however, the developmental relationships between these distinct DC subsets remain largely undefined. More important, the functional differences between these distinct DC phenotypes are relatively unclear. DCs can be derived from at least two ontogenically distinct pathways: the myeloid and lymphoid pathways (79). The relationship of DCs to the myeloid lineage is based mainly on *in vitro* experimentation showing that DCs can be generated from BM or cord blood progenitors, as well as PB mononuclear cells, using a combination of granulocyte-macrophage

CSF (GM-CSF) and other cytokines such as TNF-α (83,84,85,86 and 87), IL-4 (84,85), and KL (86,87). In contrast, certain DC subsets can arise from the most immature T-cell precursors, which can also generate NK and B cells, but not cells of the myeloid lineage (65,88,89 and 90). Unlike myeloid-related DCs, DCs derived from the putative lymphoid-committed precursors have been shown to express high levels of the CD8α homodimer (80,90,91) and do not require GM-CSF for *in vitro* development (89,92). Differences between these two subsets of DCs are supported by the fact that mice treated with a polyethylene glycol–modified form of murine GM-CSF display increased numbers of myeloid-related DCs in both spleen and other lymphoid tissues, whereas no significant increases in the CD8α+ lymphoid-related DC subset were observed (77). The increased levels of GM-CSF present in GM-CSF-expressing transgenic mice does not significantly increase the number of DCs in lymphoid tissue (93). Furthermore, mice deficient in the GM-CSF receptor-β chain show only marginal decreases in the numbers of DCs in the lymphoid tissues, suggesting that growth factors other than GM-CSF are important for DC generation *in vivo* (94).

The efficiency with which DCs initiate and regulate lymphocyte-mediated immunity has led to the study of DCs as cellular vaccine adjuvants for the immunotherapy of cancer or infectious disease (95,96). Numerous studies in mouse models have demonstrated efficacy of DC-based immunization protocols for generation of antitumor responses (95,96). Despite promising results from mouse models, the use of DCs as vaccine vectors for immunotherapy is limited by the extremely small numbers of DCs found in human PB and the uncertainty as to which *in vitro*-generated DC subset generates the most appropriate T-cell immunity *in vivo*. In this regard, the preferential use by most clinical groups of only one type of DC precursor (i.e., monocyte) in clinical studies may not necessarily provide the diversity in Ag-presenting cell–derived signals that can result in the generation of effective and long-lasting T-cell immunity (97). The use of cytokines, which increase the number of DCs *in vivo* without altering subset diversity, may obviate many of the potential problems surrounding current DC-based immunotherapy strategies.

Flt-3 Ligand Stimulates Dendritic Cell Development in Mice

Part of "24 - Flt-3 and Flt-3 Ligand "

Daily subcutaneous injections of mammalian cell–expressed recombinant human FL for 10 days resulted in a dramatic increase in the numbers of hematopoietic progenitors in the BM, PB, and spleen (98,99). Examination of the effects of systemic FL on more mature, lineage-committed cells indicated that the FL-mediated expansion and mobilization of BM progenitors was accompanied by an increase in myeloid lineage cells, early B lymphocytes, and NK cells (data not shown), but there was no apparent effect on T lymphocytes or erythroid or megakaryocyte-lineage cells (98,99). A significant increase in MHC class II+ Thy-1- CD8α+ cells was also observed in the PB of FL-treated mice, a phenotype consistent with DCs. Under normal conditions, DCs constitute only a small percentage of total spleen cells (<1%) and require enzymatic digestion to be released from the stroma (100). In FL-treated mice, however, approximately 20% of spleen cells coexpress MHC class II and the DC marker, CD11c (101). These MHC class II+ CD11c+ DCs express low levels of surface CD86, are morphologically indistinguishable from the rare DCs that can be extracted from the spleens of untreated mice (control DCs), and can be separated into three subpopulations using CD11b expression [CD11b-, CD11b^dull and CD11b^bright (101)]. A proportion of the CD11b- and CD11b^dull subsets express the lymphoid-related DC marker, CD8α, whereas the CD11b^bright subset is CD8α- and expressed myeloid-related DC markers such as F4/80 and 33D1 (102). These observations indicate that systemic treatment of mice with FL expands both myeloid- and CD8α+ lymphoid-related DCs *in vivo.*

Daily injections of mice with FL results in a 17-fold increase in the absolute number of DCs in the spleen, a fourfold increase in the lymph nodes (LNs) and sixfold increase in the PB by day 9 (101). Increased numbers of DCs could be detected as early as day 5 in the spleen and by day 7 in LNs and PB (101). The FL-mediated DC expansion was transient and reversible as DC numbers returned to basal levels within 7 days after cessation of growth factor administration (101). FL-generated DCs were as efficient as control DCs at stimulating the proliferation of allogeneic T cells or of Ag-specific T cells in *in vitro* assays (101). Furthermore, FL-generated spleen DCs were as efficient as control DCs at generating Ag-specific T cells *in vivo* after being pulsed with Ag *ex vivo* (77,101). Elevated numbers of DCs were detected in both lymphoid- and nonlymphoid tissue in FL-treated mice, including the BM, gut-associated lymphoid tissue, liver, LNs, lung, PB, peritoneal cavity, spleen, and thymus (101). Of particular interest is the elevated numbers of DCs in the gut-associated lymphoid tissue, lung, and PB, which are sites amenable to vaccine delivery in clinical immunotherapy regimens.

Mechanism of Flt-3 Ligand–Mediated Dendritic Cell Development and Immune Consequences

Part of "24 - Flt-3 and Flt-3 Ligand "

The mechanism(s) by which FL influences DC generation *in vivo* and *in vitro* is not completely understood. It is unlikely that FL treatment simply causes the mobilization of existing mature DCs from other sites into the lymphoid tissue. First, Flt-3 is not detected on mature DCs (as assessed by flow cytometry), and mature DCs do not proliferate when cultured in FL alone (as assessed either by microphysiometric analysis of cytoplasmic pH changes or by thymidine incorporation of proliferating cells). Second, elevated numbers of DCs have been detected in multiple organs and tissues in FL-treated mice, indicating that there is a generalized expansion of DCs throughout these animals. Third, the effects of FL on the expansion of DCs from BM progenitors, its described effects on primitive progenitors *in vitro*, and the potent effects of FL on hematopoiesis *in vivo* suggest that FL expands the primitive progenitor cell pool in the BM and other organs, whereas other signals potentiate and induce DC maturation *in vivo.* In this way, FL may facilitate the terminal development of a primitive, FL-sensitive, rapidly expanding progenitor population into functionally mature DCs.

Dendritic Cell Development in Flt-3 Ligand–Deficient Mice

Part of "24 - Flt-3 and Flt-3 Ligand "

The importance of FL for DC generation from progenitors is further highlighted by examination of mice rendered genetically deficient in FL. McKenna and colleagues have reported that FL$^{-/-}$ mice show a significant reduction in leukocyte cellularity in the BM, PB, LN, and spleen, but not in the thymus. Furthermore, the absolute numbers of primitive BM progenitors, BM-myeloid cells, and B cells are significantly reduced. The absolute number of NK cells in the spleen of FL-deficient mice is also dramatically reduced (103). Additionally, these animals display deficient DC development and reduced numbers of mature DCs in the peripheral lymphoid tissues. Although both myeloid-related and lymphoid-related DCs were reduced, a significantly greater reduction in CD8α$^+$ lymphoid-related DCs was observed. The residual splenic DCs present in these mice are functionally normal with respect to their capacity to stimulate the proliferation of alloreactive T cells *in vitro*, suggesting that FL is not essential for optimal DC functional maturation *in vivo*, but is required for DC expansion from the progenitor pool.

Flt-3 Ligand Stimulates *In Vitro* Dendritic Cell Development from Human CD34$^+$ Bone Marrow Progenitors

Part of "24 - Flt-3 and Flt-3 Ligand "

The importance of FL in DC development *in vitro* is further supported by studies showing that FL can increase the absolute numbers of mature myeloid-related DCs generated in serum containing culture systems from CD34$^+$ BM progenitors using GM-CSF, IL-4, TNF-α, and KL (97,104,105). Transforming growth factor-ß has also been shown to enhance *in vitro* DC development in serum-free culture systems (106). Regardless of the cytokine combinations used, these *in vitro*-generated DCs express high levels of CD1a and CD13 and are positive for HLA-DR, CD80, and CD86. The addition of FL to GM-CSF, IL-4, and TNF-α-containing cultures enhanced the total expansion of CD34$^+$ BM progenitors by eightfold (Table 24-1). However, no significant change was observed in the percentage of progeny coexpressing CD1a, HLA-DR, and CD86 relative to cells generated in the absence of FL. As a result, the enhanced expansion of the starting progenitor pool translated into an eightfold increase in the absolute numbers of DCs. Sorted CD1a$^+$, HLA-DR$^+$, CD86$^+$ DCs from FL-containing cultures were as efficient at stimulating the proliferation of alloreactive T cells or processing and presenting tetanus toxoid to autologous tetanus toxoid-specific T cells as DCs generated in the absence of FL (103). This suggests that the addition of FL into these cultures enhances the expansion of the cultured cells, but has little effect on the proportion of cells that differentiate into DCs or on their functional development.

Table 24-1 Analysis of Proliferation and Generation of Dendritic Cells from *In Vitro*-Cultured CD34$^+$ Bone Marrow Progenitors

Growth Factor Conditions	Total Number of Cultured Cells (×10^{-6})	Percent CD1A$^+$, HLA-DR$^+$, CD86$^+$ Cells	Total Number of CD1A$^+$, HLA-DR$^+$, CD86$^+$ Cells (×10^{-6})
GM-CSF, IL-4, TNF-α	6.0 ± 0.8	48.3 ± 12.3	2.9 ± 0.9
+ FL	48.5 ± 1.6	46.2 ± 10.2	22.4 ± 1.6

FL, Flt-3 ligand; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-4, interleukin-4; TNF-α, tumor necrosis factor-α.

Data are derived from the mean ± SD of five experiments. Cultures were initiated with 1×10^6 CD34$^+$ cells.

Flt-3 Ligand Stimulates Dendritic Cell Development in Humans

Part of "24 - Flt-3 and Flt-3 Ligand "

DCs represent a minor fraction (<1%) of PB mononuclear cells (PBMCs) (<1%) in humans and can be distinguished from other mature cell lineage by their characteristic dendritic morphology; the lack of surface expression of CD3, CD14, CD19, and CD56; and high expression of CD1b/c, CD4, CD11c, CD33, and HLA-DR. Additionally, a DC precursor subset lacking CD11c expression and expressing high levels of surface IL-3 receptor-α (CD11c$^-$ DC) and previously referred to as the *plasmacytoid T cell* has been identified in lymphoid tissue and PB (107,108).

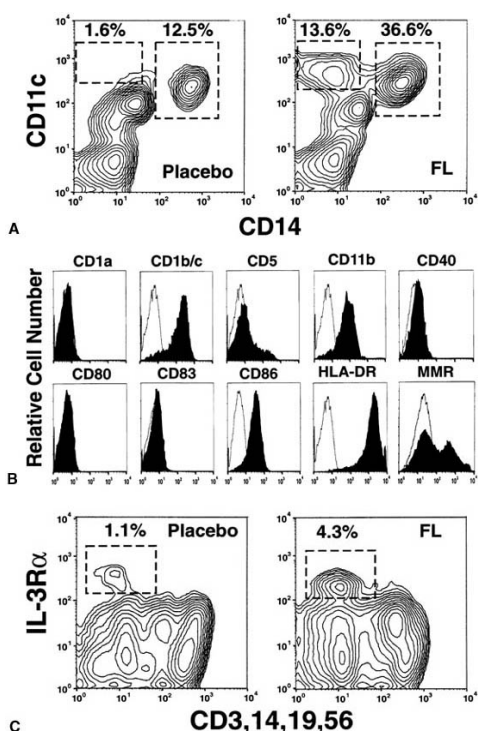
The effect of FL treatment on expansion of DC has been examined in a randomized, placebo-controlled, double-blind study. Twenty healthy human volunteers received daily subcutaneous doses of either placebo or FL at five dose levels (10, 25, 50, 75, or 100 μg per kg per day) for 14 consecutive days. Each dose group consisted of three FL-treated individuals and one placebo control. Samples of PB were collected every 2 days for 21 days and analyzed by flow cytometry for changes in the distribution of various leukocyte populations. FL treatments were well tolerated by all subjects at all doses tested compared to the placebo controls, and resulted in increased numbers of white blood cells (WBCs), PBMCs, and CD14$^+$ monocytes, but not lymphocytes (109). PBMCs lacking the monocyte marker CD14, but expressing CD11c, were rare in the blood of both placebo-treated individuals (Fig. 24-2A). After 14 days of FL treatment, however, approximately 14% of PBMCs expressed CD11c, but not CD14 (see Fig. 24-2A). This population of cells was determined to be DCs lacking surface expression of the mature-lineage markers CD3, CD14, CD19, CD56 (Lin-) and expressing CD33 or HLA-DR (110). FL treatment also increased the proportion of the CD11c$^+$CD14$^\pm$ monocyte fraction.


FIGURE 24-2. Flow cytometric analysis of peripheral blood cells from Flt-3 ligand (FL)-treated healthy volunteers. The distribution of CD11c and CD14 on total peripheral blood mononuclear cells from either FL-treated or placebo protein-treated healthy volunteers is shown. Healthy individuals were injected once daily, subcutaneously, with placebo protein or FL (50 μg per kg) for 14 consecutive days. (IL-3Rα, interleukin-3 receptor-α; MMR, macrophage mannose receptor.) [From Maraskovsky E, Daro E, Roux ER, et al. *In vivo* generation of human dendritic cells by Flt3 ligand. *Blood* 2000 *(in press)*.]

FL-generated CD11c$^+$CD14$^-$ PBMCs were CD1a$^-$ but CD1b/c$^+$ and were CD11b$^+$, CD40$^-$, CD80$^-$, CD83$^-$, CD86$^-$, and HLA-DR$^+$ (Fig. 24-2B), a phenotype consistent with blood DCs. The expression of CD11b and low-to-undetectable levels

of CD40, CD80, CD83, and CD86 suggests that the CD11c$^+$ DCs are not fully mature (62,66,111,112 and 113). These CD11c$^+$ DCs represent a heterogenous population, as they can be further subdivided on the basis of CD5 and macrophage mannose receptor expression (see Fig. 24-2B). FL was also able to increase the numbers of CD11c$^-$ IL-3 receptor-α$^+$ DCs (Fig. 24-2C), representing the plasmacytoid DC subpopulation. When cultured in IL-3 and CD40L, these cells develop into functional DCs. Furthermore, once matured, these DCs appear to differentially regulate IL-4-, IL-5-, and IL-10-secreting T cells compared to CD11c$^+$ DCs, which induce IFN-γ-secreting T cells (78). The CD11c$^+$ DCs are efficient stimulators of Ag-specific T cells *in vitro* (110). Finally, as is the situation in mice, FL-mediated DC expansion in humans is transient and reversible, resolving to baseline levels within 2 weeks after cessation of treatment (110).

Flt-3 Ligand Enhances Antigen Presentation *In Vivo* to Induce Immunity or Tolerance

Part of "24 - Flt-3 and Flt-3 Ligand "

It seems reasonable to hypothesize that the expansion of distinct DC subpopulations *in vivo* should result in a more robust or sensitive immune response to antigenic challenge. FL has been tested as a cytokine adjuvant for either the tolerization or immunization of mice to soluble Ag (77,114,115). Depending on the route of Ag administration, FL pretreatment could either enhance the level of tolerance induced against an orally administered Ag or prevent tolerance and amplify the degree of immunization against a systemically administered Ag. In a model of oral tolerance, mice fed high doses of soluble ovalbumin are tolerant to a subsequent challenge with the same Ag. In contrast, when fed low doses of Ag, normal mice are rendered immune to that Ag. Mice fed low doses of Ag and simultaneously treated with FL are rendered tolerant, however, suggesting that FL-mediated expansion of DCs can alter the immune response outcome for orally administered Ag (114). In contrast, mice administered with tolerizing doses of soluble ovalbumin by a systemic route during FL treatment exhibited an augmented immune response to the Ag, indicating that induction of systemic tolerance was prevented by FL administration (115).

Some results have also demonstrated that distinct DC subsets generated with FL are capable of differentially regulating the quality and class of immune response generated in mice (76,77). The data indicate that the CD8α$^+$ lymphoid-related DC subset, which produces the highest levels of inducible IL-12, generates a predominantly IFN-γ-secreting, Ag-specific T-cell repertoire *in vivo.* In contrast, the myeloid-related DC subset generates a mixture of IL-4 and IFN-γ-secreting T-cell effectors. These reports not only emphasize the importance of the route of vaccination and how critical the repertoire of Ag-presenting cells present at the site of Ag entry is, but also emphasize how FL administration can alter the balance of a developing immune response by expanding the numbers of DCs in those same sites. However, conclusions as to which DC subset influences particular immune responses requires further evaluation, as demonstrated by others (78,116).

Flt-3 Ligand Can Induce Immune-Mediated Anti-Tumor Activity *In Vivo*

Part of "24 - Flt-3 and Flt-3 Ligand "

As noted earlier, repeated administration of FL leads to the generation of comparatively larger numbers of DCs *in vivo*. Knight et al. noted that transfer of relatively low numbers of DCs into tumor-bearing mice had a significant inhibitory effect on the growth of a mouse sarcoma *in vivo* (117). Results from a number of studies in humans have also shown a correlation between the numbers of DCs infiltrating a tumor and clinical prognosis (118,119,120 and 121). In addition, culture-derived DCs pulsed with either tumor Ags or peptides from a tumor Ag have been shown to induce a protective antitumor immune response *in vivo* (122).

These observations led us to hypothesize that by enhancing the numbers of DCs *in vivo* we would also enhance the generation of T-cell responses to tumors. To address this hypothesis, C57BL/10 (B10) mice were intradermally injected with B10.2 tumor cells, a methylcholanthrene-induced fibrosarcoma of B10 origin, followed by systemic administration of FL (10 μg per day) over a 19-day period. Compilation of results from six independent experiments comparing tumor growth in mice treated with FL to tumor growth in control mice demonstrated that the tumors grew at similar rates in both groups of mice over the first 2.0 to 2.5 weeks, followed by a decrease in mean tumor size in FL-treated mice (Fig. 24-3). Complete tumor regression was observed in 38% (19 of 50) of FL-treated mice compared to 3% (1 of 30) control mice (p <0.0001, using Fisher's exact test). Additionally, the rate of tumor growth in FL-treated mice was significantly reduced compared to control mice (the mean tumor sizes of the two groups at week 5 post tumor challenge was 60 ± 11 mm^2 in FL-treated mice versus 185 ± 15 mm^2 in control mice; p <0.0001 by analysis of variance).
FIGURE 24-3. Treatment of tumor-bearing mice with Flt-3 ligand (FL) induces tumor regression. Groups of mice (five mice per group) were injected intradermally with 5×10^5 viable B10.2 tumor cells, followed by 19 daily injections with either control buffer (•) or FL (□), and tumor sizes monitored over the ensuing 5-week period. The mean tumor size of only those mice bearing detectable tumors is plotted, and the number of tumor-bearing mice per number challenged is noted. (Data from Lynch DH, Andreasen A, Maraskovsky E, Whitmore J, Miller RE, Schuh JCL. Flt3 ligand induces tumor regression and anti-tumor immune responses *in vivo*. *Nat Med* 1997;3:625-631.)

The observed beneficial effects of FL treatment were found to be not only dose-dependent, but also dependent on the length of time over which FL is administered. As noted earlier, although as few as nine daily injections of FL result in the production of maximal numbers of DCs in the periphery, the absolute number of these cells decreases rapidly on cessation of such treatments and returns to baseline levels within 7 days (101). As might be expected, mice treated for short periods (4 or 7 days) showed only limited benefit with regard to their ability to mount effective tumor immune responses *in vivo* (123). However, groups of mice treated for 14 or 19 days manifested similar responses in that there was a higher proportion of complete tumor regressions compared to that of untreated mice (Table 24-2), and the rate of tumor growth in the remaining mice was significantly reduced compared to the control group (p <0.0001). Mice treated with FL for 10 days showed an intermediate response in that there was only a slight increase in the number of complete regressions, but a clear decrease in tumor size compared to controls. It is also of interest that this time course of treatment corresponds to the kinetics of DC generation *in vivo*—that is, 9 days of FL treatment results in higher numbers of DCs in spleen than 5 or 7 days of treatment. Indeed, only modest increases in the numbers of DCs from LN or PB were detected after 7 days of treatment (101), and this was substantially increased after an additional 2 days of treatment. These data suggest a pivotal role for DCs in the generation of antitumor immune responses after FL treatment.

Table 24-2 Effect of the Number of Flt-3 Ligand (FL) Treatments on Tumor Regression *In Vivo*[a]

Cytokine Treatment	No. of Treatments	No. TBA/No. Challenged[b]	Mean Tumor Size (mm^2)[c]
Control buffer	19	10/10	182.5 ± 31
FL	4	9/10	199 ± 32.5
FL	7	9/10	101 ± 20
FL	10	10/15	71.5 ± 11
FL	14	4/15	82 ± 27
FL	19	3/15	40 ± 17.5

[a]Composite results from three independent experiments.

[b]Number of tumor-bearing animals per number challenged 5 weeks after tumor implantation.

[c]Mean tumor size of only those mice bearing tumors at the termination of the experiment at week 5.

Data from Rosnet O, Mattel MG, Marchetto S, Birnbaum D. Isolation and chromosomal localization of a novel FMS-like tyrosine kinase gene. *Genomics* 1991;9:380-385.

Histologic analysis of tumors revealed a substantial difference in both the quantity and quality of cells infiltrating the tumors of FL-treated mice compared to those of control mice. In control mice, the tumors became progressively larger and showed both superficial and central necrosis over time. A thin infiltrate composed of lymphocytes, plasma cells, infrequent granulocytes, and fibroblasts bordered the tumors in these mice (Fig. 24-4A). In addition to the cellular infiltrate found in control mice, the tumors in FL-treated mice were surrounded by an extensive infiltrate of mononuclear cells with large, vesiculated, and, often, folded

nuclei (Fig. 24-4B). Although this infiltrate was also present in control mice, the infiltrate was more pronounced, extended deeper into the tumor tissue, and was associated with destruction of tumor cells in FL-treated mice with visible tumor regression.
FIGURE 24-4. High-power views of histologic sections from subcutaneous B10.2 fibrosarcomas obtained from mice treated for 2 weeks with either a control buffer (A), or Flt-3 ligand (FL) (B), or 2 weeks after cessation of treatment with FL (C). (Data from Lynch DH, Andreasen A, Maraskovsky E, Whitmore J, Miller RE, Schuh JCL. Flt3 ligand induces tumor regression and anti-tumor immune responses *in vivo. Nat Med* 1997;3:625–631.)

The morphology of the mononuclear cell infiltrate in the tumors from FL-treated mice at week 2 is consistent with DC or myeloid precursors, or both, and immunohistochemical staining has shown a clear increase in the numbers of CD86+ cells. Some flow cytometric analyses indicate that FL treatment of tumor-bearing mice induces a similar array of DCs within the tumor mass as seen in peripheral lymphoid tissues, including both myeloid- and lymphoid-related DCs, suggesting that these subsets may also be actively involved in the induction of antitumor immune responses *in vivo.*

It is important to point out that the nature of the cellular infiltrates in tumors of FL-treated mice is substantially different at weeks 4 and 5, with a pronounced shift toward lymphocytes (Fig. 24-4C). It seems likely that the lymphocytic infiltrates seen in those tumors in FL-treated mice that have only been partially rejected by week 5 after tumor inoculation are tumor-reactive effector cells that are actively involved in the destruction of tumor cells and may be responsible for the decrease in tumor growth rates in those mice that have not completely rejected the tumor challenge. Similar results have also been obtained with breast cancer cells transduced with a cDNA expressing FL (124). Injection of these cells into mice leads not only to their rejection, but also to the subsequent rejection of freshly transplanted, untransduced, breast cancer cells.

The conclusion that tumor rejection is associated with the generation of a cognate T-cell mediated immune response is supported by the finding that those mice that had rejected the tumor challenge subsequent to treatment with FL were immune to a rechallenge with the same tumor, but not to unrelated tumors. Phenotypic analysis of cells mediating tumor rejection *in vivo* clearly demonstrated that FL treatment of tumor-bearing mice promotes the generation of Thy1+, CD4-CD8+ effector cells, which play a pivotal role in tumor rejection *in vivo* (123).

Data have also been obtained in several other tumor models, demonstrating that FL treatment of mice with preexisting tumors results in complete tumor rejection in a high proportion of cases, and significant decreases in tumor growth rates are seen in a majority of cases in which no rejections are observed (125,126,127 and 128). This effect was influenced by both the size of the tumor when FL treatments were begun and the dose of FL per treatment (Fig. 24-5). The results demonstrated that increasing the amount of FL used from 10 µg per day to 30 µg per day significantly enhanced both the number of tumor rejections observed and the degree of growth inhibition in mice with tumors established up to 7 days previously (123). Finally, although the data also demonstrated that increasing the dose of FL to 30 µg per day did not increase the rejection frequency in tumors established 10 to 14 days previously, there was a clear dose-dependent reduction rate of tumor growth ($p = 0.0041$).
FIGURE 24-5. Flt-3 ligand (FL) treatment induces a nonimmunologic mechanism that slows tumor growth *in vivo.* B6 (severe combined immunodeficiency disease) mice were intradermally injected with B10.2 tumor cells followed by 19 daily treatments with either control buffer (▪) or FL (□). Mean tumor size of only those mice bearing tumor and the number of tumor-bearing animals/the number challenged at the termination of the experiment is shown. (Data from Lynch DH, Andreasen A, Maraskovsky E, Whitmore J, Miller RE, Schuh JCL. Flt3 ligand induces tumor regression and anti-tumor immune responses *in vivo. Nat Med* 1997;3:625–631.)

An unexpected finding from our studies was that, in addition to induction of cognate immune responses to tumor Ags, FL treatment of tumor-bearing mice also induces a non-T cell–mediated mechanism that can substantially decrease the rate of tumor growth *in vivo.* This conclusion is based on the fact that the rate of tumor growth in B6 (severe combined immunodeficiency

disease) mice relative to that of control mice declined dramatically during FL treatment (Fig. 24-6). After cessation of FL treatment, the rate of tumor growth gradually increased until it equaled that of control mice. Preliminary histologic evaluation of tumors in severe combined immunodeficiency disease mice suggests that FL treatment induces a similar cellular infiltrate of monocytes and myeloid precursor cells, as seen in immunologically intact mice. The infiltrates disappeared on cessation of FL treatment. Thus, the potential role of nonmyeloid DCs in mediating a nonspecific tumoricidal function must also be considered. An additional possibility is a role for NK cells in the nonimmunologic mechanism of the inhibition of tumor growth, because these cells are also elevated (approximately tenfold) in mice after FL treatment (129). Indeed, both Peron et al. (127) and Fernandez et al. (125) have also shown that induction of innate immune mechanisms by treatment with FL leads to decreases in tumor burden. The effects of FL in these settings seems to be primarily due to the generation of increased numbers of NK cells from hematopoietic progenitors and not activation of mature NK cells (129). This concept is further supported by the results of McKenna et al. (103) who found that there is a nearly complete absence of NK cells in FL gene knockout mice, but that NK cells could be generated by a 10-day course of treatment with FL.

Day of Flt3L Treatment Initiation
FIGURE 24-6. Flt-3 ligand (FL) treatment of mice with established tumors induces tumor regression. Mice were intradermally injected with 5×10^5 viable B10.2 tumor cells, followed by 19 daily injections with either control buffer on day 0 or FL (30 mg per injection) beginning day 0, 4, 7, 10, or 14 (as indicated). Tumor incidence and size at week 6 of the experiment are shown. (Data from Lynch DH, Andreasen A, Maraskovsky E, Whitmore J, Miller RE, Schuh JCL. Flt3 ligand induces tumor regression and anti-tumor immune responses *in vivo. Nat Med* 1997;3:625–631.)

In conclusion, the data demonstrate that systemic administration of FL to tumor-bearing mice can have dramatic effects on tumor regression *in vivo.* FL treatment resulted in complete tumor rejection in a high proportion (approximately 40%) of the mice tested and led to a dramatic decrease of tumor growth rate in the remaining mice. Both of these events are associated with the development of an effective antitumor immune response mediated by CD8[+] T cells. The data also indicate that FL treatment induces a non-T cell-mediated mechanism that can inhibit tumor growth *in vivo.* Collectively, these data suggest that FL may prove to be an important cytokine in the treatment of cancer *in situ*, either alone or in combination with other therapeutic strategies.

Potential Therapeutic Uses of Flt-3 Ligand

Part of "24 - Flt-3 and Flt-3 Ligand "

Data on the systemic effects of FL in humans indicate that FL has a good safety profile with only minor adverse events (109). This is consistent with animal data showing that no adverse events were detected during short courses of FL treatment *in vivo.* Because FL acts synergistically with several cytokines it is also possible to envision its use in combination with cytokines that affect both primitive and differentiated hematopoietic cells.

Stem Cell Mobilization

FL may prove to be useful in mobilizing or expanding stem and progenitor cells *in vivo.* These stem cells can be used in either autologous or allogenic stem cell transplantation of cancer patients after high-dose chemotherapy. FL has been shown to stimulate the expansion and mobilization of stem and progenitor cells in animal models and nonhuman primates (99,130). The use of FL in combination with a second cytokine, such as

G-CSF or GM-CSF, appears to increase the number of stem cells mobilized *in vivo* (109,131,132,133,134 and 135).

Ex Vivo Stem Cell Expansion

One clinical modality being extensively investigated is the area of *ex vivo* stem cell expansion. The generation of sufficient numbers of autologous or HLA-matched, primitive stem/progenitor cells *in vitro* may become an effective way of reducing the number of BM harvests or leukaphereses required for stem cell reconstitution, thereby enabling repetitive cycles of high-dose chemotherapy to be performed on cancer patients. Furthermore, because contaminating tumor cells in autologous stem cell harvests can contribute to tumor relapse (136,137), selective *ex vivo* expansion of stem or progenitor cells may also reduce or eliminate these tumor cells (138). FL as a single factor is able to maintain human BM-derived colony forming unit-GM and high-proliferative potential *ex vivo* for 3 to 4 weeks, and this can be further enhanced when combined with factors such as IL-1, IL-3, IL-6, and EPO (47,57). Furthermore, long-term culture-initiating cells, which represent the most primitive human hematopoietic progenitors, can also be expanded *in vitro* with FL alone and this can be further augmented when combined with IL-3 and KL (57). It is unclear, however, whether *ex vivo* expansion protocols for human progenitor or stem cells contain sufficient numbers of pluripotent long-term repopulating cells (LTRCs) to provide long-lasting cellular reconstitution in cancer patients. In this regard, the predominant function of stem cell grafts in current high-dose chemotherapy regimens is to provide efficient short-term reconstitution. Long-term reconstitution in current procedures may be significantly facilitated by endogenous stem cells, which survive the high-dose chemotherapy rather than from the stem cell transplant itself. However, for multicycled chemotherapy regimens, it is crucial that the stem cell harvests contain LTRCs for long-lasting engraftment and cellular recovery in cancer patients (138,139).

FL has been found to be efficient at stimulating the production of progenitor cells from CD34$^+$CD38$^-$ progenitors cultured *in vitro* on stroma for up to 56 days (140). Furthermore, FL was required for the generation of LTRC from CD34$^+$ BM progenitors cultured in IL-3, IL-6, and KL before transfer into immune-deficient mice (141) and was found to act on myeloid as well as multipotent BM progenitors expressing differing levels of c-kit (142). A promising combination of factors for the *ex vivo* expansion of cord blood stem and progenitor cells is the combination of FL and thrombopoietin, which has been shown to expand these cells over a 5-month period (143). FL is currently being evaluated by several groups for its clinical potential in *ex vivo* stem cell expansion.

Gene Therapy

Hematopoietic stem cells are considered excellent candidates for gene therapy due to their extensive capacity for self-renewal and to generate large numbers of progeny that can be widely distributed throughout the body. Furthermore, stem cells can be readily isolated from BM, mobilized PB, or cord blood and can therefore be easily manipulated *in vitro* (128). Although gene transfer into mouse LTRC has been successfully performed with high efficiency (144,145), such studies on human stem cells have been rather disappointing (56,146). The use of retroviruses for integrating into host cell DNA is currently the most widely used in gene therapy protocols that target stem cells. However, a limitation of retroviral vectors is that they are inefficient at integrating into quiescent stem cells, which therefore requires that these stem cells be induced into cell cycle during gene transduction. FL has been shown to efficiently trigger cell cycle in stem cells, this being more efficient than that seen with later-acting factors such as IL-3 or IL-6 (56,147). Furthermore, FL appears to better preserve the pluripotent capacity of stem cells (i.e., their self-renewal and engrafting potential) than either KL or later-acting cytokines and KL (56).

Immunotherapy

Although mouse models suggest that DCs can be used as cellular vectors for tumor immunotherapy (95,96), the feasibility of this strategy requires in-depth clinical evaluation. The extremely small numbers of DCs found in the PB of cancer patients, the functional competence of these DCs in light of impaired DC function in cancer patients (96,148), and the uncertainty as to which DC subsets are the most appropriate for the induction of immunity *in vivo* underscore the need for further research into DC development and functional heterogeneity. Clinical trials currently examining the safety and efficacy of using DCs to deliver tumor Ag vaccines *in vivo* are primarily targeting the monocyte-derived DC subset (96). Functional distinctions between monocyte-derived DC and other DC subsets have been reported and suggest that they are not equivalent in their capacity to stimulate T- and B-cell responses (78,97,149). These studies emphasize how understanding the functional heterogeneity of DC subsets is essential for their appropriate use in immunotherapy. In this respect, the most successful immunotherapy strategies are likely those that maintain the diversity of DC subsets or those that can specifically target their distinct functional characteristics *in vivo.*

The ability of FL to expand the numbers of DCs *in vivo* for immunotherapy offers an alternative strategy to the use of *in vitro*-generated DCs. First, FL treatment of healthy volunteers generated functionally competent DC subsets and DC precursors *in vivo* in the presence of inhibitory serum factors (such as M-CSF). Second, both myeloid-related and lymphoid-related DC subsets are expanded in FL-treated mice (101,102,150), and in humans, both CD11c$^+$ and CD11c$^-$ DC (and subsets therein) have been increased in FL-treated individuals. The ability to expand a diverse repertoire of DC subsets may bypass many of the issues regarding which type of *in vitro*-generated DC population is most appropriate for the generation of clinically effective immunity *in vivo.* Finally, FL has been shown to generate effective T cell- and NK cell-mediated antitumor responses in tumor-bearing mice, suggesting that FL may augment antitumor immunity *in vivo* (123,126). Thus, FL may be an important cytokine for augmenting immunotherapy of cancer.

Of great interest is the capacity of FL to generate functionally competent DCs in cancer patients. Clinical studies using FL in cancer patients are currently under way. By increasing the

numbers of DCs in the circulation, the uptake and presentation of endogenous tumor Ag may be augmented as may the direct immunization of cancer patients with antitumor vaccines. Alternatively, transient *ex vivo* manipulation of specific FL-expanded blood DC subsets with tumor vaccines before their reinfusion into cancer patients can be examined in greater detail. Finally, FL can also be used to increase the number of circulating DC precursors (e.g., CD34⁺ cells, monocytes, or myeloid precursors), that can be differentiated *in vitro* into mature DCs for vaccine delivery.

The stage is now set for testing the feasibility of DC-mediated immunotherapy. The identification of which FL-generated DC subset is most appropriate for the induction of effective T cell-mediated immunity, the identification of their distinct ontogenic derivation, and whether FL can generate functionally competent DCs in cancer patients may result in the effective use of FL in the modulation of the immune responses.

T-Cell Activation Is Regulated by Stimulatory, Costimulatory, and Inhibitory Signals

Part of "25 - CTLA-4 Blockade in Tumor Immunotherapy "

Advances in the understanding of the mechanisms that regulate T-cell activation allow the rational design of new strategies for immunotherapy of tumors. It has been known for some time that engagement of the T-cell antigen receptor is by itself not sufficient for full T-cell activation—a second costimulatory signal is required for induction of interleukin-2 production, proliferation, and differentiation to effector function of naïve T cells. Abundant data indicate that the primary source of this costimulation is mediated by engagement of CD28 on the T-cell surface by members of the B7 family on the antigen-presenting cell (1). Expression of B7 has been shown to be limited to professional antigen-presenting cells (APCs); specialized cells of the hematopoietic lineage, including dendritic cells, activated macrophages, and activated B cells. It has been suggested that this sharply defined restriction of B7 expression is a fail-safe mechanism for maintenance of peripheral T-cell tolerance ensuring that T-cell activation can only be stimulated by appropriate antigen-presuming cells (2). The fact that tumor cells do not express B7 is one factor that contributes to their poor capacity to elicit immune responses (3 , 4). The demonstration that induction of expression of B7 on many tumor cells by transfection, transduction, or other mechanisms can heighten tumor immunogenicity led to some great interest to pursue this as an approach to tumor immunotherapy. However, the utility of B7 expression as a vaccination approach is limited by several factors:

1. B7+ tumor cell vaccines are only effective when the tumor cells have a high degree of inherent immunogenicity.
2. Although B7+ vaccines have been shown in many cases to be effective in inducing protective immune responses, there has been only limited utility inducing responses to previously established tumors.
3. Inactivation of tumor cells by radiation has been shown to destroy the immunoenhancing activity of the B7 gene product (5 , 6).

In the late 1990s, it has become apparent that costimulation is even more complex than originally thought. After activation, T cells express a close homologue to CD28, cytotoxic T lymphocyte-associated antigen 4 (CTLA-4), that binds members of the B7 family with a much higher affinity than CD28 (7). Although there was initially some controversy as to the role of CTLA-4 in regulating T-cell activation, it has become clear that CTLA-4 downregulates T-cell responses (8). This was initially suggested by *in vitro* observations that (a) blockade of CTLA-4/B7 interactions with antibody-enhanced T-cell responses, (b) the cross-linking of CTLA-4 along with CD3 and CD28 inhibited T-cell responses, and (c) the administration of antibodies to CTLA-4 *in vivo* enhanced response of mice to peptide antigens or superantigens (9 , 10 , 11 and 12).

The most convincing demonstration of the downregulatory role of CTLA-4 came from examination of deficient mice (13 , 14 and 15). CTLA-4 knockout mice have apparently spontaneously activated T cells beginning at approximately a week after birth, followed by rampant lymphoproliferation and lymphadenopathy. These mice die by approximately 3 weeks of age, either as a result of polyclonal T-cell expansion and tissue destruction or as a result of toxic shock resulting from lymphokine production by the T cells. Because thymocyte differentiation and selection proceed normally in CTLA-4-deficient mice, the rampant T-cell expansion that occurs in the mice indicates that CTLA-4 plays a critical role in downregulating T-cell responses in the periphery (16).

It is unclear from the phenotype of CTLA-4-deficient mice whether the T-cell expansion that occurs is a result of a failure of the mice to regulate expansion of T cells responding to environmental

antigens or as a result of initiation of responses in T cells that would not have been activated in the presence of CTLA-4. Support for the former idea has been based on the assumption that because it is detectable only after T-cell activation, CTLA-4 could not be operative in the early stages of T-cell responses. However, we have shown that CTLA-4 cross-linking can inhibit many aspects of T-cell activation at stages at which expression of a protein is not readily apparent (17). This has led us to propose that CTLA-4 may serve as an attenuator of T-cell responses that effectively raise the threshold of costimulatory and perhaps antigen receptor-mediated signals that are necessary to achieve full activation of naïve T cells (8 , 18). This suggests that CTLA-4 may contribute to the maintenance of peripheral T-cell tolerance by damping signals resulting from chance encounters of self-reactive T cells with tissue-specific antigens in the absence of high levels of B7 (19). This scenario does not exclude the possibility that after its induction to maximal levels CTLA-4 could not also contribute to termination of ongoing responses. Whether one or both of these proves to be the case, the fact that CTLA-4 plays an important and obvious role in downregulation of T-cell responses has led us to explore the possibility of manipulation of the signaling pathway to develop new strategies for enhancing immunotherapeutic approaches to cancer.

In this review, we present evidence suggesting a role for CTLA-4 in maintaining peripheral tolerance and avoiding autoimmunity, and the evidence suggesting that CTLA-4 blockade can serve as a powerful approach to tumor immunotherapy.

Inhibitory Signals Mediated by CTLA-4 May Play a Role in Peripheral Tolerance

Part of "25 - CTLA-4 Blockade in Tumor Immunotherapy "

The fact that we and others have shown that administration of CTLA-4 antibody-enhanced T-cell response to peptides and super antigens *in vivo* led us to explore the effects of CTLA-4 blockade in several models of autoimmunity. One model that has been examined extensively is experimental autoimmune encephalomyelitis (EAE), a murine model of multiple sclerosis. This disease is characterized by TH1-CD4⁺ responses that are antigens in the central nervous system (CNS), either myelin-basic protein or proteolipid protein. Immunization of certain susceptible strains of mice, such as SJL or PLJ with peptides derived from these proteins, leads to a cycling progressing and remitting paralysis accompanied by infiltration of the CNS with autoreactive T cells. We and others have shown that administration of CTLA-4 antibodies during either immunization or during active disease can exacerbate the severity of both clinical and histopathologic signs of disease and prolong it, confirming again the ability of CTLA-4 blockade to enhance and perhaps sustain T-cell responses (20 , 21 and 22).

More recently, we have sought to address the role of CTLA-4 during induction of EAE-like syndromes in normally resistant mice on immunization with CNS tissues. For example, we have found that immunization of Balb/c mice with homogenized syngeneic spinal cord emulsified in complete Freund's adjuvant does not lead to T-cell infiltration of the CNS nor to clinical manifestation of EAE. However, similar immunization together with anti-CTLA-4 leads to extensive CNS infiltration and to clinical signs of EAE (Hurwitz and Allison, manuscript in preparation). Although our work on the basis for this effect is continuing, the explanation that we favor is that CTLA-4 lowers the threshold of activation, allowing responses of self-reactive T cells and the breaking of peripheral tolerance. These data support the notion that CTLA-4 may play a role in the maintenance of peripheral tolerance.

CTLA-4 Blockade and Tumor Immunotherapy

Part of "25 - CTLA-4 Blockade in Tumor Immunotherapy "

Our initial studies with CTLA-4 blockade focused on moderately immunogenic tumors in which we had found induction of B7 expression to be partially effective in reducing tumorigenicity. We sought to determine whether CTLA-4 blockade would enhance rejection of the B7-transfected tumor. Colon carcinoma 51Blim10 cells transfected with B7 grow for approximately 2 weeks before being slowly rejected. Injection of anti-CTLA-4 antibodies in the first week after implantation led to rapid rejection of the tumors by all of the mice. This was not unexpected, because administration of anti-CTLA-4 had been shown to increase T-cell responses *in vivo* (12). However, a more startling finding was made in the treatment of wild-type tumors that did not express B7. We found that administration of CTLA-4 after tumor implantation again resulted in tumor rejection (23). Similar results were found with the fibrosarcoma SA1N. In both these tumors, we found that rechallenge of the mice as late as 4 months after initial rejection of the tumor resulted in protection against tumor growth. We also found administration of the antibodies could be delayed as late as two weeks or until the tumors had reached a size of approximately 150 mm². For SAIN, complete tumor rejection was again accomplished in more than 80% of the animals even when started after prolonged tumor growth.

These studies were subsequently extended to a panel of tumors including those listed in Table 25-1 . These tumors can be divided into three groups:

1. Tumors that are sensitive to anti-CTLA-4–induced rejection. In these tumors, we regularly obtained complete eradication and long-lasting immunity.
2. The second group consisted of tumors whose growth was significantly slowed by CTLA-4 blockade but in which rejection was only rarely obtained.
3. The third group typified by mammary carcinoma SM1 and the melanoma B16BL6, was largely resistant to the effects of anti-CTLA-4. For these tumors, we observed a slight retardation of tumor growth but did not succeed in obtaining tumor rejection.

Table 25-1 Anti-CTLA-4 in Combination Immunotherapy

	Treatment			
	Vaccine	Anti-CTLA-4	Tumor Rejection	Autoimmunity
SM-1	GM-SM-1	-	No effect	—
—	GM-SM-1	+	Yes	Not examined
B16 melanoma	GM-B16	-	Occasional	—
—	GM-B16	+	Yes	Vitiligo
Prostate adenocarcinoma in TRAMP mice	TRAMP	-	No effect	—
—	TRAMP	+	Diminished incidence and severity[a]	—
—	GM-TRAMP	-	No effect	—
—	GM-TRAMP	+	Diminished incidence and severity[a]	Prostatitis

GM, granulocyte-macrophage; TRAMP, transgenic adenocarcinoma of mouse prostate.

[a]Significant decrease in incidence of primary tumor 8 weeks after treatment of transgenic mice.

The defining property seems to be the inherent immunogenicity of the tumors. Tumors that were susceptible to CTLA-4 blockade tended to be those that were also rejected on induction of B7 expression and included those shown to be immunogenic by the capacity of irradiated cells to protect mice against subsequent challenge with a tumor. Tumors resistant to CTLA-4 blockade, SM1 and B16BL6, were considered to be nonimmunogenic

by the opposite criteria, such as the immunization of mice with irradiated tumor cells did not lead to protection nor did the induction of B7 lead to tumor rejection. Having demonstrated that CTLA-4 blockaded by itself was sufficient to achieve rejection of immunogenic tumors, we turned our attention to developing strategies to obtain rejection of the resistant, presumably poorly immunogenic or nonimmunogenic tumors.

CTLA-4 Can Be Effective in Combination Immunotherapy of Poorly Immunogenic Tumors

Part of "25 - CTLA-4 Blockade in Tumor Immunotherapy "

SM1 Mammary Carcinoma

We chose granulocyte-macrophage colony-stimulating factor (GM-CSF)–transduced tumor cell vaccines as a first approach for evaluation of CTLA-4 as a component of combination immunotherapy because it had been previously shown that immunization with GM-CSF expressing B16 melanoma cells could lead to protection against subsequent challenge (24). However, vaccination with GM-CSF cells alone had not been found to lead to rejection of preestablished tumor (25). We initially tried combination therapy for treatment of the poorly immunogenic mammary carcinoma SM1 (26). We found that neither irradiated SM1 cells, irradiated GM-CSF–transfected SM1 cells (GM-SM1), nor anti-CTLA-4 given alone beginning on the day of tumor implantation had any significant effect on tumor growth. The combination of irradiated SM1 cells with anti-CTLA-4 slightly slowed tumor growth but did not lead to rejection. However, vaccination with GM-SM1 cells followed by anti-CTLA-4 regularly resulted in complete tumor rejection.

B16 Melanoma

The B16 melanoma is an extremely aggressive tumor model, characterized by a low median lethal dose and high capacity for metastasis. These features made this model a compelling one in which to assess the effectiveness of CTLA-4 blockade as a component of immunologic treatment (27). We found that neither CTLA-4 blockade nor immunization with irradiated B16 cells alone or in combination had significant effects on tumors of subcutaneous implants of B16BL6, even when administered beginning on the day of implantation. Vaccination on the same day of tumor implantation with irradiated B16 cells transduced to express GM-CSF (GM-B16) resulted in a slight retardation of the rate of tumor growth, but rejection was only rarely obtained. However, vaccination with GM-B16 together with administration of anti-CTLA-4 antibodies prevented outgrowth of tumors in virtually all mice. Similarly, complete eradication of tumors was regularly obtained when initiation of the combination therapy was delayed until day 4 (in 68 of 85, or 80%, of treated mice). Tumor-free mice were found to be resistant to rechallenge 4 months later, indicating that rejection was accompanied by the induction of potent immunologic memory. Finally, we also found that the combination therapy was capable of protecting mice from death due to pulmonary metastases induced by intravenous injection of the B16 subline F10.

The mechanism of protection elicited by the anti-CTLA-4 combination therapy appears to differ from that in previously reported studies of prophylactic immunization with GM-CSF/B16. Prophylaxis by GM/B16 has been shown to be mediated largely, if not exclusively, by $CD4^+$ T cells and their cytokines (25). In contrast, we found that rejection of preestablished tumors by the combination immunotherapy was not effected by depletion of $CD4^+$ T cells. The basis for this difference remains to be established. One possibility is that CTLA-4 blockade may lower the threshold of signaling needed for activation of CD8 to a level sufficient for full activation even in the absence of $CD4^+$ helper T-cell licensing of APCs by CD40 ligand and CD40 interactions (28 , 29 , 30 and 31). The cellular and molecular requirements for effectiveness of the combination immunotherapy are currently under investigation.

One important limitation observed in these studies was that the effectiveness of treatment began to wane after approximately a week of tumor growth. When treatment was begun on day 8 after tumor implantation, the rate of tumor growth was slowed considerably, but complete eradication was obtained in only a minority of animals (<20%). After 12 days, tumor growth was significantly delayed, but complete regression was not obtained. This is in stark contrast to our results with the more immunogenic

tumors, where anti-CTLA-4 alone was capable of inducing regression in some models even after weeks of tumor growth. The basis for the limited period of effectiveness in the B16 system is not clear at present. It is possible that it is a consequence of the extreme aggressiveness and lethality of this inherently metastatic tumor line. It has also been shown that many tumors can downregulate T-cell responses, including induction of antigen-specific nonresponsiveness (31). Whether this is the case for the B16 melanoma remains to be determined and is an area of active investigation.

One striking phenomenon that developed in the majority of mice that had undergone tumor rejection was progressive depigmentation of the fur beginning at approximately 1 month after tumor rejection. Depigmentation is accompanied by infiltration of the skin with mononuclear cells along with the loss of normal melanocytes in the affected areas. The depigmentation is reminiscent of the vitiligo observed in those melanoma patients showing clinical responses in the immunotherapy trials carried out by Rosenberg and his colleagues (32). Normal melanocyte gene products have been shown to be frequent targets of antimelanoma responses in human patients (33). There have been several examples of the induction of depigmentation or protection against challenge, or both, with B16 melanoma in mice after immunization with peptides derived from the murine equivalents of normal melanocyte antigens (34 , 35 , 36 , 37 , 38 and 39). However, the responses obtained have been shown to be sufficient to obtain rejection of established tumors. The effectiveness of CTLA-4 blockade in obtaining both tumor rejection and progressive depigmentation may reflect a more efficient mobilization of a larger spectrum of T cells reactive with normal melanocyte-associated antigens.

These results taken together establish

1. That combination immunotherapy with CTLA-4 blockade can be used to obtain eradication of this poorly immunogenic transplantable tumor.
2. That the immune response is at least in part directed to normal melanocyte-specific gene products, resulting in tissue-specific autoimmunity.

CTLA-4 Blockade Can Be Effective in Immunotherapy of Primary Prostatic Adenocarcinoma

It is clear that experiments using transplantable tumors can provide extremely valuable insight into immunologic principles and the rational design of immunotherapeutic strategies. However, the use of transplantable models raises several issues concerning the relevance of the specifics of data obtained to ultimate clinical application. One of these issues is that ectopic sites of tumor implantation are often used; most models use subcutaneous inoculation. This may be less of an issue for melanoma lines, but the skin is richly endowed with APCs for the initiation of immune responses and may not reflect what occurs in other tissues. Additionally, other organ sites may not be readily accessible to lymphocytes, and it is also possible that tumor growth might provide additional barriers such as interstitial pressure that would further compromise access. Finally, the use of transplantable tumors with long histories of passage raises questions of genetic drift in both the tumor and mouse host as sources of new antigenic differences.

To avoid at least some of these problems, we have used the transgenic adenocarcinoma of mouse prostate (TRAMP) (40). In these mice, the androgen-regulated rat probasin promoter drives expression of the SV40-Tag oncogene in prostatic epithelium. We found that CTLA-4 blockade was sufficient to obtain partial or complete remission of early passage cell lines (TC1 and TC2) derived from these mice in nontransgenic syngeneic hosts (41 , 42). We then explored the use of CTLA-4 blockade in the treatment of primary cancer in the transgenic mice. Male TRAMP mice have developed a series of cellular changes beginning at puberty that closely reflect prostate carcinogenesis in man, including hyperplasia, frank neoplasia, and, finally, invasive adenocarcinoma (40). Mice were treated at 14 to 16 weeks of age, when most would be expected to bear early adenocarcinoma, with irradiated TRAMP (TC) cells and GM-CSF–expressing TRAMP cells (GM-TC) with anti-CTLA-4 or control hamster antibodies. We found that anti-CTLA-4 given along with the tumor cell vaccines resulted in a significant reduction in both tumor incidence and severity as determined by histopathologic analysis of prostatic tissue 8 weeks after treatment (43). Treatment of the mice with the vaccines or anti-CTLA-4 alone had no effect on tumor incidence. However, tumor incidence was significantly reduced in mice receiving either cell vaccine along with anti-CTLA-4. The effect was most pronounced in mice treated with anti-CTLA-4 and GM-TC at 14 weeks, in which the incidence was only 15% compared with 75% in control mice. We also observed a reduction in the severity of the tumors as indicated by clinical grading. Mice treated with the GM-TC vaccine alone had a mean score of 5.3, whereas those treated with GM-TC and anti-CTLA-4 had a score of 3.5. We also observed that the prostates of mice treated with GM-TC and anti-CTLA-4 showed extensive inflammation marked by accumulation of mononuclear cells, presumably lymphocytes, in the interductal spaces. There was no significant inflammation in the prostates of mice in the groups vaccinated in the absence of anti-CTLA-4. Together these results suggest that combination immunotherapy using CTLA-4 blockade can decrease incidence and severity of primary tumors in this transgenic model. This is a particularly significant finding given the aggressive nature of the transgene whose expression is presumably leading to the transformation of essentially all epithelial cells in the prostate.

One issue that arises from this work is whether the transgene product itself, the viral T antigen, is itself the target for immunologic responses. We thought this improbable because T-antigen expression cannot be detected by highly sensitive reverse transcriptase-polymerase chain reaction technique in the TRAMP cell lines used for immunization, nor were these cell lines susceptible to cytolysis by T-cell lines specific for H2B-restricted epitopes of SV40 Tag [(42), and S. Tevethian, *personal communication*, 1999]. To address this question more directly, however, we immunized nontransgenic BL6 mice with the GM-TC vaccine with or without anti-CTLA-4. We observed that a month after vaccination in the presence of anti-CTLA-4 there was a marked infiltration of the normal prostate with mononuclear

cells along with large-scale destruction of epithelium. These results indicate that the immune response elicited by the combination treatment protocol was not limited to the viral oncogene, but is at least in part due to induction of T cells reactive with normal prostate-associated antigens.

Taken together, these results demonstrate for the first time that the immunotherapeutic approach can be effective or at least partially effective in the treatment of primary cancer in this mouse model. Additionally, the immune response is directed at least in part to normal prostate tissue-specific antigens. We think that this finding is particularly important because there is a paucity of data on immune responses directed against normal prostatic tissue. Identification of the target antigens of this autoimmune prostatitis should allow the development of specific targets for the immunologic treatment of prostate cancer.

CTLA-4 Blockade in the Induction of Autoimmunity and Tumor Immunity

Part of "25 - CTLA-4 Blockade in Tumor Immunotherapy "

The data outlined in the previous sections have demonstrated that manipulation of signals involved in regulation of T-cell activation can be used effectively in the therapy of these experimental tumors. Consistent with our finding in autoimmune models, one of the consequences of the successful therapy of tumors seems to be the induction of tissue-specific autoimmunity. It should be stressed that in mice in that we have observed tissue-specific effects, there is no evidence of systemic autoimmune disease or of any other factors that detract from the general health of the animal. The immune responses seem to be limited to targets with which the animals are being vaccinated. Thus, we believe that these strategies offer considerable promise in the treatment of human cancers, at least of tissues that are not essential for survival such as prostate, melanocyte, breast, ovary, and testicle. In collaboration with others, we have produced a panel of antibodies reactive with human CTLA-4 for clinical trial evaluation of its therapeutic potential. These trials should begin in the year 2000.
